INTRODUCTION

Purpose of study

This report presents the results of a geochemical survey of the Wallace 1° x 2° quadrangle, Montana and Idaho. Samples of stream-sediment and heavy-mineral concentrate were collected as part of the U.S. Geological Survey CUSMAP program. CUSMAP is the acronym for Conterminous United States Mineral Resource Appraisal Program. The heavy-mineral concentrates and stream-sediments were analyzed by semiquantitative emission spectrograph methods. Selected elements in the stream-sediments were determined by atomic absorption spectrometry. Chemical data for all samples are tabulated in the following sections. In addition, a summary of selected statistical estimates for the elements is presented. No data interpretation is included in this report. The purpose of this report is to make the data available to the public in a timely manner, and to provide sufficient information for users of the data, to make their interpretations.

Location

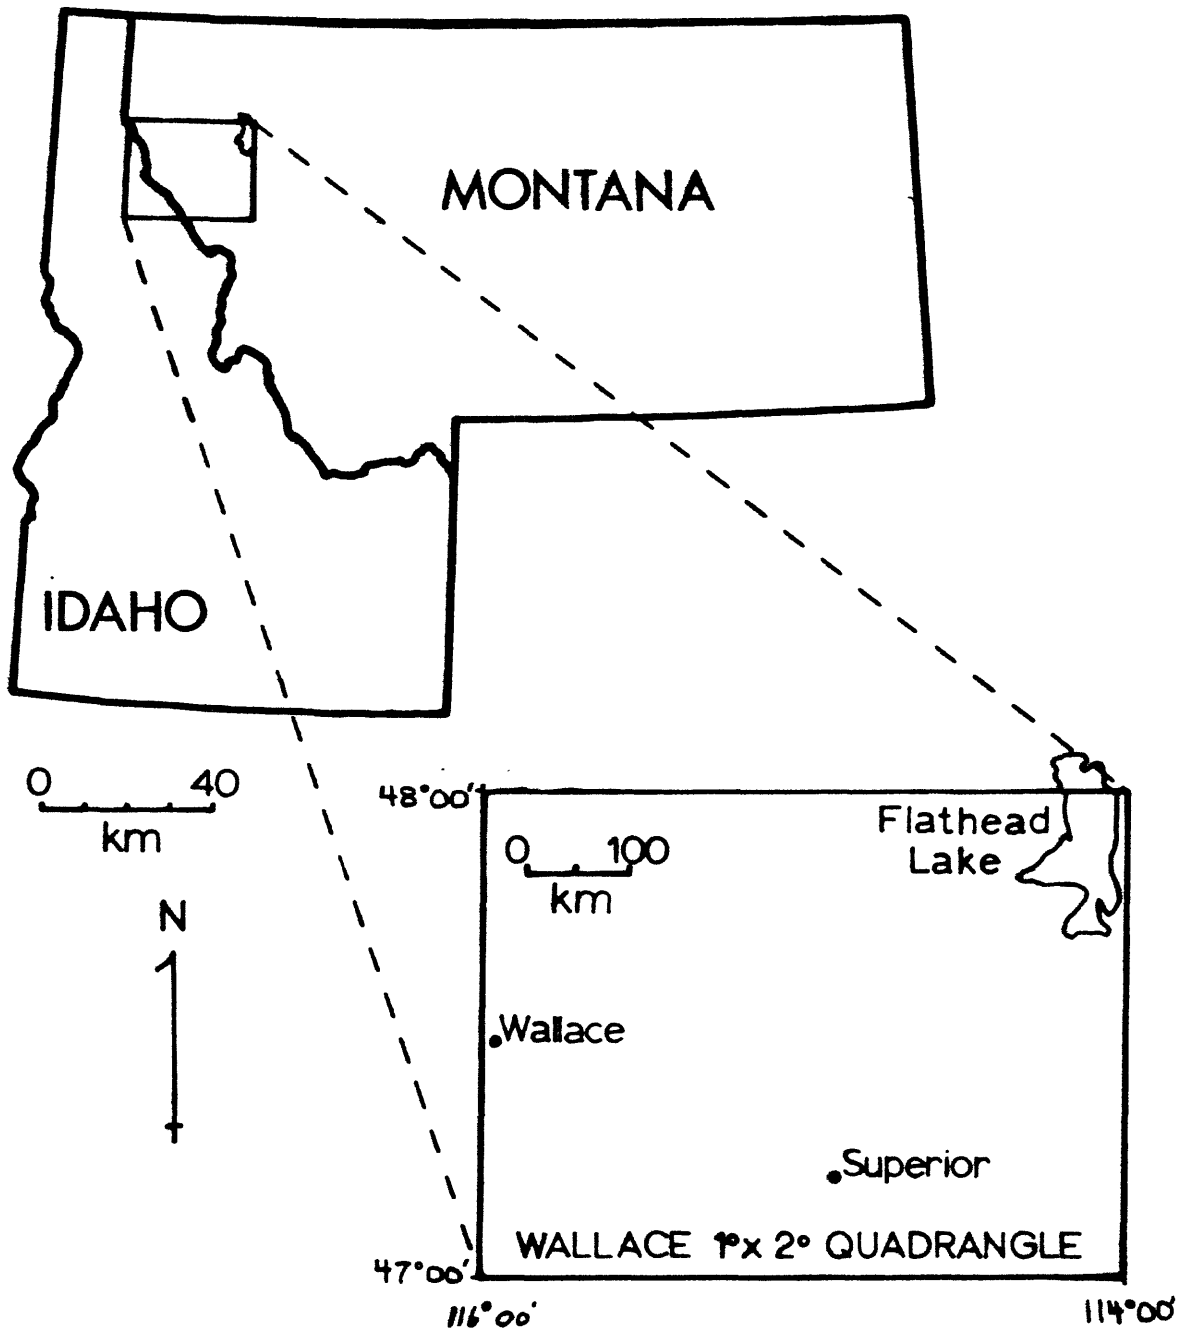
The Wallace 1° x 2° quadrangle area is in northwest Montana and the panhandle of northern Idaho (fig. 1). The area includes parts of the St. Joe, Lolo, and Coeur d'Alene National Forests. The Flathead Indian Reservation, located in the eastern part of the quadrangle was not included in this study. Plate 1 shows sample site locations.

Geology

Much of the Wallace 1° x 2° quadrangle area consists of deeply dissected mountains of the Bitterroot Range, which extends on both sides of the Idaho-Montana state line. The area is characterized by moderate relief, but is as much as 100 m at places. Major river drainages include the Clark Fork, St. Joe, Thompson, Coeur d'Alene, and St. Regis Rivers.

Most of the area is underlain by Proterozoic Y rocks of the Belt Supergroup, in what is referred to as the Precambrian Belt basin of the northwestern United States and adjacent parts of Canada. The thickness of the Belt section in parts of the Wallace 1° x 2° quadrangle may exceed 20,600 m (Harrison, 1972, p. 1219). The rocks comprising the Belt Supergroup consist largely of fine-grained clastic rock--quartzites, siltites, and argillites. The terms argillite, siltite, and quartzite are used rather than claystone, shale, siltstone, and sandstone because of the widespread low-grade metamorphism in the Belt basin. The rocks are generally monotonous in appearance, due to the fine-grain size and drab colors. For more detailed discussions about Belt basin rocks, the reader is referred to Harrison and Grimes (1970) and Harrison (1972).

Figure 1.--Location map of the Wallace 1° x 2° quadrangle.



INDEX MAP OF WALLACE 1°x 2° QUADRANGLE

The rocks in the Wallace 1° x 2° quadrangle area are highly faulted and fractured. Perhaps the most strikingly deformed area is the northwest-trending Lewis and Clark line, which is a wide crustal flaw that has existed probably since the middle Proterozoic. The highly faulted and fractured ground, characteristic of the Wallace 1° x 2° quadrangle, contains a series of mafic to felsic intrusives that include Precambrian and Tertiary mafic dikes and sills, and Cretaceous and Tertiary felsic plutons. In a regional sense, the Cretaceous and Tertiary intrusives outliers the Idaho batholith, which is about 25 km to the south of the quadrangle, and of the batholithic terrane of eastern Washington and northern Idaho, which is about 45 km northwest of the quadrangle. The Belt rocks have been metamorphosed to greenschist facies regionally and to amphibolite facies locally near the intrusives.

Known mineral occurrences

Part of the Coeur d'Alene mineral district is located at the western edge of the quadrangle boundary in the vicinity of Wallace, Idaho. This district is one of the most important mining districts in the world; through 1980 the district has had produced from it approximately 935,287,000 ounces Ag; 500,553 ounces Au; 7,679,772 tons Pb; 160,985 tons Cu; and 3,051,743 tons Zn (Donald C. Springer, Consulting Geologist, Osburn, Idaho, personal commun., 1980). The mines in the district have yielded more Ag than any other in the world. The district is one of the few where the ore is mined principally for its silver content. The principal veins in the district contain galena, tetrahedrite, and sphalerite. In addition to the ore-bearing veins within the Coeur d'Alene district, there are numerous mesothermal veins throughout most of the quadrangle area that carry galena, sphalerite, bornite, and chalcopyrite, accompanied by varying amounts of gold and silver.

Stratabound Cu-Ag occurrences are found in almost all formations of the Belt, excluding the Prichard, Bonner, and Pilcher and their stratigraphic equivalents (Harrison, 1972, p. 1232). The sulfides are dominately bornite, chalcocite, and digenite with lesser amounts of chalcopyrite, tetrahedrite, and covellite. The mineralogy of Ag in the stratabound occurrences is uncertain, but silver may occur as native metal. Ore occurrences known to date are in the northwest part of the Wallace 1° x 2° quadrangle and the adjacent area to the north in quartzites of the Revett Formation. Galena may be an important constituent in the occurrences in the Revett Formation.

The single known occurrence of a stockwork porphyry molybdenum-tungsten deposit in the Wallace quadrangle is approximately 6 km north of the mouth of the Thompson River. The deposit is associated with a buried intrusive, which is indicated by a prominent positive aeromagnetic anomaly.

Epithermal high-grade silver deposits are associated with a small volcanic center in the northeastern part of the Wallace quadrangle (Johns, 1970; Shenen and Taylor, 1936). Veins and pockets of primary ore occur in fumerole holes and tubes, and at contacts between porphyry plugs and their host rocks.

Placer gold has been found in many areas of the Wallace 1° x 2° quadrangle in stream sediments of Tertiary and Pleistocene age, as well as in modern drainages or other valley-fill deposits (Lynden, 1948). The most important areas are those where modern streams are reworking Pleistocene glacial sediments--particularly in small tributaries to the Clark Fork, St. Regis, and Coeur d'Alene Rivers.

Platinum-group metals, primarily platinum and palladium, occur in sheared and altered zones in a dioritic to gabbroic dike in the Burke Formation, located along Revais Creek, 5 km southwest of Dixon (R. L. Earhart and S. E. Van Loenen, unpub.data).

SAMPLE COLLECTION AND PREPARATION

Sampling plan

Most sample sites were chosen on small-order drainages, generally first- or second-order drainages. Stream-sediment sampling sites were selected at a minimum density of one site per cell with the cell being an area of approximately 10.4 km^2 (4 square miles). Some cells may not contain a sample site because of factors such as lack of small-order stream drainage or inaccessibility. Some cells may contain more than one sample site because of resampling for various reasons. Twenty-four cells (2 percent) were randomly chosen for duplicate sampling. A duplicate sample was collected 100 m downstream from the original site to provide an estimate of intrastream compositional variation. The intrastream duplicate samples were split into 2 samples to provide an estimate of analytical variations. Additional small-order streams within the 24 cells were sampled to estimate intracell variation (stream-to-stream within the same cell).

Possible contamination from mining activity

We generally avoided sampling streams that contain mines within the stream catchment area, which explains the lack of sample sites within the most active part of the Coeur d'Alene district. The numerous prospects and mines scattered throughout the Wallace quadrangle undoubtably have contributed contamination to a small number of samples even though we attempted to avoid such contamination. Many of the potentially contaminated samples are near the mines and smelter activity in the Coeur d'Alene district. A limited number of samples were collected from selected stream drainages that contain exposures of mineralized rocks or mines that may represent the various types of mineral resources known in the quadrangle. In addition, a detailed geochemical study was conducted near a stratabound Cu-Ag occurrence in the Cabinet Mountains Wilderness, north of the quadrangle boundary (Cazes and others, 1981, Cazes, 1981). The data from these samples were used to characterize the suite of elements associated with each known mineral-resource type. This information is summarized in table 1.

Table 1.--Characteristic suite of anomalous elements for mineral resource-types known in the Wallace quadrangle

Mineral-resource type	Characteristic suite of anomalous elements[1]			Examples of samples from data tables 10 and 11[2]	References
	Total metal concentration in stream sediments	Partially extractable metals in stream sediments	Nonmagnetic heavy-mineral concentrates		
Mesothermal veins (Includes deposite in Ceour d'Alene district)	Ag, Pb, Zn, Cu, Sb, Cd, minor Bi, Mo, Mn	Ag, Pb, Zn, Cu, Sb, Cd, Bi	Ag, Pb, Zn, Cu, Sb, As, minor Cd, Bi, Mo,	1820-1825, 6238, 6444, 3104, 6254, 2151	Gott and Cathrall, 1980
Stratabound Cu-Ag	Cu, Ag± Pb, very minor Bi, Mo, Hg	Cu, Ag±Pb	Cu, Ag±Pb	_____	Harrison, 1972; Cazes and others, 1981; Cazes, 1981
Stockwork porphyry Molybdenum-tungsten	Pb, Cu, Cd, Zn, Bi	Pb, Cu, Zn, Bi	W, Mo, Bi	2208-2214

Placer gold	none detected	none detected	Au, minor Ag	3066, 3700	

[1]Not all elements may be present as anomalous concentration in all samples for each mineral-resource type.
[2]Does not include all samples that may represent each deposit type

Stream sediments

At least 5 grab samples were collected at each site along a 10-m stretch of the active stream channel using a polyethylene or aluminum scoop. The grab samples were composited into a single sample and then air-dried. The composited sample was sieved using a stainless steel 80-mesh (180-μm opening) screen. The material passing through the 80-mesh screen was pulverized to less than 100 mesh for analysis. The discussion that follows used "stream sediment" as synonymous with the minus-80-mesh fraction.

Heavy-mineral concentrates

A heavy-mineral concentrate sample was collected at most sites using a standard gold pan. Heavy-mineral concentrates were not collected from some sites because of the near absence of heavy-minerals in some stream sediments. Commonly, 3 to 4 kg of composited sediment were collected to yield the desired 30-60 g of concentrate. At the laboratory, the sample was air-dried, and the highly magnetic material (i.e., magnetite, ilmenite) was removed by an electromagnet magnet. Any light-weight material remaining in the concentrate was then separated by allowing the heavier fraction to settle through bromoform (specific gravity 2.82). The resulting heavy-mineral fraction was then separated into a nonmagnetic and magnetic fraction using a Frantz Isodynamic separator at a setting of 0.6 ampere, with 15° forward and 15° side settings. The nonmagnetic fraction was pulverized in an agate mortar before analysis.

ANALYTICAL PROCEDURES

Semiquantitative Emission Spectrography

Each stream-sediment and nonmagnetic heavy-mineral concentrate sample was analyzed semiquantitatively for 31 elements using an optical emission spectrograph, according to the method outlined by Grimes and Marranzino (1968). The semiquantitative spectrographic values are reported as the approximate geometric midpoints: 1.0, 0.7, 0.5, 0.3, 0.2, 0.15 (or appropriate powers of 10) of ranges, whose respective boundaries are: 1.2, 0.83, 0.56, 0.38, 0.22, 0.18, and 0.12 (or appropriate multiples).

The precision of the results of the semiquantitative spectrographic analyses varies from rock type to rock type and from element to element within the various sample media. In general, the precision of the results of the method is plus or minus one reporting value of the actual value given 83 percent of the time and within two intervals 96 percent of the time (Motooka and Grimes, 1976). Analyses performed by one analyst over a relative short period of time exhibit a degree of precision greater than that quoted. A reference sample was included on every spectrographic plate to insure the quality of the analyses.

The lower limits of detection for the 31 elements determined in stream sediments, are given in table 2. Because heavy mineral concentrates yield a complex spectra due to higher concentrations for various interfering elements (i.e., Zr, Ti) the analytical sample size was reduced by one-half. The lower limits of detection were correspondingly raised by a factor of two.

Table 2.--Visual lower limits of detection for semiquantitative emission spectrographic analyses of samples of stream sediment. The lower limits of detection for heavy-mineral concentrates are twice the values shown
[Limits calculated either in percent or in parts per million (ppm)]

Element	Percent	ppm	Element	Percent	ppm
Calcium	0.05	--	Molybdenum	--	5

Manganese	--	10			

Atomic absorption spectrometry

Each stream-sediment was analyzed by atomic absorption spectrometry for total metal concentration of Ag, Bi, Cd, Cu, Pb, Sb, and Zn to obtain lower detection limits than available by emission spectrographic methods. This suite of elements was selected because they are important constituents of most of the mineral-resource types in the quadrangle. Analyses for As were not completed in time for this report. Atomic absorption spectrometry was also used to determine weak-HCl partially-extractable concentrations of the mentioned elements except Cd in each sample of stream sediment. Partially-extractable Cd concentrations were determined for a selected set of samples. The weak acid extraction dissolves the loosely-bound metals associated with clays and surface coatings on Fe-Mn oxides. The extraction also dissolves the majority of secondary minerals such as sulfates, carbonates, and oxides, stable under oxidizing conditions, but will not significantly dissolve most sulfide minerals.

The partial-extractable digestion method, similar to the method described by Viets and others (1979) uses a 3.6N hydrochloric-acid solution containing 20 percent ascorbic acid and 10 percent potassium iodide in contact with the sample for 30 minutes at room temperature. The metals that have gone into solution are then selectively extracted into an organic phase composed of Aliquat-336 (tricaprylymethylammonium chloride) and methyl isobutyl ketone. The elements are then determined from the organic phase by atomic absorption spectroscopy. Total metal concentrations are determined by digestion of the sample in a solution of hydrofluoric and nitric acids followed by extraction into the Aliquat-336/methyl isobutyl ketone phase, and analyzed by atomic absorption spectrometry. These methods are described in detail by D. M. Hopkins (unpub. data).

Detection limits attained by the partial-extractable and total metal methods are 1 ppm for Bi, Cu, Pb, Sb, and Zn, and 0.05 ppm for Ag and Cd. Tables 3, 4, and 5 present estimates of the precision and accuracy for some elements with these methods.

Table 3.--Analytical precision for total digestion (HNO_3/HF) metal concentrations of some stream sediments from the Wallace quadrangle

STATISTICAL SUMMARY OF THE WALLACE 1° X 2° QUADRANGLE

In this report, no data interpretation is presented. Therefore, to assist users of the data, we have included several univariate statistical estimates and graphical displays of the data.

We have used the "boxplot" (Tukey, 1977) to conveniently show the range of observed concentrations for the elements reported. The boxplots for the stream-sediment and heavy-mineral concentrates data are shown in figures 2 and 3, respectively. For each boxplot, the maximum, the upper 1 percentile, the upper 5 percentile, the upper quartile, the median, the lower quartile, and the minimum value are shown. For a number of elements, the detection limit for the analysis was above the concentration of many samples; therefore, some of the boxplots are abbreviated. Reported qualified concentrations for a particular element are indicated by an arrow at the top of the boxplot to show greater-than (G); or at the bottom to show less-than (L); or not-detected (N) qualified data. In addition, because of the reporting intervals for semi-quantitative emission spectrographic analysis, it may not be possible to distinguish between the median value and either the upper or lower quartile concentrations for certain elements. For these boxplots, one of the quartile boxes is omitted. For example, see the Mn boxplot for the sediment data (fig. 2), where it was not possible to distinguish between the median and the upper quartile value. For Mn, the 700 ppm reporting interval contains both the 50th percentile and 75th percentile of all observations.

Using the spectrographic intervals as class widths, histograms of most of the elements are shown in figures 4 and 5. Elements that have highly censored data are not plotted. The histograms conveniently show the range of the log data, the modes for each, and the general form of the density distribution. The number of samples below the detection limit (N) is indicated by "n" at the left of the histograms whereas the number of samples that exceed the limit of measurement (G) is indicated by "n" at the right of the histograms.

Tables 6 and 7 present some univariate statistics which help describe the distribution of the data. Many of the values were singly censored, either above or below the analytical detection levels for the analytical standards used. Detection ratios, the number of uncensored values divided by the total number of samples analyzed for a given element, describe the degree to which the data were censored (Miesch, 1976). Generally, univariate statistics were computed for those elements that have detection ratios greater than 0.50.

Mean logs, log variances, log standard deviations, kurtosis, and skewness were calculated through the use of the U.S. Geological Survey STATPAC program for Fisher K-statistics (Miesch and VanTrump, 1977). This program allowed the mean log and log variance to be calculated using Cohen's (1959) method for the maximum-likelihood estimate for normal and singly censored distributions. Geometric mean and geometric deviation were taken as the antilogs of the mean log and log standard deviation. For lognormal data, 95 percent of all values fall within an expected range from: $\frac{\text{geometric mean}}{(\text{geometric deviation})^2}$ to geometric mean X $(\text{geometric deviation})^2$.

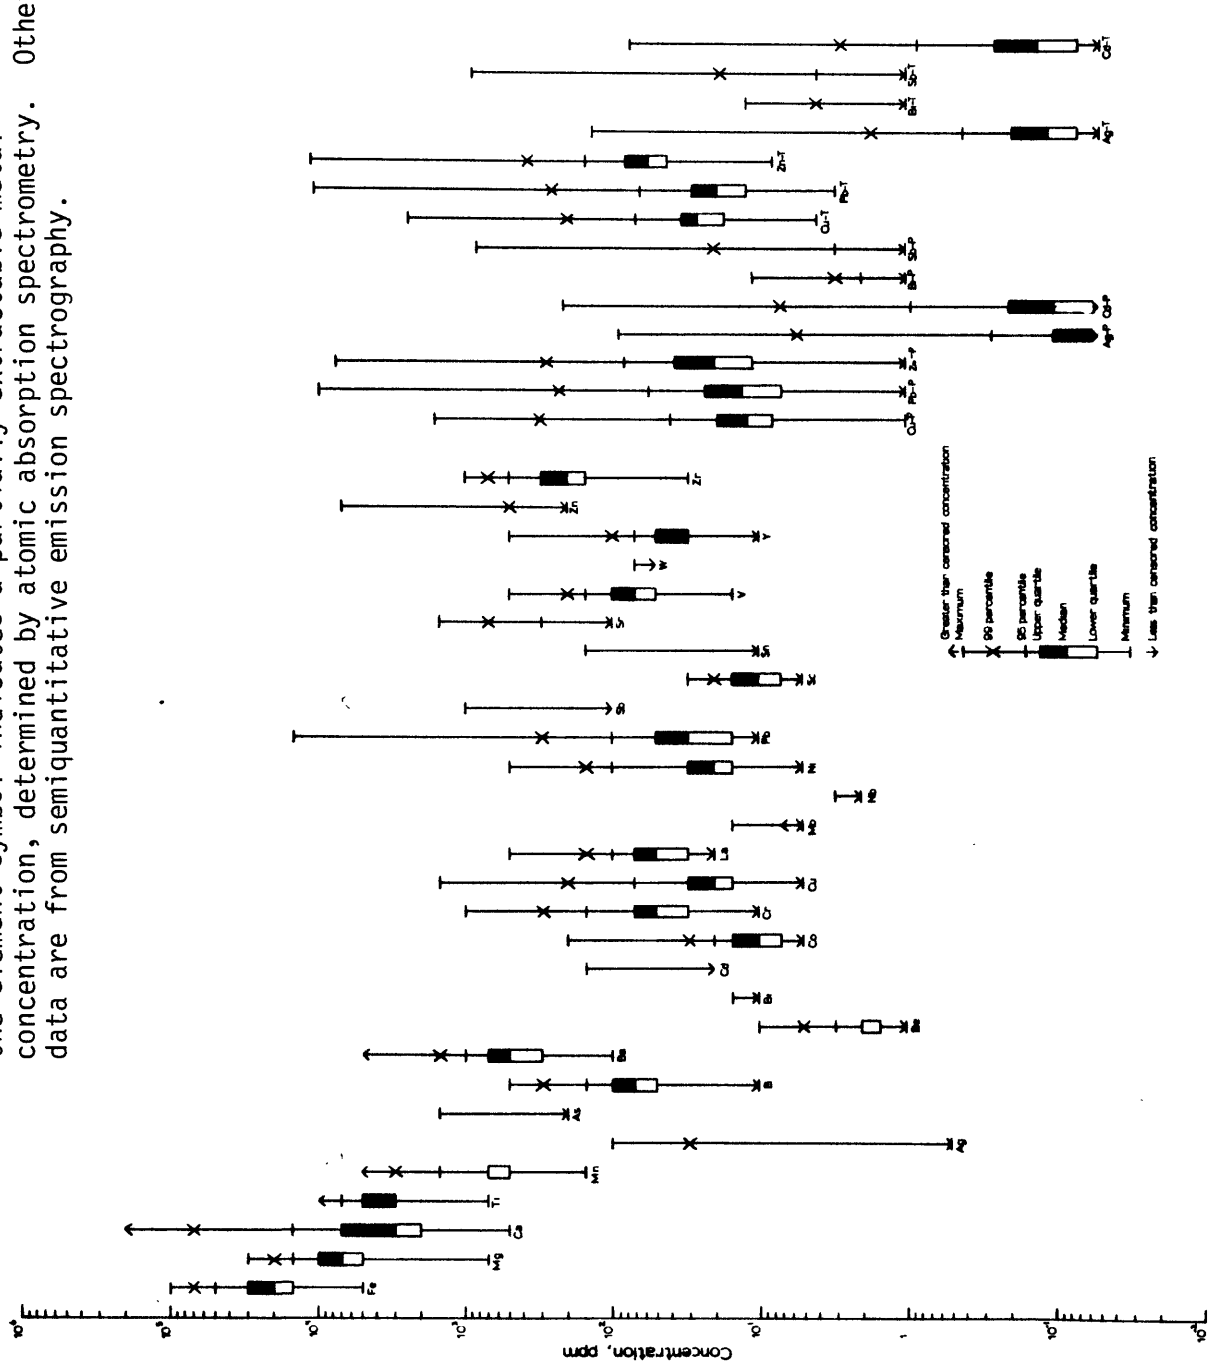

Figure 2.--Boxplot of the stream sediment data. A "T" following the element symbol indicates total metal concentrations and a "P" following the element symbol indicates a partially extractable metal concentration, determined by atomic absorption spectrometry. Other data are from semiquantitative emission spectrography.

[1]Detection ratio is the number of uncensored values divided by the total number of samples analyzed for a given element.
[2]Expected range is the distribution of 95 percent of all data expected for lognormal data.
[3]Valid is the number of samples with unqualified concentrations.
[4]L is the number of samples with concentrations reported as observable but less than the lower sensitivity limit.
[5]N is the number of samples with concentrations reported as not detected at the lower sensitivity limit.
[6]G is the number of samples with concentrations reported as greater than the upper limit of analytical measurement.
[7]B is the number of samples where the element was not analyzed.

[1]Detection ratio is the number of uncensored values divided by the total number of samples analyzed for a given element.
[2]Expected range is the distribution of 95 percent of all data expected for lognormal data.
[3]Valid is the number of samples with unqualified concentrations.
[4]L is the number of samples with concentrations reported as observable but less than the lower sensitivity limit.
[5]N is the number of samples with concentrations reported as not detected at the lower sensitivity limit.
[6]G is the number of samples with concentrations reported as greater than the upper limit of analytical measurement.
[7]H is the number of samples where spectra interference prevented measurement of the concentrations.

ANALYSIS OF VARIANCE (ANOVA)

To evaluate the data in terms of variability at different scales, an unbalanced, four-level, nested analysis of variance (ANOVA) design was constructed (fig. 6). The total variability was partitioned among the four levels using the STATPAC system Program D0038--Analysis of variance (Miesch and VanTrump, 1978). The program follows the technique of Anderson and Bancroft (1952) for computation of variance components. Estimates of variance components for elements in stream-sediment and heavy-mineral concentrate samples are given in tables 8 and 9, and are compared graphically in figures 7 and 8.

These results are useful in a general evaluation of the data in the following ways:

(1) The results of ANOVA may be used to evaluate the relative value of a particular element, either in the heavy-mineral concentrate or stream-sediment data, to detect broad-scale geochemical features relative to the sampling density chosen for the Wallace quadrangle area. Elements with a relatively large intercell variance provide more confidence in defining broad-scale geochemical features than do elements with a low intercell variance. For example, Pb in stream sediments provides a better definition of broad-scale geochemical features than do Be or Cr.

(2) The results of ANOVA also provide some estimate of the adequacy of the selected sampling density to detect broad-scale geochemical features for particular elements. For example, if a particular element of interest shows a significant variability at the intracell level, samples from other stream within the cells would have improved the definition of broad-scale geochemical features. However, if a large amount of variation is at the intrastream level, i.e. Sn, the variation in the data may provide limited information about broad geochemical features and will indicate very localized geochemical controls.

Figure 6.--Sample design for ANOVA.

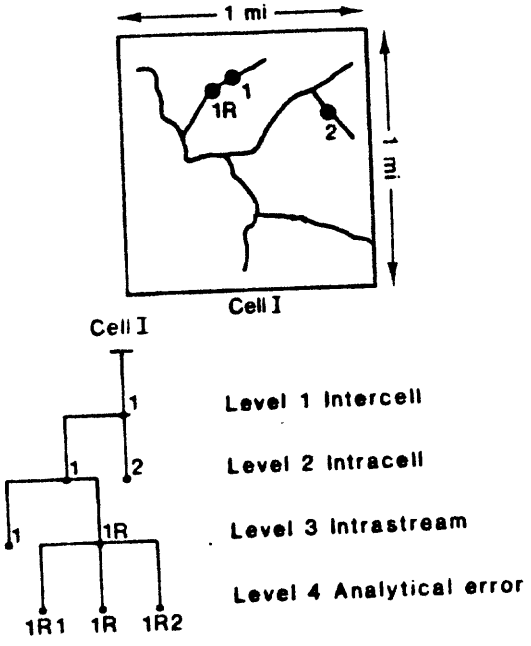

Figure 7.--Percent of total logarithmic variance at each of the four levels for stream-sediments.

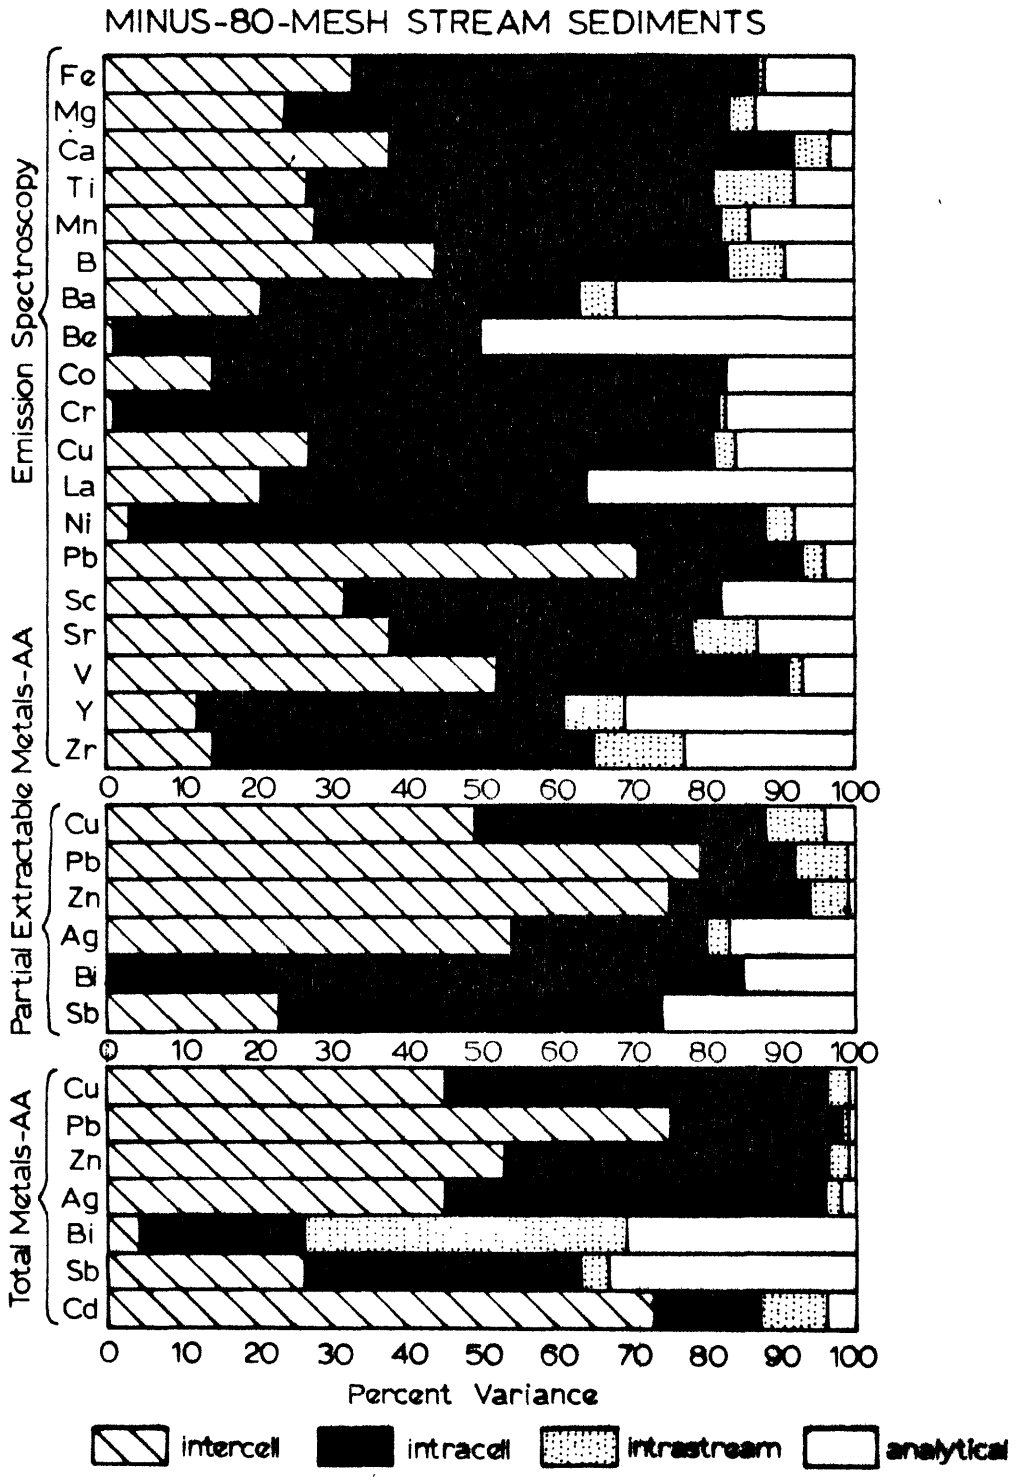

Figure 8.--Percent of total logarithmic variance at each of the four levels for nonmagnetic heavy-mineral concentrates.

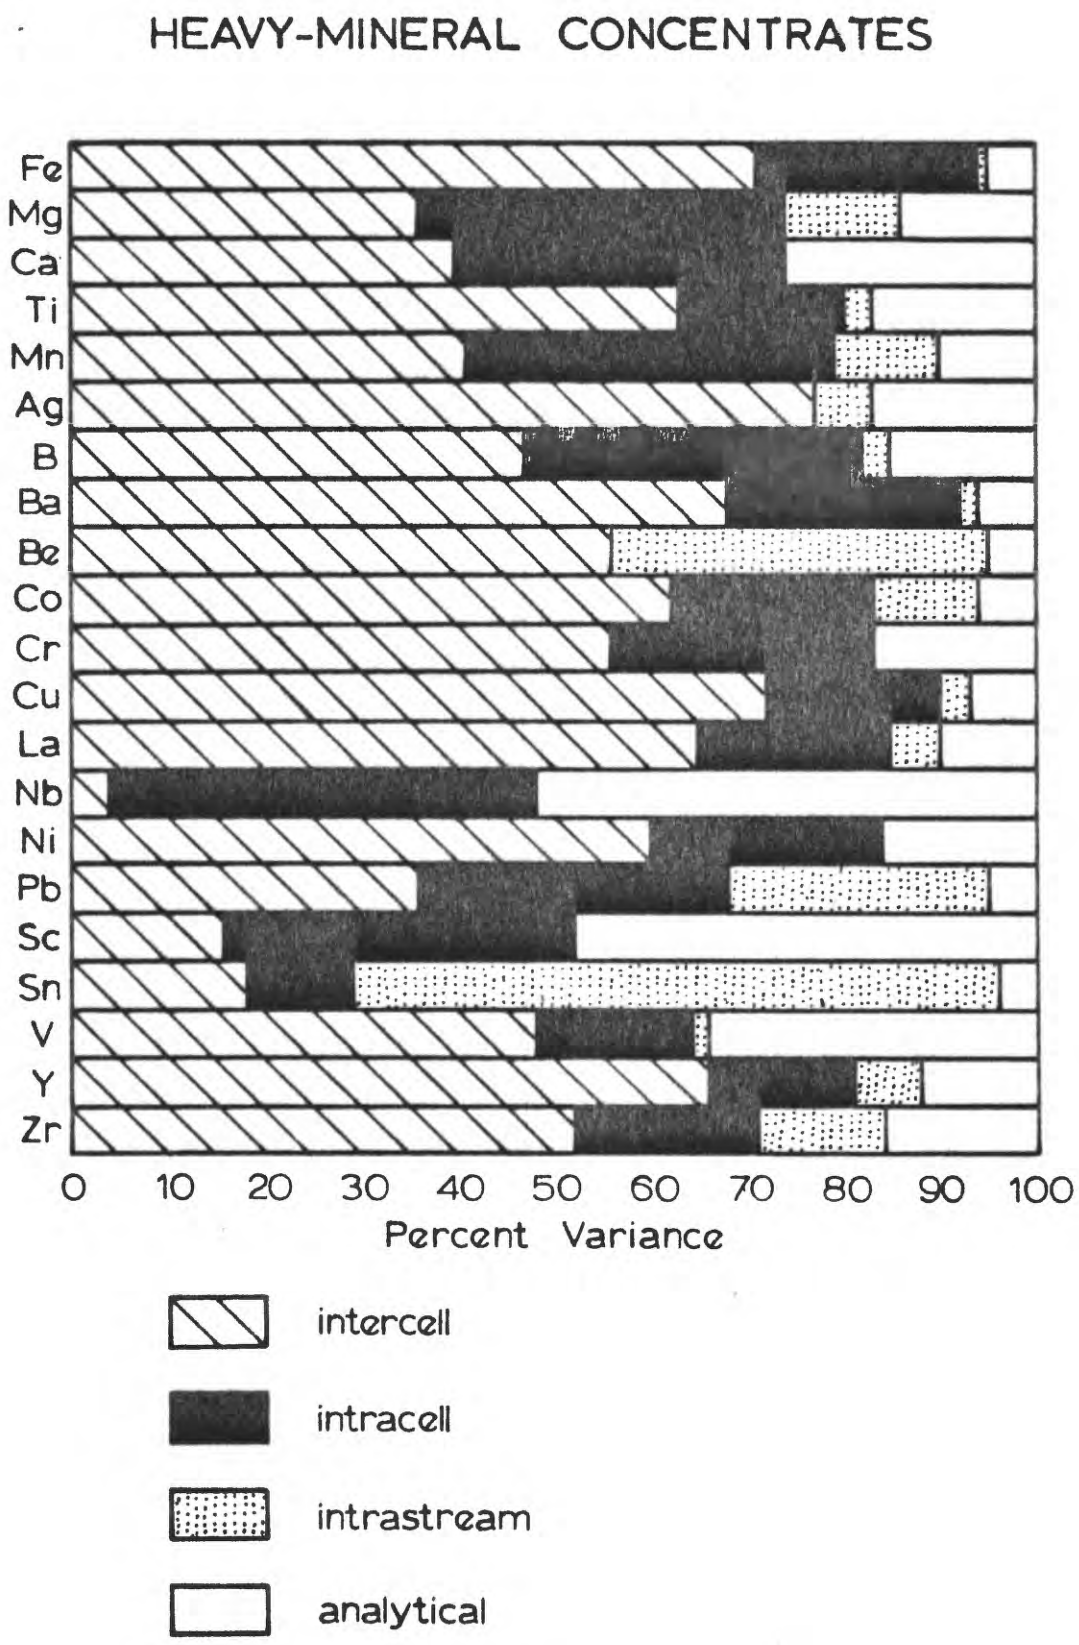

Table 8.--Analyses of variance for stream-sediments

[Variance components are expressed as percent of total variance. Significance, as defined by the F-test at the 95-percent confidence level (Snedcor, 1956) are shown by *. Atomic absorption data for total and partially-extractable metals are indicated by a T and P, respectively, following the element symbol. All other data were determined by semiquantitative emission spectrographic methods]

Y	.2871	66*	15	7*	12
Zr	.1312	52*	19	13*	16

(3) The ANOVA may also be used to compare the analytical variation for each element relative to the natural variation observed in the data for the Wallace quadrangle area. For most elements, the analytical variance is significantly less than the variance at the higher levels. However, some of the elements have analytical variances that are significantly greater than expected for the analytical techniques used in this study. Part of the apparent analytical error includes uncertainties in sample preparation. In addition, the apparent high analytical variances for some elements is the result of the relatively low natural variation for these elements in the Wallace quadrangle area with respect to the analytical techniques used. For example, 90 percent of the concentrations of Be in stream sediments fall within three spectrographic reporting intervals (fig. 4), which is also reflected in the low variances calculated for the levels above the analytical level. Therefore, by default, the analytical variance for Be in stream sediments is high relative to the variances at higher levels. This should not be interpreted as a criticism of the analytical techniques; rather, it reflects the lack of significant variation in the concentration of certain elements.

DESCRIPTION OF DATA TABLES

Data in tables 10 and 11 are arranged so that column 1 contains the assigned field number that is plotted on the location map (plate 1). An R, following the field number indicates the sample is a replicate sample collected 100 m downstream of the sample with the identical preceding digits. R1 and R2 indicate that these samples are analytical splits of the replicate sample. Latitude north and longitude west (in degrees, minutes, and seconds) are given in columns 2 and 3. The remaining columns contain the concentrations of the elements reported. All determinations made by semiquantitative emission spectrometry are indicated by an S preceding the element symbol. Total metal determinations made by atomic absorption spectrometry are indicated by AA preceding the element symbol and a T following the element symbol. Partially extracted metal determinations in samples of stream sediment made by atomic spectrometry are indicated by an AA preceding and a P following the element symbol. All element concentrations are given in parts per million (ppm) except for Fe, Mg, Ca, and Ti, which are given in percent.

If an element was looked for in the spectrographic analysis but not detected in the sample, an N is given in place of an analytical value. If an element showed spectral interferences, parentheses were placed around the analytical value. If the concentration of an element exceeded the upper limit of measurement, a > is given and the upper analytical value is noted; similarly, if the concentration is determined below the lower limit of detection a < is given in addition to the lower limit. If data does not exist for a particular element in a sample, a dash (--) is given.

We have made a reasonable effort to verify the quality of the data within the time and personnel constraints on this study. However, some discrepancies and uncertainties are always associated with large data bases of this nature. In the data presented here, some discrepancies may occur for a particular element in a sample analyzed by both semiquantitative emission spectrographic and atomic absorption methods. In addition, the reported concentrations of partially extractable metal may exceed the total metal concentrations reported for some samples. The latter discrepancies are most common for Ag and Sb, for

samples near the detection limit for these elements. In general, the few minor discrepancies that may be present in the data presented here are within the inherent uncertainties associated with analytical subsampling and techniques used. Samples with significant discrepancies have been reanalyzed when possible and the corrected values included in the following tables.

ACKNOWLEDGEMENTS

We wish to thank the following persons who contributed to this study: Eric Stenberg, Betty Adrian, Debra Cazes, Martha Knowlton, and Nick Kohlmann assisted in collection of the samples; Wendy Speckman, Steve McDanal, and Chris McDougal provided data-base management; Jack Harrison provided many helpful suggestions and geological guidance in the design of the study.
