For use in small streams and canals, where the gager standing on a low bridge or boat can readily reach all parts of the cross section with the meter mounted on short rods, the direct recording form of instrument is still preferred. The Colorado type of wheel, figured on page 7 of the second irrigation report, is used to a considerable extent, the form of meter being improved in minor details. One of the most important changes has been in making the method of locking and release of the registering wheels depend not upon a spring but upon a direct geared motion. In the new form the registering wheels are stopped or allowed to start by turning a small rod placed inside of the rod upon which the meter is held. This later form of meter is shown by the accompanying drawing (Fig. 7). This meter has no direction tail, but is used only under circumstances such that the

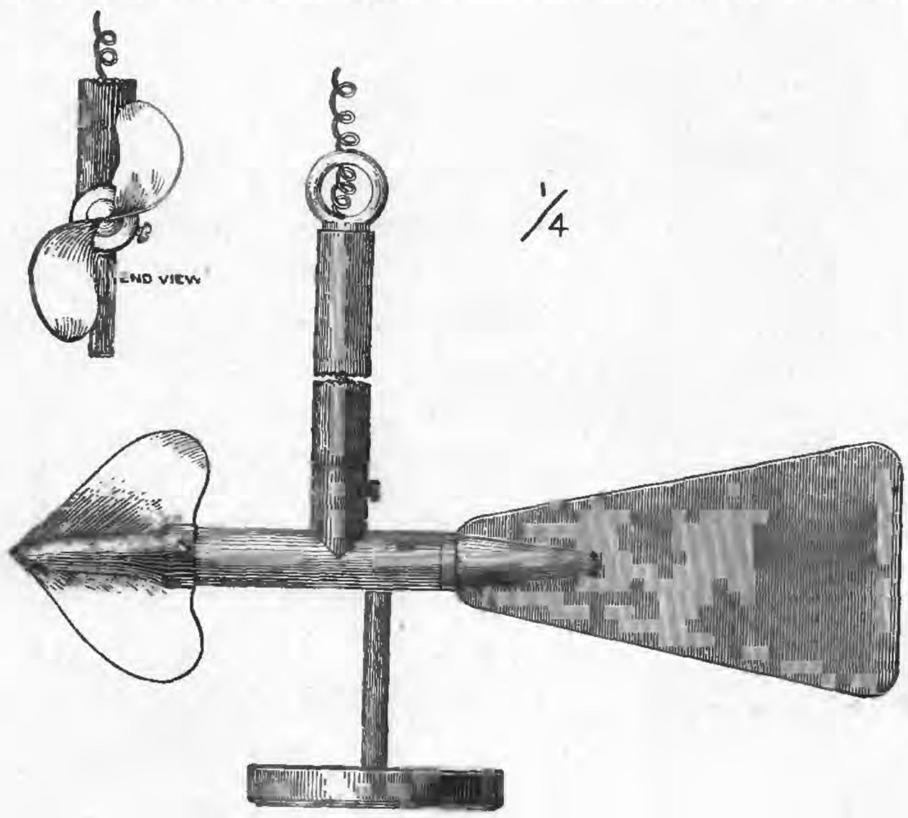

FIG. 6.—Small form of Haskell electric current meter.

gager can at all times see that it is pointed upstream. In practical use the method of employment of this meter is that sometimes known as integration; that is to say, instead of obtaining the velocity at one point at a time, as in the case of deep rivers measured by the electric meter, this instrument is lowered and raised alternately with very slow motion from top to bottom of comparatively shallow streams. This lowering and raising, if performed at a uniformly slow rate, should not affect the revolutions of the wheel, and the meter should thus indicate the average velocity of that section.

Besides the electric and direct recording meters mention should be made of a third type of instrument, the sounding meter, which, although not in use by the Geological Survey to any considerable extent, possesses certain advantages. In its ordinary form this is the simplest and most durable of measuring apparatus of its kind, since it has but one moving part, the vane or wheel. These meters, devised by Joseph P. Frizell and used by the Engineer Corps on the headwaters of the Mississippi, are described as consisting merely of a rotating wheel, so monnted that when in motion the wheel is forced forward at each revolution by a small cam or helical step from one-thirty-second to one-sixty-fourth of an inch. The two surfaces bearing the step fit exactly in one position, but as the wheel turns it is forced forward on the supporting spindle, and as the steps pass each other drops

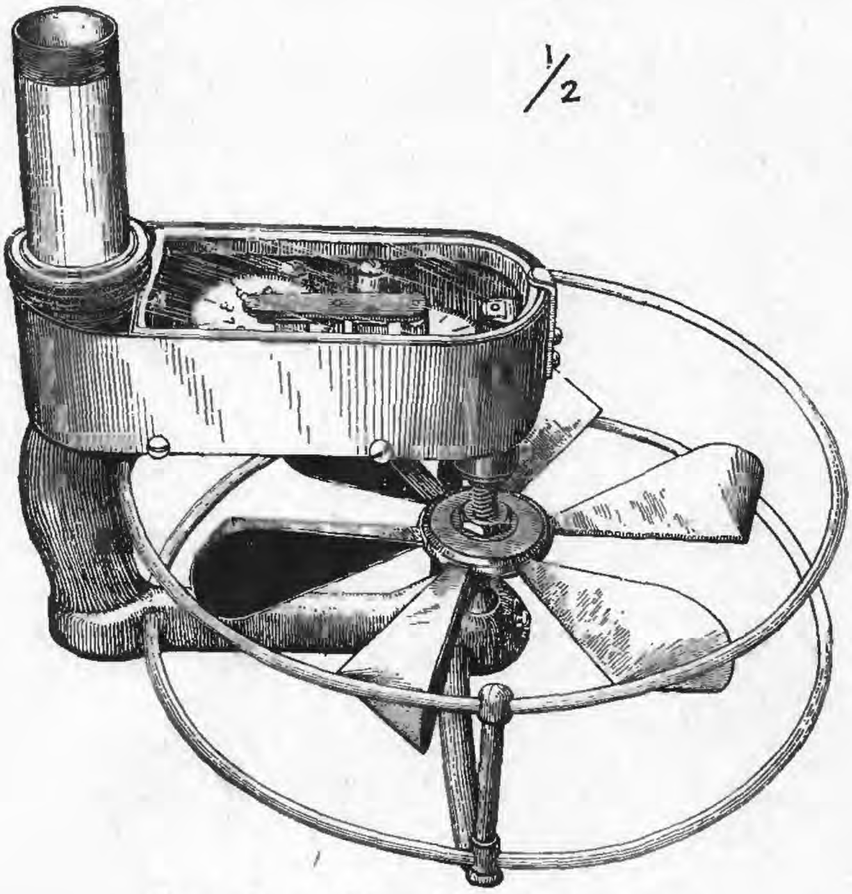

FIG. 7.—Improved form of the Colorado meter.

back, causing a distinct "click," audible along the metallic rod upon which the meter is held. The operator holding the meter at the desired place in the stream, with his ear near the rod, counts the clicks and notes the number of seconds, usually by means of a stop-watch. It is customary either to take the time of one hundred revolutions or to count the number of revolutions in fifty or one hundred seconds.

Electric recording meters have also been converted into sounding meters by making connections with an ordinary telegraphic "sounder." They have, however, the very disadvantage that the original sounding meter was devised to overcome, namely, a complication of parts requiring considerable skill in their successful employment. A careful man, though not experienced as an engineer or mechanician, can be quickly instructed in the use of the simple sounding meter and can take observations from time to time, sending in his notes for computation by the engineer in charge.

following pages in connection with the discharge data for the Arkansas and other rivers.

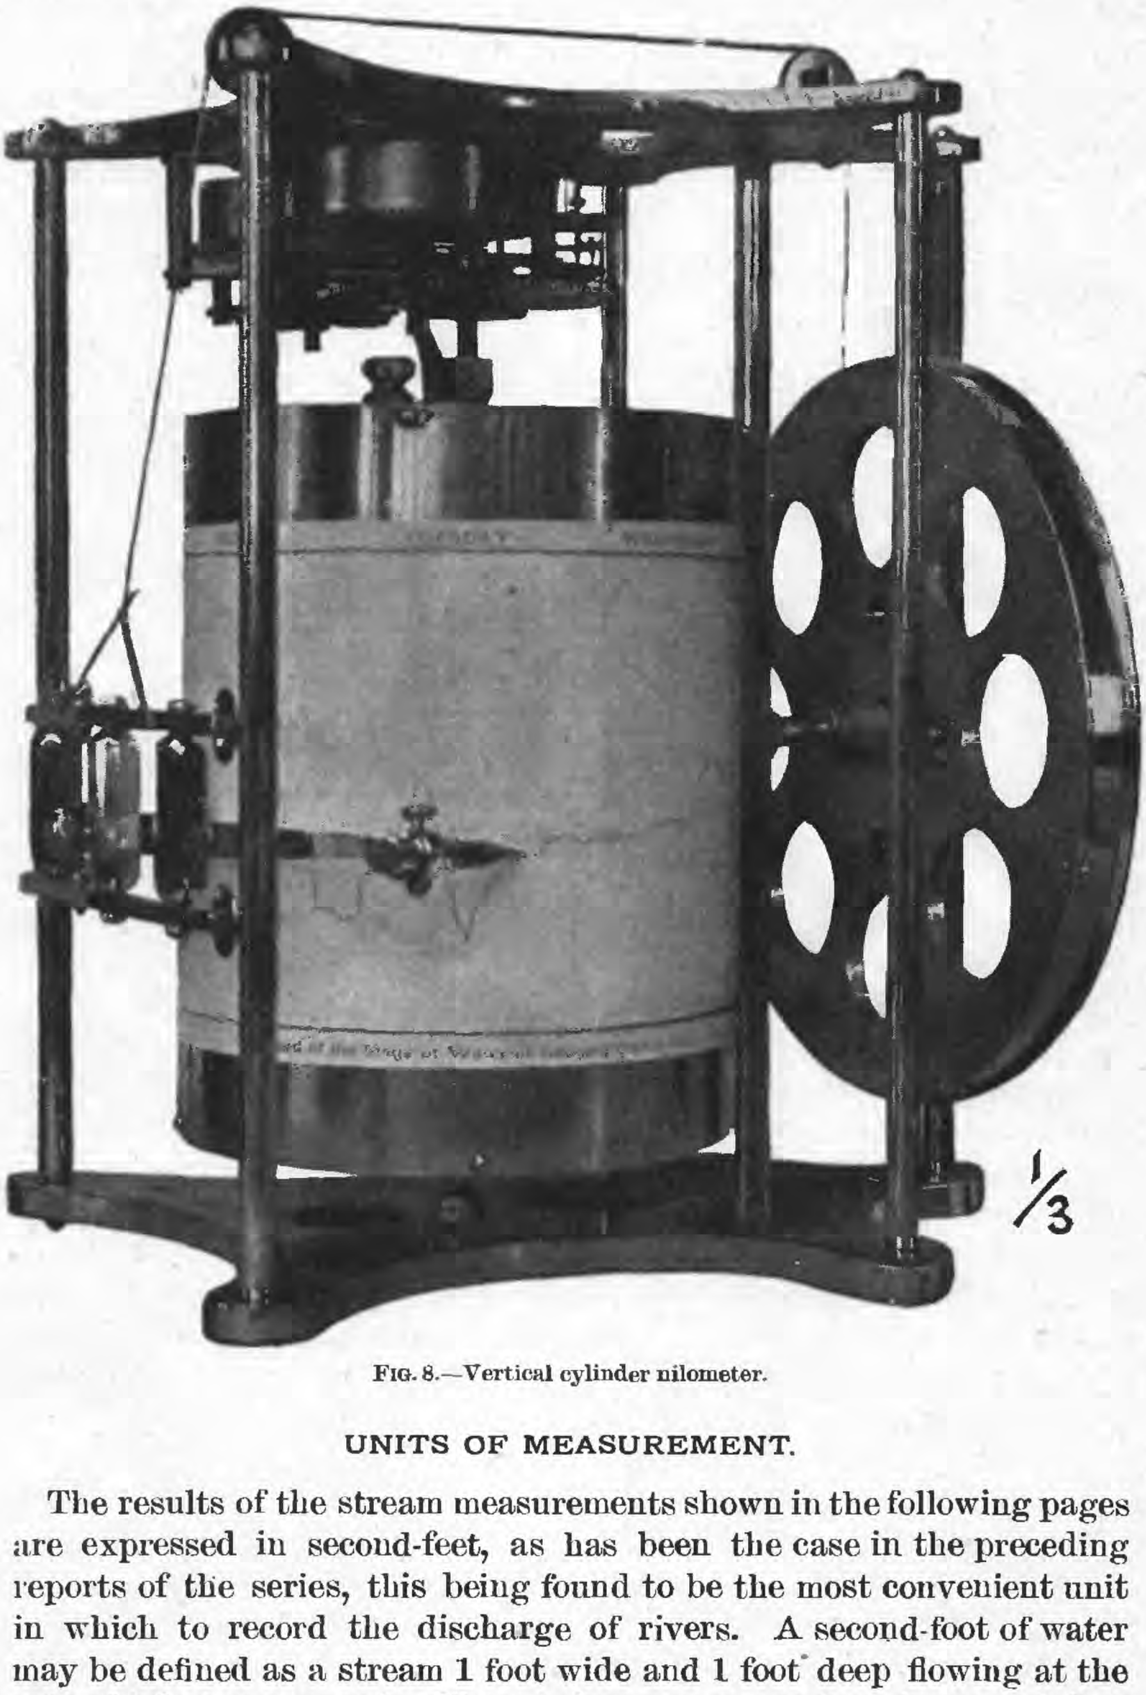

FIG. 8.—Vertical cylinder nilometer.

UNITS OF MEASUREMENT.

The results of the stream measurements shown in the following pages are expressed in second-feet, as has been the case in the preceding reports of the series, this being found to be the most convenient unit in which to record the discharge of rivers. A second-foot of water may be defined as a stream 1 foot wide and 1 foot deep flowing at the rate of 1 foot per second. There is in common use by miners and irrigators throughout the West another unit, the miner's inch, which will probably continue to be employed. This is an indefinite quantity, but it is generally coming to be recognized as the fiftieth part of a sec-

TUSCAN FORMATION.

On the western border of the Sacramento valley the most southern exposure yet observed is on Thomes creek, 4 miles east of Paskenta. Its best exposures, however, in that district are 6 miles northeast of Paskenta, on Mill creek, near the old headquarters of the Nomlaki Indian reservation. At this point the tuff is 35 feet in thickness. It weathers reddish above, but is white below, and, although usually fine, the material contains small fragments of pumice. It is quarried and extensively sold for chimneys, water coolers, etc., for which purpose, being soft, porous, and a nonconductor of heat, it is well adapted.

Farther westward, but still south of Elder creek, the tuff may be seen in the Bald hills, having a thickness of 12 feet. This exposure is represented with both underlying and overlying formations in Fig. 45, and is of special interest, as it is one of the most western outcrops of the tuff found in that region. The three newer formations are conformable among themselves, but they are very clearly unconformable upon the shales of the Shasta-Chico series beneath them.

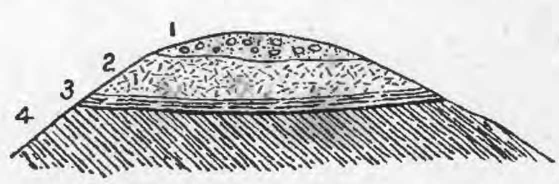

Fig. 45.—Section of Bald hill, between Lowrey's and Paskenta, Tehama county, California: 1, gravel of Red Bluff formation; 2, Tuscan tuff, 12 feet; 3, clay, 4 feet—Ione formation; 4, Cretaceous shales.

On Elder creek, 4 miles east of Lowrey's and about 6 miles northeast of the locality last noted, the tuff, as shown in Fig. 46, is well exposed in a bluff. It is of fine material and about 50 feet in thickness. A little farther down the stream only a thin layer of clay separates it from the tilted beds, but at this point it rests directly on the Cretaceous rocks. The tuff dips eastward very gently, but the Chico beds, composed of thin sandstones and shales, are much tilted, and at one place very sharply folded. They dip steeply to the east, so that the unconformity is conspicuous.

The three exposures last noted hold such a relation to one another as to show that the tuff is thinning out rapidly to the west upon the baselevel of erosion, and less rapidly to the south. It thickens toward the northeast, indicating that the source of its material was in the volcanoes of the Lassen peak region.

Beds of fine light colored tuff, composed of volcanic dust like that thrown out from Lassen peak, have been found west of the Bully Choop mountains in Redding creek basin and at Hyampome in Trinity county. It is not certain, however, that the material at the last two places came from Lassen peak. Similar material is reported by Mr. Fairbanks[1] at points in the Coast range. Prof. A. C. Lawson called

valley. At this place the tuff has not been found. It was either swept entirely away from the border of the valley about Reading before the deposition of the Red Bluff formation, or has been overlapped by that formation. A short distance to the east, however, along Stillwater, the tuff again appears and extends as the great mass of tuff

GEOLOGICAL MAP OF BEAR MOUNTAIN AND VICINITY.

CALIFORNIA

JULIUS BIEN & CO. N.Y.

The narrow streak of the Mariposa slates, referred to under the third heading, seems certainly to have been deposited in a trough between preexisting ridges of the Calaveras formation, and to have been folded up with the rocks of the Calaveras formation at the time of the post-Mariposa upheaval. Evidence similar to this may also be obtained by noting the strike of the two main belts of the slates.

The eastern belt is said to terminate to the south near Bridgeport, in Mariposa county, where it is cut off and metamorphosed by the granite, and to the north, according to Mr. Lindgren, north of Colfax, having thus a length of about 120 miles, and a width varying from one-half mile to 2 miles or more. The strike of this belt, as a whole, is northwesterly from its south end to Plymouth, in Amador county; thence nearly north to near Placerville, bending again northwesterly to the north of that town. The western area has a width about the same as that of the eastern area, and a length of about 100 miles, extending from Folsom, on the American river, where it has been altered by the intrusion of the granite, to beyond Merced Falls, on the Merced river.

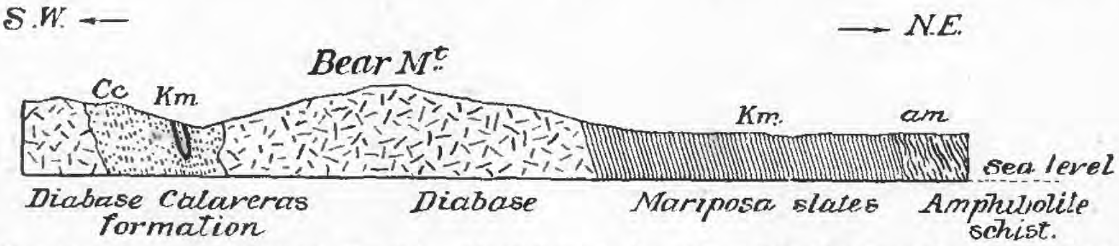

FIG. 49.—Section across Bear mountain. Cc, Calaveras formation; Km, Mariposa formation. Horizontal and vertical scales, about 7,400 feet to the inch.

The strike of this western belt is northwesterly throughout its entire course, and the strike of the slates in both belts corresponds nearly everywhere with the trend of the belts, the dip being usually to the east at an angle of 50° or more. The two belts have thus a nearly parallel trend till in the latitude of Plymouth, where the northward turn of the eastern belt causes them to diverge so that across the strike at Folsom the belts are 18 miles apart, while at Plymouth they are only about 6 miles apart.

This divergence is perhaps in part due to the intrusion of igneous rocks at the time of the post-Mariposa upheaval, but chiefly, so it appears to the writer, to the two belts having been laid down in two long troughs between preexisting ridges of the Calaveras formation.

The phthanite conglomerate occurs at the south end of Bear mountain, only about one-fourth mile north of the Texas ranch fossil locality, and in the narrow streak of slates 1 mile west of Elkhorn station, where it forms a bed a few feet in thickness and about 1 mile in length. Where the narrow strip of Mariposa slates crosses the area of the Calaveras formation, springs were noted at the contact at two or three points, suggesting a fracture or an unconformity. This narrow strip

nificent granite exposures about the lake. In fact there is nothing but granite in the vicinity, and as the loose material has been swept away by the glacier that formerly covered the spot the rocks are beautifully exposed. The granite-porphyry occurs about the head of the lake, and the contact there and at other points in the neighborhood with the biotite-hornblende-granite is everywhere sharp. Dike-like protrusions of the granite-porphyry were seen extending into the biotite-hornblende-granite, indicating that the former is the younger rock.

FIG. 50.—Granite-porphyry. Scale, $\frac{1}{8}$.

The granite-porphyry may be described as a holocrystalline rock of hypidiomorphic structure, with a coarse groundmass of plagioclase, orthoclase, and sometimes microcline, a good deal of brown mica, a little primary brown hornblende, and titanite and iron oxide. In this groundmass are developed large orthoclase phenocrysts, which usually contain abundant inclusions of the minerals of the groundmass, both in the interior and along the edge of the phenocrysts. Plagioclase, biotite, quartz, titanite, and iron oxide were noted in the porphyritic orthoclases, which are often more than 2 inches in length. It is evident that the phenocrysts were formed after some of the other constituents of the rock, and in this particular the granite-porphyry appears to strongly resemble the porphyrite with large orthoclase phenocrysts, described by Mr. W. Cross in this volume as forming part of the laccolites of the Elk mountains, Colorado. Prof. A. C. Lawson[1] has lately described a granite-porphyry from the Santa Lucia mountains, in the coast ranges of California.

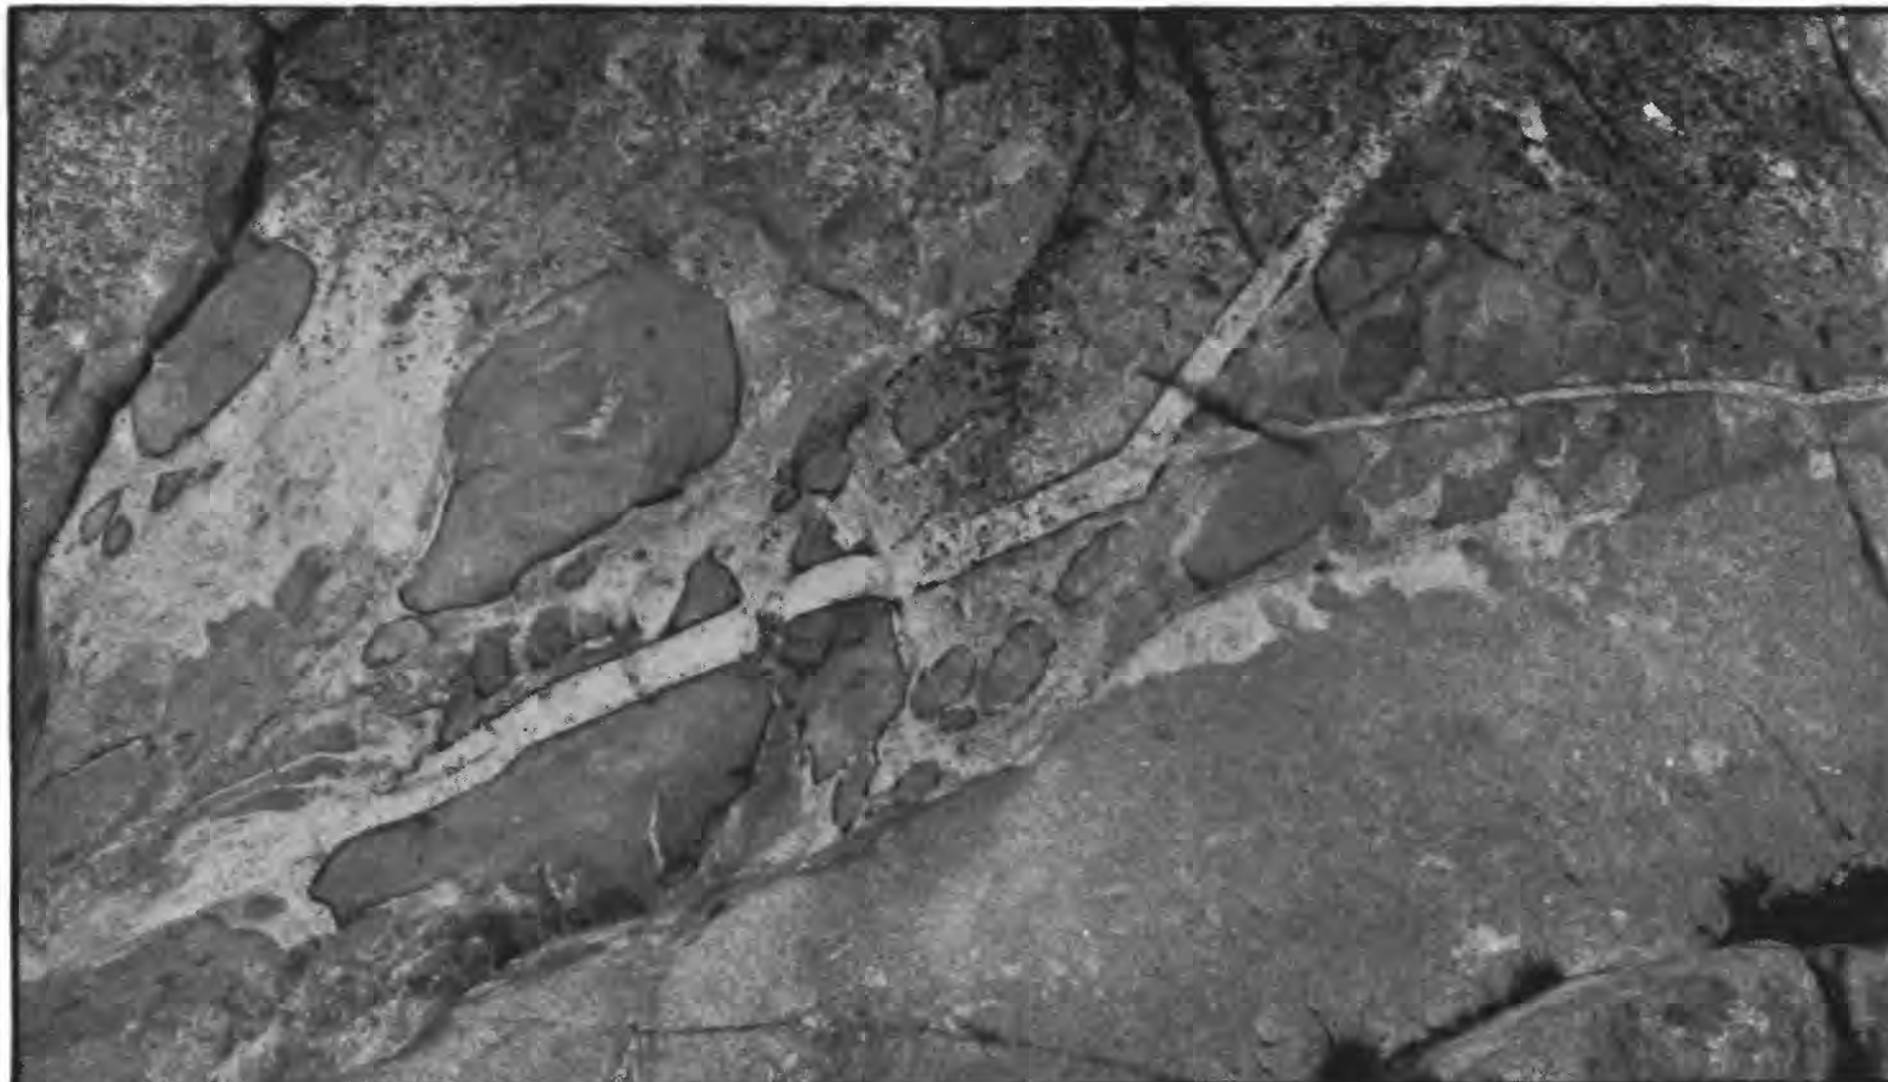
EXFOLIATING GRANITE, CREST OF SIERRA NEVADA, SOUTHWEST OF SILVER MOUNTAIN CITY.



NODULES AND DIKES IN GRANITE, WEST OF GRANITE LAKE, TUOLUMNE COUNTY, CALIFORNIA.

appearance. This seems to be due to the silica of the rhyolite being leached out by atmospheric moisture and deposited nearly in place. The same phenomenon was previously noted by Mr. Goodyear[1] at several places.

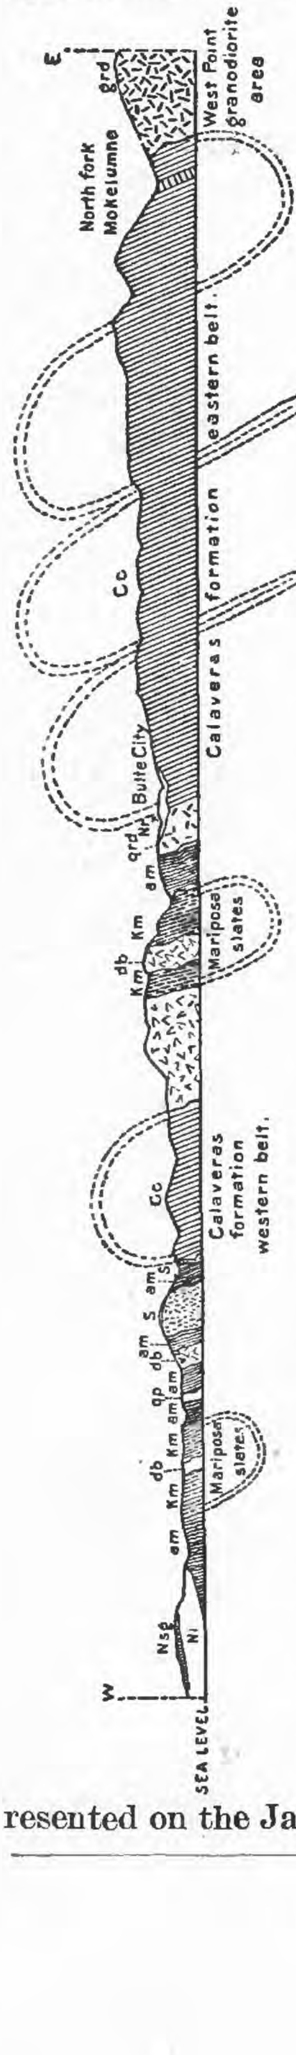


FIG. 51.—Section across the Gold Belt in Amador county, Cal. Horizontal scale, about 5 miles to the inch; vertical scale, about 8,000 feet to the inch.

The old mining town called Butte, 1 mile southwest of Jackson butte, in Amador county, is on an area of fragmental rhyolitic material. A careful examination of this area disclosed the curious fact that there is here a basin entirely surrounded by rocks of pre-Tertiary age (the bed-rock series.) This basin was evidently formed by orographic or volcanic disturbances after the old river gravels were deposited, for these Neocene river gravels now occupy higher points on the surrounding ridges.

According to a resident of Butte, who was there at the time, four shafts were sunk some years ago in this white detrital material. Three of these, 220, 180, and 130 feet in depth, respectively, did not reach bed rock or gravel; another which I saw, near the margin of the basin and 80 feet in depth, struck the bed rock. The rhyolitic material shows evidence in its slightly rolled fragments of having been washed into this basin from rhyolite areas in the neighborhood. There are some pebbles of pyroxene-andesite and fragments of the neighboring diorite mixed with the rhyolitic detritus, showing that a portion of the deposit formed after the andesite eruptions had begun. A stream has made a narrow cut in the bed-rock rim of this basin at one point on the south side, and the stage road from Jackson to Mokelumne hill passes through this cut, which has an elevation of about 1,000 feet, and the bottom of the basin must be at least 150 feet below the cut. The section across the Gold Belt (Fig. 51) north of the Mokelumne river shows this basin and the rhyolitic area.

It is by no means improbable that we have here an old volcanic orifice, and that underneath the surface fragmental rhyolitic material there is rhyolite in place. The area is represented on the Jackson sheet.

STRATIGRAPHIC POSITION.

The stratigraphic position of the strata forming the Grand Canyon series will be first considered, and then the position of the lava beds within that series.

With the exception of a trace of unconformity by erosion at the summit of the Unkar terrane, there is no recognized interruption in the sedimentation between the base of that terrane south of Vishnu's Temple and the summit of the Chuar terrane at Nunkoweap butte. At the base of the Unkar terrane there is a bed of conglomerate that rests unconformably on the eroded edges of indurated sandstones and micaceous schists. The unconformity is absolute from the line of contact at the base of the Tonto sandstone to the point where the plane upon which the conglomerate was deposited passes beneath the river. A sketch (Fig. 52) made from the south side of the canyon by Mr. G. K. Gilbert presents an extended view of the unconformity.[1]

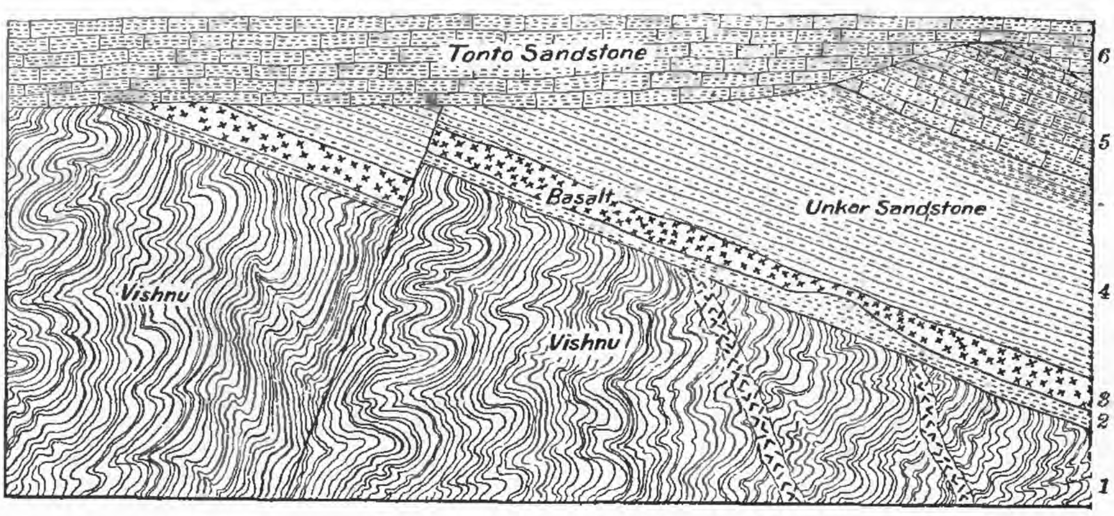

FIG. 52.—Section of the north side of the Grand canyon of the Colorado, as seen from the south wall near the mouth of Congress canyon. 1, Vishnu terrane (Archean ?); 2 to 5, Unkar terrane (2, conglomerate, sandstone, etc.; 3, sheet of basaltic lava; 4, reddish sandstone and sandy shale; 5, thick-bedded, reddish brown sandstone); 6, Tonto sandstone.

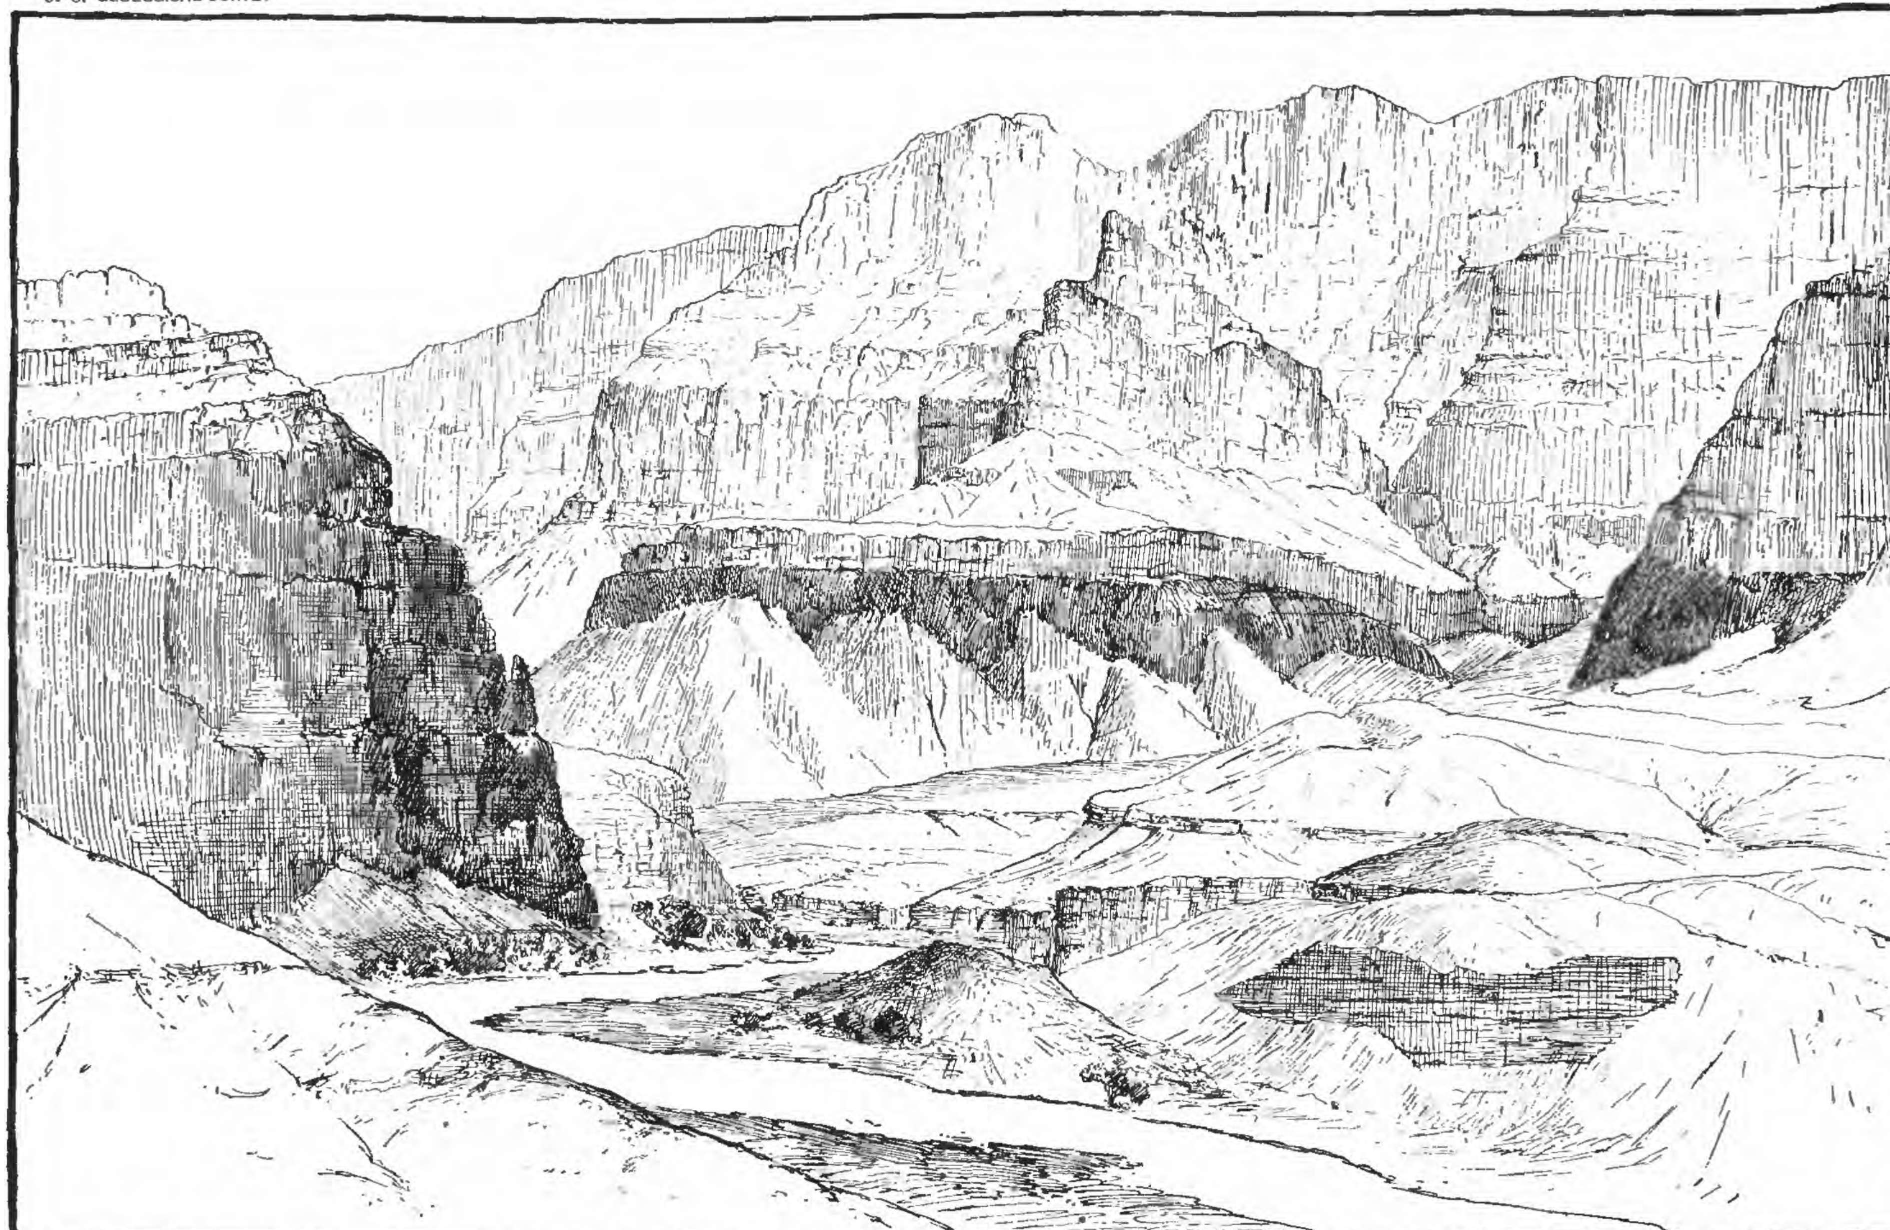
From the base of the Unkar terrane south of Vishnu's Temple the strata dip 10° to the northeast, and then, as shown on the map (Pl. LX and accompanying section), they flatten out on the line of the divide between Unkar and Chuar valleys, dip 25° to the north in the heart of Chuar valley, and thence extend in low, broad undulations to the syncline of Nunkoweap butte. North of the butte the strata rise, the dip being from 20° to 25° southeast. The summit of the series is at Nunkoweap butte, between Kwagunt and Nunkoweap valleys. From the point south of Vishnu's Temple to where the strata of the Chuar terrane pass beneath the basal beds of the Tonto sandstone, on

[1] In many places the pre-Unkar strata are gneisses and schists, cut by dikes of granite that are probably of Archean age. The Vishnu strata were clearly shown where my section crossed, and from photographs taken by Mr. Robert B. Stanton they appear to be extensively developed a few miles farther down the river.



CLIFFS FORMED BY LAVA BEDS ON THE COLORADO RIVER ABOUT TWO MILES SOUTH OF CHUAR LAVA HILL.

forced up from below. Several large dikes were seen cutting through the Vishnu series, but not in a position to connect with the Unkar lavas above. In one of the side canyons leading down to the east from Vishnu's Temple a section of 500 feet of the lower portion of the vermilion sandstones of the Unkar terrane is exposed above the chocolate-colored sandstones. A dike of basaltic lava, 6 feet in width at its base, cuts through obliquely to the bedding of the sandstone, and several offshoots occur that do not appear to have any relation to the stratification. The impression made upon me when examining this dike was that the lava found its way upward through crevices formed in a sandstone that gave resistance as a solid mass to the force that shattered it. The sketch

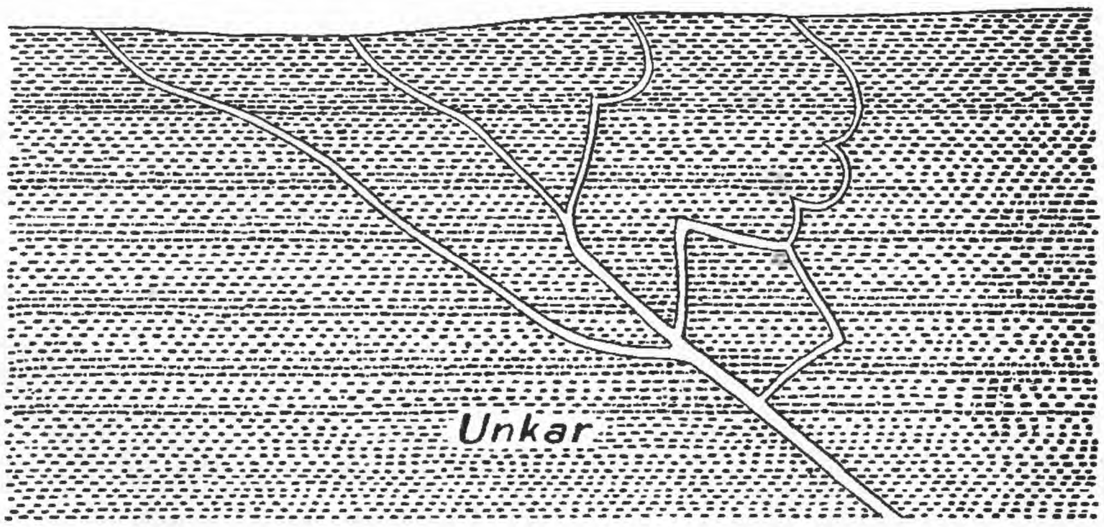

FIG. 53.—Dike in the sandstones of the Unkar terrane.

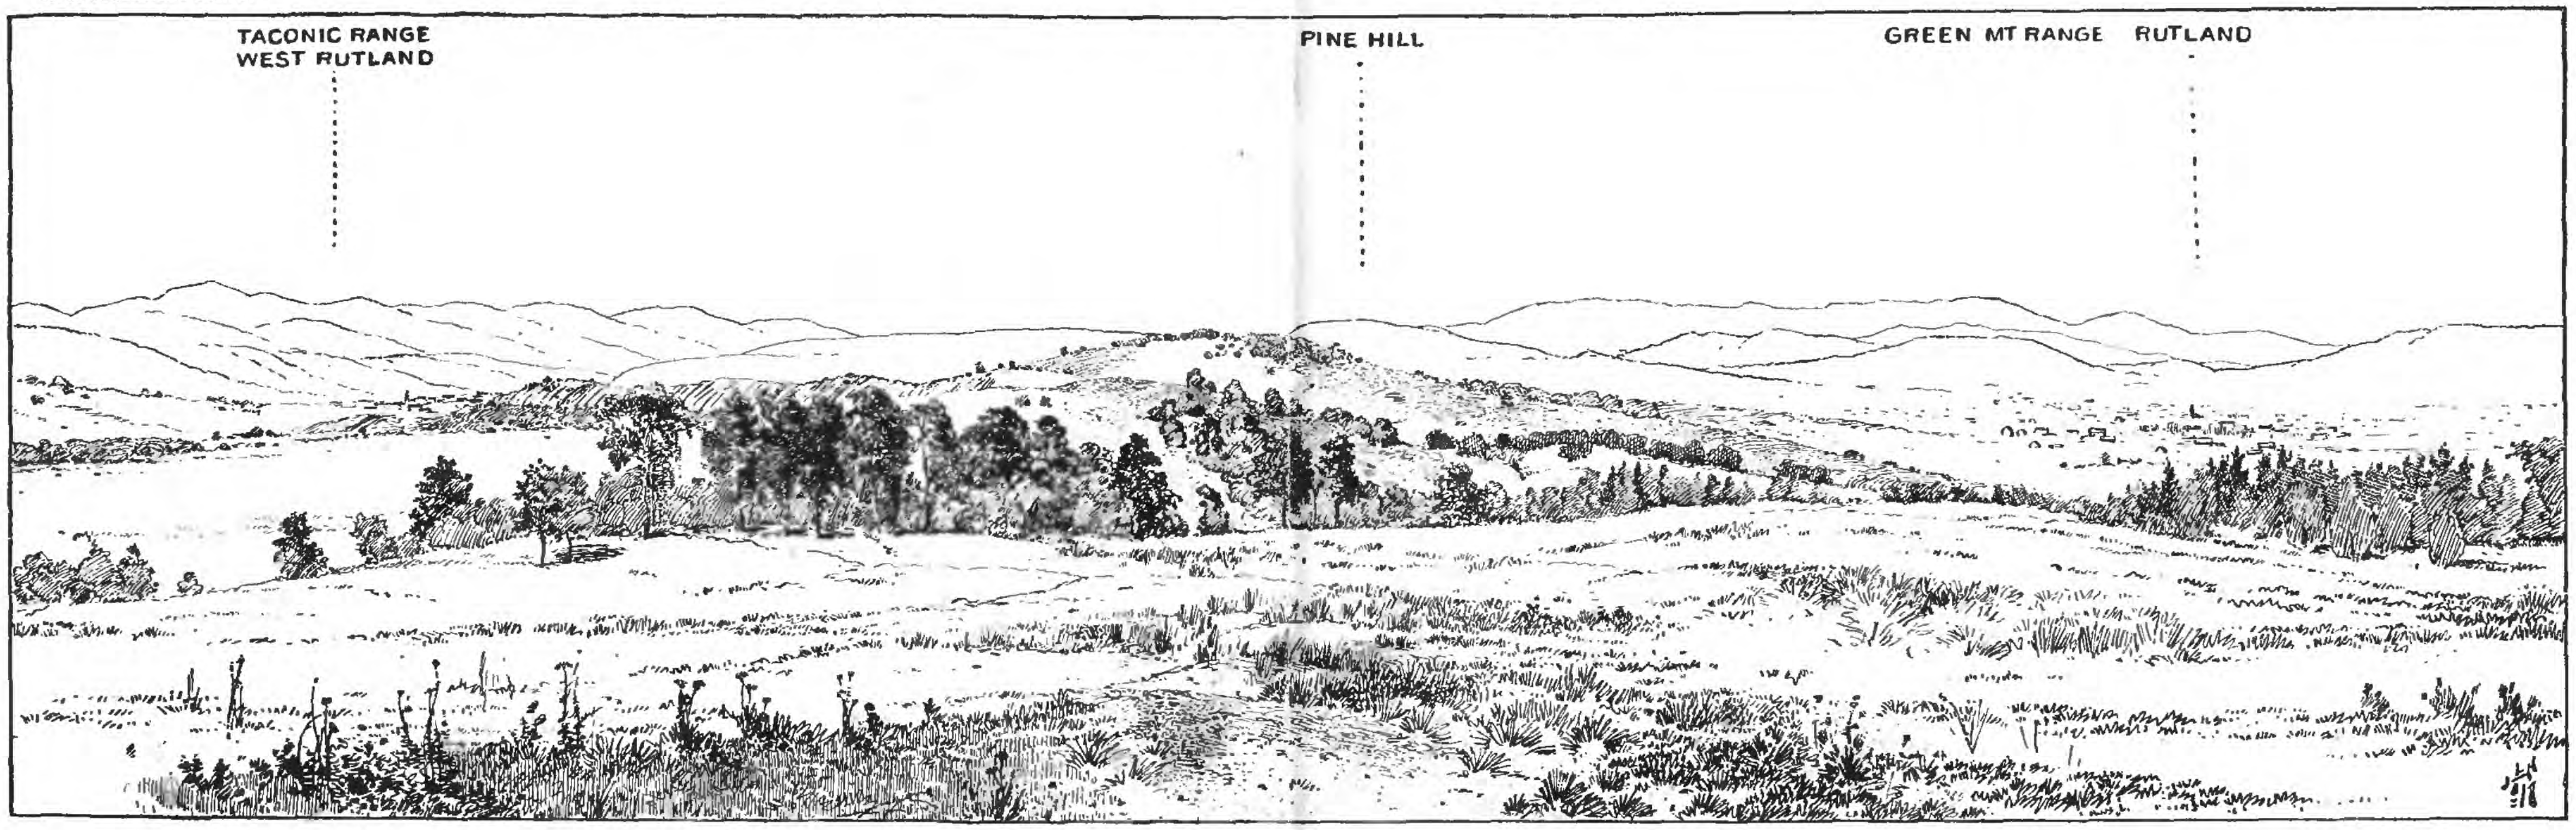
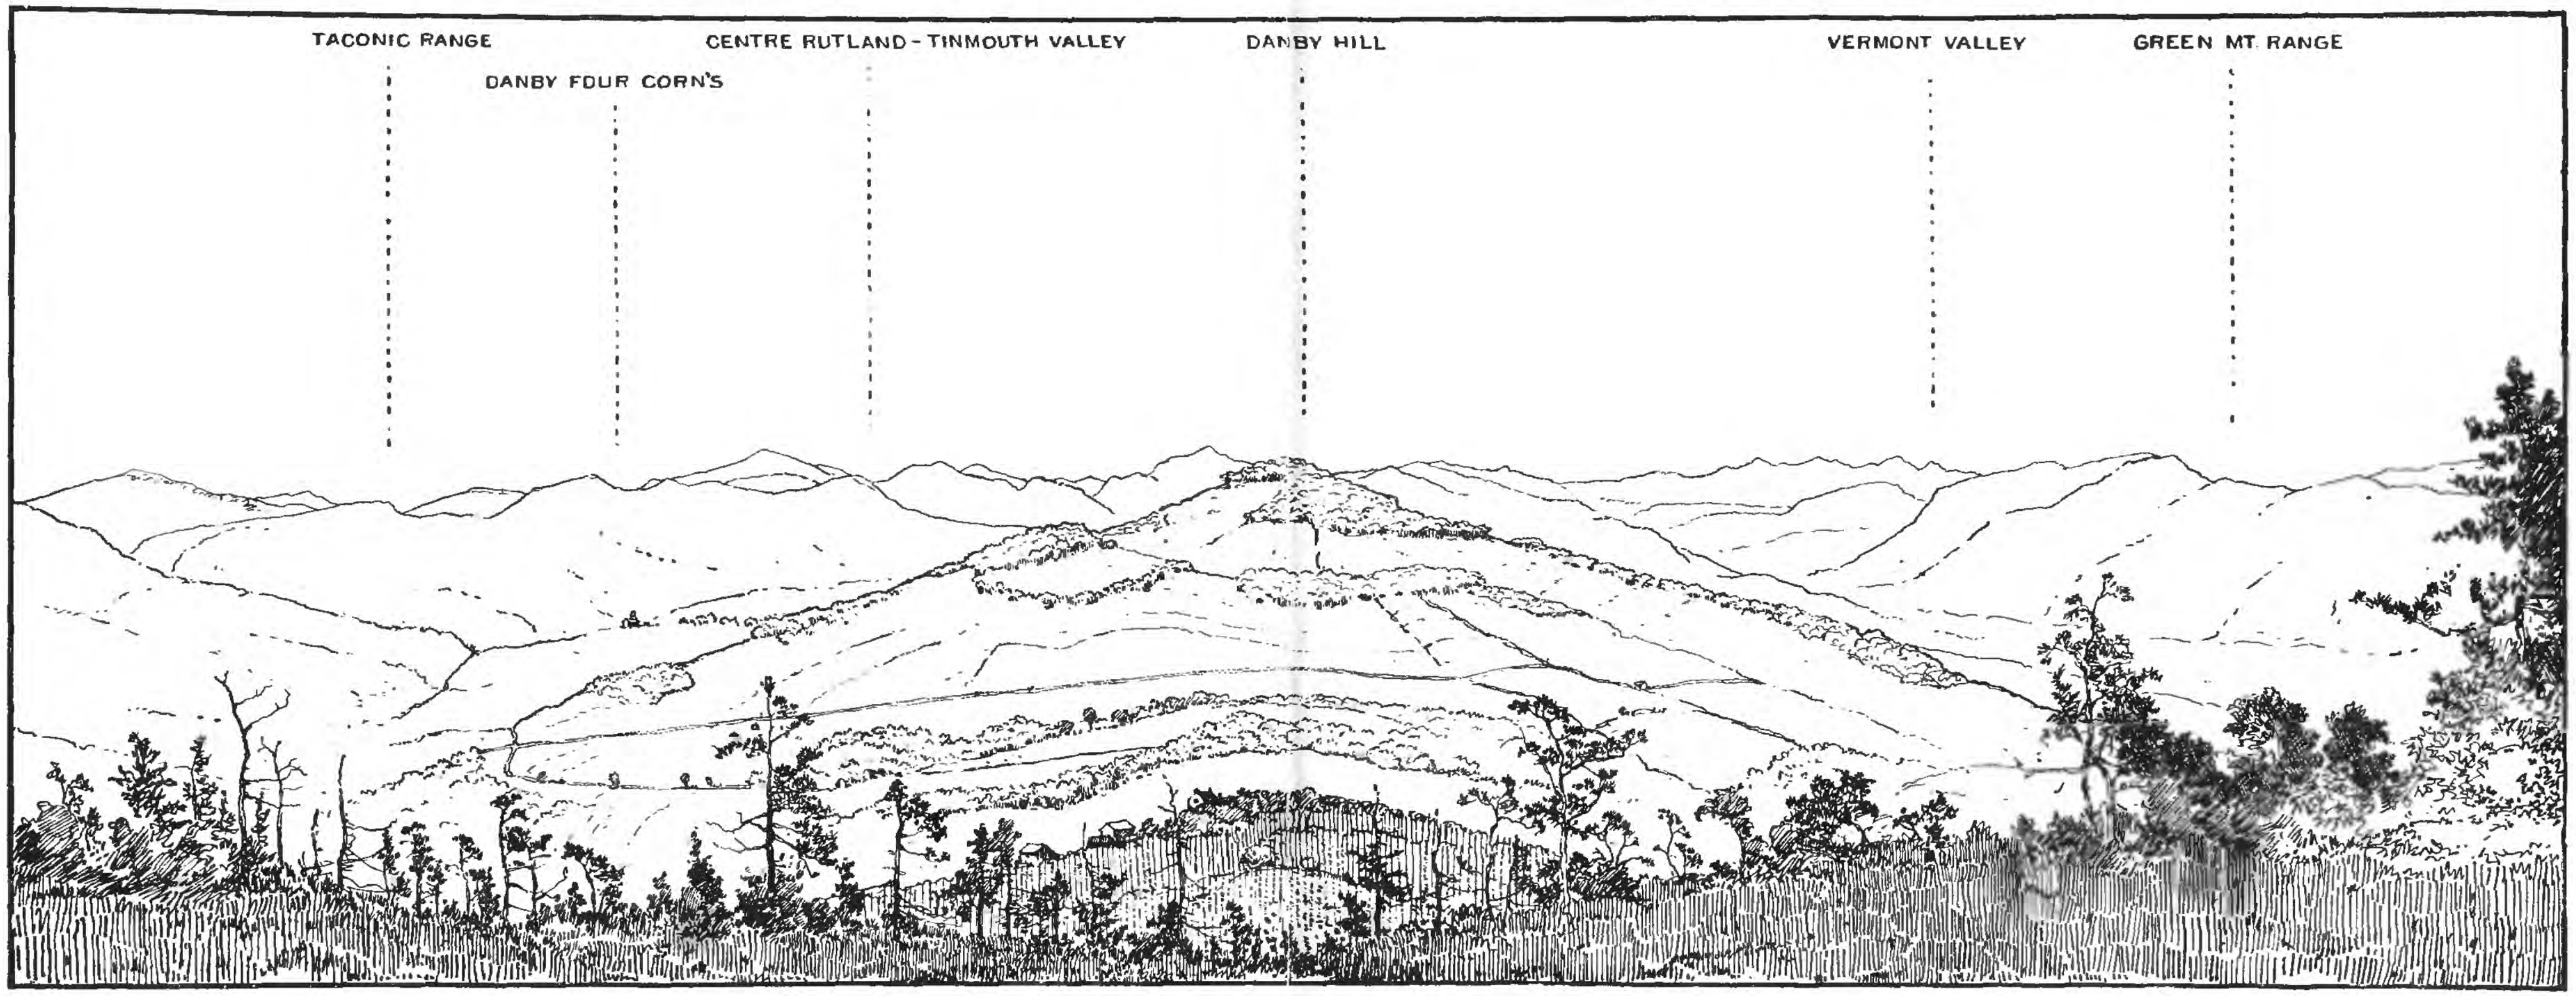
(Fig. 53) was taken from the opposite side of the canyon, on a cold winter day, but the general position of the various portions of the dike is approximately correct.

CONDITIONS OF DEPOSITION.

All of the igneous rocks appear to have come from true fissure eruptions, although, as Mr. Iddings has suggested, this does not necessarily follow from the data we now have. In the upper portion of the Unkar terrane the lava flowed out in successive sheets, a sufficient period of time intervening between the larger outflows to permit of the accumulation of from 3 to 35 feet of sand on the surface of the various flows. The wide distribution of thin layers of sandstone, shale, etc., of uniform thickness over considerable areas, indicates a relatively smooth sea bed at the time of the spreading of the first sheet of lava over it; and that the sea was shallow is shown by ripple marks and the filling of sun cracks. The occurrence of the latter just beneath the basal flow and the presence of beds of sandstone between the flows prove a gradual subsidence of the sea bed during the deposition of the lava. Portions of some of the lava sheets, especially the basal one, bear evidence of having been broken into fine, rounded fragments, apparently by the hot lava pouring into the sea. This phenomenon was



A. THE INTERMEDIATE RANGE AND PINE HILL, FROM THE NORTHERN PART OF THE CLARENDON RIDGE, NEAR LOCALITY 281.



B. THE INTERMEDIATE RANGE AND DANBY HILL, FROM THE NORTHERN SLOPE OF DORSET MOUNTAIN, WITH THE TACONIC RANGE ON THE WEST AND THE GREEN MOUNTAINS ON THE EAST.

A small lenticular area of similar limestone occurs in the quartzite on the east side of the ridge. The steep isolated knoll southwest of Clarendon flats consists of such limestone, with a small area of quartzite on its east side. South of this a series of limestone outcrops stretches across the intervale to Clarendon falls. The Vermont report represents the limestone areas of the Vermont and Tinmouth valleys as uniting between Dorset and Equinox mountains. We have here to do, therefore, with the Stockbridge limestone, Hitchcock's Eolian limestone.

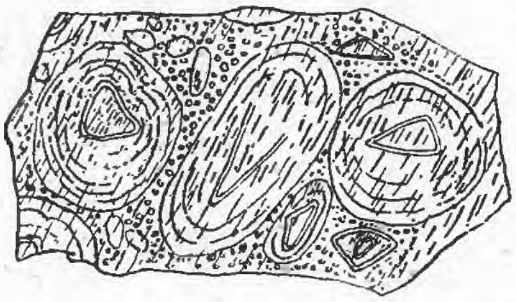


FIG. 54.—Concretionary structure of lower Cambrian limestone at West Clarendon, Vermont, with pteropod shells (Hyolithes) as nuclei. The rock also abounds in minute quartz grains.

In the northern part of the western side of the ridge is an area of graphitic sericite-schist much like that which forms the lower part of the schists of the Taconic range, both in Vermont and Massachusetts—the Berkshire schist. South of the saddle a narrow belt of this recurs with a strip of quartzite west of it and the quartzite and fine-banded gneiss east of it. A lenticular limestone area less than a quarter of a mile long occurs in the schist tract near the road in the northwestern corner of the map. This is the most southerly fossiliferous locality indicated on Mr. Wolff's map.[1] Another much smaller limestone area occurs at 260, about three-quarters of a mile southeast of this one and close to the quartzite.

PALEONTOLOGY.

Traces of fossils were observed by the writer near H, on July 9, 1891. On August 4 they were found in abundance at locality 292, and a few were sent to Mr. Walcott for determination. This fossiliferous bed measures about 25 feet in thickness, and crops out, off and on, for 1,600 feet in a northeast and southwest direction, as shown on the map. The rock is made up in many places of spherical or elliptical nodules from one-tenth to eleven-tenths of an inch in diameter. (See Fig. 54).

In structure, the nodules are oolitic, the calcite particles being arranged in concentric rings about the nucleus, and the form of the nucleus generally determining that of the nodule. The nuclei are more or less perfect pteropods (Hyolithes) which appear in longitudinal, transverse, or diagonal sections on the surface of the rock. The shells are sometimes partially filled with quartz.

Although, as Mr. Walcott suggests, the concentric arrangement of the limestone in the nodules resembles Stromatopora, the sections have not yielded any evidence of their organic origin.

Mr. Walcott's determinations are as follows:

SECTIONS.

Section C.

In order to cross important outcrops this line has been drawn from east-northeast to west-southwest. There is an anticline in the Cambrian quartzite and gneiss. At 255 (Fig. 56) the westerly dipping stratification meets the fault plane, which dips 60° east. The Siluriau schists (sericite, biotite, quartz, and graphite)

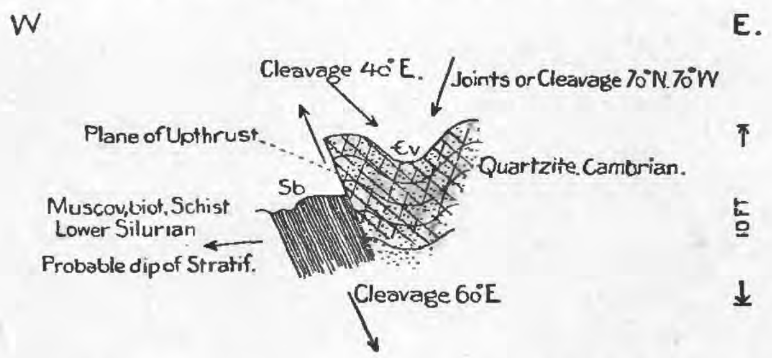

FIG. 56.—Structure of Cambrian quartzite and Silurian schist at the fault, locality 255, Clarendon.

are in contact with the Cambrian quartzite, and have a cleavage foliation parallel to the fault plane. They present an interesting case of a certain type of slip cleavage[1] (Fig. 57). The acute-angled folds of locality 350 (Fig. 55) are repeated here on a microscopic scale, but much more compressed, resulting in extreme slip cleavage.

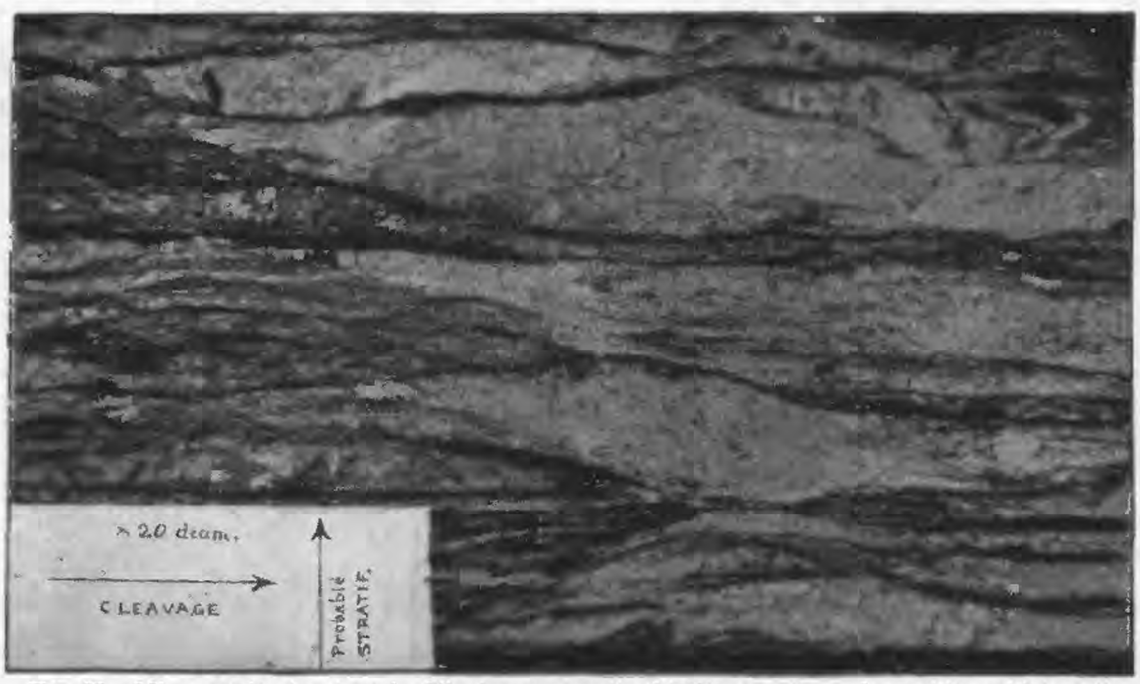

FIG. 57.—Microscopic structure in Silurian muscovite, biotite, quartz, and graphite schist at the fault shown in Fig. 56. The plications have been so compressed as to become extremely acute, then to rupture, and finally to merge into the slip-cleavage foliation thus caused.

Here and there some of the folia of mica have not yet entirely conformed to the cleavage foliation, and thus preserve some indication of the direction of the dip of the stratification, which was probably west or horizontal, i. e., about at right angles to the cleavage.[2] The fault line north of this section is marked by quartz veins. Easterly cleavage foliation pervades the entire mass of schist. On the west side of

[1] See Monograph XXIII, U. S. Geol. Survey, Part III, p. 158.

[2] See Henry Clifton Sorby: On the structure and origin of noncalcareous stratified rocks. Quarterly Journal Geol. Society, London, Vol. XXXVI, 1880, p. 73. Stages of slip cleavage, fig. 3, plication without cleavage; fig. 4, plications faulted. The structure in Fig. 57 above would form the next or third stage. See also J. E. Marr: On some effects of pressure, etc.; Geol. Mag., London, 1888, Vol. V, p. 219, figs. 1–1c.

the ridge the Stockbridge limestone dips conformably under the schist, which forms a westerly facing cliff in which there are indications (locality 298) of a westerly dip, and thus of a fold between that point and 294.

Section D.

Between sections C and D the fault line makes a sudden bend to the west, with the Silurian schists still on its west and south side. The north-northwest and north-

FIG. 58.—The contract of the Cambrian quartzite (Ꞓv) and Silurian schist (Sb) at the overthrust, locality 318, Clarendon, as seen looking east. The sharp edge of the hammer is exactly on the line which divides the two formations. Length of hammer handle, 30 inches. From a photograph.

northeast dip of the quartzite indicates a northerly pitching anticline. At locality 318 the Cambrian quartzite directly overlies the Silurian schists (Fig. 58). The strati-

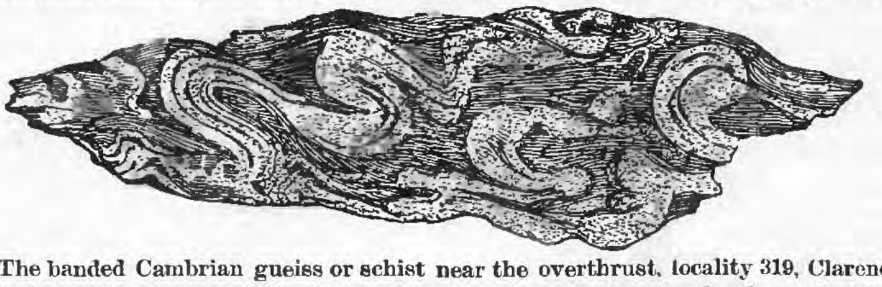

FIG. 59.—The banded Cambrian gneiss or schist near the overthrust, locality 319, Clarendon. The highly plicated light bands consist of a feldspathic quartzite, the dark bands of sericite-biotite schist with slip cleavage.

fication strike of the quartzite is north 60° east, and its general dip 20° to 30° north-northwest, while the cleavage strike of the underlying schist is north 25° east, and its dip 75° east-southeast, but decreasing a few feet away. Its stratification is indeterminable. The hade of the fault could not be exactly determined. The whole mass of the quartzite north of the angle in the fault line may have been thrust horizontally over the Silurian schists. The vertical west face of the quartzite (Fig. 58) strikes north to south and is very smooth in places, being either a joint or the vertical upper part of the thrust plane. At 319, 100 feet north of 318, the Cambrian is represented by the fine banded and plicated close grained gneiss described on page 533, dipping 20° north-northwest, with a cleavage dip of 45° south southeast. (See Fig. 59.) A few feet east this is conformably overlain by a thin-bedded quartzite.

Section E.

This is on the south side of the saddle. A syncline is shown in the Cambrian quartzite and gneiss, the west side of which dips nearly if not quite parallel to the

FIG. 60.—Structural character of the gneiss at locality 317, on the east side of the ridge in Clarendon, looking west-northwest. Area 20 by 20 feet. From a photograph.

fault plane and also to the cleavage of the adjoining Silurian schists. The stratification of this schist mass can only be conjectured from its surface relations. The absence of the schists in the deeper part of the saddle between the two fault planes is readily explained by erosion. The schist masses north and south of the road were once continuous, covering the limestone, and therefore necessarily dipping at a low angle east or west.[1] If horizontal the present extreme thickness south of the saddle would be 170 feet, and north of it at least 360 feet.

Section F,

A little south of Section E, shows an anticline east of the syncline of F and the narrowing of the schist mass. It probably also increases in depth.

Section G.

This section begins at the top of the southern summit at the contact of the Cambrian quartzite and sericite schist with the chloritic gneisses and altered granite. The Cambrian series here may measure about 1,000 feet in thickness. Between F

[1] A half mile south of the most southerly house shown on map, on west side of ridge, the Silurian schists dip west.

The small limestone areas, 339 to 345 and 260, in the schist area, may either be anticlines of the Stockbridge limestone protruding through a thin sheet of the Berkshire schist or may represent local calcareous sediments formed during the Berkshire schist period. The fossils of these areas, lower Silurian, indicate, therefore, the age either of the top of the limestone or of a portion of the schist itself.[1]

FIG. 61.—Specimen of Cambrian quartzite, two-thirds natural size, from locality 337, Clarendon, showing ridges and furrows crossing the fold diagonally. The front edge is a joint face. From a photograph. Size of specimen, 4 by 5½ inches.

INFERENCES.

From the foregoing data the following conclusions are drawn:

The ridge at Clarendon consists of the following series:

		Feet
Berkshire schist (Sb), upper Lower Silurian		360
Stockbridge limestone (€Ss) (1,000 to 1,400 feet.)	Lower Silurian; Upper and middle Cambrian (?)	730
	Lower Cambrian	470
Vermont formation, in part (€v), lower Cambrian		(?) 800
Total		2,360

[1] See The Rensselaer grit plateau, loc. cit., p. 312.

These form an anticline, the eastern and lower portion of which consists, at the surface, of at least five minor folds, all striking northeast to southwest, i. e., diagonally across the ridge. Possibly the saddle marks the place of a change in the pitch of this anticline, and there may be some connection between this and its erosion. However this may be, there is a northerly pitch throughout the northern half of the Clarendon map, which is more conspicuous and general on the west side in the limestone.

This anticline was ruptured and faulted in a general north-to-south direction, some of the upper layers of the quartzite being thrust up a distance equal to the entire thickness of the Stockbridge limestone, 1,200 feet, besides at least 360 feet[1] of the Berkshire schist, i. e., the vertical displacement amounted to about 1,500 feet (sections B and C). In the northern part this fault resulted in an overthrust, bringing the Cambrian quartzite over onto the Silurian schist (section D). In and south of the saddle the fault is double, a more or less wedge-shaped

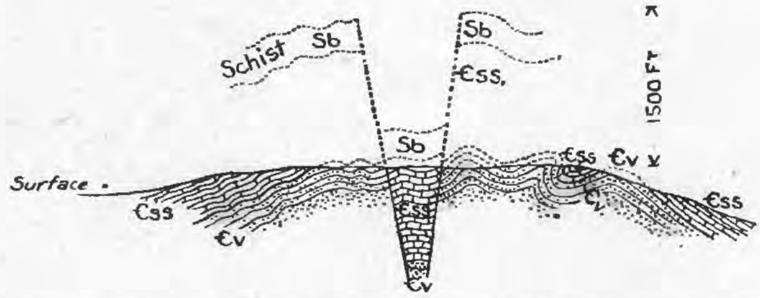

FIG. 62.—Diagram-section showing the general structure of the saddle in the ridge at Clarendon and the amount of erosion implied by the fault.

mass of the limestone and schist, 200 to 650 feet wide, having dropped down between masses of quartzite and gneiss.[2] It is quite possible that in this part of the fault the strata of quartzite and gneiss on either side of the wedge do not correspond vertically; in other words, there has been also some differential vertical motion. This interpretation of the Clarendon sections has been embodied in Fig. 62. The position of the schist between the faults is taken from its lowest outcrop north of the saddle.

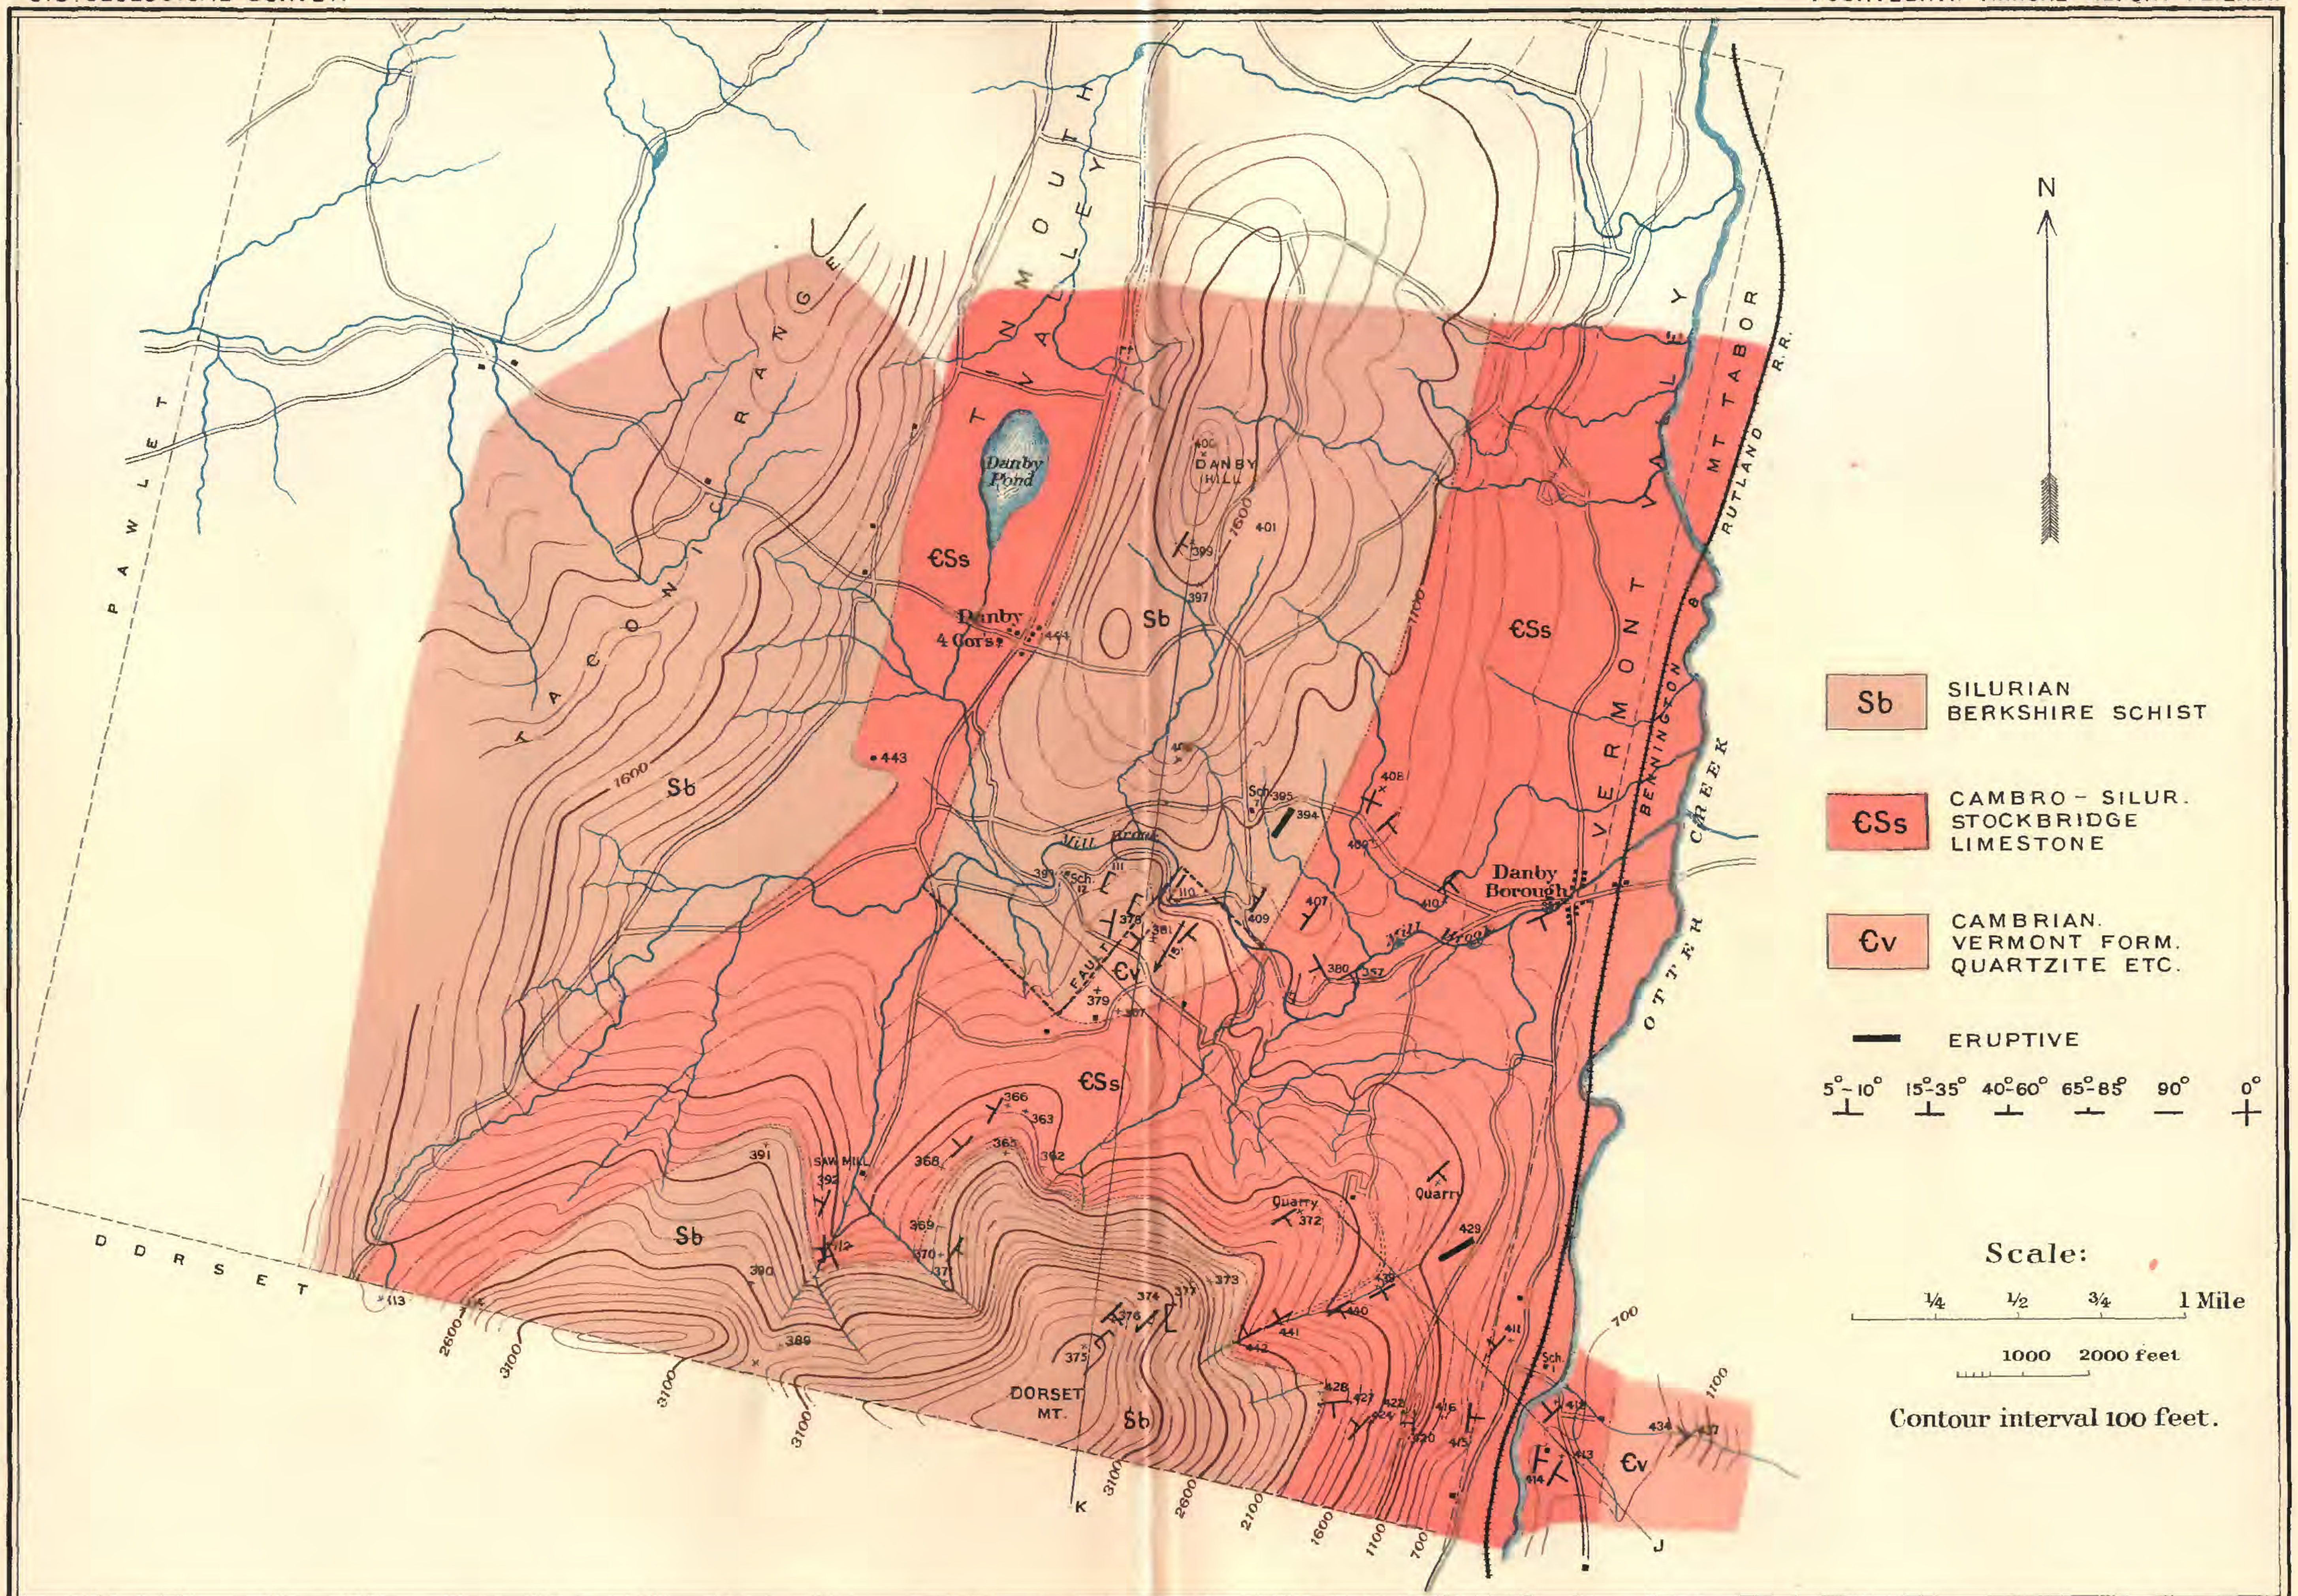
The peculiar areal geology shown on the map is the complex effect of erosion, laying bare at different levels this northerly-pitching anticline of quartzite, limestone, and schist, faulted in these different ways along a line now intersecting the axes of its minor folds at an angle of about 20°, and now parallel with them.

It is also evident that if sedimentation during Cambro-Silurian time

---

[1] This is calculated from the contours between localities 248 and 205.

[2] The westerly fault ending on the map at locality 235 probably joins the easterly one, perhaps near locality 248.



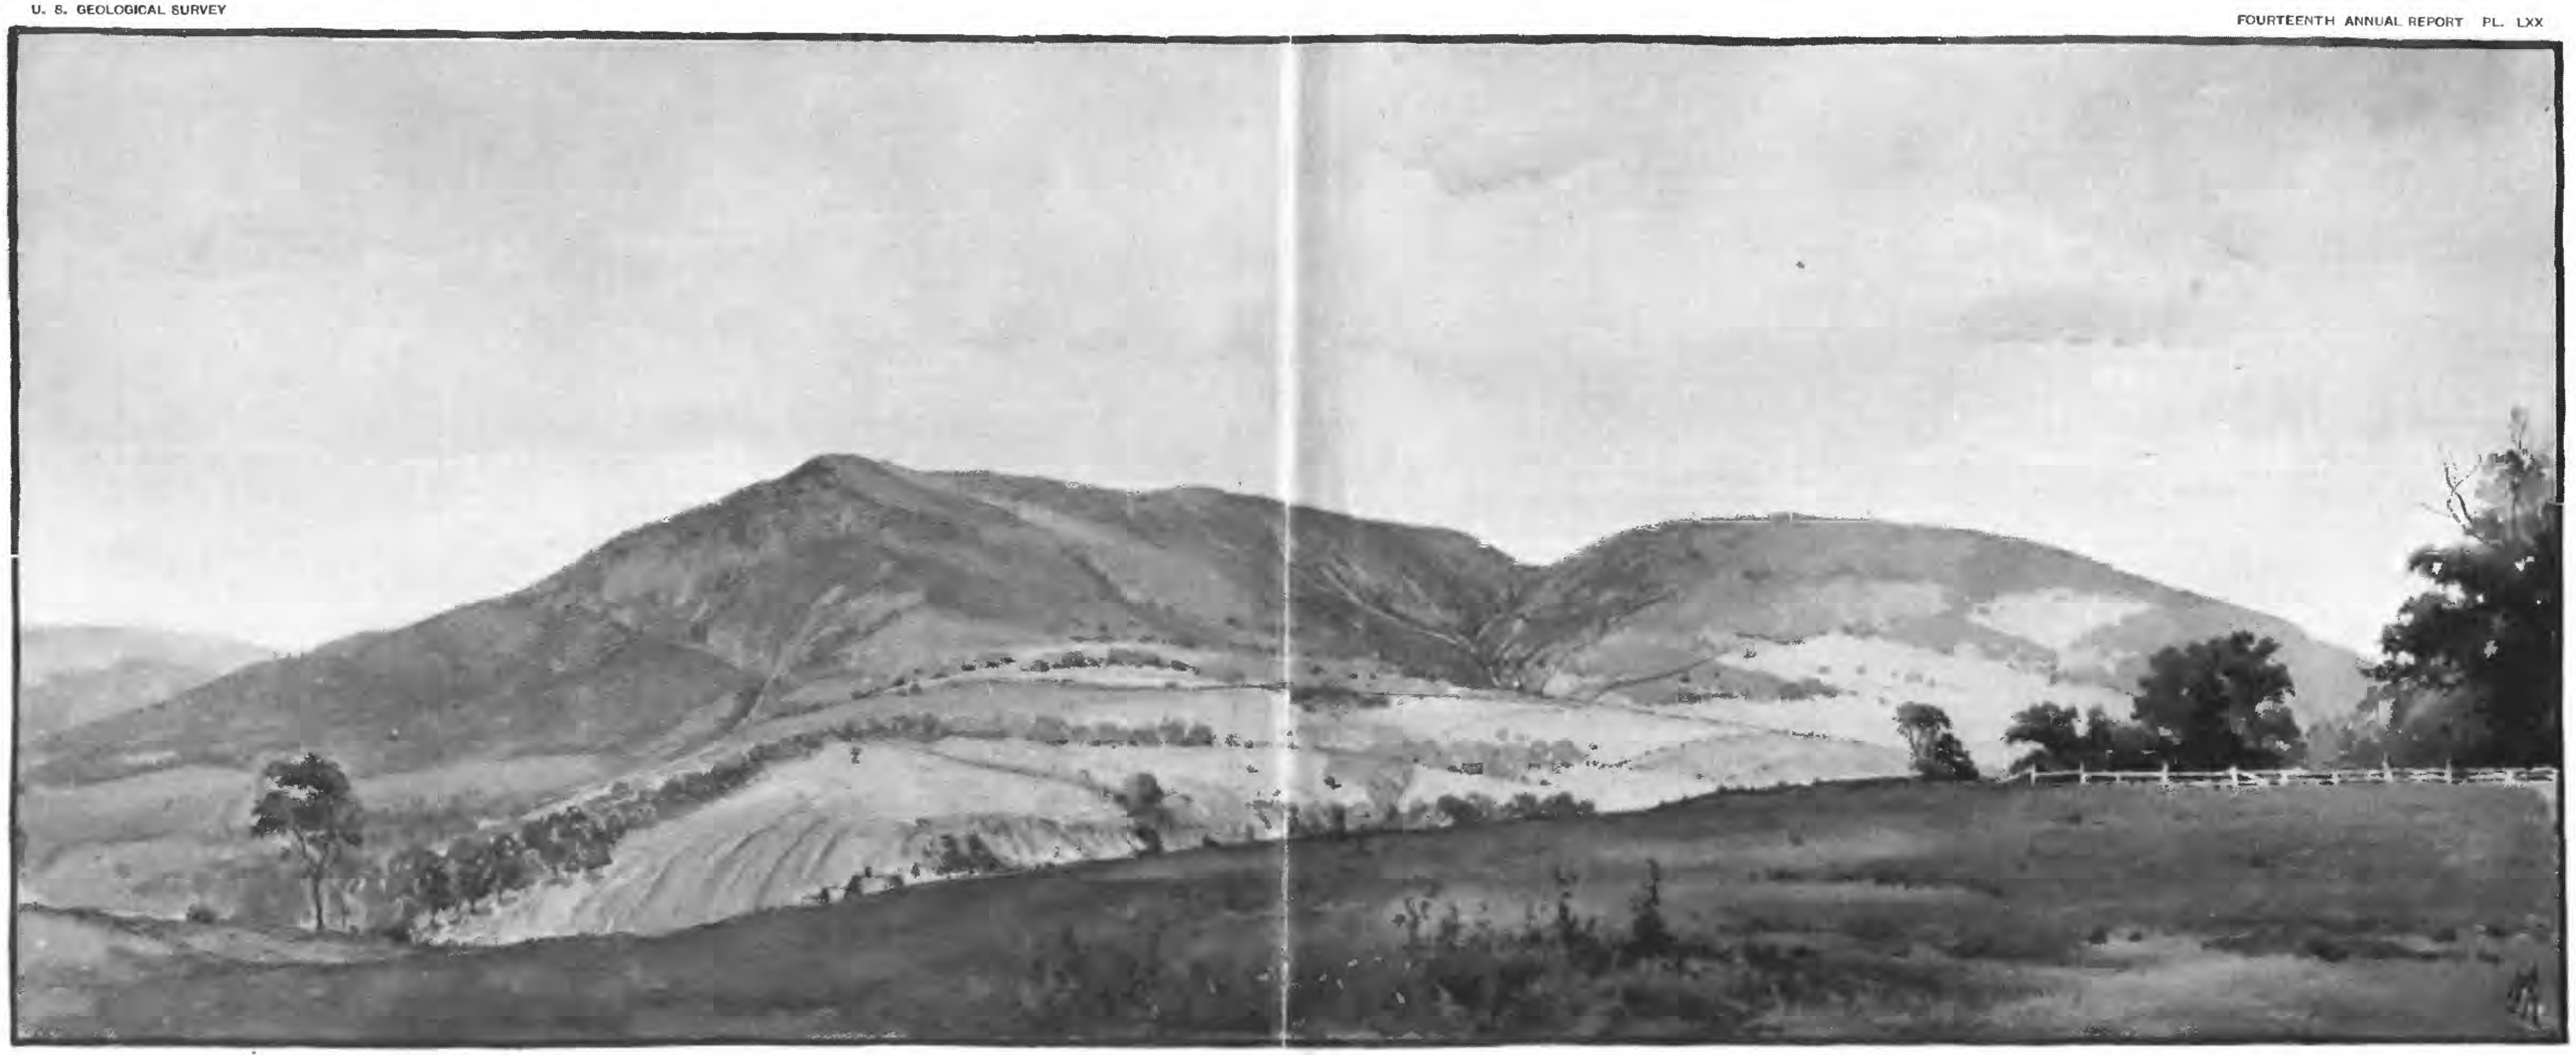
SKETCH MAP OF DANBY TOWNSHIP, RUTLAND CO., VT.

FROM BEERS' ATLAS

CONTOURS ROUGHLY DRAWN FROM PROFILE SKETCHES AND BAROMETRIC OBSERVATIONS

by T. NELSON DALE.

1892.



NORTHERN FACE OF THE DORSET MOUNTAIN MASS, FROM DANBY HILL.

schist were studied at two points—at Proctor (Sutherland Falls) on the west side of the center Rutland valley, and west of the extreme north end of Pine hill. In the most westerly marble quarry the bedding dips 85° east for a vertical distance of 100 feet aud then below turns west at an angle of 45°. The nearest schist at the foot of the ridge west has a cleavage dip of 55° to 65° east and indications of a westerly dipping stratification, but there is room for minor folds between the limestone and the schist.

At West Rutland, along the foot of the Taconic range and about three-fourths of a mile northwest of the Catholic church, there are some large, conspicuous, sericite-chlorite-schist ledges, with a cleavage foliation dipping 20° to 40° east and another dipping about 80° east, but stratification dipping 5° to 20° west, and vertical joints striking east to west.[1]

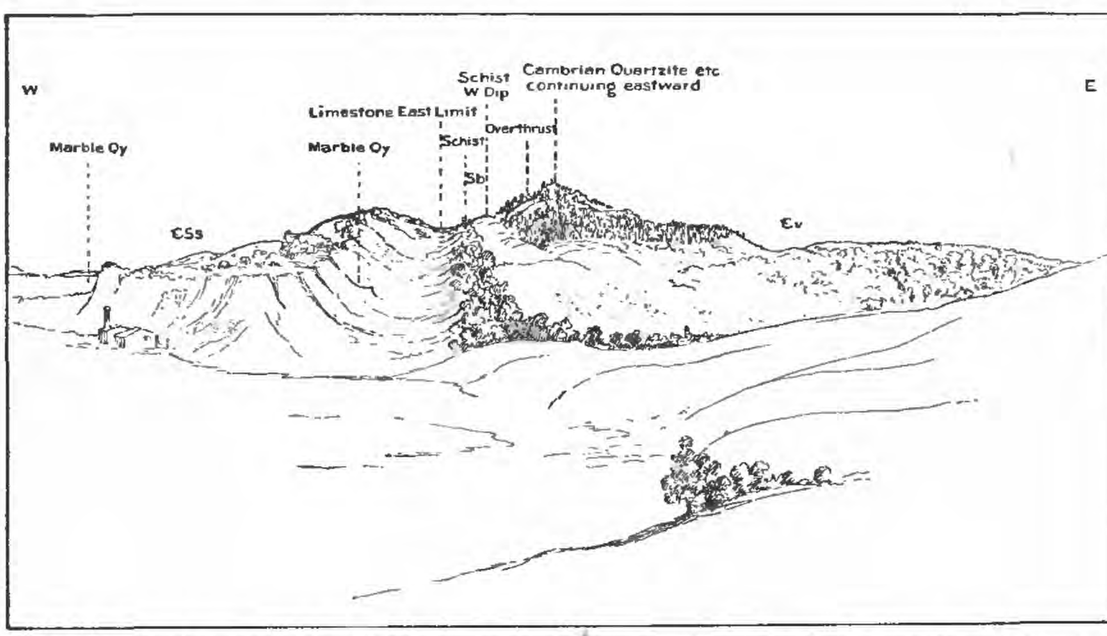


FIG. 64.—Southern side of Pine hill, near Rutland, showing the surface features at the overthrust.

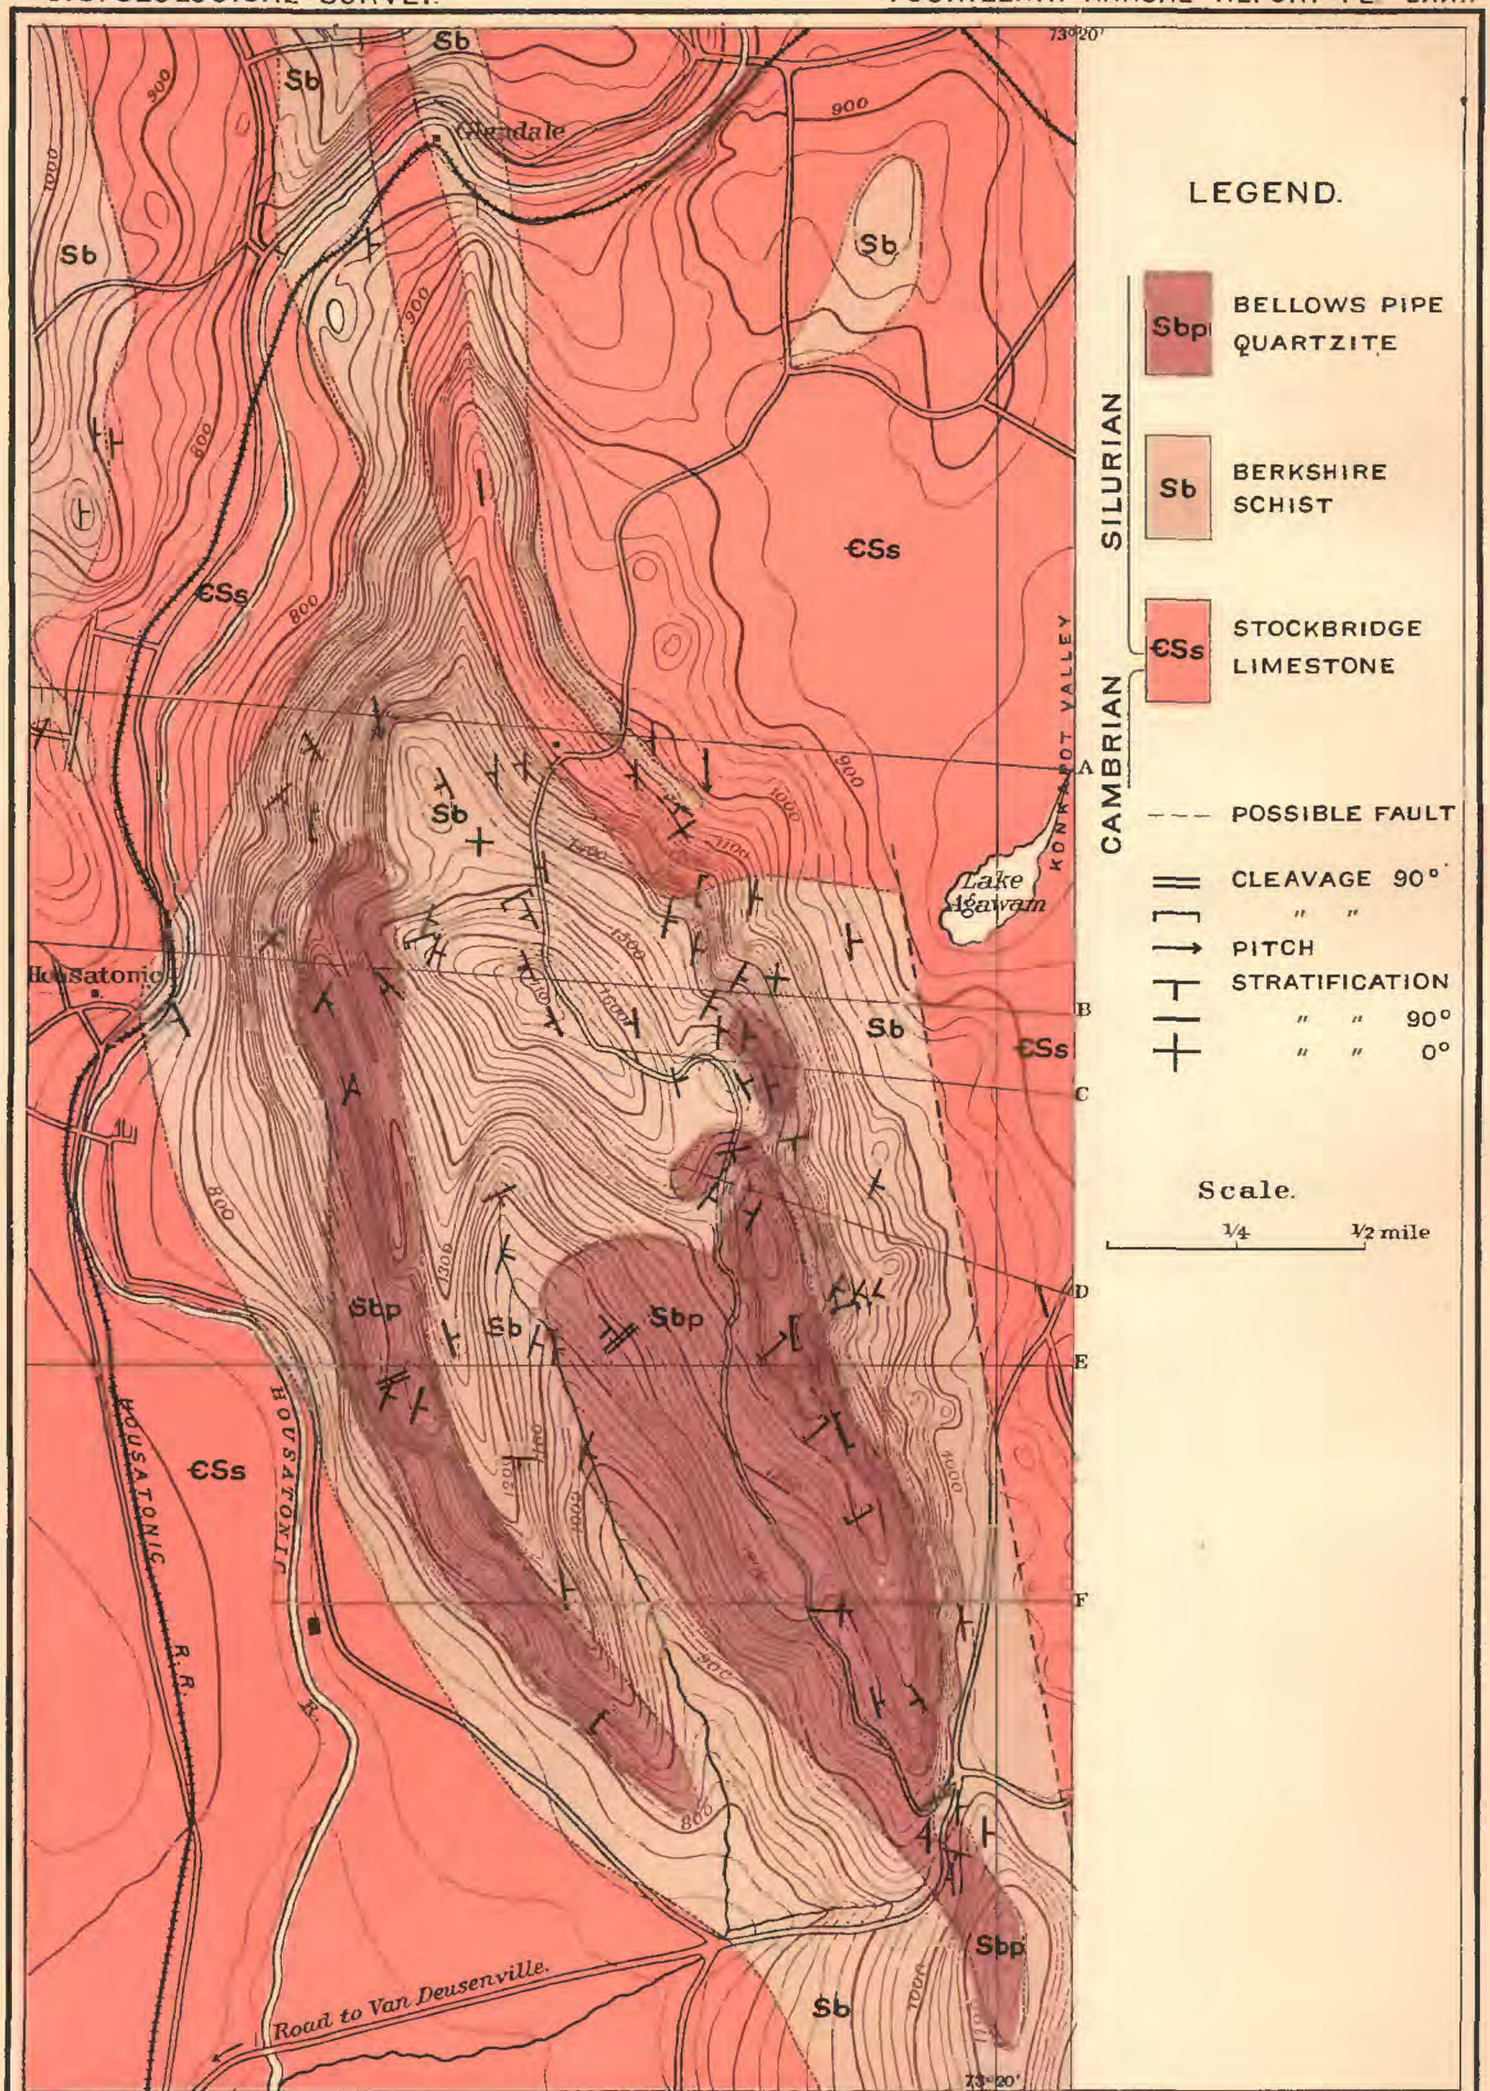
A little farther north, about north-northwest of the Catholic church, the same schists crop out in the meadow east of the road, with a cleavage dip of 20° east and stratification dipping rather high west.

Both of these localities indicate, therefore, westerly dips for the limestone and schist on the west side of both the center Rutland and west Rutland valleys; but as those rocks are in minor folds it is quite possible that the contact may occur now on the east and now on the west side of a fold, or that these may be overturned in places.

ECONOMIC GEOLOGY.

The structure of the schist ledges on the west side of the West Rutland valley, as thus made out, may possibly prove to have an important bearing on the marble industry of that valley. As the real dip of the

[1] For full description of this interesting locality see Thirteenth Ann. Report U. S. Geological Survey, The Rensselaer grit plateau, p. 321, and Am. Jour. Science, 3d ser., Vol. XVIII, April, 1892, p. 317, On plicated cleavage-foliation.



TOPOGRAPHY BY U. S. GEOL. SURVEY. GEOLOGY BY T. NELSON DALE.

MONUMENT MOUNTAIN BERKSHIRE CO. MASSACHUSETTS

THE STRUCTURE OF MONUMENT MOUNTAIN IN GREAT BARRINGTON, MASS.

By T. Nelson Dale.

PHYSIOGRAPHY.

Monument mountain forms part of a range of hills between the Taconic range (Silurian) on the west and the Hoosac range (Cambrian and pre-Cambrian) on the east, extending from a little south of Pittsfield to the vicinity of the village of Great Barrington, a distance of about 18 miles. It lies in the line of the Greylock synclinorium, from which, however, it is cut off by the broad limestone plain about Pittsfield. Owing to the westward offset in the Hoosac range between Lee

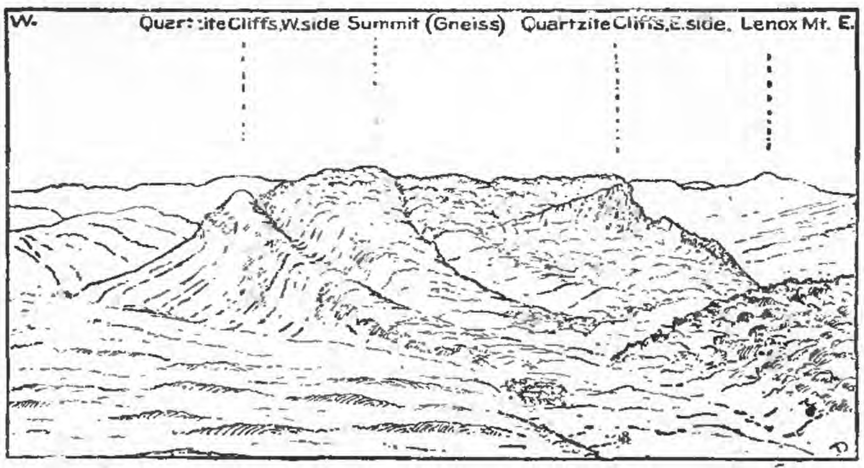


Fig. 65.—Monument mountain, south side, from Mount Keith, in Great Barrington.

and Stockbridge, Monument mountain lies but 2 miles west of the pre-Cambrian gneisses (Beartown mountain). Its area is only about 3 square miles; its higher parts range from 1,640 to 1,710 feet above the sea level and from 740 to 950 feet above the adjoining valleys; its general form is not unlike that of an old-fashioned bootjack, sending out a central spur to the north and two lateral ones to the south. These southern spurs present to the east and west precipitous cliffs of quartzite several hundred feet in height, with considerable talus below. The

Scale $\frac{1}{30000}$: $\frac{1}{25}$ INCH = 100 FT.

STRUCTURE.

Dana's hypotheses.—Prof. J. D. Dana[1] offers two hypotheses:

(*a*) The mass is an extremely compressed syncline, so completely overturned to the west as to give the strata a very low inclination to the east. (See Fig. 67.) This makes the Stockbridge limestone pass under the mass, and places the schists above the limestone and the quartzite on the west side, and puts both schist and quartzite in the Silurian. It involves the recurrence of the quartzite along the eastern foot between the limestone and the schist and the absence of the schist along the western foot.

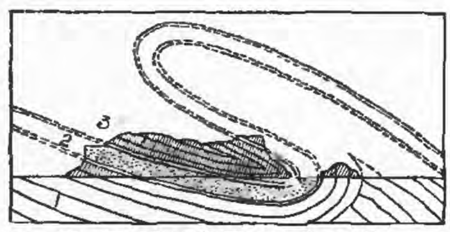

FIG. 67.—Prof. J. D. Dana's hypothesis *a*. 1. Limestone. 2. Quartzite. 3. Gneiss.

(*b*) The mass is an extremely compressed anticline turned over to the west. (See Fig. 68). This places the schists below the quartzite and both below the Stockbridge limestone, i. e., makes them Cambrian. It also involves the recurrence of the quartzite along the eastern foot between the limestone and the schist and the absence of the schist on the west side between the limestone and the quartzite.

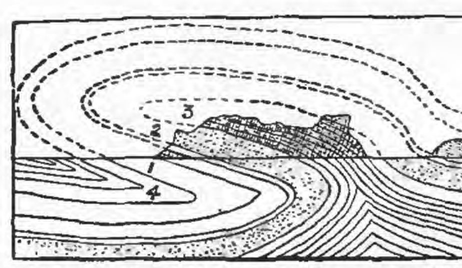

FIG. 68.—Prof. J. D. Dana'shypothesis *b*. 1. Limestone. 2. Quartzite. 3. Gneiss. 4. Schist.

The hypothesis *a* would involve the erosion of twice the thickness of the Stockbridge limestone, 2,000 to 2,800 feet, besides the thickness of the muscovite-biotite-schist, 500 feet, and of the quartzite, 500 to 600 feet, from above the cliffs on the east side. As these are 1,640 feet above sea level, this would make the original altitude of that part of the mass 4,640 to 5,540 feet, from which, however, some deduction should be made for stretching.

Hypothesis *b* would involve the erosion of the thickness of the limestone, 1,000 to 1,400 feet, and of the Berkshire schist, 300 feet, from above the cliffs, making the original altitude of that part from 2,940 to 3,340 feet, with some deduction for stretching.

While the erosion of great loops of rock 1,300 to 3,000 feet thick is quite within scientific possibilities, as shown by modern Alpine geology, it seems safer not to resort to these great loops until simpler theories are shown to be impossible. The chief objection to either of these explanations of Monument mountain lies in the fact of the occurrence of the muscovite-biotite-schist along the western side of the western quartzite and the absence of the quartzite between the limestone and

[1] Loc. cit.

the schist along the eastern foot, although there is a possibility here of its being covered by drift, and this objection has, therefore, not the same weight as the first.

Another theory would explain some of the facts: A fault can be supposed to zigzag from the east to the west, across the north part of the mountain, separating the typical Berkshire schists on the north from the muscovite-biotite-schists on the south. The latter might be regarded as continuous with the similar schists of Cambrian age on the north side of Mount Warner and Mount Keith, near Great Barrington, and the whole mass of Monument mountain conceived as thrust up so as to bring these Cambrian schists in contact with the Berkshire schist (Silurian) coming down from West Stockbridge and Lenox mountains. The quartzite would overlie the muscovite-biotite-schist and, like it, be of Cambrian age. The objection to this theory is that it involves the recurrence of the quartzite along the western as well as along the eastern foot of the mountain, or else the supposition of two longitudinal faults, one on either side, thrusting the limestone down to the level of the schists, neither of which is supported by observation.

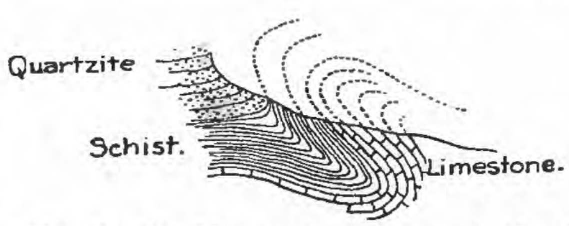

FIG. 69.—Possible structure along east side of Monument mountain.

Another hypothesis would make the central gneiss mass and the lateral quartzites Cambrian, and the graphitic schists on the north side would then represent argillaceous sediments of the age of the Stockbridge limestone. But the quartzite ought then to pitch under them, which it does not.

The structural interpretation shown in Pl. LXXII is advocated on the following grounds: There is a marked parallelism in the features of the mountain (shown on map, Pl. LXXI, and in Fig. 65), the quartzite on the east corresponding to that on the west, pointing to a parallelism of structure. The synclinal structure of the western quartzite appears near its northern end. The presence of an anticline along the east foot of the eastern cliffs is shown by the dips where the road from Muddy brook (Konkapot creek) to Van Deusenville crosses the quartzite. A syncline would naturally follow this anticline on the east, and of this there are also indications in the southern part of the eastern quartzite north of this road. (See map and Section F.) The presence of a gentle syncline and of an anticline east of it, both traversing the central schist mass, and the former traversing also the western part of the eastern quartzite, is also shown on the map. (See Sections B and E.) That two synclines with an intervening anticline enter into the structure of the mountain may be inferred from the two schist synclines which project into it from the schist mountain on the north. (See Section A and map.) The maximum amount of erosion from the surface of the mountain involved in the construction here presented does not exceed 800 feet, and this from the central portion, and abont 500 feet from the summit, making its original height about 2,300 feet. (See Sections B, E, and F.)

The difficulty of this interpretation arises along the east foot, where the schists on a level with the limestone have an easterly dip, in places a low one, with the limestone a thousand feet east of them dipping vertically (section D). The strnctnre here may be regarded either as a very sharp syncline overturned to the west (see Fig. 69), donbling up all the schists along the eastern foot (and overturned folds are very frequent in western Massachusetts), or else, as shown in the sections, Pl. LXXII, as an ordinary syncline resulting in a normal fanlt which brought the Berkshire schist down to the level of the Stockbridge limestone by depressing the eastern side of the mountain 400 to 500 feet.[1] The eastern cliffs, now 1640 feet, would have measnred about

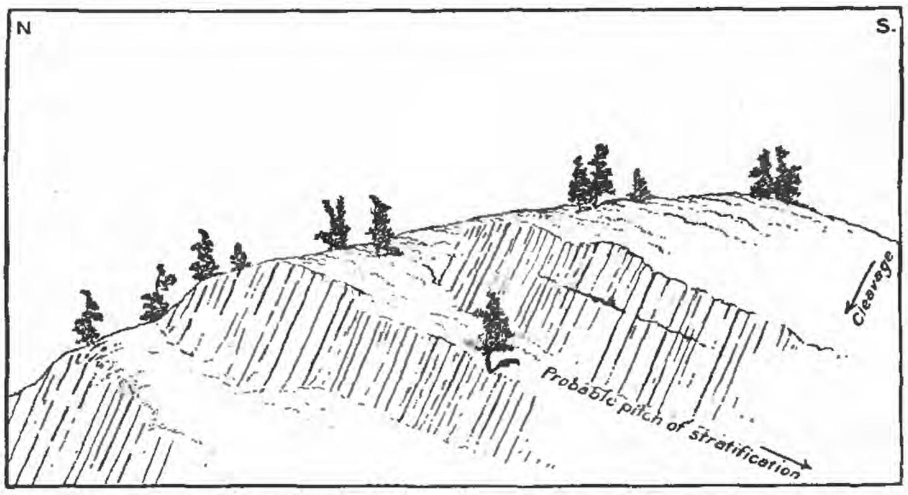

FIG. 70.—The northerly dipping cleavage on the west face of the eastern quartzite of Monument mountain as seen from the west spur.

2200 feet before the fanlting. It is quite possible, however, that the quartzite was originally thicker than 500 feet. The drift along the eastern foot prevents nearly all strnctnral observations. That the top of the Stockbridge limestone is represented in the valley east of the mountain is shown by the occurrence of several masses of the overlying Berkshire schist along its center.

In further support of this general interpretation comes the fact that on Mount Greylock the Berkshire schist, although measuring 1,000 feet, and even more, in thickness, is overlaid by a mass 600 feet thick of more or less impure limestone, quartzite, calcareous sericite-schist and mnscovite-biotite-schist, constituting the Bellowspipe formation, and that the quartzite, calcareons, and noncalcareous muscovite-biotite-schists of Monument mountain correspond to such a series. In the geological coloring of the map, Pl. LXXI, everything but the quartzite

[1] There are some indications of a fracture along the west foot of Beartown mountain, e. g., Ice Glen, in Stockbridge.

and Stockbridge limestone has been thrown into the Berkshire schist formation, owing to the difficulty of defining the boundary between the various schists and the facility of defining the quartzite area. The observed thickness of the sericite-chlorite and graphite schists on Monument mountain is about 300 feet, i. e., 700 feet less than the minimum thickness of the Berkshire schist. All the schists and the quartzite on Monument mountain measure from 1,300 to 1,400 feet. On Greylock the Berkshire schist and Bellowspipe series measure at least 1,600 feet.

Petrographically, such a construction does not offer serious difficulties. As biotite passes by decomposition into chlorite, the difference between a muscovite-biotite-schist and a muscovite-chlorite-schist is not a radical one. Biotite is also a characteristic mineral of the Berkshire schist of a large area in Dutchess county, New York. But the difference between the two schists on Monument mountain is

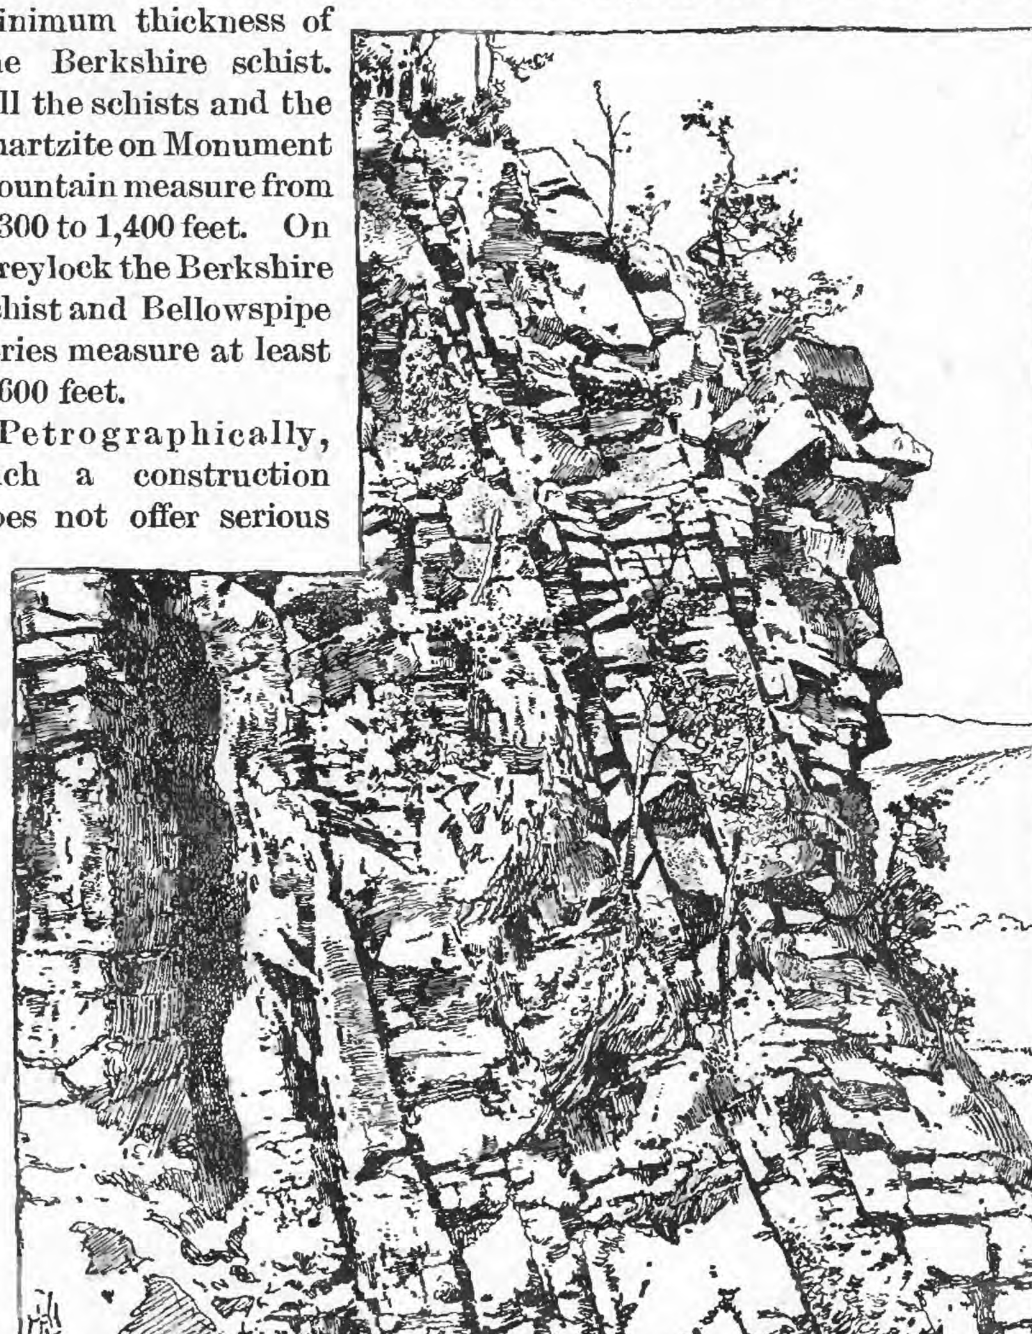

FIG. 71.—Quartzite cliffs, east side of Monument mountain, south face of jog, showing a cleavage dipping north and another dipping east at high angle.

more probably due to a difference of sedimentation, the muscovite-(sericite)-chlorite-schists originating in more argillaceous sediments and the muscovite-biotite and far more quartzose schists, with porphyritic feldspars, in more siliceous sediments. It is also probable that these schists have been subjected to different amounts of pressure and strain, resulting in different metamorphic processes. The fact that the muscovite-biotite-schists are in places calcareous is also true of the Berkshire schists in western Massachusetts and Vermont, and the interbedding of quartzite and impure limestone is quite characteristic of the Bellowspipe formation.

Cleavage and pitch.—Among the marked features of the quartzite of Monument mountain are its various systems of cleavage or jointing. The more general of these coarse foliations are shown on the

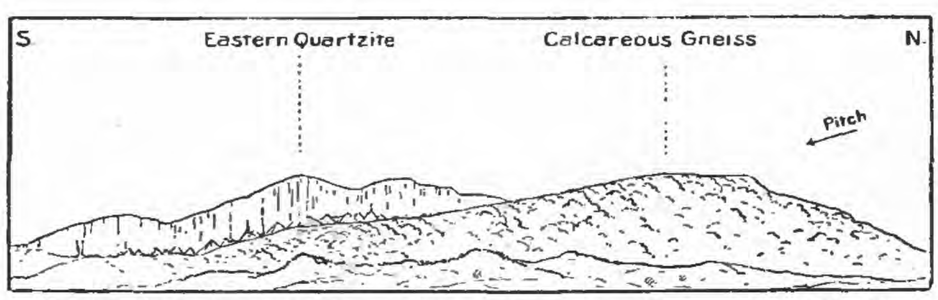

FIG. 72.—The outlines of Monument mountain from the east side of Konkapot valley, showing some of the relations of the gneiss or schist to the quartzite.

map by cleavage symbols. The most conspicuous is that which strikes east-northeast to west-southwest across both the east and west cliffs, and dips either vertically or northerly at a high angle. (See Fig. 70.) Another strikes about north-northwest and dips east at a high angle. (See Fig. 71.) The pressure which in the more pliable schists found relief in minor folds and minute cleavage, produced these sets of fractures in the more coherent and brittle quartzite. In the schist area there is occasionally a southerly dipping cleavage. Sections A and B, taken together, show a marked southerly pitch, the limestone descending with the increasing thickness of the overlying schists, and it is quite possible that the north and south dipping cleavage are related to this southerly pitch and a north to south pressure, while the easterly cleavage is associated with the strike of the folds and an east to west pressure. The southerly pitch of the schists under the quartzite shows itself in the surface features of the east side (see Fig. 72), and the low southerly dipping planes seen in the west face of the eastern quartzite (Fig. 71) are probably due to the pitch of the quartzite.

The southward termination of several schist masses west of Van Deusenville points to a northerly pitch along that latitude, which may extend far enough east to affect the south end of the Monument mountain mass. The termination of the quartzite outcrops on the south, with their decreasing altitude, would add somewhat to this probability.

Though quite a number of veins of coal have been found here, as will be seen from the sections given below, the veins worked are known locally as the Thomas and Davis veins, so called after the Davis brothers, Henry G. and Thomas B., who were the pioneers in the development of this region. The Thomas vein is the Upper Freeport; the Davis vein the Lower Kittanning. The Upper Freeport or Thomas vein of this region has a thickness of nearly 8 feet, but a bony coal or slate near the center of the bed leaves about 6 feet of merchantable coal. The coal is valuable for both steam and coking purposes. The Lower Kittanning, or Davis vein, has a thickness of nearly 11 feet. With reference to its content of sulphur this is one of the purest coals mined. It is not only used largely for steam, but is especially valuable for blacksmithing purposes. For coking it is a most excellent coal.

At the head of the North Potomac and on the Cheat river side of the great Alleghany watershed, we get a fine exposure of these Lower Coal Measures in the vicinity of Thomas. The exposures have been made by the mining and grading operations of the West Virginia Central Railroad, and there the section reads as follows[1]:
