# Loch Vale Watershed Long-Term Ecological Research and Monitoring Program: Quality Assurance Report, 2003-09 

By Eric E. Richer ${ }^{1}$ and Jill S. Baron ${ }^{2}$

#### Abstract

The Loch Vale watershed project is a long-term research and monitoring program located in Rocky Mountain National Park that addresses watershed-scale ecosystem processes, particularly as they respond to atmospheric deposition and climate variability. Measurements of precipitation depth, precipitation chemistry, discharge, and surface-water quality are made within the watershed and elsewhere in Rocky Mountain National Park. As data collected for the program are used by resource managers, scientists, policy makers, and students, it is important that all data collected in Loch Vale watershed meet high standards of quality. In this report, data quality was evaluated for precipitation, discharge, and surface-water chemistry measurements collected during 2003-09. Equipment upgrades were made at the Loch Vale National Atmospheric Deposition Program monitoring site to improve precipitation measurements and evaluate variability in precipitation depth and chemistry. Additional solar panels and batteries have been installed to improve the power supply, and data completeness, at the NADP site. As a result of equipment malfunction, discharge data for the Loch Outlet were estimated from October 18, 2005, to August 17, 2006. Quality-assurance results indicate that more than 98 percent of all surface-water chemistry measurements were accurate and precise. Records that did not meet quality criteria were removed from the database. Measurements of precipitation depth, precipitation chemistry, discharge, and surface-water quality were all sufficiently complete and consistent to support project data needs.

## Introduction

The National Park Service (NPS) initiated the Loch Vale watershed (LVWS) project in 1982 with funding from the Aquatic Effects Research Program of the National Acid Precipitation Assessment Program. The LVWS is a $7-\mathrm{km}^{2}$ (square kilometer) basin located within Rocky Mountain National Park (RMNP) in the Colorado Front Range. The project is currently a cooperative effort of the NPS, U.S. Geological Survey (USGS), and Colorado State University (CSU). The long-term research and monitoring program addresses watershed-scale ecosystem processes, particularly as they respond to atmospheric deposition and climate variability.

[^0]Monitoring of climate, hydrology, precipitation chemistry, and surface-water quality allows analysis of long-term trends and distinction between natural and human-caused disturbances. Research efforts are diverse, and include vegetation responses to nitrogen deposition, algal response to nitrogen availability, microbial activity in subalpine and alpine soils, hydrologic flow paths, and the response of aquatic organisms to disturbance. These research activities provide knowledge about the broad range of processes that influence high-altitude ecosystems in the Rocky Mountains.

## Research Objectives

1. To understand and differentiate natural processes from unnatural, human-caused drivers of change.
2. To understand and quantify the effects of atmospheric deposition and climate change on high-altitude ecosystems.

## Program Objectives

1. To share knowledge gained from research activities with the public, scientific community, and natural-resource managers.
2. To offer a program of graduate education and research that develops future scientists and knowledgeable resource managers.
3. To maintain the LVWS long-term ecological research project as a successful example of ecosystem-study design, interdisciplinary collaboration, long-term monitoring, and sustainable natural-resource management.

As results from the long-term monitoring and research program are used by resource managers, scientists, policy makers, and students, it is important that all data collected in LVWS meet high standards of quality. Therefore, the USGS must ensure the integrity of all data collected as part of the program.

## Purpose and Scope

This report describes quality assurance (QA) procedures and results used in support of long-term data-collection efforts in the LVWS. Since 1982, all LVWS samples and data have been analyzed according to standard methods. This report addresses data collected from January 1, 2003, through December 31, 2009. Previous QA reports evaluated the quality of data collected during 1983-87 (Denning, 1988), 1989-90 (Edwards, 1991), 1991-94 (Allstott, 1995), 1995-98 (Allstott and others, 1999), and 1999-2002 (Botte and Baron, 2004). Variables addressed in this report include precipitation depth and chemistry, hydrologic measurements, and surface-water chemistry. Support for sampling in the LVWS is jointly provided by USGS Western Mountain Initiative (WMI) and Water, Energy, and Biogeochemical Budgets (WEBB) programs. The WMI supports LVWS personnel, which includes USGS employees, CSU employees, and NPS volunteers. LVWS personnel monitor precipitation depth, precipitation chemistry, and surfacewater chemistry, which are the focus of this report. Meteorological, streamflow, and additional water-chemistry measurements are made within the LVWS and evaluated for data quality as part of the WEBB program.

## Approach

Streamflow data were collected and processed by LVWS personnel during 1983-2006. In August 2006, responsibility for collection and QA of all discharge data in the LVWS was transferred from LVWS personnel to the WEBB program. Surface-water samples were collected weekly at the Loch Outlet and less frequently at many other sites in RMNP (fig. 1). Surfacewater chemistry was determined according to U.S. Environmental Protection Agency (USEPA) protocols at the U.S. Forest Service Rocky Mountain Research Station (USFS-RMRS) Water Chemistry Laboratory and Natural Resource Ecology Laboratory (NREL) at CSU in Fort Collins, Colorado. Protocols for sampling and for measuring surface-water chemistry are documented in Richer and others (2011).

Precipitation depth and chemistry were monitored at the Loch Vale National Atmospheric Deposition Program (NADP) site, CO98 (fig. 1). Precipitation samples were collected according to NADP protocols (Dossett and Bowersox, 1999), and analyzed at the NADP Central Analytical Laboratory (CAL) in Champaign, Illinois. QA procedures for precipitation samples are outlined in the NADP Quality Assurance Plan (QAP; National Atmospheric Deposition Program, 2009a) and Quality Management Plan (QMP; National Atmospheric Deposition Program, 2009b). To further evaluate the quality of data collected at CO98, a colocated NADP site, CO89, was installed in October 2009.

LVWS data are available at multiple locations on the Internet (table 1), or by request from the Principal Investigator of the Loch Vale research program, U.S. Geological Survey, Fort Collins, Colorado.

## Precipitation Data

Precipitation was monitored at the Loch Vale NADP sites using rain gages and precipitation collectors. Cumulative precipitation depth was recorded to a data logger every 15 minutes, whereas precipitation samples were collected weekly. Precipitation depth was measured with an Alter shielded weighing bucket rain gage. Two types of rain gages were used at the Loch Vale NADP site during 2003-09. An Alter shielded Belfort Model 5-780 rain gage measured precipitation depth from August 1983 to August 2010. NADP resolved to upgrade all precipitation gages in 2006, and an Alter shielded ETI NOAH IV electronic rain gage (e-gage) was installed at the CO98 NADP site on June 18, 2007. After more than 2 years of colocated precipitation data collection, the Belfort rain gage was dismantled on August 9, 2010. Analysis of the colocated precipitation data for CO 98 revealed that the NOAH IV captured approximately 7 percent more precipitation than the Belfort (fig. 2), which is within the expected margin of error associated with interpretation of Belfort strip charts. To compare variability in precipitation depth and chemistry between sites, a colocated NADP site, CO89, was installed in October 2009 but was not fully operational until January 2010. The Loch Vale NADP sites, CO98 and CO89, are located at an altitude of $3,160 \mathrm{~m}$.

Aerochem Metrics Model 301 precipitation collectors were used at NADP sites to capture precipitation for chemical analysis. Although precipitation depth is reported for collector buckets, the catch efficiency of the Aerochem Metrics wet deposition sampler is limited because the sampler is not shielded, especially during winter months when precipitation falls as snow

Figure 2. Cumulative precipitation measured at the colocated Belfort and NOAH IV rain gages at the Loch Vale CO98 National Atmospheric Deposition Program site during 2008-09. (The light grey line represents the 1:1 line.)
(table 2). Alter shielded rain gages are more effective than the Aerochem collectors for catching solid precipitation in wind-prone areas. The World Meteorological Organization reports that Alter shielded rain gages capture approximately 75 percent of winter precipitation, whereas unshielded gages similar to the Aerochem collector capture approximately 57 percent (Goodison and others, 1998). CO98 collector catch efficiency ranged from 99 percent in the summer to just 33 percent in the winter on average (table 2). Poor winter catch efficiency can invalidate samples as a result of inadequate sample volume for complete chemical analysis.

Table 2. Annual catch efficiency of the CO98 site Aerochem Metrics precipitation collector relative to the Alter shielded rain gage by season during 2003-09.

| Season | Relative catch efficiency, in percent |  |  |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathbf{2 0 0 3}$ | $\mathbf{2 0 0 4}$ | $\mathbf{2 0 0 5}$ | $\mathbf{2 0 0 6}$ | $\mathbf{2 0 0 7}$ | $\mathbf{2 0 0 8}$ | $\mathbf{2 0 0 9}$ | Average |
| Winter | 51 | 27 | 25 | 27 | 47 | 29 | 22 | 33 |

| Annual | 57 | 70 | 62 | 62 | 73 | 61 | 54 | 63 |

Chemical analysis and quality assurance for all precipitation samples were conducted in accordance with NADP protocols (National Atmospheric Deposition Program, 2009a; 2009b). The quality-control program includes weekly blanks, check samples, blind network replicates, and internal blind audits with predetermined samples. The CAL was in compliance with the NADP QAP and QMP during 2003-09 (Rothert, 2008a; Rothert, 2008b; Rothert, 2009; Rothert, 2010; Dombek, 2011). Instruments used at CAL for chemical analysis of precipitation samples are listed in table 3. In 2004, CAL switched from a flame atomic absorption spectrometer to an inductively coupled plasma-optical emission spectrometer for analysis for calcium $\left(\mathrm{Ca}^{2+}\right)$, potassium $\left(\mathrm{K}^{+}\right)$, magnesium $\left(\mathrm{Mg}^{2+}\right)$, and sodium $\left(\mathrm{Na}^{+}\right)$, and began using a Broadly-James electrode to measure pH . Detection limits for all ions measured at CAL are listed in table 4.

As part of the project, 363 precipitation samples were collected from CO98 for chemical analysis from December 31, 2002, to December 29, 2009. Of these 363 samples, 271 (75 percent) were considered valid according to NADP criteria. Only valid samples with adequate sample volume were used to calculate annual precipitation-weighted mean concentrations, deposition, and data completeness. Annual sample validity is summarized in table 5. Of the 92

invalid samples, 33 were invalid because the sample volume was inadequate for analysis, 30 were contaminated, 14 were undefined (that is, the collector was open when no precipitation occurred), 11 were invalid because the collector was open continuously (that is, the sample was a bulk sample), 3 were invalid because the sampling interval was greater than 8 days, and 1 was invalid as a result of a departure from field protocol.

Inadequate sample volume was the most common reason for sample invalidation. There are three primary reasons for inadequate sample volume: (1) inadequate precipitation depth, (2) failure of the precipitation collector to open during snow storms due to insensitivity of the precipitation sensor, and (3) loss of sample when snow is blown back out of the collector bucket. Contamination was the second most common reason for sample invalidation. The most common types of contamination were dirt particles and plant matter. In the fall of 2009, approximately 20 trees around the Loch Vale NADP site were trimmed or felled to reduce sample contamination from plant matter. Cloudy or discolored samples, which may result from natural dust events, or the presence of insects in the collector bucket also contaminated samples. Of all precipitation samples sent to NADP during 2003-09, 7 percent were invalidated as a result of equipment malfunction (that is, bulk and undefined samples). Additional solar panels and batteries were installed in 2010 to reduce equipment malfunction from power loss.

## Discharge Data

The Loch Outlet is located at the northeastern edge of the basin at an altitude of $3,105 \mathrm{~m}$ (fig. 1). Discharge at the Loch Outlet has been monitored with a Parshall flume and stilling well since 1983. Accuracy of the Parshall flume is estimated at $\pm 5$ percent (Winter, 1981). In this section, discharge data for water years (WY) 2003-06 are evaluated. In August 2006, responsibility for collection and QA of discharge data at the Loch Outlet was transferred from LVWS personnel to the WEBB program. Stage was recorded with a Leupold and Stevens chart recorder through 2006. The chart recorder has since been replaced with a pressure transducer. As a quality check of flow data, stage height was recorded weekly from a staff gage located inside the flume, unless the flume was covered with snow.

Because stage records were incomplete as a result of a malfunctioning chart recorder, discharge data for the Loch Outlet from October 18, 2005, to August 17, 2006, were estimated from observed flows at the Andrews Creek streamgage. Discharge data for Andrews Creek and the Loch Outlet during 2000-09 were used to develop the simple linear model with an $\mathrm{R}^{2}$ value of 0.89 (fig. 3). Qualitative analysis of hydrographs for 2003-06 shows that estimated discharge values agree with streamflow patterns observed in the watershed (figs. 4-7). These qualitative comparisons of discharge at the Andrews Creek, Icy Brook, and Loch Outlet streamgages show that runoff generally peaked within 1 week at the three sites. Discharge values were greatest at the Loch Outlet as a result of the larger contributing area, which includes both the Andrews Creek and Icy Brook subbasins. (Discharge data are available from the USGS National Water Information Web site at http://waterdata.usgs.gov/nwis.)

## Surface-Water Chemistry Data

Water samples from the Loch Outlet were collected and processed weekly; sample collection from the other sites was less frequent. During 2003-09, 565 samples were collected, 55 (10 percent) of which were QA samples. Data quality was evaluated using field blanks, field duplicates, charge balance calculations (that is, ion percent difference), and theoretical conductance (that is, conductance percent difference). Sample-collection and -processing procedures were assessed through the use of blank and duplicate samples. Field blanks were used to examine contamination from collection and processing procedures, whereas precision was evaluated with field duplicate samples. Differences in constituent concentrations in normal, blank, and duplicate samples highlight deficiencies in the analytical process. Quality-control check samples and laboratory blanks were analyzed every 10 samples to ensure internal quality control for each laboratory. All protocols used in the preparation, collection, processing, and shipment of samples are described in the LVWS methods manual (Richer and others, 2011). Changes in laboratory and field procedures during 2003-09 are summarized farther on in this report.

## Natural Resource Ecology Laboratory

LVWS surface-water samples were processed at the NREL before delivery to the RMRS laboratory. Specific conductance at $25^{\circ} \mathrm{C}$ (that is, field conductivity) and water temperature were measured prior to sample collection with a Thermo Orion 105Aplus conductivity meter, which was checked against standard reference solutions weekly and calibrated as needed. Water samples were analyzed at the NREL for dissolved organic carbon (DOC) and total dissolved nitrogen (TDN) with a Schimadzu TOC-V CPN Total Organic Carbon Analyzer. The Schimadzu measures total organic carbon (TOC) and total nitrogen (TN) but, because the samples were filtered prior to analysis, the analytes measured are operationally defined as dissolved organic carbon (DOC) and total dissolved nitrogen (TDN). Dissolved silica (as $\mathrm{SiO}_{2}$ ) was measured with a Thermo Spectronic $20 \mathrm{D}^{+}$spectrophotometer using the silicomolybdate method adapted from Clesceri and others (1998).

Detection limit is the lowest quantity of a substance that can be distinguished from the absence of that substance. This limit is defined as three times the standard deviation of signals produced by 10 nonconsecutive blank samples (U.S. Environmental Protection Agency, 1987). Detection limits for all analyses conducted at NREL were calculated in 2009 (table 6). Prior to 2009, detection limits were not evaluated annually. The calculated detection limits for DOC and TDN are below the required USEPA values (U.S. Environmental Protection Agency, 1987). The NREL detection limit for $\mathrm{SiO}_{2}$ is just slightly higher than the estimated detection limit for the method, which is $0.3 \mathrm{mg} \mathrm{SiO}_{2} / \mathrm{L}$. Because phosphorus concentrations in LVWS waters were dilute, measurements of total phosphorus (TP) and orthophosphate $\left(\mathrm{PO}_{4}{ }^{3-}\right)$ at NREL were suspended because detection limits have proved inadequate for these analyses (for example, greater than $0.001 \mathrm{mg} / \mathrm{L}$ for $\mathrm{PO}_{4}{ }^{3-}$ ). TP samples were acidified and stored at $4^{\circ} \mathrm{C}$ until analytical capabilities improve or another laboratory with a lower TP detection limit is identified. pH analyses at NREL were discontinued in January 2010 because they were redundant with pH measurements made at the RMRS laboratory.

Table 6. Detection limits for carbon, nitrogen, and silica at the Natural Resource Ecology Laboratory during 2009.
[ $\mathrm{mg} / \mathrm{L}$, milligrams per liter; DOC, dissolved organic carbon; TDN, total dissolved nitrogen; $\mathrm{SiO}_{2}$, dissolved silica as silicon dioxide]

| Analyte | Detection limit (mg/L) | Method of analysis |
| :--- | :---: | :--- |
| DOC | 0.06 | Oxidative combustion-infrared analysis |
| TDN | 0.05 | Oxidative combustion-chemiluminescence |
| $\mathrm{SiO}_{2}$ | 0.4 | Spectrophotometry-silicomolybdate |

## U.S. Forest Service Rocky Mountain Research Station Water Chemistry Laboratory

Major cations and anions were measured at the RMRS Water Chemistry Laboratory. Specific conductance at $25^{\circ} \mathrm{C}$ (that is, laboratory conductivity), pH , and acid neutralizing capacity (ANC) were also determined at the RMRS. Samples were delivered to the RMRS, where they were stored in a cold, dark environment, within 48 hours of collection and were processed in accordance with USEPA guidelines. Guidelines established in the Handbook of Methods for Acid Deposition Studies (U.S. Environmental Protection Agency, 1987) and the Standard Methods for the Examination of Water and Wastewater (Clesceri and others, 1998) were followed for all analyses at the RMRS laboratory. Control charts and control samples were utilized daily to monitor internal quality control. Field and laboratory blanks were analyzed as well as lab duplicates and check standards (every 10 samples). The lab manager, lab analyst, and data analyst checked, verified, and archived all data collected. The published detection limits for the RMRS laboratory, which was formerly affiliated with the Air Resource Management Laboratory (ARML), are listed in table 7. The detection limit for ANC is difficult to quantify as a result of the gran titration method used for the analysis and seasonality of the data, which vary widely throughout the year.

The performance of USGS, cooperator, and contractor analytical laboratories that measure chemical constituents in environmental samples is evaluated in the Standard Reference Sample (SRS) project. SRS testing is performed at the RMRS laboratory every 6 months to assess the quality of laboratory methods and procedures while evaluating analytical precision and

| $\mathrm{PO}_{4}{ }^{3-}$ | 0.04 | Ion chromatography with separator column |

accuracy. All pertinent SRS information and data are available at http://bqs.usgs.gov/srs/. SRS results for the RMRS laboratory (SRS lab \#2) during 2003-09 are listed in table 8. The RMRS laboratory performed well for all SRS samples, with the exception of $\mathrm{PO}_{4}{ }^{3-}$ and $\mathrm{NH}_{4}{ }^{+}$ measurements. Results for $\mathrm{PO}_{4}{ }^{3-}$ have been variable over the years, and the RMRS laboratory has chosen not to report some values because they are typically below detection limit. $\mathrm{NH}_{4}{ }^{+}$ concentrations are generally very low for LVWS waters. In addition, high $\mathrm{Na}^{+}$concentrations make it difficult for the chromatography program to separate $\mathrm{Na}^{+}$and $\mathrm{NH}_{4}{ }^{+}$peaks. As a result of the problem associated with determining $\mathrm{NH}_{4}{ }^{+}$concentrations when $\mathrm{Na}^{+}$concentrations are high, the effective detection limit for $\mathrm{NH}_{4}{ }^{+}$in LVWS surface waters is $0.05 \mathrm{mg} / \mathrm{L}$ (Derek Pierson, U.S. Forest Service, written commun., 2010). Therefore, $\mathrm{NH}_{4}{ }^{+}$values less than $0.05 \mathrm{mg} / \mathrm{L}$ cannot be resolved.

## Data Outliers

Outliers are defined as points that markedly deviate from all other data in the sample. Only two erroneous points were detected (table 9) from graphical analysis of the 2003-09 data. The low field conductance value reported on December 8, 2009, is indicative of a frozen probe. The $\mathrm{NH}_{4}{ }^{+}$concentration reported on May 17, 2005, is an outlier. Although no other ion concentrations in this sample appear suspicious, the reported value is substantially higher than all other $\mathrm{NH}_{4}{ }^{+}$concentrations. This result indicates possible sample contamination or an analytical error. Given the extremely low $\mathrm{NH}_{4}{ }^{+}$concentrations in LVWS waters, a single breath can contaminate a sample for $\mathrm{NH}_{4}{ }^{+}$. Both of the outlying data points in table 9 were removed from LVWS data records and replaced as missing data.

Table 9. Data outliers removed from the Loch Vale watershed surface-water records for 2003-09.
$\left[\mathrm{NH}_{4}+\right.$, ammonium as ammonium; $\mu \mathrm{S} / \mathrm{cm}$, microsiemens per centimeter at $25^{\circ}$ Celsius; $\mathrm{mg} / \mathrm{L}$, milligrams per liter]

| Analyte | Units | Site | Date | Reported value | Mean value (2003-09) |
| :--- | :--- | :---: | :---: | :---: | :---: |
| Field conductivity | $\mu \mathrm{S} / \mathrm{cm}$ | Loch Outlet | $12 / 8 / 2009$ | 0.7 | 18.3 |
| $\mathrm{NH}_{4}{ }^{+}$ | $\mathrm{mg} / \mathrm{L}$ | Loch Outlet | $5 / 17 / 2005$ | 0.21 | 0.02 |

## Ion and Specific Conductance Balances

Loch Vale surface-water samples were checked for ion percent difference (IPD) and specific conductance percent difference (CPD) (U.S. Environmental Protection Agency, 1987; Stednick and Gilbert, 1998; U.S. Environmental Protection Agency, 2004). Because all samples are electrically neutral, the sum of the measured cations should equal the sum of the measured anions, if it is assumed that all major ions are measured. The ion balance is expressed by the IPD, which is calculated as:

$$
I P D=\frac{\sum \text { cations }-\sum \text { anions }}{\sum(\text { cations }+ \text { anions })} \times 100
$$

where

$$
\begin{gathered}
\Sigma \text { cations }=\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{Mg}^{2+}\right]+\left[\mathrm{Na}^{+}\right]+\left[\mathrm{K}^{+}\right]+\left[\mathrm{NH}_{4}^{+}\right]+\left[\mathrm{H}^{+}\right], \\
\Sigma \text { anions }=\left[\mathrm{SO}_{4}{ }^{2-}\right]+[\mathrm{Cl}]+[\mathrm{F}]+\left[\mathrm{NO}_{3}^{-}\right]+\left[\mathrm{HCO}_{3}\right], \text { and } \\
\mathrm{HCO}_{3}=\mathrm{ANC}+\mathrm{H}^{+}
\end{gathered}
$$

with all concentrations expressed in microequivalents per liter.
A negative IPD represents an excess of anions and a positive IPD represents an excess of cations. The IPD is an indicator of analytical accuracy and samples that fall outside criteria in table 11 are flagged and the analysis rerun. If the IPD is still outside the acceptable range after the sample has been reanalyzed, each sample is checked, ion by ion, for possible contamination. If one analyte is the obvious cause of the charge imbalance, it can be dropped from the record as long as the concentrations of the remaining analytes are normal for that time of year.

The theoretical conductance of a water sample is calculated by the formula:

Theoretical conductance $=\left(\left[\mathrm{Ca}^{2+}\right] 59.47+\left[\mathrm{Mg}^{2+}\right] 53.0+\left[\mathrm{Na}^{+}\right] 50.08+\left[\mathrm{K}^{+}\right] 73.48+\left[\mathrm{NH}_{4}^{+}\right] 73.50+\right.$ $\left.\left.\left[\mathrm{H}^{+}\right] 349.65+\left[\mathrm{SO}_{4}{ }^{2-}\right] 80.0+[\mathrm{Cl}] 76.31+\left[\mathrm{NO}_{3}\right]\right] 71.42+\left[\mathrm{HCO}_{3}{ }^{-}\right] 44.5\right) / 1000$
with all concentrations expressed in microequivalents per liter.
The CPD is calculated as:

$$
\begin{equation*}
\text { CPD }=\frac{\text { Theoretical conductance }- \text { Measured conductance }}{\text { Measured conductance }} \times 100 \tag{3}
\end{equation*}
$$

CPD calculations were performed for all surface-water samples using the specific conductance measured at the RMRS laboratory (that is, laboratory conductivity). Positive CPD values indicate that theoretical conductance exceeds the laboratory measured value, and can indicate an analytical error in one or more of the solute measurements. Negative CPD values indicate an unmeasured or under measured ion. Deviations from zero also can result from errors in specific conductance measurements. CPD values that fall outside the ranges reported in table 10 are flagged and the sample reanalyzed.

Of the 534 non-blank environmental samples (that is, normal and duplicate samples) collected during 2003-09, no samples were flagged for IPD after reanalysis. Three samples, all of which had positive CPD values, did not meet quality criteria for CPD after reanalysis (table 11), which could indicate an analytical error in one of the measurements. However, none of the samples flagged for CPD were flagged for IPD, which indicates that the solute analyses were complete and balanced. Therefore, data associated with these samples (table 11) were not removed from the database, but are reported here for completeness.

Table 10. Surface-water sample reanalysis criteria for ion percent difference and conductance percent difference.
[ueq/L, microequivalents per liter; IPD, ion percent difference; $\mu \mathrm{S} / \mathrm{cm}$, microsiemens per centimeter at $25^{\circ}$ Celsius; CPD, conductance percent difference; <, less than; $\geq$, greater than or equal to; criteria from U.S. Environmental Protection Agency, 1987]

|  | lon percent difference |  |

| Sky Inlet South | $09 / 16 / 08$ | Normal | 22.2 | 16.7 | 33.1 |

## Measures of Contamination

Contamination of low-ionic-strength streamwater samples is quantified by measuring solute concentrations in field blank samples. Field blanks consist of deionized (DI) water that is processed with the same methods used for environmental water samples (that is, normal and field duplicate samples). Sources of contamination can include improper bottle-washing procedures, errors in the handling and processing of samples, and contamination of DI water columns. Twenty-seven field blanks were collected at the Loch Outlet during 2003-09. No known instances of contamination of the NREL DI water system occurred during 2003-09 (Dan Reuss, Natural Resource Ecology Laboratory, oral commun., 2010). The $25^{\text {th }}$ - and $75^{\text {th }}$-percentile concentrations of each analyte for field blanks and environmental samples are listed in table 12.

The blank concentration values of most concern are those for DOC, as noted in previous QA reports (Allstott and others, 1999; Botte and Baron, 2004). Elevated DOC values are most likely caused by the inability of the DI water filtration system to effectively remove all organic carbon from the water. $\mathrm{SiO}_{2}$ has also been detected in NREL DI water in the past (Allstott and others, 1999), but the concentrations reported in table 12 are well below the reported detection limit of $0.4 \mathrm{mg} / \mathrm{L} . \mathrm{SiO}_{2}$ concentrations greater than $11 \mathrm{mg} / \mathrm{L}$ were reported for three consecutive blank samples collected during December 2004-April 2005. As no instances of DI water contamination were reported at NREL during this time period, the abnormally high values are likely the result of operator error. Therefore, these three $\mathrm{SiO}_{2}$ values were removed from the LVWS database and were not used in calculating values in table 12.

## Measures of Precision

Analytical precision is quantified by determining differences between analyte concentrations in normal samples and field duplicates. Field duplicates are samples collected from the same location as normal samples, with identical methods and as close to the same time as possible. Twenty-eight duplicate samples were collected from the Loch Outlet during 200309. Duplicate samples are processed and analyzed exactly as are normal samples. Median absolute differences (MADs) for each analyte were calculated for paired normal and duplicate samples. Precision can be calculated by determining the ratio of MAD values for the normal/duplicate sample pairs to the $10^{\text {th }}$-percentile concentration value for the analyte in environmental samples from all sites. Analytical precision ranged from $\pm 0.6$ percent of the $10^{\text {th }}-$ percentile value for fluoride to $\pm 9.2$ percent of the $10^{\text {th }}$-percentile value for DOC (table 13). Analytical precision for all analyses was acceptable at less than $\pm 10$ percent of the $10^{\text {th }}$-percentile value for all constituents.

Table 12. Analyte concentration percentiles for field blanks and environmental samples collected for the Loch Vale watershed project during 2003-09.
[ $\mathrm{P}_{25}, 25^{\text {th }}$ percentile; $\mathrm{P}_{75}, 75^{\text {th }}$ percentile; n, sample size; NREL, Natural Resource Ecology Laboratory; RMRS,

## Changes in Field and Laboratory Procedures during 2003-09

Changes in the LVWS field operating procedures:

- Sky Outlet was not sampled during 2003-06.
- Louise Inlet was not sampled during 2005-07 and 2009.
- Sky Inlet North sampling was discontinued in 2006.
- A NOAH IV electronic rain gage was installed at Loch Vale NADP site CO98 on June 18, 2007.
- Colocated NADP site (CO89), with Aerochem Metric precipitation collector and NOAH IV electronic rain gage, was installed on September 29, 2009.

Changes in LVWS laboratory procedures:

- Orthophosphate and total phosphorus measurements at NREL were suspended in 2005. Samples are still collected, acidified, and stored at $4^{\circ} \mathrm{C}$ for measurement of total phosphorus concentrations until analytical capabilities improve or an alternate laboratory is identified.
- NADP discontinued support for field chemistry measurements (that is, pH and specific conductance) effective January 1, 2005. LVWS continued to measure pH of all precipitation and surface-water samples at NREL through December 2009.
- The Milton Roy Spectronic 301 Photo spectrometer was replaced with a Thermo Spectronic $20 \mathrm{D}^{+}$spectrometer in 2007.
- The ion chromatographs for $\mathrm{Na}^{+}$and $\mathrm{NH}_{4}{ }^{+}$were modified in 2009 to improve detection of $\mathrm{NH}_{4}{ }^{+}$in the presence of $\mathrm{Na}^{+}$. Because of the influence of $\mathrm{Na}^{+}$on detection of $\mathrm{NH}_{4}{ }^{+}$, the effective detection limit for $\mathrm{NH}_{4}{ }^{+}$is estimated at $0.05 \mathrm{mg} / \mathrm{L}$.
- In 2010, all NREL pH measurements were discontinued because pH is also measured at the CAL and RMRS.

## Summary

Measurements of precipitation depth, precipitation chemistry, discharge, and surfacewater quality were all sufficiently complete and consistent to support project data needs.

Bias of new e-gages for precipitation-depth measurement at the Loch Vale National Atmospheric Deposition Program (NADP) site CO98 was approximately +7 percent. Annual average wet-deposition collector catch efficiency ranged from 54 to 73 percent. The percentage of valid weekly NADP wet-deposition samples ranged from 62 to 92 percent. Approximately 25 percent of precipitation samples collected during 2003-09 did not meet NADP criteria for valid samples. The primary reasons for sample invalidation were inadequate sample volume, contamination, and equipment malfunction.

Improvements were made to field instrumentation at the Loch Vale site CO98 and in the laboratories of the NADP Central Analytical Laboratory (CAL). In accordance with NADP site criteria, trees surrounding the CO98 site were trimmed or felled to reduce sample contamination from plant matter. Additional solar panels and batteries were installed to minimize equipment malfunction from power loss at the NADP site. Field instruments are now (2011) more reliable and provide more accurate precipitation measurements. A colocated site, CO89, was installed in 2009 to quantify the overall variability in NADP measurements of precipitation depth and chemistry at Loch Vale. Laboratory instruments currently used have lower detection limits to resolve low chemical concentrations in wet-deposition samples. The NADP CAL continues to produce accurate and precise data for the Loch Vale watershed (LVWS) long-term monitoring and research program.

As a result of equipment malfunction, discharge data for the Loch Outlet were estimated from October 18, 2005, to August 17, 2006. Discharge records are consistent among the three streamgaging stations for each water year during 2003-09.

More than 98 percent of all LVWS surface-water samplers met project quality criteria. Failures to meet quality criteria were attributable to sample contamination or analytical error. Rocky Mountain Research Station (RMRS) and Natural Resource Ecology Laboratory (NREL) data were quality assured using ion balance, specific conductance balance, blank samples, and duplicate samples. Quality-assurance results indicate all analyses were accurate and precise. The U.S. Forest Service (USFS)-RMRS Water Chemistry Laboratory and NREL continue to produce accurate and precise data for the LVWS long-term monitoring and research program.

## Acknowledgments

The authors thank Louise O'Deen (U.S. Forest Service, Air Resource Management Laboratory) and Derek Pierson (U.S. Forest Service, Rocky Mountain Research Station) for their years of high-quality laboratory work, the many volunteers and field technicians who helped collect samples, and Shenavia Balcom and Matt Schoolmeester-Winnick for their help with lab work at the NREL. We also appreciate the helpful insight and constructive criticism from our peer reviewers, Greg Wetherbee and David Clow (U.S. Geological Survey).
