Organic Contaminants, Trace and Major Elements, and Nutrients in Water and Sediment Sampled in Response to the Deepwater Horizon Oil Spill

By Lisa H. Nowell, Amy S. Ludtke, David K. Mueller, and Jonathon C. Scott

Abstract

Beach water and sediment samples were collected along the Gulf of Mexico coast to assess differences in contaminant concentrations before and after landfall of Macondo-1 well oil released into the Gulf of Mexico from the sinking of the British Petroleum Corporation's Deepwater Horizon drilling platform. Samples were collected at 70 coastal sites on the Gulf of Mexico between May 7 and July 7, 2010, to document baseline, "pre-landfall" conditions. A subset of these sites was resampled during October 4 to 14, 2010, after oil had made landfall on the Gulf of Mexico coast ("post-landfall") to determine if actionable concentrations of oil were present along shorelines.

Few organic contaminants were detected in water; their detection frequencies were generally low and similar in pre-landfall and post-landfall samples. Only one organic contaminant, toluene, had significantly higher concentrations in post-landfall than pre-landfall water samples. No samples exceeded any human-health benchmarks, and only one sample exceeded an aquatic-life benchmark—the toxic-unit benchmark for polycyclic aromatic hydrocarbons (PAH) mixtures was exceeded in one post-landfall water sample from Louisiana. No exceedance was observed in the corresponding pre-landfall water sample at this site.

In sediment, several PAHs were detected at over 20 percent of sites. Concentrations of 3 parent PAHs and 17 alkylated PAH groups were significantly higher in post-landfall samples than pre-landfall samples. One pre-landfall sample from Texas exceeded the sediment toxic-unit benchmark for PAH mixtures; this site was not sampled during the post-landfall period, so no comparison between sampling periods could be made. Twenty-seven percent of sediment samples exceeded empirical sediment-quality benchmarks (upper screening values) for PAHs, indicating these samples are in the probable-effect range. A higher percentage of post-landfall samples exceeded upper screening-value benchmarks (37 percent) than did pre-landfall samples (22 percent), but there was no significant difference in the proportion of samples exceeding one or more benchmarks between paired pre-landfall and post-landfall samples. Seven sites had the largest concentration differences between post-landfall and pre-landfall samples for fifteen alkylated PAHs. Five of these seven sites (1 site in Louisiana, 1 in Mississippi, and 3 in Alabama) were identified on the basis of diagnostic geochemical biomarkers as containing Macondo-1 oil in post-landfall sediments and tarballs, as described in a companion report by Rosenbauer and others (2010).

For trace and major elements in water, analytical reporting levels for several elements were highly variable; after censoring to a common reporting threshold, concentrations were significantly different between pre-landfall and post-landfall samples for a few elements, all of which are elements in seawater. No human-health benchmarks were exceeded, although these were available for only two elements. Aquatic-life benchmarks for trace elements were exceeded in almost 50 percent of water samples. Post-landfall samples exceeded one or more acute benchmarks in 21 percent, and chronic benchmarks in 93 percent of samples, compared to 1 percent (acute) and 39 percent (chronic) for pre-landfall samples. The elements responsible for the most exceedances in post-landfall samples were boron (48 samples), copper (22), and manganese (12). Nickel and vanadium, which U.S. Environmental Protection Agency specifically identified as relevant to the oil spill, were responsible for exceedances in only one of the fifty-two post-landfall samples with exceedances. These results represent the minimum number of exceedances for several trace elements because a substantial number of samples could not be compared with benchmarks because the element was determined during only one sampling period (boron and vanadium) or the reporting level for the sample was higher than the applicable benchmark value (for example, cobalt, copper, lead, and nickel). The high and variable reporting levels for trace elements in water also precluded the statistical comparison between sampling periods of the proportion of samples exceeding benchmarks.

For trace elements in whole (unsieved) sediment, 47 percent of samples exceeded empirical upper screening-value benchmarks, indicating these samples are in the probable-effect range. However, there was no significant difference in the proportion of samples exceeding one or more benchmarks between paired pre-landfall post-landfall samples. Benchmark exceedance frequencies could be conservatively high, because they are based on measurements of total trace-element concentrations, including the sediment matrix. In fine sediment (the less than 63-micrometer sediment fraction), one or more trace or major elements were anthropogenically enriched relative to national baseline values for U.S. streams for almost all sediment samples (123 of 124). Sixteen percent of sediment samples exceeded upper screening-value benchmarks for, and were enriched in, one or more of the element(s) barium (in 14 samples), vanadium (5), aluminum (3), manganese (3), arsenic (2), chromium (2), and cobalt (1). These samples, collected from Louisiana and Texas, were evenly divided between the pre-landfall (9 samples) and post-landfall (10 samples) periods.

Considering all the information evaluated in this report, there were significant differences between pre-landfall and post-landfall samples for PAH concentrations in sediment. Pre-landfall and post-landfall samples did not differ significantly in concentrations or benchmark exceedances for most organics in water or trace elements in sediment. For trace elements in water, aquatic-life benchmarks were exceeded in almost 50 percent of samples, but the high and variable analytical reporting levels precluded statistical comparison of benchmark exceedances between sampling periods. Concentrations of several PAH compounds in sediment were significantly higher in post-landfall samples than pre-landfall samples, and five of seven sites with the largest differences in PAH concentrations also had diagnostic geochemical evidence of Deepwater Horizon Macondo-1 oil from Rosenbauer and others (2010).

Introduction

On April 20, 2010, the British Petroleum (BP) Corporation's Deepwater Horizon Mississippi Canyon 252 (MC252) drilling platform sank following an explosion, and oil and gas began to be released into the northern Gulf of Mexico (GOM) from the ruptured Macondo-1 (M-1) well, approximately 5,000 feet below the sea surface. About 4.93 million barrels (205.8 million gallons) of oil were released into the northern GOM by the time the well was successfully capped on July 15, 2010 (Operational Science Advisory Team, 2010). To disperse the oil, 1.84 million gallons of chemical dispersants were applied to surface oil and at the well-head (Operational Science Advisory Team, 2010). In response to the potential threat of oil to sensitive habitat along the shores of the GOM, the U.S. Geological Survey (USGS) collected near-surface beach water and sediment at coastal sites from Texas to Florida, both before the oil made landfall (pre-landfall; May 7 to July 7, 2010) and after landfall (post-landfall; August 23 and October 4 to 14, 2010). The post-landfall study was requested by the U.S. Coast Guard (Wilde and Skrobialowski, 2011) and was used in conjunction with data from other sources (including the U.S. Environmental Protection Agency, National Oceanic and Atmospheric Administration, the GOM coast states, and BP) to assess the distribution of actionable (that is, amenable to removal actions) oil-related chemicals that remain in the water column, sediments, or both, and to inform decision makers on further oil-removal operations (Unified Area Command, 2010; Operational Science Advisory Team, 2010).

The purpose of this report is to characterize the water and sediment chemistry in pre-landfall and post-landfall samples, and to ascertain whether there were significant changes between the two sampling periods. This report complements activities of other USGS scientists and USGS production and research laboratories who are determining surfactants in water samples, analyzing geochemical markers for the presence of M-1 oil (also called MC252 oil) in sediment and tarballs, evaluating bacterial populations capable of degrading oils, assessing the toxicity of sediment pore water to the sea urchin (*Arbacia punctulata*), and assessing benthic macroinvertebrate indicators of shoreline habitat conditions (Donna N. Myers, Chief, Office of Water Quality, U.S. Geological Survey, Reston, VA, written communication, September 9, 2011).

Specific objectives of this report are to

- Summarize the occurrence of organic contaminants, trace and major elements, and nutrients in water and sediment samples at sites along the GOM coast sampled by the USGS before and after oil made landfall;
- Compare contaminant concentrations in pre-landfall samples to post-landfall samples for water and sediment; and
- Compare measured concentrations of contaminants to applicable existing benchmarks for protection of human health, aquatic life, and sediment quality.

This report presents one of multiple lines of evidence documenting conditions along the GOM coast before and after landfall of M-1 oil.

Methods

This study had two phases: pre-landfall and post-landfall. Pre-landfall samples were collected during the period of May 7 to July 7, 2010, which was after the oil spill began but before oil made landfall on the GOM coast. Post-landfall samples were collected on August 23 and during October 4 to 14, 2010, after oil made landfall at the sampled sites.

Post-landfall sampling was conducted at a subset of the pre-landfall sampling sites, plus one oil-affected site that was not sampled during the pre-landfall period. Although the sample-collection methods remained largely the same during pre-landfall and post-landfall phases, the priorities for chemical analyses changed somewhat between the pre-landfall and post-landfall phases as more information became known. As a result, the choice of some chemical analysis methods and laboratories was revised in the second phase. Differences in methods between pre-landfall and post-landfall phases are described below, and are detailed in the ‘Chemical Analyses’ section. Methods for chemical analysis changed over time as more information became available from the National Oceanic and Atmospheric Administration (NOAA) and the U.S. Environmental Protection Agency (USEPA) about methods and priorities for oil-related chemical contaminant testing (Operational Science Advisory Team, 2010, Appendix F).

Study Area and Site Selection

The initial response of the USGS to the Deepwater Horizon oil spill required rapid mobilization to collect water and sediment samples before landfall of the oil in order to establish a baseline chemical and biological profile. This baseline profile could later be used to understand any post-landfall effects on, or changes to, GOM coastal environments (Wilde and Skrobialowski, 2011). The USGS Science Centers in Texas, Louisiana, Mississippi, Alabama, and Florida coordinated efforts to sample water and sediments at 70 sites from beaches, barrier islands, and coastal wetlands that could suffer environmental damage as a result of oil from the spill coming ashore (fig. 1). High priority was given to coastal wetlands, Department of Interior lands at risk for oil contamination, such as National Wildlife Refuges, Bureau of Land Management (BLM) lands, National Seashore areas, and State Parks (Rosenbauer and others, 2010; Donna Myers, written communication, September 9, 2011). The purpose of the sampling was to define pre-landfall conditions (pre-existing or baseline conditions) in the physical, chemical, biological, and microbiological quality of the nearshore environment. Pre-landfall samples were collected between May 7 and July 7, 2010 (fig. 1, table 1). Global Positioning System (GPS) coordinates were recorded at each site so that any subsequent samples could be collected in the same location.

Post-landfall sampling was conducted following a request by the U.S. Coast Guard to assess whether actionable levels of Deepwater Horizon-related oil-spill contamination were present after the extensive clean-up efforts of coastal areas by BP (Wilde and Skrobialowski, 2011). Sampling was performed by the same USGS Science Centers that collected data for the pre-landfall assessment. Post-landfall samples were collected at 48 of the original 70 pre-landfall sites, plus 1 oil-affected wetland site at Bay Jimmy, Louisiana, which was not sampled before landfall, making a total of 71 sites (fig. 1, table 1). Post-landfall sites were selected from among the pre-landfall site locations on the basis of the extent of oil observed at the surface (ascertained from ships, aircraft, satellites, and *in situ* sampling), knowledge of the nearshore physical oceanography (that is, movement of water and sediments), and trajectory modeling by NOAA (http://response.restoration.noaa.gov/dwh.php?entry_id=809#downloads; Unified Area Command, 2010). The purpose of the post-landfall sampling was to document residual (actionable) oil.

Sample Collection

One water sample and one composite sediment sample were collected at each pre-landfall and post-landfall site. All pre-landfall samples were collected between May 7 and July 7, 2010. All post-landfall samples were collected between October 4 and 14, 2010, except the Bay Jimmy site, which was sampled on August 23, 2010 (table 1). Post-landfall sampling was conducted after the arrival of M-1 oil at the sampled sites. USGS field teams collected pre-landfall and post-landfall samples and site data by following protocols and procedures described in Wilde and Skrobialowski (2011) and in the USGS National Field Manual for the Collection of Water-Quality Data (variously dated). Post-landfall samples at each site were collected at the same location, or close to, the pre-landfall sampling location (Wilde and Skrobialowski, 2011). All samples of water and sediment were collected near the land/water interface, as described in the following sections. Samples were intended to be representative of ambient conditions at the time of sample collection (Wilde and Skrobialowski, 2011). Water samples were collected first and packed in coolers, and then sediment samples were collected. The collected samples were held on ice at 4 degrees Celsius (°C) from collection and during transport under Chain-of-Custody to the respective laboratories for chemical analysis.

Water Samples

Water samples were collected to represent surf and suspended-sediment conditions at the time of sampling (Wilde and Skrobialowski, 2011). Samples were collected in wadable water about 60 to 90 centimeters (cm) deep by using the direct dip method. Samples were collected from depths of 15 to 30 cm below the surface, and at least 15 cm from the sea bottom to avoid collection of re-suspended bottom material. In general, sample containers were submerged to an appropriate depth, uncapped to fill the container to the appropriate volume, and recapped underwater. For analysis of trace and major elements and nutrients, water was collected in field-rinsed bottles, then poured into smaller sample bottles containing the appropriate chemical preservative (table 2). Bottles used for organic-contaminant samples were not field rinsed prior to sample collection to avoid over-representing oil in the water sample (Wilde and Skrobialowski, 2011). Quality-control (QC) samples collected for water included field (ambient) blanks, trip blanks, matrix spikes, and field replicates; these are described later in the report. Water samples were preserved, if appropriate, then stored on ice in coolers and shipped chilled (less than 4°C) to the appropriate laboratory. Table 2 lists the laboratory, method code, sample containers, and preservatives for each class of analytes determined in water samples.

Sediment Samples

Wet-sediment core samples were collected from a 2-square meter or larger area at the land/water interface (swash zone) on beaches and from bottom materials of streams that dissect wetland or marsh areas (Wilde and Skrobialowski, 2011). For post-landfall samples, samples were collected from an area and at a depth horizon to which oil could have penetrated (Wilde and Skrobialowski, 2011). Beach sediment samples were collected to a depth of 25 cm from the swash zone by using a Teflon scoop or core tube and were stored in a Teflon-lined bucket. Where possible, post-landfall sediment collection was conducted at a comparable stage of tide as the pre-landfall sample collection at the same site. Marsh sediment samples were collected from a depth of 10 to 15 cm in submerged sediment by using a Teflon scoop and were stored in a Teflon-lined bucket. A single bulk-sediment sample was subdivided into subsamples for different analyses, including various chemical contaminants, percent moisture, pore-water toxicity, microorganisms, and oil-fingerprinting characteristics. Those sub-samples for chemical analyses were chilled (less than 4°C) and shipped to the appropriate laboratory (table 3).

Chemical Analyses

Water and sediment samples were analyzed for a variety of contaminants known to be associated with oil. Crude oil contains a complex mixture of many types of hydrocarbons, which range in size from 1 to 50 carbon atoms per molecule and in structure from simple linear alkanes to branched or cyclic molecules (Georgia Coastal Research Council, 2010). These include polycyclic aromatic hydrocarbons (PAH), which are important because of their potential adverse effects on humans and aquatic life (<http://www.epa.gov/bpspill/water-benchmarks.html>). Crude oil typically contains 1 to 2 percent PAHs, with the majority being alkylated PAHs (Operational Science Advisory Team, 2010). The M-1 well oil is a light, sweet oil with about 84 percent carbon and 4 percent hydrogen, and often less than 1 percent sulfur by weight (Georgia Coastal Research Council, 2010) and an American Petroleum Institute (API) gravity of 38.8 degrees (Rosenbauer and others, 2010). “Light” indicates that the material has a low density due to the relatively high abundance of smaller, saturated alkane hydrocarbons. “Sweet” indicates there is little sulfur contamination (Georgia Coastal Research Council, 2010). The U.S. Environmental Protection Agency (2011a) identified nickel and vanadium as relevant to the Deepwater Horizon oil spill, and the general category of Louisiana sweet crude oil was reported to be low in trace elements, with 0.1 to 0.8 percent sulfur by weight, 0 to 4 milligrams per kilogram (mg/kg) vanadium and 0 to 6 mg/kg nickel (Nadkarni, 1991). In two surveys of the general category of light crude oils (having an API gravity of 33 degrees or more) reported by the American Petroleum Institute (2011), maximum trace element concentrations were less than 1 mg/kg for arsenic, barium, cadmium, chromium, cobalt, copper, mercury, molybdenum, lead, antimony, selenium, and thallium. Concentrations were higher for iron, nickel, tin, vanadium, and zinc, which had mean values in the 2 to 4 mg/kg range, and maximum concentrations of 16 mg/kg for iron, 7 mg/kg nickel, 10 mg/kg tin, 20 mg/kg vanadium, and 8 mg/kg zinc. Concentrations of most trace elements are similar in different crude types, but nickel and vanadium tend to increase as crude oils become heavier (American Petroleum Institute, 2011).

In general, after oil is released into the environment, it is subject to various weathering processes (dissolution, evaporation, emulsification, photo-oxidation, sedimentation) and biodegradation. The lower molecular-weight components tend to be lost via dissolution and evaporation, and photo-oxidation forms more water-soluble products, such as phenols, carboxylic acids, and ketones (Operational Science Advisory Team, 2011). Intermediate molecular-weight components can float and disperse on water, form emulsions, or sorb to sediment; and the viscous, heavy components can form solid aggregates, or tarballs, that float or sink in water, or sorb to sediment (American Petroleum

Institute, 2003). Meanwhile, oil molecules are subject to microbial degradation at rates depending on the complexity of the oil molecules; degree of dispersion; environmental factors, such as temperature, oxygen, and nutrient concentrations; and the species and abundance of microbial organisms (Operational Science Advisory Team, 2011). The result is “weathered” crude oil that has a different composition than when originally released. A sample of weathered M-1 oil collected on April 27, 2010, was determined to contain aliphatic and cyclic hydrocarbons of, or greater than, C14 (that is, with 14 or more carbon atoms). Benzene, toluene, ethylbenzene, xylene and related volatile (BTEX) compounds were not detected (State of Florida Oil Spill Academic Task Force, 2010). One goal of the nearshore sampling and chemical analysis was to characterize the weathering and shoreline degradation of the oil (Unified Area Command, 2010).

In the present study, contaminant classes determined in water and whole sediment included various organic compounds, trace and major elements, nutrients, and organic carbon. Trace and major elements, nutrients, and carbon also were analyzed in the fine sediment fraction (also called the silt-clay fraction), defined as less than 63-micrometer (μm) in size. As noted previously, there were changes in target analytes and analytical methods between the pre-landfall and post-landfall sampling periods. In September, 2010, the Operational Science Advisory Team (2010, appendix F) recommended that future sample analyses in water and sediment include 43 PAH analytes, other organic compounds required for comparison to USEPA benchmarks for PAH mixtures, and metals. In the case of PAHs, this represented an expanded analyte list, and a change in analytical method was made. For PAHs in sediment, pre-landfall samples were subsequently reanalyzed using the updated method recommendations. The analytical methods and laboratories that conducted them are listed by analyte type in table 2 for water samples and in table 3 for sediment samples, and described briefly in the following sections. More detail is provided in the publications cited in tables 2 and 3. Analytical reporting levels are summarized in appendix A.

Water

Organic contaminants analyzed in water included volatile organic compounds (VOC), PAHs and other semivolatile organic compounds (SVOC), dissolved organic carbon (DOC), gasoline-range organics (6 to 10 carbon atoms), diesel-range organics (10 to 28 carbon atoms), and oil and grease (table 2). Most organic contaminants were determined by using gas chromatography with mass spectrometry (GC/MS). Most analyses were conducted at either the USGS National Water Quality Laboratory (NWQL) in Denver, Colorado, or the TestAmerica Laboratory in Pensacola, Florida (table 2), except that DOC was determined at the USGS Organic Carbon Research Laboratory (OCRL) in Boulder, Colorado.

Trace and major elements and nutrients were determined in water by various methods, including cold vapor atomic absorption spectrometry for mercury, and inductively-coupled plasma–mass spectrometry for other trace elements (table 2). Analyses of water samples were conducted at either the USGS NWQL or the TestAmerica Laboratory in Florida (table 2).

Individual analytes and their reporting levels in water are listed in appendix tables A-1 and A-3, and references for the analytical methods used are cited in table 2.

Sediment

Contaminants determined in whole (unsieved) sediments included PAHs, alkylated PAH groups, other SVOCs, oil and grease, trace and major elements, nutrients, and carbon (table 3). Oil and grease in sediment was analyzed by the TestAmerica Laboratory in Arvada, Colorado, for pre-landfall samples and the TestAmerica Laboratory in Florida for post-landfall samples (table 3). PAHs in sediment were analyzed by GC/MS at the USGS NWQL for pre-landfall samples and the TestAmerica Laboratory in Florida for post-landfall samples. In addition, both pre-landfall and post-landfall samples were analyzed for PAHs and alkylated PAH groups at the TestAmerica Laboratory in Burlington, Vermont, using GC/MS in the selective ion monitoring mode (SIM). Because the GC/MS SIM mode resulted in lower method detection limits (MDL), analytical results from the GC/MS SIM method were given precedence over results obtained by using GC/MS, when both were available. Pre-landfall sediment samples were frozen for approximately 8 months prior to reanalysis in February 2011, by GC/MS SIM.

For most trace and major elements, whole sediment was subjected to strong acid digestion prior to chemical analyses at the USGS Sediment Chemistry Laboratory (SCL) in Atlanta, Georgia (table 3). This analysis generated total trace and major element concentrations (that is, 95 percent or more of the element present) in sediment (Horowitz and Stephens, 2008). Silver, cadmium, and lead were determined by flame atomic absorption spectrometry (AAS), and other constituents by inductively-coupled plasma-atomic emission spectroscopy (AES). Mercury was digested separately and determined by cold vapor atomic absorption spectrometry. Total nitrogen, total carbon, and total organic carbon were determined by combustion.

Additional sediment subsamples were wet-sieved through a 63- μ m polyester mesh to obtain the silt-clay fraction, which was subjected to the same digestion procedure and analyzed for the same trace and major elements, for comparison to national baseline concentrations in fine sediment. Sieving sediment at 63 μ m limits the grain size effect, which results from finer material typically containing higher trace-element concentrations than coarser material, and facilitates spatial and temporal comparisons (Horowitz and Stephens, 2008). The less than 63- μ m fraction tended to have markedly lower sample mass than whole sediment. For about 20 samples, the less than 63- μ m sample mass was insufficient to run a chemical analysis.

Individual analytes and their reporting levels in sediment are listed in appendix tables A-2, A-4, and A-5, and references for the analytical methods used are cited in table 3.

Quality Control Samples

Three types of field QC samples were collected: blanks, replicates, and matrix spikes. The number of blanks, replicate sets, and matrix samples for laboratory spiking submitted to the various laboratories are shown in table 4.

Blanks

Blanks consist of samples prepared with water that is certified to be free of the analytes that will be measured by the laboratory. Blanks are used to estimate positive bias that may be caused by incidental contamination, which is the unintentional introduction of an analyte into the sample. For evaluation of potential contamination in water samples, three types of blanks were collected: field blanks, trip blanks, and equipment blanks. For evaluation of potential contamination in sediment samples, the only blanks collected were equipment blanks.

Field blanks were prepared by pouring blank water directly into sample bottles under ambient conditions at field sites. These are “field” blanks because they were prepared in the field by the same procedure used to collect environmental samples. In Wilde and Skrobialowski (2011), they were called “ambient” blanks because they were exposed to the atmosphere. In general, they did not contact any sampling equipment other than the sample bottles. Blanks and environmental samples for DOC and total nitrogen collected during the pre-landfall period were pumped from a collection bottle through a filter into a sample bottle. Field blanks enable the assessment of potential contamination of environmental water samples during sample preparation. However, sources of contamination are not necessarily the same for pre-landfall and post-landfall samples because (1) conditions could vary from one sampling period to the next and (2) pre-landfall samples and post-landfall samples were not analyzed at the same time and, in some cases, were analyzed by different laboratories (tables 2 and 4). Thus, pre-landfall field blanks should be compared only to pre-landfall water samples and post-landfall field blanks only to post-landfall water samples.

Trip blanks were prepared at the TestAmerica Laboratory in Florida during the post-landfall period. These blanks were shipped to USGS offices, transported to field sites during sampling trips, and returned to the laboratory with environmental samples. Trip blanks generally are prepared only for VOCs and are used to evaluate whether contamination of environmental samples occurred during sample transport and analysis. Absence of detectable contaminants in a trip blank indicates there is no evidence that environmental samples were contaminated during transport and processing, but does not necessarily rule out contamination from other sources, such as ambient conditions at the site.

Equipment blanks were prepared in USGS offices by pumping blank water through water-sampling equipment, or by pouring blank water over sediment-sampling equipment, and collecting the rinsate in sample bottles. Blanks prepared using water-sampling equipment are useful in this study only for comparison to environmental samples that were pumped through a filter—that is, pre-landfall samples analyzed for organic carbon and total nitrogen. Even for these analytes, the field blanks provide a more useful comparison than equipment blanks because they more completely represent potential sources of contamination. For sediment, equipment rinsate (rinse water) blanks were intended to indicate the potential for incidental contamination of environmental sediment samples from collection equipment and containers. Blank-water rinsate can be assumed to pick up contaminants that are removed easily from the sampling equipment, but it might not represent certain processes, such as abrasion, that can occur during sediment-sample collection. Also, laboratory analysis of the blanks is done using methods for water, rather than methods for sediment, and the potential sources of contamination during sample processing and laboratory analysis are not exactly the same for water as for sediment.

Data from blank samples can be used to estimate the potential for contamination in environmental samples in excess of concentrations that actually occur in the sampled matrix (water or sediment). If a representative blank can be associated with each environmental sample, analytical results for the blanks can be used to qualify results for the environmental samples (U.S. Environmental Protection Agency, 1989, pages 5-16 and 5-17). If the blank contains detectable levels of an analyte, concentrations of that analyte in the associated environmental samples should be censored unless they exceed five times the amount in the blank—or if the analyte is considered a common laboratory contaminant, such as acetone, ten times the amount in the blank.

Field Replicates

Field replicates are two or more environmental samples that are collected and prepared such that they are considered to be essentially identical in composition. Replicates are used to estimate variability of the analytical result. In this study, replicate water samples were collected sequentially by filling one set of sample bottles, followed immediately by filling a second, third, and, in some cases, a fourth set of bottles. Replicate sediment samples were collected by compositing a large amount of material in a single container. This material was homogenized, and replicate subsamples were scooped into separate sample containers.

Statistical evaluation of replicate variability is based on the standard deviation of measured values in the primary environmental sample and the replicate sample or samples. For many analytes, variability is correlated with the mean concentration of that analyte in the replicates (Martin, 2002; Mueller and Titus, 2005). Within a range of low concentrations, standard deviation of replicates generally is uniform, but at higher concentrations, standard deviation tends to increase in proportion to concentration. Within this high range, the relative standard deviation (RSD), defined as the standard deviation of replicate results divided by the mean concentration, is generally uniform. Over the low-concentration range, variability is estimated as the average standard deviation of replicates; over the high-concentration range, variability is estimated as the average RSD.

Typically, replicate variability is similar to the analytic error of laboratory methods, with RSDs ranging from a few percent to around 10 percent. If variability is substantially higher than this range, it might interfere with certain types of data interpretation. For example, high variability adds uncertainty to the comparison of data to a standard or benchmark. Also, it can reduce the likelihood of finding statistically significant differences in comparisons among groups of data over time or space. Variability is less likely to affect the central tendency (mean and median) of data distributions, but can increase the spread and range.

Matrix Spikes

Matrix spikes are samples fortified (spiked) with known concentrations of analytes that will be measured by the laboratory. Spikes are used to estimate positive or negative bias in the analytical result caused by matrix effects—that is, chemical, physical, or biological characteristics of the sample matrix (water or sediment) that can interfere with chemical analysis of the sample. Matrix samples were collected in the same manner as field replicates; then these samples were spiked in the laboratory to introduce a known amount of the analytes of interest.

Method performance is determined by spike recovery, which is the measured amount of analyte expressed as a percentage of the known spiked amount. Recovery is calculated from analyte concentrations in the spiked sample compared to a replicate environmental sample that was not spiked. Recovery can be poorly estimated if the analyte concentration in the background environmental sample is similar to, or greater than, the expected concentration of the spiked addition.

Generally, recovery is within a few percent less than or greater than 100 for analytes that are not affected by method or sample-matrix interferences, though the acceptable range can extend to plus or minus 10 to 20 percent for some analytes. Poor recovery is more typically low, rather than high. For constituents with chronically poor recovery, some aspects of data interpretation require qualification; for example, the detection frequency and the likelihood of exceeding a standard or benchmark can be underestimated.

Spikes are used most often for organic compounds, because the analytical methods involve extraction and analysis steps that can be affected by other chemicals in the sample. For example, naturally occurring organic matter can be co-extracted with anthropogenic organic compounds in a sample and interfere with GC analysis.

Laboratory Quality-Control Procedures

Laboratory QC procedures include analysis of reagent blanks (also called method blanks), spikes, standard reference materials, and surrogate compounds. Each laboratory conducts its own QC procedures and analyses in order to assess the quality of the data and meet performance standards. It is beyond the scope of this report to describe the laboratory QC sampling, except in one regard—where contamination was detected in reagent blanks, this information was considered in data analysis for this report. Laboratory reagent blanks are processed and analyzed along with each set of environmental samples and are used to monitor for incidental contamination introduced during sample processing and analysis at the laboratory.

Water- and Sediment-Quality Benchmarks

Concentrations of trace and major elements and organic contaminants were compared to various benchmarks to assess the potential for adverse effects on human health or aquatic life. Benchmark comparisons were made for all available samples, including field replicate samples and samples from sites sampled in only one study period, to maximize the information gained from the dataset regarding benchmark exceedance at the sampled sites.

Contaminant concentrations in water were compared to benchmarks for protection of human health and aquatic life, whereas concentrations in whole sediment were compared to sediment-quality benchmarks for protection of benthic organisms. The benchmarks used were those recommended by the U.S. Environmental Protection Agency (2010, 2011a,b) on its web site, “EPA Response to BP Spill in the Gulf of Mexico, Coastal Water Sampling” (<http://www.epa.gov/bpspill/water.html#understanding>), supplemented by benchmarks from Buchman (2008), which are available from the NOAA Office of Response and Restoration ([http://response.restoration.noaa.gov/topic_subtopic_entry.php?RECORD_KEY\(entry_subtopic_topic\)=entry_id,subtopic_id,topic_id&entry_id\(entry_subtopic_topic\)=783&subtopic_id\(entry_subtopic_topic\)=5&topic_id\(entry_subtopic_topic\)=2](http://response.restoration.noaa.gov/topic_subtopic_entry.php?RECORD_KEY(entry_subtopic_topic)=entry_id,subtopic_id,topic_id&entry_id(entry_subtopic_topic)=783&subtopic_id(entry_subtopic_topic)=5&topic_id(entry_subtopic_topic)=2)). In addition, trace- and major-element and nutrient concentrations in the less than 63- μ m sediment fraction were compared to national baseline concentrations in bed sediments of U.S. rivers from Horowitz and Stephens (2008). Benchmark values are listed for organic contaminants in table 5, and for trace and major elements in table 6. Table 6 (part D) also lists baseline concentrations for trace and major elements and nutrients in the less than 63- μ m sediment fraction.

Human-Health Benchmarks for Water

Human-health benchmarks are based on potential cancer and non-cancer risks associated with recreational exposure to oil-contaminated water. They were developed by U.S. Environmental Protection Agency (2010) in coordination with the U.S. Department of Health and Human Services. These benchmarks consider both skin contact and incidental ingestion of water by a child swimmer, assuming 90 hours of exposure. Human-health benchmark values are available for five VOCs, six PAHs, and two trace elements (nickel and vanadium) in water (tables 5C and 6B).

Aquatic-Life Benchmarks for Water

For water samples, potential toxicity to aquatic life was assessed by comparison to two types of benchmarks: (1) a toxic-unit approach for mixtures of PAHs and BTEX compounds (table 5A), supplemented by (2) marine benchmarks for individual contaminants (tables 5B and 6A).

Toxic-unit benchmarks for PAH-BTEX mixtures in water

Because PAHs and BTEX compounds share a common mechanism of action, toxicity is expected to be additive. A toxic-unit approach is used, therefore, in which the concentration of each component (i) of the mixture is divided by a potency factor to determine its toxic-unit concentration (TU_i). The TUs are summed for all components in the mixture ($\sum TU_i$) and compared to a hazard index of 1 (U.S. Environmental Protection Agency, 2011a). Separate TU computations are made for acute and chronic toxicity using acute and chronic potency factors, respectively (table 5A). Because alkylated PAHs (such as C1- and C2-alkylated naphthalenes) tend to have comparable or greater toxicity to aquatic life than parent PAHs (such as naphthalene), it is important to include alkylated PAHs in TU calculations. Because alkylated PAHs were not measured in water in this study, concentrations of alkylated PAHs were estimated from parent PAHs by using appropriate alkylation multipliers, as recommended by USEPA (<http://www.epa.gov/bpspill/water/explanation-of-pah-benchmark-calculations-20100622.pdf>). USEPA developed these multipliers using the analysis of a tarball that was collected at Dauphin Island during the current oil spill, and checked them against oil composition data from other sources, including the Exxon Valdez oil. Because the present study did not analyze two of the 18 parent PAHs that should be included in the $\sum TU_i$ value for water, benzo(e)pyrene and perylene, these two compounds were omitted from $\sum TU_i$ calculations, which therefore could be biased low.

An acute or chronic $\sum TU_i$ value greater than 1 indicates that the sample has the potential to cause an acute or chronic effect, respectively, on aquatic organisms such as fish, crabs, and clams. The PAHs and BTEX contaminants included in the TU calculations for water are provided in table 5A, along with their acute and chronic potency factors and alkylation multipliers.

Marine benchmarks

In addition, marine benchmarks for acute or chronic exposure to individual contaminants are available from various sources for many organic contaminants (table 5B) and trace elements (table 6A). These values were obtained from Buchman (2008), who compiled acute and chronic marine benchmarks from multiple sources; most values were from USEPA (ambient water-quality criteria or Tier II Species-Acute Values), supplemented by some benchmarks from Canada, British Columbia, and New Zealand. As such, individual benchmarks were not necessarily derived the same way and exceedance of one benchmark may mean something slightly different from exceedance of another, as shown in these examples:

- The USEPA chronic water-quality criterion is the highest concentration of a pollutant that aquatic organisms can be exposed to for an extended period, and the acute water-quality criterion is the highest concentration that aquatic organisms can be exposed to for a short period (1-hour average), without deleterious effects. Both are intended to protect 95 percent of a diverse group of genera and should not be exceeded more than once every 3 years.
- Canadian aquatic-life guidelines are based on toxicity data for the most sensitive species of plants and animals found in Canadian waters; they are intended to protect all forms of aquatic life during all stages of the aquatic life cycles and should not be exceeded at any time (Canadian Council of Ministers of the Environment, 1999).
- The British Columbia guidelines set safe conditions or levels that have province-wide application and are designed to protect marine aquatic life (http://www.env.gov.bc.ca/wat/wq/wq_guidelines.html). They are intended to protect all forms of aquatic life and all stages of their life cycle during indefinite exposure (Meays, 2010). If a single guideline is recommended, it represents a long-term no-effect level and should not be exceeded at any time. For some substances, both maximum (acute) and average (chronic) guidelines are recommended; acute guidelines apply in the initial dilution zone and chronic guidelines apply everywhere else (Meays, 2010). In addition, British Columbia has working guidelines for additional contaminants that were obtained from various North American jurisdictions, but have not yet been fully assessed by the Ministry of Environment; they represent the best guidance the Ministry can provide about safe levels of these substances in the environment (<http://www.env.gov.bc.ca/wat/wq/BCguidelines/working.html>).
- Trigger values from New Zealand are derived by fitting an appropriate statistical distribution to the no-observed-effect-concentration data available for a given contaminant, and estimating a concentration that protects 95 percent of species in the environment (Australian and New Zealand Environment and Conservation Council, 2000, Ch. 3).

Sediment-Quality Benchmarks

Potential effects of sediment contaminants on benthic organisms were assessed by comparing contaminant concentrations to benchmarks derived using two different approaches: equilibrium partitioning and empirical biological-effects correlation. In the equilibrium-partitioning approach, an equilibrium partition coefficient (K_{oc}) is used to calculate the contaminant concentration in sediment that corresponds to the concentration in interstitial water (pore water) above which toxic effects on aquatic organisms could occur (Di Toro and others, 1991). This approach assumes that contaminants are in equilibrium between water and sediment organic carbon, and postulates a theoretical causal relation between chemical bioavailability and chemical toxicity in different sediments. Equilibrium-partitioning

(EqP) benchmarks are available for nonionic organic contaminants, including PAH mixtures and some individual organic contaminants (described later in this section).

In contrast, the biological-effects correlation approach consists of matching sediment-chemistry measurements with biological-effects measurements to relate the incidence of biological effects in field sediments to the concentration of an individual contaminant at a particular site. The matching measurements come primarily from field studies, and sometimes from spiked sediment bioassays. The dataset of matching measurements is used to identify a level of concern for an individual contaminant that is associated with a certain probability of observing adverse effects on benthic organisms in studies where that contaminant was measured. This approach is empirically based, and does not indicate a direct cause-and-effect relation between chemical contamination and biological effects. It assumes that the contaminant measured is responsible for the effects observed, although field sediment samples typically contain complex mixtures of chemical contaminants (for example, MacDonald and others, 1996; Hyland and others, 2003; Burgess and others, 2003). Empirical (correlative) benchmarks for both organic contaminants and trace elements are available from a number of sources, which are described later in this section.

EqP sediment benchmarks for PAH mixtures

As in water, toxicity to PAHs and BTEX compounds in sediment is expected to be additive. The bioavailability of nonionic organic compounds in sediment, however, is assumed to be controlled by sorption to sediment organic carbon. Therefore, the toxic unit approach in sediment first requires that measured concentrations of the contaminants be normalized to the total organic carbon (TOC) content of the sediment. Then, the TOC-normalized concentration of each component compound (i) is divided by its potency factor to obtain its equilibrium-partitioning sediment benchmark toxic-unit concentration (ESBTU_i), and the ESBTU_i values are summed for all components in the sediment mixture to obtain the equilibrium-partitioning sediment benchmark toxic units (\sum ESBTU_i) for that sediment sample (U.S. Environmental Protection Agency, 2011b). Separate calculations are made for acute and chronic exposure by using acute and chronic potency factors. The PAHs included in \sum ESBTU_i calculations consist of both parent PAHs and alkylated PAHs, because the latter have comparable, or greater, toxicity than the former (table 5D). Just as in the TU procedure for water, the ESBTU procedure for sediment calls for using alkylation multipliers if data for alkylated PAH groups are not available. In this study, data were available for alkylated PAHs in all sediment samples, so alkylation multipliers were not used. However, BTEX compounds were not determined in sediment, so calculated \sum ESBTU_i values may be slightly low; however, this bias is expected to be minimal in shoreline sediments because these compounds are volatile, were not detected in weathered crude oil (State of Florida Oil Spill Academic Task Force, 2010), and are not expected to persist in sediment (<http://www.epa.gov/bpspill/water/explanation-of-pah-benchmark-calculations-20100622.pdf>).

An acute or chronic \sum ESBTU_i value greater than 1 indicates that the sample has the potential to cause an acute or chronic effect, respectively, on sediment-dwelling organisms, such as crabs, clams, and worms. The contaminants included in the ESBTU calculations, and their potency factors and multipliers, are provided in table 5D.

EqP sediment benchmarks for individual contaminants

As with the ESBTU approach described above for PAH-BTEX mixtures, these EqP benchmarks are based on equilibrium-partitioning theory, but they apply to individual contaminants rather than contaminant mixtures. The acute and chronic EqP benchmarks are in units of μg per gram of sediment-TOC, so that measured contaminant concentrations (dry weight) must be normalized to sediment-TOC

prior to comparison with these benchmarks (table 5E). Acute and chronic EqP benchmarks are based on acute or chronic toxicity to aquatic life, respectively, and represent the concentration of chemicals in sediment that will be predictive of biological effects, protective of the presence of benthic organisms, and applicable to the range of natural sediments from lakes, streams, estuaries, and near-coastal marine waters (U.S. Environmental Protection Agency, 2008). Exceedance of an individual EqP benchmark indicates that effects can occur if the contaminant in question is bioavailable as predicted by EqP theory; in general, the degree of effect expected will increase with increasing exceedance of the benchmark (U.S. Environmental Protection Agency, 2008). Individual EqP benchmark values are listed in table 5E.

Empirical sediment benchmarks

Several types of empirical benchmarks have been developed on the basis of correlations between measured chemical concentrations and observed toxicity in field sediments. As such, they define concentrations in sediments that are associated with certain types and levels of toxicity. These benchmarks typically come in pairs: lower screening values define concentrations below which adverse effects are not expected, and upper screening values define concentrations above which adverse effects are likely or frequent. Four such pairs of sediment benchmarks follow; benchmark types and values are shown in tables 5E and 6C. In this study, two supplementary benchmarks—Washington State’s Apparent Effect Threshold (AET; tables 5E and 6C) and USEPA’s EqP benchmark (table 5E)—are grouped with upper screening values because they indicate concentrations above which toxicity is likely.

Apparent Effect Threshold. These values are based on matching sediment chemistry and toxicity data from Puget Sound. The Apparent Effect Threshold (AET) is the concentration of an individual contaminant above which a particular adverse biological effect is always expected (Barrick and others, 1988). Different types of AETs represent different indicators of toxicity, including amphipod mortality, benthic abundance, Microtox, and oyster larval development. For a given contaminant, the AET value shown in Table 5E or 6C represents the lowest available AET value, as determined by Buchman (2008). Because of its definition, the AET was considered an upper screening value in this study.

Effects-Range Low and Effects-Range Median. These were derived from matching sediment chemistry and toxicity data. The Effects Range-Low (ERL) corresponds to the lower 10th percentile of the matched data for a given contaminant, and represents the contaminant concentration below which effects are rarely observed. The Effects Range-Median (ERM) corresponds to the 50th percentile of the matched data, and represents the contaminant concentration above which adverse effects frequently occur (Long and Morgan, 1991).

Threshold Effect Level and Probable Effect Level. The Canadian Threshold Effect Level (TEL) defines a concentration below which adverse effects are rarely anticipated and above which adverse effects are occasionally anticipated, whereas the Probable Effect Level (PEL) defines a concentration above which adverse effects are frequently anticipated. Both the Canadian TEL and PEL are empirically based and were derived by compiling data from multiple types of studies in the literature, including equilibrium partitioning studies, guidelines from other jurisdictions, spiked-sediment toxicity tests, and field studies from throughout North America (Canadian Council of Ministers of the Environment, 1995, 2001). The TEL and PEL values for a given contaminant were selected such that fewer than 25 percent adverse effects occur below the TEL and more than 50 percent of adverse effects occur above the PEL (Canadian Council of Ministers of the Environment, 2001).

Threshold Effect Concentration and Probable Effect Concentration. The consensus-based threshold effect concentration (TEC) from MacDonald and others (2000) defines the concentration below which adverse effects on sediment-dwelling organisms are not expected to occur. The consensus-based probable effect concentration (PEC) defines the concentration of sediment-associated contaminants above which adverse effects on sediment-dwelling organisms are likely to be observed. These guidelines were developed by compiling multiple sediment-quality guidelines for a given contaminant (both causally and empirically based), identifying those that meet certain selection criteria, and using the geometric mean as consensus-based guidelines.

T20 and T50. These were derived from logistic regression models that predict the probability of toxicity to marine amphipods by using a large database of matching sediment-chemistry and toxicity data representing coastal North America (Field and others, 2002). The T20 and T50 for an individual contaminant consist of concentrations of that contaminant that are associated with a 20 percent or 50 percent probability, respectively, of observing toxicity.

National Baseline Concentrations for Trace and Major Elements and Nutrients in Fine Sediment

Trace and major elements and nutrients in fine (less than 63- μm) sediment from this study were compared to national baseline concentrations from Horowitz and Stephens (2008). Although not technically benchmarks, these baseline concentrations can be used to indicate anthropogenic enrichment. Horowitz and Stephens (2008) determined national baseline concentrations for trace and major elements and some nutrients in stream sediments collected from agricultural or undeveloped areas or areas with low population density (less than or equal to 27 people per square kilometer) and low percent urban (less than or equal to 5 percent) land use. These authors found that enrichment of some elements above baseline was associated with urban land use and population density. These elements, in generally decreasing likelihood of enrichment, are lead, mercury, silver, zinc, cadmium, copper, antimony, sulfur, nickel, tin, chromium, arsenic, cobalt, iron, and phosphorus. Horowitz and Stephens (2008) computed the minimum, median, and maximum baseline concentrations for each element, where the range between the minimum and maximum baseline concentrations represents the range of natural geochemical variance. In Horowitz and Stephens (2008), sediment was wet-sieved through a less than 63- μm mesh, and subjected to total digestion prior to analysis. The processing and analytical methods used by these authors determined total concentrations (95 percent or more of the constituent present) in the less than 63- μm sediment fraction, and are comparable to those used in the present study.

In the present study, the measured concentration of each element was divided by its maximum baseline concentration (that is, the upper end of the range in baseline values for a given element determined by Horowitz and Stephens, 2008, as listed in table 6D) to obtain a maximum baseline quotient. "Enrichment" above baseline is defined as occurring when the maximum baseline quotient was greater than 1, with the following exception. For samples in which the less than 63- μm fraction makes up less than 1 percent of the total sediment, analytical errors are elevated, and there often is insufficient material to run duplicate analyses to determine degree of precision. In this case, the precision could be as poor as a 100 percent difference, especially at concentrations near the detection level (Arthur J. Horowitz, Research Chemist, USGS, Atlanta, Georgia, written communication, Feb. 3, 2011). For individual samples with less than 1 percent of total sediment in the less than 63- μm fraction, therefore, maximum baseline quotients needed to be elevated above two in order to indicate enrichment. By itself, enrichment, as indicated by maximum baseline exceedance, does not necessarily indicate a potential for adverse effects.

Interpretation of Benchmark Exceedances

For organic contaminants, exceedance of either an EqP benchmark or an upper screening value was considered to be an indication of potential toxicity to benthic organisms. Trace elements were considered to be of most concern if they met exceedance criteria for both potential toxicity and anthropogenic enrichment: (1) they exceeded one or more upper screening values in whole sediment samples, and (2) they were enriched relative to national baseline concentrations in less than 63- μ m sediment samples. Because sediment samples were analyzed for total (greater than or equal to 95 percent) trace element concentrations, exceedance rates for upper screening values could be overestimated, but are not likely to be underestimated; therefore, these rates, and resulting inferences about potential toxicity, can be considered conservatively high.

In addition, for both organic contaminants and trace elements, sediment samples were classified into one of three effect ranges using terminology from Canadian Council of Ministers of the Environment (2001): (1) minimal effect range, within which adverse biological effects rarely occur (i.e., all constituents were below their lower screening values); (2) possible effect range, within which adverse biological effects occasionally occur (one or more constituents exceeded a lower screening value, but no elements exceeded an upper screening value); or (3) probable effect range, within which adverse biological effects frequently occur (one or more constituents exceeded an upper screening value).

Data Compilation

Each distinct sampling event is recorded in the USGS database with a unique combination of agency code for the site, station-identification number, sample-collection start date, sample-collection end date, and sample medium. The agency code associated with the samples described in this report is "USGS," and the station-identification numbers are presented in table 1. In the database, sediment samples are assigned sampling-medium designations of either bottom material or soil.

The results for environmental samples from water and sediment can be retrieved from the USGS by supplying the station-identification numbers to one of the following web sites:

NWISWeb (<http://nwis.waterdata.usgs.gov/usa/nwis/qwdata>) or

Water-Quality Data Portal (<http://qwwebsiteservices.usgs.gov/portal.html>)

The Data Portal provides data in a manner consistent with similar data provided by the STORET database, except that a few of the observational metadata available from NWISWeb are omitted. Samples collected prior to July 15, 2010 are categorized as "pre-landfall," and subsequent samples are categorized as "post-landfall."

Sometimes, one or more constituents in a particular sample were reanalyzed to verify the results, or to employ an analytical method with improved sensitivity to low concentrations. When verification reruns were performed, the earliest analytical result is presented in the database, and additional results from a subsequent analysis are preserved in the "result-laboratory" comments field. When a more sensitive method was employed, however, the results from the sensitive method are presented in the database, and results from the less sensitive method are preserved in the "result-laboratory" comments.

Data Analyses

Data for all analyses described in this report were obtained on March 28, 2011 (March 24 DWH GOM Data Release), and used as received from the participating laboratories without further rounding. Benchmark comparisons were made for all samples, including environmental and field-replicate samples. For most sites, if multiple samples were collected during a sampling period (pre-landfall or post-landfall), one was designated as the primary (environmental) sample and the other(s) were considered to be replicates. Sample designations were adjusted in some cases, if no primary sample was designated or if the primary sample was missing data for some groups of analytes (e.g., trace elements or organics); in that case, the replicate sample with the earliest date and time, or with data for the missing analytes, was typically designated as a primary sample. This “primary-sample” dataset was used for statistical summaries of contaminant occurrence, so that each site was represented only once for each sampling period and analytical method.

A subset of the primary-sample dataset, consisting of paired pre- and post-landfall samples, was used for statistical comparison of pre-landfall to post-landfall sample concentrations at these sites. This “paired-sample” dataset was generated by dropping data for all sites that were sampled during only one sampling period (pre-landfall or post-landfall). The resulting paired-sample dataset contained exactly two samples per site—one collected during each of the pre-landfall and post-landfall periods.

Detection frequencies and percentile concentrations were determined using procedures in the statistical software package SAS 9.2 TS Level 2M3 (SAS Institute Inc., 2009a,b). Summary statistics were presented separately for each chemical class (either organic contaminants, or trace and major elements and nutrients) in each sampling medium (water or sediment). The detection frequency for a given analyte varies with the sensitivity of the analytical method (for example, of two methods for a given analyte, the method with the lower reporting level is likely to result in a higher detection frequency). Therefore, to facilitate comparison of detection frequencies between sampling periods and for different contaminants, detection frequencies were calculated at multiple detection thresholds appropriate for the chemical class and sampling medium. These detection thresholds are discussed in detail below in the section on “Data Censoring.” Briefly, for each analyte, one “optimal” detection threshold was determined to facilitate comparison between pre-landfall and post-landfall samples. In addition, detection frequencies for all analytes within the same contaminant group (organics or trace elements) and sampling medium (water or sediment) were computed at each of four common detection thresholds to allow comparison of detection frequencies among analytes. In the context of this study, data censoring refers to the process of distinguishing detections (quantified values) from nondetections (censored data), and censored datasets are those with some portion of the results composed of nondetections.

Percentile concentrations (percentiles) were determined in the primary-sample dataset by using one of four methods, depending on the amount of censored data (nondetections) for a given analyte (fig. 2). For analytes detected in 100 percent of samples (no censored data), the SAS UNIVARIATE procedure was used to compute concentration percentiles. For analytes with some, but less than 50-percent, censored data, percentiles were estimated using the nonparametric Kaplan-Meier method (Helsel, 2005) in the SAS LIFETEST procedure. For analytes with 50- to 80-percent censored data, percentiles were estimated using a SAS freeware macro, Censored Data Regression on Order Statistics (Helsel, 2005). For analytes with more than 80-percent censored data, all data for that analyte were censored at a common detection threshold, and only the 95th percentile concentration was calculated.

Statistical comparisons of contaminant concentrations in pre-landfall to post-landfall samples were made using the paired Prentice-Wilcoxon (PPW) test. This test was implemented using the USGS S-PLUS library version 4.0 (Lorenz and others, 2011) for the statistical software package Spotfire S+ (TIBCO Software, Inc., 2008). The PPW test is appropriate for comparing two groups with matched pairs of data and can be applied to censored datasets. The PPW test evaluates whether there is a difference in the distributions of the two sample groups. First, the data are stacked into one column, a score is computed for each observation (both censored and uncensored data) on the basis of the Kaplan-Meier estimate of the survival function, and then the scores are divided back into the two groups of matched pairs. The PPW test computes the differences between the paired scores and determines whether the sum of these differences is significantly different from zero by using a normal approximation for the test statistic (Helsel, 2005). In this study, the PPW test was performed on the paired-sample dataset (48 sites that were sampled during both the pre-landfall and post-landfall periods), as described previously.

Additional PPW tests were used to compare concentrations in pre-landfall and post-landfall samples collected at a subset of 19 paired-sample sites that were identified by Rosenbauer and others (2010) as having geochemical evidence (fingerprint) of M-1 well oil in post-landfall samples of sediment, tarballs, or both. At this subset of sites (called the “fingerprint-sample” dataset), there is direct evidence from Rosenbauer and others (2010) of residual M-1 well oil at the sites during the post-landfall period.

Benchmark exceedance frequencies were computed by using the Spotfire S+ program. All field samples, including primary and replicate samples, were compared to benchmarks to maximize the information on benchmark exceedance. However, direct comparison between exceedance frequencies for the pre-landfall and post-landfall sampling periods must be qualified because data from the two sampling periods do not represent exactly the same sites. Specifically, 22 pre-landfall sites and 1 post-landfall site were not sampled during the other sampling period (table 1); also, 20 of the 71 total sites were sampled more than once during one or both sampling periods.

For each combination of contaminant group (organic contaminants, or trace elements) and sampling medium (water or sediment), Fisher’s exact test was used to determine whether the proportion of samples exceeding applicable benchmarks was significantly different ($p < 0.05$) during the pre-landfall and post-landfall sampling periods. This test was performed on the 48 sites in the paired-sample dataset, so that the same sites are represented only once in both sampling periods.

For comparison of measured contaminant concentrations to various benchmarks for human health and aquatic life, some data manipulations were necessary because of the nature of the dataset. Specifically,

- In this study, trace-element concentrations are reported as total concentrations in water. Because most benchmarks for trace elements are expressed in terms of dissolved concentration in the water column, estimates of these benchmarks as total trace-element concentrations were calculated using marine conversion factors from USEPA (<http://water.epa.gov/scitech/swguidance/waterquality/standards/current/index.cfm>) prior to comparison with measured concentrations (Buchman, 2008).
- As previously described, water samples were not analyzed for the alkylated PAH groups required for calculation of USEPA benchmarks for mixtures of PAH and BTEX compounds ($\sum TU_i$). Concentrations of each alkylated PAH group were estimated from the corresponding parent PAH concentrations using multipliers, as specified in the USEPA procedures for benchmark calculation (<http://www.epa.gov/bpspill/water/explanation-of-pah-benchmark-calculations-20100622.pdf>).

- For sediment samples, BTEX compounds were not determined, so calculated $\sum \text{ESBTU}_i$ values could be slightly low; however, this bias is expected to be minimal because these compounds are volatile, were not detected in weathered crude oil (State of Florida Oil Spill Academic Task Force, 2010), and are not expected to persist in sediment (<http://www.epa.gov/bpspill/water/explanation-of-pah-benchmark-calculations-20100622.pdf>).

Results and Discussion

The results are presented first for QC analyses because these findings affect interpretation of field sample data. Following the QC data discussion, results are presented separately by contaminant group (for organic contaminants, and then trace and major elements and nutrients) and by sampling medium (water and sediment). In each case, contaminant occurrence is assessed, statistical comparisons are made between concentrations in pre-landfall and post-landfall samples, and measured concentrations are compared to water- or sediment-quality benchmarks.

Quality-Control Analyses

Analytical results for the various QC samples follow. These results were considered in computing occurrence statistics and making benchmark comparisons, as discussed later in this section.

Blank Samples

Results were available for 166 analytes in at least 4 pre-landfall field blanks. Most of these results were from the USGS NWQL. In addition, results were available from TestAmerica Laboratory in Colorado for six analytes, four of which overlap with analytes analyzed by the USGS NWQL, and results were available from the USGS OCRL for dissolved organic carbon. Of the 885 total results, 861 (97 percent) were reported as censored values (nondetections). There were 24 quantified results (detections) reported in blanks, affecting a total of 21 analytes (table 7). Five of the quantified values were less than the highest reporting level for that analyte. These were quantified by using corroborating evidence of analyte presence in the mass spectrogram, even though the concentration was below the typical reporting level for the method.

During the post-landfall sampling period, four field blanks were collected and shipped to the TestAmerica Laboratory in Florida for analysis. Of the 584 total reported results for 146 analytes, 564 (97 percent) were censored values (nondetections). There were 20 quantified values (detections) reported for 12 analytes (table 8), of which only 3 are organic contaminants. Ammonia plus organic nitrogen and phosphorus were quantified in each of the four blanks. Trip blanks also were analyzed by the TestAmerica Laboratory during post-landfall sampling. These have limited utility for comparison to environmental samples; however, quantified results reported for three analytes (table 8) might indicate potential for contamination during laboratory processing and analysis. None of these three analytes was detected in field blanks analyzed at this laboratory. The benzene result was from a blank associated with an environmental sample collected in Louisiana on October 12; the other results were from a blank associated with a sample collected in Florida on October 13.

There was little consistency in blank contamination between sampling periods. Only four analytes (calcium, magnesium, naphthalene, and sodium) were detected in blanks from both the pre-landfall and post-landfall periods. Six analytes detected in the pre-landfall blanks (1,4-dichlorobenzene, 4-chloro-3-methylphenol, arsenic, dichloromethane, ethyl methyl ketone, and silver) were quantified at concentrations less than the reporting level for post-landfall blanks. Similarly, copper was detected in two post-landfall blanks, but at concentrations less than the highest reporting level for pre-landfall blanks. Because of these discrepancies, it was not possible to evaluate differences in incidental contamination between sampling periods. In subsequent data analyses, potential contamination in environmental samples was determined separately for each period by using field blanks collected during that period.

Sediment-equipment rinsate blank results were available for 146 analytes from the TestAmerica Laboratory in Florida and for one analyte from the USGS OCRL. Of the 389 total reported results, 365 (94 percent) are censored (nondetections). There were 24 quantified results (detections) reported for 14 analytes (table 9). Similar to results for the post-landfall field blanks, ammonia plus organic nitrogen and phosphorus were detected in each of the sediment-equipment rinsate blanks. Naphthalene and toluene were the only organic compounds detected. The extremely high concentration of boron in one blank could have been caused by residue from a cleaning solution used on the sampling equipment. If so, the potential for contamination of a sediment sample collected using this equipment is probably much less than the concentration in a blank-water rinse. Any residue would likely be washed away during field rinsing of the equipment.

Field Replicates

Replicate samples were analyzed at all laboratories used in this study, though most analyzed samples of only one medium or samples from only one sampling period (table 4). Replicate-sample data analysis requires quantified results (detections) for at least two samples in a set in order to compute a standard error. In this study, many analytes, particularly organic compounds in water, were not detected in most or all replicate samples. Only those analytes with at least two quantified detections in at least four replicate sets were included in this analysis of variability.

The number of replicate sets generally was too small to evaluate variability over low and high ranges of concentration, so variability was simply estimated as the average RSD. This can be considered a conservatively high estimate of variability, because RSD values for low-concentration replicates typically are much higher than the average for high-concentration replicates. In subsequent interpretation of environmental data, variability was noted as a possible source of uncertainty for any contaminant with a replicate RSD greater than 10 percent for water or 20 percent for sediment.

Replicate water samples collected during the pre-landfall period were analyzed at the USGS NWQL, the USGS OCRL, and the TestAmerica Laboratory in Colorado. The USGS OCRL also analyzed replicate water samples from the post-landfall period, and these were combined with the pre-landfall samples for data analysis. Replicate sets with quantified results were available for only 21 analytes: 2 organic compounds and 17 major ions, nutrients, or trace elements from the USGS NWQL, plus dissolved organic carbon and dissolved nitrogen from the USGS OCRL. The number of pre-landfall replicate sets ranged from 4 to 27, depending on the analyte, and the resulting mean RSD ranged from about 1 percent to almost 19 percent (table 10). The mean RSD exceeded 10 percent for 8 of the 21 analytes in pre-landfall water samples.

Replicate water samples collected during the post-landfall period were analyzed at the TestAmerica Laboratory in Florida. Quantified results were available to assess the variability for 12 major ions, nutrients, or trace elements. The number of replicates sets ranged from 4 to 7, depending on the analyte, and the mean RSD ranged from less than 1 percent to almost 30 percent (table 10). The mean RSD exceeded 10 percent for 4 of the 12 analytes in post-landfall water samples.

Replicate sediment samples collected during the pre-landfall period were analyzed at the USGS NWQL, the USGS SCL, and the TestAmerica Laboratories in Colorado and Vermont (table 4). Samples collected during the post-landfall period were analyzed at the USGS SCL and the TestAmerica Laboratories in Florida and Vermont. There were too few detections in replicate data from the USGS NWQL and the TestAmerica Laboratory in Florida to compute representative mean RSD values. For the other laboratories, replicate data from both sampling periods were combined for this analysis. Quantified results were available for 15 organic contaminants from the TestAmerica laboratories, and for 31 trace and major elements and nutrients from the USGS SCL. Analyses at the SCL included both whole sediment and the less than 63- μm (silt-clay) fraction. Mean RSD values were computed for all 31 analytes in the less than 63- μm sediment fraction, but quantified results were available to compute mean RSD values for only two analytes (molybdenum and tin) in the whole-sediment samples.

Table 11 lists mean RSD values for organic contaminants in whole sediment and for trace and major elements and nutrients in the less than 63- μm sediment fraction. For organic contaminants, the number of replicate sets ranged from 5 to 17, depending on the contaminant, and the resulting mean RSD ranged from about 9 percent to more than 47 percent. Mean RSD exceeded 20 percent for 12 of the 15 organic contaminants in sediment. For trace and major elements and nutrients, the number of replicate sets ranged from 4 to 17, and the mean RSD ranged from about 2 percent to more than 28 percent. Mean RSD exceeded 20 percent for 4 of the 31 constituents in sediment.

Matrix Spikes

The USGS NWQL spiked 85 organic compounds in 5 separate water-matrix samples collected during the pre-landfall period. Mean recovery for individual analytes ranged from about 52 to 134 percent. The lowest recovery was for dichlorodifluoromethane; otherwise, all recoveries were greater than 60 percent. The highest recovery was for acetone, which is a common laboratory contaminant and was measured at 4.5 micrograms per liter ($\mu\text{g/L}$) in one field blank analyzed at the USGS NWQL. The next highest recovery was only about 110 percent. Thus, almost all recoveries for this group of spikes were between 60 and 110 percent.

The TestAmerica Laboratory in Florida prepared duplicate spikes for 107 organic compounds and 24 trace elements in 5 water-matrix samples during the post-landfall period. Mean recovery for individual analytes ranged from about 19 to 124 percent. The lowest mean recoveries were for 3,3'-dichlorobenzidine (19.2 percent) and N-nitrosodiphenylamine (43.4 percent); otherwise, all recoveries were greater than 52 percent. The highest recoveries were for aluminum (124 percent) and mercury (117 percent). Mercury also was found in two field blanks at the TestAmerica Laboratory in Florida, with a maximum concentration of 0.18 $\mu\text{g/L}$; therefore, the high recovery could have been due to contamination.

Spikes at the two laboratories had 41 analytes in common. Differences in recoveries were generally small—less than 17 percent for all but five analytes.

The USGS NWQL spiked 37 organic compounds into 4 separate sediment-matrix samples collected during the pre-landfall period. Mean recovery for individual analytes ranged from about 23 to 62 percent. The lowest mean recoveries were for 1,2,4-trichlorobenzene (22.9 percent) and naphthalene (33.7 percent); otherwise, all recoveries were greater than 44 percent. The TestAmerica Laboratory in Florida prepared duplicate spikes for 59 organic compounds in either 3 or 4 sediment-matrix samples during the post-landfall period. Mean recovery for individual analytes ranged from 43 to about 88 percent. The lowest mean recoveries were for N-nitrosodiphenylamine (43.0 percent) and 4-chloroaniline (56.2 percent); otherwise, all recoveries were greater than 61 percent. Spikes at the 2 laboratories had 18 analytes in common; mean recoveries in spikes from the TestAmerica Laboratory in Florida were consistently higher by about 13 to 35 percent.

Analytes with low spike recovery might also have a low bias in environmental-sample results. In the present study, recovery is considered to be within acceptable limits if it is between 70 and 115 percent for organic analytes in water samples and between 50 and 115 percent for organic analytes in sediment samples. Table 12 provides a list of analytes with less than 70 percent or more than 115 percent recovery in water spikes, or with less than 50 percent or more than 115 percent recovery in sediment spikes. Concentrations reported for these analytes in environmental samples could be substantially lower than their true concentrations. Analytes with overly high spike recovery could have high bias, possibly due to laboratory contamination, in environmental-sample results. This condition primarily affects acetone in water samples analyzed at the USGS NWQL, and aluminum and mercury in water samples analyzed by the TestAmerica Laboratory in Florida. Concentrations were not recovery-corrected, but analytes with exceptionally low or high recovery are footnoted in tables within this report.

Data Censoring

If an analyte cannot be reliably quantified—for example, if the measured value is less than the detection level or if there is no evidence (for example, from mass spectra) that the analyte is present—then the analytical result reported by the laboratory is censored (that is, reported as less than a specified concentration, called a reporting level). In statistical terms, this practice results in censored data, which require special methods for data analysis. Many constituents were not quantified in any environmental sample collected for this study. Table 13 lists 114 organic contaminants that were censored (not detected) in every water sample, and table 14 lists 51 organic contaminants and 3 trace elements that were censored in every sediment sample. These constituents were excluded from subsequent statistical tests and benchmark comparisons. Concentrations of some detected analytes in environmental samples were censored by using results of the QC analysis, as described below.

Censoring on the Basis of Quality-Control Results

For analytes detected in laboratory, field, or trip blanks, concentrations in environmental samples were censored at raised censoring levels on the basis of guidance from the U.S. Environmental Protection Agency (1989, pages 5-16 and 5-17). Field and trip blanks were available for water samples only, and laboratory reagent blanks were available for both water and sediment. For analytes detected in these blanks, a raised censoring level equal to five times the maximum concentration detected in blanks was applied to results in associated environmental samples. This raised censoring level ensures that a reported detection has a high probability of reflecting the actual concentration in the environmental sample, rather than the effect of incidental contamination from sampling and analysis procedures.

Quantified results less than this raised censoring level were changed to censored values (nondetections) and reported as less than the quantified value. For example, naphthalene was detected in a post-landfall field blank, so was censored at a raised censoring level of 0.8. A quantified result of 0.5 would be censored to less than 0.5, indicating that the environmental contaminant concentration in that sample is no more than 0.5 in that sample, but it could be less. For a few common laboratory contaminants (acetone, dichloromethane, diethyl phthalate, methyl ethyl ketone, and toluene), the censoring level was raised to 10 times the maximum concentration detected in the blank.

Four organic contaminants, four trace or major elements, and two nutrients had one or more detections in laboratory reagent blanks. Concentrations in all environmental samples, however, were more than five times the reagent blank concentration, except for the two nutrients—ammonia plus organic nitrogen and phosphorus. Because a reagent blank sample is associated with a particular set of environmental samples, censoring for reagent-blank contamination was applied only to those environmental samples that had contamination in the associated reagent blank. Results for both nutrients subsequently were censored in more than half of the post-landfall samples, and phosphorus was censored in 2 of the 110 pre-landfall samples.

In this study, it was not possible to associate a particular field blank with each environmental sample, so an alternative procedure had to be used to estimate potential contamination. One option was to determine the statistical distribution of concentrations in a set of representative blanks and assume this same distribution applies to potential contamination in the environmental samples (Mueller and Titus, 2005; Apodaca and others, 2006). This procedure requires more than 20 blanks to estimate the 90th percentile of this distribution with reasonable confidence. Using the six blanks available for this study, only the lower 60th to 70th percentile of this distribution can be estimated; therefore, using this approach could underestimate the extent of contamination in environmental samples. In the present study, the most conservative approach was used, which assumes that contamination identified in any field or trip blank could occur in all environmental samples collected during the same sampling period. Although this approach can overestimate the extent of incidental contamination, no other procedure would ensure that this extent would not be underestimated. Therefore, detection of an analyte in any field or trip blank resulted in the censoring of concentrations of that analyte in all environmental samples collected during the same sampling period.

Table 15 lists the constituents that were affected by censoring on the basis of contamination in laboratory, field, and trip blanks. Eight organic compounds and two trace elements were left with no detections in either sampling period after blank-censoring. Four additional organic compounds were left with no detections in the pre-landfall period; benzene and ammonia plus organic nitrogen were left with no detections in the post-landfall period. Four other constituents were censored to some extent, though some results still were quantified; two of these constituents were left with only one quantified value during the post-landfall period. Overall, 223 results, out of a total of 1,189 results, for 19 constituents were censored because of contamination in blanks; but 174 of these censored results were for only 5 constituents: toluene, ammonia plus organic nitrogen, mercury, organic carbon, and phosphorus.

Determination of Common Censoring Thresholds

Although the PPW test can be used with data censored at multiple reporting levels, it requires that the different reporting levels be randomly distributed between the two sample groups being compared. In this study, however, there were systematic differences in reporting levels between pre-landfall and post-landfall samples, especially for analytes that were determined using different methods, by different laboratories, or both, for the two sampling periods (Appendices A, B). Therefore, all data for a given contaminant were censored to an “optimal” censoring threshold prior to statistical analysis

(described below). For example, acenaphthene in sediment has an optimal censoring threshold of 0.36. Reported concentrations of 0.4, 0.2, and less than 1 would be censored, respectively, to 0.4, less than 0.36, and indeterminate (defined in the next paragraph). Two-sided PPW tests were performed, and the sign of the test statistic indicated whether pre-landfall concentrations were higher than post-landfall concentrations, or vice versa.

An optimal censoring threshold was computed for each analyte for which data were censored for one or more of the 96 samples in the paired-sample dataset (sites sampled during both the pre-landfall and post-landfall periods). Many analytes had a wide range of reporting levels (one to three orders of magnitude). Selection of an optimal censoring threshold balanced two competing objectives: to include as many quantified detections as possible, but also to minimize the number of “indeterminate” samples. An indeterminate sample is defined as a sample with censored data (i.e., reported as less than a specified reporting level) for which that specified reporting level is higher than the applied censoring threshold, so it cannot be classified as either a detection or nondetection at that threshold. As an example, censored data (nondetections) for acenaphthene in sediment ranged from less than 0.2 to less than 19 micrograms per kilogram ($\mu\text{g}/\text{kg}$), and quantified detections ranged from 0.34 to 2.1 $\mu\text{g}/\text{kg}$. If acenaphthene data are censored at the lowest possible censoring threshold (0.2), then any censored value with a higher reporting threshold (that is, from less than 0.22 to less than 19 $\mu\text{g}/\text{kg}$) must be considered as indeterminate because we do not know whether the acenaphthene concentration is less than 0.2, or greater than or equal to 0.2 $\mu\text{g}/\text{kg}$. On the other hand, if we censor at the highest threshold (19 $\mu\text{g}/\text{kg}$), then all samples with a detected concentration less than 19 $\mu\text{g}/\text{kg}$ —in this case, all of the reported detections—become censored (less than 19 $\mu\text{g}/\text{kg}$). The optimal censoring threshold was operationally defined as the lowest censoring level that converted no more than 5 percent of results from censored to indeterminate values, maximized the number of quantifiable detections, and (if possible) also minimized the number of indeterminate values. Because the optimal censoring threshold was designed for comparison of pre-landfall to post-landfall samples, it was determined using the paired-sample dataset. For practical reasons, the maximum limit allowed for indeterminate values was raised slightly for some analytes that were determined in substantially fewer than the 96 samples typical of the paired-sample dataset, because it was difficult to meet the 5 percent maximum indeterminate value requirement and still preserve detections. Therefore, up to 7 percent indeterminate values were allowed for trace and major elements in the less than 63- μm sediment fraction (for which there were only about 70 samples) and up to 8 percent for selected analytes measured only during one sampling period (for which there were about 48 samples).

The procedure for calculating the optimal censoring threshold for comparison of pre-landfall to post-landfall samples for a given analyte is illustrated for acenaphthene in sediment as an example (fig. 3). The x-axis shows possible censoring threshold concentrations for acenaphthene, which consist of all the reporting levels for censored samples. For acenaphthene, there are 94 samples, of which nine are quantified values. Of the observed reporting levels (from 0.2 to 19 $\mu\text{g}/\text{kg}$), all were considered as possible censoring thresholds for this analyte, and each (except for 19 $\mu\text{g}/\text{kg}$, which is off the x-axis scale) is represented in figure 3 with a gray bar showing the percentage of quantified values that would be “detections” if data were censored at that censoring threshold. The blue bars represent the percentage of samples that would be indeterminate at that threshold concentration because their reporting levels exceed the censoring threshold. The highest censoring threshold at which all 9 quantified values would still be “detections” after censoring (i.e., gray bar at 100 percent) would be 0.34. At a censoring threshold of 0.34, however, 6 percent of samples would be considered indeterminate because their reporting levels exceed 0.34. The maximum allowable limit for indeterminate samples is 5 percent (shown as the red line in fig. 3), so a censoring threshold of 0.34 would not be acceptable. The lowest

censoring threshold that meets the maximum indeterminate sample requirement is 0.35, which corresponds to 5 percent indeterminate samples. However, raising the censoring threshold slightly to 0.36 would decrease the percentage of indeterminate samples slightly (to 4 percent) without censoring any quantified values. Increasing the censoring threshold again, for example, to 0.40, would further reduce the indeterminate samples to 3 percent, but it also would result in loss of one more detection. The optimal censoring threshold selected was 0.36, which minimized the indeterminate samples and maximized quantifiable detections, while meeting the less than or equal to 5 percent criterion for maximum indeterminate samples.

Optimal censoring thresholds are shown in table 16 for individual analytes with at least 38 samples. Detection frequencies were calculated for each analyte at its optimal censoring threshold, so that pre-landfall and post-landfall samples can be compared at a common detection threshold. Also, contaminant concentrations were censored at the optimal censoring threshold prior to statistical comparisons between sampling periods.

For all analytes of the same general type (organics, or trace and major elements and nutrients) and sampling medium (water or sediment), detection frequencies also were computed using four common detection thresholds that allowed comparison among analytes with different MDLs. A range of common thresholds was used because the lower thresholds preserve more of the low-level quantified values, whereas higher thresholds allowed comparisons among a greater number of analytes. The four detection thresholds for a given contaminant type and sampling medium correspond to the 10th, 25th, 50th, and 70th percentiles in the distribution of optimal censoring thresholds for that contaminant type and sampling medium.

Organic Contaminants in Water

For organic contaminants in water, samples were analyzed by different laboratories, with pre-landfall samples analyzed by the USGS NWQL and post-landfall samples by the TestAmerica Laboratories in either Colorado or Florida. This complicates the comparison of contaminant occurrence between sampling periods, as described in the following section.

Contaminant Occurrence

Few organic contaminants were detected in water samples (table 17). For each contaminant, table 17 provides an optimal censoring threshold (described previously) to use in comparing detection frequencies between pre-landfall and post-landfall samples, as well as a series of four common detection thresholds to use in comparing detection frequencies among analytes. A common detection threshold must be applied when comparing detection frequencies for analytes with different or variable reporting levels, as is discussed later in this report.

Of the 41 contaminants analyzed only in pre-landfall samples, where the number of samples (n) is 60 to 65 sites, depending on the analyte, 5 contaminants were detected in one or more samples: 1,3,5-trimethylbenzene, 2-ethyltoluene, n-propylbenzene, dibromomethane, and benzo[ghi]perylene. Of the 24 contaminants analyzed only in post-landfall samples (n is 48 sites), 5 contaminants were detected in one or more samples: a mixture of C8 to C36 organics, oil range organics (C28-C35), gasoline-range organics (C6 to C10), diesel-range organics, and total xylene. Of 94 organic contaminants analyzed in both pre-landfall samples and post-landfall samples, one or more detections were observed for 28 analytes in pre-landfall samples and for 9 analytes in post-landfall samples, with 7 of these analytes (including dissolved organic carbon) detected in samples from both sampling periods. Two analytes (toluene and trichloromethane) were detected in one or more post-landfall samples, but no pre-landfall samples. Although more analytes were detected in pre-landfall than post-landfall samples, two factors

need to be considered: (1) more sites distributed over a wider geographic area were sampled during the pre-landfall period (typically 60 to 68 sites) than during the post-landfall period (typically 47 to 48 sites) and (2) reporting levels were lower for many analytes in pre-landfall than in post-landfall samples, which were analyzed by different laboratories. Thus, the detection frequencies are not directly comparable without adjustment for these factors.

This is illustrated in figure 4, which shows the cumulative frequency distributions of concentrations determined for two example contaminants in water, isophorone and benzene. (Appendix B provides a complete set of cumulative frequency plots for all individual contaminants determined in water and sediment.) For isophorone in water (fig. 4A), the detections observed in many pre-landfall samples were well below the reporting level for isophorone in post-landfall samples. Although it is possible that isophorone was present in post-landfall samples at concentrations comparable to those in pre-landfall samples, the analytical method used for post-landfall samples was not sensitive enough to detect these values. Similar results were observed for several PAHs in water (appendix B-1). The benzene example (fig. 4B) illustrates the effect of blank censoring. In this case, comparison of pre-landfall to post-landfall occurrence is limited because the censoring level for all post-landfall samples was raised to 2.1 $\mu\text{g/L}$ because of benzene detection in a blank from the post-landfall period. Because the raw benzene concentrations detected in post-landfall samples were less than the censoring threshold, there is uncertainty as to whether these concentrations were the result of incidental contamination, so all post-landfall samples were reported as less than 2.1 $\mu\text{g/L}$. Concentrations detected in pre-landfall samples (0.02 to 0.05 $\mu\text{g/L}$) were much lower than the censored results for post-landfall samples (less than 2.1 $\mu\text{g/L}$), so pre-landfall and post-landfall sample concentrations cannot be compared quantitatively.

When detection frequencies above the optimal censoring threshold (which varies by analyte, as shown in table 17) were computed for organic contaminants in water, dissolved organic carbon was detected in about 40 percent of samples from both pre-landfall and post-landfall sampling periods, and 14 additional analytes were detected in one or more samples. Of these 14 analytes, 12 were detected in only one sample each. The remaining two detected analytes were toluene and the mixture of C8 to C36 organics. Toluene was detected above an optimal censoring threshold of 0.7 $\mu\text{g/L}$ in 13 percent of post-landfall samples and no pre-landfall samples; the C8 to C36 organics were detected above an optimal censoring threshold of 47 $\mu\text{g/L}$ in 7 percent detection of post-landfall samples, but were not analyzed in pre-landfall samples. Toluene is the only analyte of the 94 determined in both sampling periods to show much difference between the two sampling periods in detection frequencies above the optimal censoring threshold (table 17). A more rigorous, statistical comparison between contaminant concentrations in pre-landfall and post-landfall samples is given below.

Comparison of Pre-Landfall to Post-Landfall Samples

Of the approximately 100 organic compounds that were determined in at least 100 water samples, only 11 compounds had enough quantified results above the optimal censoring threshold to make a statistical comparison of pre-landfall to post-landfall samples. Of these, only toluene showed a significant difference between pre-landfall and post-landfall samples in the PPW test ($p < 0.05$; table 18); toluene concentrations were significantly higher in post-landfall samples than in pre-landfall samples. This statistical test result supports the previous observation that toluene in water had a higher detection frequency in post-landfall samples (13 percent) than pre-landfall samples (not detected) after data were censored to an optimal threshold (0.7 $\mu\text{g/L}$; table 17). The difference in concentrations ($C_{\text{post}} - C_{\text{pre}}$) of toluene at each sampling site along the GOM coast, from west to east, is shown in figure 5A. For each site in figure 5A, the difference in concentrations ($C_{\text{post}} - C_{\text{pre}}$) of toluene is a range, which indicates that

one or both samples is censored (i.e., a nondetection); this range is derived by using both zero and the reporting level as the censored value when calculating the difference. Using this method of calculation, all of the bars that are centered on zero are cases where both pre-landfall samples and post-landfall samples were censored (e.g., most sites in fig. 5A); ranges that do not include zero are based on one censored and one uncensored value. For toluene (fig. 5A), the five bars with positive values indicate detections in post-landfall samples and censored data in the corresponding pre-landfall samples. If there is a single point instead of a range, then both samples were detections. A single negative value results when the concentration is higher in the pre-landfall sample than in the post-landfall sample (as shown in fig. 5B for LA-22), and a single positive value indicates that the concentration is higher in the post-landfall sample than in the pre-landfall sample (as shown in fig. 5B for LA-26).

Toluene was detected (at greater than 0.7 $\mu\text{g/L}$) in no pre-landfall samples and in six post-landfall samples (only five of which are in the paired data set, and therefore appear in fig. 5A). The significant PPW test result is influenced by the toluene detections in post-landfall samples from five sites: MS-37, FL-3, FL-4, FL-25, and FL-5 (fig. 5A). Additional BTEX compounds (benzene, xylenes) were detected in samples from two of these sites (MS-37 and FL-25).

The analysis of BTEX compounds from beach-water sampling does not necessarily indicate the presence or absence of M-1 oil. Weathered M-1 (MC252) oil, which was collected on April 27, 2010, and weathered for 24 to 48 hours, contained no detectable BTEX compounds; of the aliphatic and cyclic hydrocarbons detected, the lowest molecular-weight compound detected was the alkane *n*-C14 (State of Florida Oil Spill Academic Task Force, 2010). Toluene was detected in post-landfall water samples from six sites; one of these six sites (AL-7) had no paired pre-landfall sample, so was not included in the PPW test. Three of the six sites with toluene detections (MS-37, AL-7, FL-3) were reported to have the M-1 oil fingerprint in corresponding post-landfall samples of sediment, tarballs, or both—thus providing direct evidence of M-1 oil landfall at those sites at the time of post-landfall sampling (Rosenbauer and others, 2010). However, Rosenbauer and others (2010) found no evidence of M-1 oil in post-landfall sediment from the other three sites with toluene detections (FL-4, FL-25, and FL-5). Moreover, no evidence of M-1 oil was found in 69 pre-landfall sediment samples analyzed by Rosenbauer and others (2011), although a tarball from 1 site (FL-18) was similar to M-1 oil (as discussed later in the report).

Comparison with Benchmarks for Human Health and Aquatic Life

Benchmark comparisons were made for all field samples, including primary environmental samples and field replicates. Benchmark exceedances for organics in water by individual sample are listed in appendix table C-1, and the results are summarized in table 19. For those organic compounds with benchmarks, 253 water samples were analyzed: 196 pre-landfall samples from 70 sites and 57 post-landfall samples from 49 sites. Not every organic compound was analyzed in every sample, as indicated in appendix table C-1. Of the 253 water samples, 138 samples were analyzed for PAHs and BTEX compounds, 86 samples for BTEX compounds only, and 29 samples for PAHs only.

Human-health benchmarks are available for 11 organic contaminants analyzed in water (table 5C). None of these benchmarks were exceeded by any water samples in this study.

Aquatic-life benchmarks used in the present study include USEPA's toxic-unit benchmarks for mixtures of PAH and BTEX compounds (table 5A), as well as supplementary aquatic-life benchmarks for 72 individual organic contaminants (table 5B). One water sample exceeded USEPA's chronic toxic-unit benchmark for PAH and BTEX compound mixtures (table 19, appendix C-1). As noted previously, this benchmark assumes additive toxicity for compounds with the same mechanism of action, and a $\sum\text{TU}_i$ value greater than 1 indicates that chronic toxicity to aquatic life is likely. The single water

sample exceeding this benchmark was the post-landfall sample from the Mississippi River at South Pass, Louisiana (site LA-35), for which the chronic $\sum TU_i$ value was 2.4. This is substantially higher than the corresponding chronic $\sum TU_i$ value (less than 10^{-4}) for the sample collected at this site during the pre-landfall period. Neither the post-landfall nor the pre-landfall sediment from site LA-35 contained the M-1 oil fingerprint (Rosenbauer and others, 2010, 2011).

Of the 72 individual organic contaminants analyzed in this study that have aquatic-life benchmarks (table 5B), not all were analyzed in every water sample (see appendix table C-1). However, none of the aquatic-life benchmarks for any individual organic contaminants were exceeded by any water samples in this study.

Of individual organic contaminants with benchmarks, recovery in matrix spikes was less than 70 percent for six contaminants (4-nitrophenol, benzo[a]pyrene, hexachlorobutadiene, hexachlorocyclopentadiene, hexachloroethane, and N-nitrosodiphenylamine), indicating that the measured concentration could be biased low. Benchmark results in appendix table C-1 and summary statistics in table 17 are footnoted to indicate this. The single observed benchmark exceedance of the chronic TU benchmark for PAH and BTEX compounds by one post-landfall sample from site LA-35 must be considered in light of the QC data for organic contaminants in water. Of the compounds included in this benchmark, one BTEX compound (benzene) and one PAH compound (naphthalene) were detected in field or trip blanks associated with post-landfall samples; therefore, data for these two analytes were censored at five times the blank concentration to minimize the probability that incidental contamination contributed to the reported concentrations and any consequent benchmark exceedances. In the case of the LA-35 sample that exceeded the chronic TU benchmark, however, neither benzene nor naphthalene was detected in the sample; therefore, their concentrations were set to zero in computing the TU values for this sample, following USEPA's calculation procedure and examples, which assume that censored values are equivalent to zero (<http://www.epa.gov/bpspill/water/explanation-of-pah-benchmark-calculations-20100622.pdf>). Therefore, incidental contamination by benzene or naphthalene did not contribute to the chronic TU benchmark exceedance in the post-landfall sample at site LA-35.

Because there was only one benchmark exceedance, Fisher's exact test was not performed for organic contaminants in water. When chronic $\sum TU_i$ values for all 47 pairs of pre-landfall and post-landfall samples were compared, there was no significant difference between the two sampling periods (Wilcoxon signed-rank test, $\alpha=0.05$). In addition, acute $\sum TU_i$ values for PAH and BTEX compound mixtures were not greater than 1 in any water samples, and there was no significant difference in acute $\sum TU_i$ values between pre-landfall and post-landfall samples (Wilcoxon signed-rank test, $\alpha=0.05$). Again, these comparisons need to be qualified because reporting levels varied among analytes and between the two sampling periods (concentrations were not censored to a single detection threshold prior to calculation of benchmark $\sum TU_i$ values, which were calculated following the standard USEPA procedure). Because reporting levels for many analytes were higher in post-landfall samples than in pre-landfall samples, setting nondetections equal to zero could underestimate benchmark exceedance rates in post-landfall samples relative to pre-landfall samples. Also, of the 47 sites with paired data, 6 pre-landfall sites were missing data for BTEX compounds, so the benchmark $\sum TU_i$ values for these pre-landfall samples were computed for PAHs only.

Organic Contaminants in Sediment

Most organic contaminants in sediment were determined by a single laboratory (TestAmerica Laboratory in Vermont) in samples from both sampling periods. These contaminants include parent PAHs and alkylated PAH groups, which are of potential concern from the oil spill (<http://www.epa.gov/bpspill/sediment-benchmarks.html>). Fourteen additional organic contaminants, mostly individual alkylated PAH compounds, were analyzed only in pre-landfall samples by the USGS NWQL. Also, 44 miscellaneous SVOCs were analyzed in post-landfall but not pre-landfall samples; these include chlorinated phenols, nitroaromatic compounds, chlorinated alkanes and alkenes, nitroso compounds and phthalate esters.

Reporting levels for organics in sediment varied somewhat for a given compound, but not as widely as for organics in water, and reporting levels were comparable for pre-landfall and post-landfall samples (appendix B).

Contaminant Occurrence

The detection frequencies and percentile concentrations of organic contaminants in sediment are shown in table 20. Of the 14 organic contaminants analyzed only in pre-landfall samples (excluding TOC), 8 contaminants were detected in 1 to 4 samples each. Six of these were individual alkylated PAH compounds (e.g., 1,2-dimethylnaphthalene) that also were included in determination of alkylated PAH groups (e.g., C-2 naphthalenes) by TestAmerica Laboratory in Vermont. The remaining two were 9,10-anthraquinone and a mixture, petroleum hydrocarbons.

There were 52 organic contaminants (plus organic carbon) analyzed in both pre-landfall and post-landfall samples: 19 parent PAHs, 5 individual alkylated PAHs, 22 alkylated PAH groups, 5 SVOCs, and oil and grease. Of the 52 analytes, 49 were detected in pre-landfall samples and 50 in post-landfall samples, with 47 analytes detected in samples from both sampling periods. Only two analytes were not detected in any samples: the SVOCs hexachlorobenzene and diethyl phthalate. PAH detection frequencies (above the optimal censoring threshold for each analyte) ranged from 3 to 64 percent for parent PAHs and 0 to 33 percent for alkylated PAH groups; because of variable reporting limits, there were some indeterminate samples (table 20). Figure 4C shows an example of the concentration distribution observed in sediment samples for the alkylated PAH group, C3-alkylated fluorenes. The reporting levels for C3-alkylated fluorene tend to be lower for post-landfall than pre-landfall samples, which means that uncensored detection frequencies will not provide a fair comparison of occurrence in the two sampling periods. After censoring at an optimal threshold of 1.8 $\mu\text{g}/\text{kg}$, the detection frequency for C3-alkylated fluorenes was higher in post-landfall samples (15 percent) than in pre-landfall samples (1 percent).

Comparison of detection frequencies among contaminants with different reporting levels should be done at a common detection threshold (table 20). For example, the parent PAH chrysene was detected above its optimal censoring threshold (which is 0.23 $\mu\text{g}/\text{kg}$) in 50 percent of post-landfall samples, compared to 33, 29, 21, and 13 percent of post-landfall samples for the C-1, C-2, C-3, and C-4 alkylated chrysenes detected above their respective optimal censoring thresholds (which are 1.5, 1, 1, and 1.3 $\mu\text{g}/\text{kg}$). When a common detection threshold of 1.5 $\mu\text{g}/\text{kg}$ was applied, the 29 percent detection frequency for chrysene was then comparable to detection frequencies for the C-1 and C-2 alkylated chrysenes (33 and 27 percent, respectively), and closer to those for C-3 and C-4 alkylated chrysenes (19 percent and 10 percent, respectively).

Thirteen PAHs (four parent and nine alkylated) were detected at or above concentrations of 1.5 µg/kg in more than 20 percent of post-landfall samples, whereas four parent PAHs were detected at or above the 1.5 µg/kg threshold in more than 20 percent of pre-landfall samples (table 20). Overall, PAH detection frequencies in sediment (table 20) tended to be higher than in water samples (table 17)—which is expected because PAHs are hydrophobic and tend to sorb to organic material.

Comparison of Pre-Landfall to Post-Landfall Samples

Of 54 organic contaminants analyzed during both pre-landfall and post-landfall sampling periods, and with at least 80 whole-sediment samples, there were enough quantified results above the optimal censoring threshold to make a statistical comparison of pre-landfall to post-landfall samples for 49 contaminants (table 21). Most of these were PAHs (19 compounds) or alkylated PAHs (26 compounds). Of these 49 contaminants, 22 showed a significant difference between pre-landfall and post-landfall samples in PPW tests ($p < 0.05$; table 21). Concentrations were significantly higher in post-landfall samples for 20 contaminants (3 PAHs and 17 alkylated PAH groups) and in pre-landfall samples for two contaminants (naphthalene and oil and grease). The difference between concentrations in post-landfall and pre-landfall sediment samples ($C_{\text{post}} - C_{\text{pre}}$) at individual sites along the GOM coast, from west to east, is shown in figures 5B to 5H for some example contaminants with significantly higher concentrations during one sampling period than the other. The examples in figures 5B–5F are PAHs that had significantly higher concentrations in post-landfall than pre-landfall samples, and represent various PAH compounds and various degrees of alkylation. Figures 5G and 5H show naphthalene and oil and grease, respectively, for which concentrations were significantly higher in pre-landfall samples than post-landfall samples. For the three parent PAHs with significant PPW tests (chrysene, benzo[b]fluoranthene, and benzo[e]pyrene), there were high post-landfall sample concentrations at one site—LA-26 (e.g., chrysene in fig. 5B). About 1.5 to 2 times more sample pairs had a positive difference ($C_{\text{post}} - C_{\text{pre}}$) than had a negative difference for these three PAHs, consistent with the significant test result.

In contrast, the significant results for most alkylated PAHs (15 of 17) reflect particularly high concentrations in post-landfall samples at seven sites: from west to east, LA-28, LA-26, LA-31, MS-42, AL-8, AL-9, and AL-10 (e.g., figs. 5C–5F). Five of these sites showed evidence of M-1 oil in sediment, tarballs, or both, sampled post-landfall, on the basis of PAH fingerprinting by Rosenbauer and others (2010): Grand Isle Beach at State Park, Louisiana (LA-31); Petit Bois Island Beach, Mississippi (MS-42); and BLM-1 (AL-8), BLM-2 (AL-9), and Fort Morgan BLM-3 (AL-10) in Alabama. Notably, 16 of the 17 alkylated PAHs with significantly higher concentrations in post-landfall samples were identified as relatively abundant components of weathered M-1 (MC252) oil collected on April 27, 2010 (State of Florida Oil Spill Academic Task Force, 2010). Chrysene and alkylated PAHs, however, are characteristic of petrogenic PAHs in general (Iqbal and others, 2008).

For two sites with large positive ($C_{\text{post}} - C_{\text{pre}}$) differences in alkylated PAHs, LA-28 and LA-26, there was no evidence of the M-1 oil fingerprint in post-landfall sediment samples (Rosenbauer and others, 2010). The most abundant PAH compounds in these samples were consistent with pyrogenic sources. In the LA-28 sample, by far the most abundant PAH compound was anthracene, which is produced during rapid, high temperature pyrosynthesis, but tends to be less thermodynamically stable and does not persist during the slow generation of fossil fuels (Iqbal and others, 2008). In the LA-26 sample, the most abundant PAHs were fluoranthene and pyrene, and alkylated PAH concentrations were generally lower than the corresponding parent PAHs—which are characteristic of pyrogenic sources of PAHs.

Naphthalene and oil and grease concentrations were significantly higher in pre-landfall sediment samples than post-landfall samples (table 21). Naphthalene has one very large negative ($C_{\text{post}} - C_{\text{pre}}$) difference value at LA-32, but in addition, 27 sample pairs have a negative difference value, compared to only five pairs with a positive difference (fig. 5G). Oil and grease concentrations at 26 sites along the GOM coast had negative ($C_{\text{post}} - C_{\text{pre}}$) difference values, compared to 5 sites with positive difference values; concentrations in pre-landfill samples were substantially higher for sites LA-29, LA-22, LA-34, and AL-6 (fig. 5H). Oil and grease are operationally defined as hexane-extractable material, which includes relatively nonvolatile hydrocarbons, vegetable oils, animal fats, waxes, soaps, and greases (<http://h2o.enr.state.nc.us/lab/qa/documents/HEMOilandGreasepdf.pdf>).

Because hydrophobic contaminants such as PAHs tend to be associated with organic carbon, it is possible that differences in the amount of organic carbon in pre-landfall and post-landfall samples could have caused or contributed to the significant differences in PAH concentrations. Therefore, the PPW tests were repeated after normalizing organic contaminant concentrations to the sediment-TOC content (table 21). Of the 20 PAHs with significantly higher concentrations in post-landfall samples, 19 continued to show a significant difference after organic-carbon normalization (the 20th had a p-value of 0.051, only slightly larger than the criterion of $p < 0.05$). Sediment-TOC data were insufficient to normalize oil and grease concentrations; however, naphthalene concentrations were significantly higher in pre-landfall than in post-landfall samples even after organic-carbon normalization. Moreover, there was no significant difference in sediment-TOC content between the two sampling periods (table 21). These PPW test results indicate that the significant differences are not likely due to differing amounts of sediment-TOC in samples from pre-landfall and post-landfall periods.

The results of the present study, combined with direct evidence from oil fingerprinting study by Rosenbauer and others (2010), indicate that M-1 oil could have contributed to the higher alkylated PAH concentrations measured at five sites (LA-31, MS-42, AL-8, AL-9, and AL-10) sampled in October 2010, relative to pre-landfall concentrations; however, other PAH sources, including other sources of oil, cannot be excluded. There are many possible sources of oil-related contaminants to the GOM, including natural oil seepage (estimated at about one million barrels of petroleum hydrocarbons) and various oil spills (approximately 74,000 barrels) from production operations, transportation accidents, and unburned engine fuel each year (Operational Science Advisory Team, 2010). A previous study of PAH sources along the Louisiana coast (Iqbal and others 2008) reported that approximately 50 percent of PAHs were from petrogenic sources (petroleum and petroleum products), 36 percent were from pyrogenic sources (combustion of organic matter and fossil fuels), and 14 percent were from diagenetic sources (chemical or biological transformation of natural organic matter).

Comparison with Benchmarks for Aquatic Life

The USEPA ESBTU benchmarks address the additive toxicity of PAH and BTEX compound mixtures in sediment (table 5D). As noted previously, ΣESBTU_i values were calculated for PAHs only, because BTEX compounds were not determined in sediment. One sediment sample exceeded the chronic ESBTU benchmark for PAH mixtures—this was the pre-landfall sample from Trinity Bay near Beach City, Texas (site TX-52). This site was outside the area of expected oil landfall and was not sampled during the post-landfall period. Notably, sediment-TOC concentrations in the present study were very low (median of 0.1 percent), which may affect bioavailability and potential toxicity. As previously noted, equilibrium-partitioning theory is considered to predict PAH toxicity in sediments with a TOC content of 0.2 percent or above (U.S. Environmental Protection Agency, 2002).

Empirical screening values (table 5E) for 20 individual PAHs, 3 PAH mixtures, and 24 other SVOCs in sediment were used to classify sites into one of three categories: the minimal effect, possible effect, and probable effect ranges. Of 165 sediment samples analyzed for organic contaminants that have benchmarks, 116 samples (70 percent) had no lower or upper screening values exceeded by any of the organic contaminants determined in the sample, so these were in the minimal effect range (no adverse effects would be expected); 45 samples (27 percent) exceeded one or more upper screening values, so were in the probable effect range (with a high probability of adverse effects on aquatic life); and only 4 samples were in the possible effect range (table 19; appendix table C-2). Of all post-landfall samples, 37 percent (21 of 57 samples) exceeded one or more upper screening values, compared to 22 percent (24 of 108 samples) for pre-landfall samples. The reverse pattern holds for samples with no screening values exceeded (that is, no adverse effects are expected), which applied to 75 percent of pre-landfall samples (81 of 108 samples) and 61 percent of post-landfall samples (35 of 57 samples). The only upper screening value benchmarks exceeded were for PAH mixtures. Lower screening values were exceeded by PAH mixtures, a few individual PAHs, and occasionally by bis(2-ethylhexyl) phthalate. Although three PAH compounds (benzo(g,h,i)perylene, indeno(1,2,3-cd)pyrene, and perylene) were detected in laboratory reagent blanks associated with two post-landfall samples, it is unlikely that any incidental contamination contributed to benchmark exceedances for these two samples. Neither of these two samples exceeded the ESBTU for total PAHs, and only one empirical benchmark (a lower screening value for perylene) was exceeded by one of these samples. On the other hand, four organic contaminants with benchmarks had less than 50 percent recovery from matrix spikes, so their concentrations and contribution to benchmark exceedance could be biased low. These are acenaphthylene and naphthalene (PAH compounds included in the ESBTU), 1,2,4-trichlorobenzene (which had no benchmark exceedances), and N-nitrosodiphenylamine (not evaluated because the benchmark was below the reporting level).

For the five sites identified as having possible contributions to alkylated PAH concentrations from M-1 oil (LA-31, MS-42, AL-8, AL-9, and AL-10), PAH concentrations did not exceed ESBTU benchmarks. Chronic Σ ESBTU_i values in post-landfall samples from these sites ranged from 0.17 to 0.29, so were below the hazard index of 1; this indicates that PAHs levels in these post-landfall samples were not high enough to cause toxicity to benthic organisms by these criteria. On the other hand, these samples did exceed empirical upper screening-value benchmarks for total PAHs, indicating a high probability of toxicity to benthic organisms at these sites by comparison with other field studies.

Because of differences in how various benchmarks are derived, it is not surprising that empirical benchmarks were exceeded more often than the ESBTU benchmarks. The (empirical) upper screening values are probabilistic—they are associated with frequent occurrence of toxicity in field sediments, which often contain mixtures of contaminants. Exceedance of an empirical benchmark is an indicator that toxicity is likely; it does not guarantee toxicity, and concentrations above the benchmark do not necessarily cause toxicity. In contrast, the ESBTU benchmark is causally based, and designates concentrations expected to result in PAH-induced toxicity to benthic organisms.

Direct comparison between benchmark exceedance frequencies for pre-landfall and post-landfall sampling periods must be qualified because, as noted previously, data from the two sampling periods do not represent exactly the same sites: 22 pre-landfall sites in Florida and Texas and 1 post-landfall site in Louisiana were only sampled during one sampling period (table 1). Also, 20 of the 71 total sites were

sampled more than once during one or both sampling periods. Differences in benchmark exceedances, however, were evaluated for the paired-sample dataset, which excludes exceedance data for field replicate samples and for sites sampled during only one period. Fisher's exact test indicated there was no significant difference in benchmark exceedance frequency between pre-landfall and post-landfall samples in this dataset ($p > 0.05$). This was true for exceedance of both upper and lower screening-value benchmarks.

Trace and Major Elements and Nutrients in Water

For trace and major elements and nutrients in water, two different laboratories analyzed pre-landfall samples (USGS NWQL) and post-landfall samples (TestAmerica Laboratory in Florida). For some trace elements and nutrients, the method used to analyze pre-landfall samples was more sensitive than the method used for post-landfall samples.

Constituent Occurrence

The detection frequencies and percentile concentrations for trace and major elements and nutrients in beach water samples are shown in table 22. Detection frequencies are provided for a series of detection thresholds, and a common detection threshold must be applied when comparing detection frequencies between pre-landfall and post-landfall samples or for two different constituents.

Several patterns of trace element occurrence were observed. Uncensored detection frequencies for many constituents tended to be higher in pre-landfall samples than in post-landfall samples. For some constituents, however, this simply reflects the typically lower reporting levels used to analyze these constituents in pre-landfall samples. When data were censored to a common reporting level, detection frequencies and concentrations were similar (table 22). For example, zinc concentrations in pre-landfall water samples (filled blue circles in fig. 4D) were generally below the laboratory reporting levels for post-landfall samples (unfilled squares in fig. 4D), but the detection frequencies for zinc in water samples from the two sampling periods were the same (about 2 percent; table 22) after censoring at the optimal censoring threshold of 80 $\mu\text{g/L}$. Additional examples of this pattern are lead, which was detected above a threshold of 20 $\mu\text{g/L}$ in 2 to 3 percent of samples from both sampling periods, and iron, which was detected above a threshold of 500 $\mu\text{g/L}$ in 41 to 42 percent of samples from both periods. Molybdenum in water (fig. 4E) showed a different pattern, in which uncensored detection frequencies were higher in pre-landfall samples than post-landfall samples, but the concentration distribution was higher in post-landfall samples. After censoring to the optimal threshold (20 $\mu\text{g/L}$), the molybdenum detection frequency was actually higher in post-landfall (8 percent) than in pre-landfall (0 percent) samples. Aluminum and manganese also showed higher detection frequencies above their respective optimal censoring thresholds in post-landfall than pre-landfall samples. The nutrients phosphorus and ammonia were more frequently detected in pre-landfall than post-landfall samples, even after censoring to a common detection threshold. Phosphorus concentrations (fig. 4F) in post-landfall water samples had to be blank-censored first, to minimize the possibility that the detected concentrations were the result of incidental contamination. Because the blank-censoring procedure is intentionally conservative, this could have overestimated the extent of incidental contamination, thus lowering the post-landfall sample detection frequency. Similarly, ammonia plus organic nitrogen (fig. 4G) was blank-censored in post-landfall water samples because of detection in each of four field blanks for the post-landfall sampling period. The conservative blank-censoring procedure resulted in censored data with high reporting levels for all post-landfall samples. When detection frequencies were computed at the optimal censoring threshold of 2.4 mg/L as N, the detection frequencies were zero in both sampling periods.

Barium, calcium, magnesium, potassium, and sodium were detected in 100 percent of both pre-landfall and post-landfall samples, although some concentrations in post-landfall samples were higher than in pre-landfall samples (e.g., potassium in fig. 4H; appendix B-3).

Comparison of Pre-Landfall to Post-Landfall Samples

Statistical comparisons of trace and major element and nutrient concentrations in water were made for 16 of 33 constituents determined in water during this study (table 23). For 9 of the 33 constituents, no detections remained after censoring, so no significant differences between sampling periods were apparent; these are listed in table 23. The remaining eight constituents were not determined in a sufficient number of samples during both sampling periods to be evaluated. The PPW test indicated significant differences between concentrations in pre-landfall and post-landfall water samples for seven constituents (table 23). Concentrations were higher in post-landfall samples for barium, calcium, magnesium, molybdenum, potassium and sodium. These are all elements in seawater (Turekian, 1968), and barium sulfate is a standard additive in drilling mud (<http://web.ead.anl.gov/dwm/techdesc/lower/index.cfm>). Using molybdenum as an example, figure 6A shows the difference in molybdenum concentrations in water between post-landfall and pre-landfall samples at individual sites along the GOM coast from west to east. Many sites had censored data for one or both samples; these are represented by bars that touch or cross the x-axis, where y is equal to zero. Eighteen sites showed a positive ($C_{\text{post}} - C_{\text{pre}}$) difference, indicating higher post-landfall sample concentrations than pre-landfall, and six showed a negative difference, indicating the opposite.

Of nutrients, only ammonia showed statistically significant differences (table 23), having a higher detection frequency (table 22) and higher concentrations in pre-landfall samples than post-landfall samples (fig. 6B). Data were insufficient to assess ammonia plus organic nitrogen. Statistical comparisons were made, but were not significant, for organic nitrogen, dissolved nitrogen, and phosphorus.

Comparison with Benchmarks for Human Health and Aquatic Life

U.S. Environmental Protection Agency (2010) recommended that concentrations of nickel and vanadium in water be compared to human-health benchmarks for recreational exposure. Neither was exceeded in any water samples collected in the present study, and recreational exposure-based human-health benchmarks were not available for other trace elements.

Aquatic-life benchmarks were available for 18 trace elements in water (table 6A). Benchmarks were identified from a number of sources, including USEPA and NOAA, and included both acute and chronic marine benchmarks. As noted previously, trace-element concentrations were converted from total to dissolved concentrations by the use of marine conversion factors from USEPA (as per Buchman, 2008). Acute aquatic-life benchmarks for one or more trace elements were exceeded in 23 of 158 water samples (table 24A, appendix table C-3), of which 22 samples were from the post-landfall period and 1 was from the pre-landfall period. The elements responsible for acute benchmark exceedances were copper (in all 23 samples) and zinc (in 2 samples). The one pre-landfall sample with exceedances was from Louisiana, whereas post-landfall samples with exceedances were found in all five states sampled. In addition, chronic aquatic-life benchmarks were exceeded by concentrations of one or more trace elements in 74 of 158 samples, including 22 of 102 pre-landfall samples and 52 of 56 post-landfall samples; the samples with exceedances represent 22 percent of total pre-landfall samples and 93 percent of total post-landfall samples. The chronic benchmarks exceeded were boron (exceeded in 50 water

samples), manganese (30), copper (24), cobalt (19), nickel (7), lead (6), barium (3), zinc (2), and vanadium (1). One post-landfall sample (from site LA-25, Rockefeller Refuge Beach, Louisiana) exceeded chronic benchmarks for eight trace elements, including nickel and vanadium; excluding this sample, the other post-landfall chronic benchmarks exceeded were for boron (in 47 water samples), copper (21), manganese (11), and barium (1).

For trace elements in water, statistical comparison between the pre-landfall and post-landfall sampling periods as to the proportion of samples exceeding aquatic-life benchmarks was precluded because of the highly variable reporting levels and the large number of censored values at reporting levels greater than the applicable benchmarks. For example, 31 samples had arsenic reported as less than 40 µg/L, so it is unknown whether or not arsenic concentrations in these samples would have exceeded the chronic aquatic-life benchmark of 36 µg/L. In this sense, the uncensored benchmark exceedance frequencies presented in this report are essentially minimum exceedance frequencies; if the analytical methods used had been more consistently sensitive, it is possible that a higher number of benchmark exceedances would have been identified. For several trace elements in the paired sample dataset, comparisons to benchmarks were limited because either the trace element was analyzed largely during only one sampling period (e.g., boron and vanadium) or between 35 and 100 percent of samples for that element and sampling period had concentrations reported as censored values that were higher than the applicable benchmark (arsenic, cadmium, cobalt, copper, lead, nickel, and silver). For the following analytes and sampling periods, therefore, the exceedance frequencies presented in this report could be substantially underestimated: boron and vanadium in the pre-landfall period; arsenic, cadmium, cobalt, lead, nickel, and silver in the post-landfall period; and copper in both sampling periods.

Two of the elements with benchmark exceedances, boron and copper, were detected in one of four field blanks for the study, so their concentrations were blank-censored prior to comparison to benchmarks. The maximum boron concentration detected in blanks (10 µg/L) was less than 1 percent of the benchmark value (1,200 µg/L), indicating there is reasonable certainty that measured concentrations above the benchmark were not affected by incidental contamination. For copper, however, the maximum concentration detected in blanks (2.2 µg/L) was close to the benchmark values (chronic and acute aquatic-life benchmarks of 3.1 and 4.8 µg/L, respectively). Therefore, measured concentrations were considered to be benchmark exceedances only when they exceeded 11 µg/L, or five times the maximum blank concentration.

A total of seven samples exceeded chronic aquatic-life benchmarks for nickel, vanadium, or both, which were specifically identified by U.S. Environmental Protection Agency (2011a) as relevant to the Deepwater Horizon oil spill in the GOM. Of these seven samples, six were from the pre-landfall period and exceeded the chronic benchmark for nickel, and one sample from the post-landfall period exceeded chronic benchmarks for both nickel and vanadium (appendix table C-3). Nickel benchmark exceedance could be substantially underestimated because the reporting level during the post-landfall period (15 to 75 µg/L) was too high to ascertain whether the chronic aquatic-life benchmark (8.2 µg/L) was exceeded. Vanadium was analyzed in all post-landfall samples, but in only two pre-landfall samples.

The frequency at which aquatic-life benchmarks for trace elements were exceeded (47 percent) in GOM water samples indicates there is potential for toxicity to aquatic life. Because of high and variable analytical reporting levels for trace elements in water, it was not possible to do a rigorous statistical comparison of benchmark exceedances between the pre-landfall and post-landfall sampling periods.

Trace and Major Elements and Nutrients in Sediment

Trace and major elements and the nutrients phosphorus and total nitrogen were analyzed in both whole sediment and fine (less than 63- μm fraction) sediment by the USGS SCL for both pre-landfall and post-landfall samples. Concentrations in whole sediment were used to assess contaminant occurrence and for comparison to sediment-quality benchmarks. Concentrations in the fine fraction (less than 63 μm) of sediment were compared to national baseline concentrations in bed sediments of rivers and streams from Horowitz and Stephens (2008).

Constituent Occurrence

The detection frequencies and percentile concentrations for trace and major elements and nutrients in sediment are shown in table 25 for whole sediment and table 26 for fine (less than 63- μm) sediment. Because sediment samples were subjected to strong-acid digestion, which destroys the sediment matrix, the analyses yielded total trace element concentrations (Horowitz and Stephens, 2008).

Detection frequencies for constituents in whole sediment ranged from zero for thallium and uranium to over 90 percent for barium, manganese, phosphorus, sodium, strontium, and sulfur in one or both sampling periods, at a common detection threshold of 0.1 mg/kg (table 25). For almost all constituents, detection frequencies in pre-landfall and post-landfall samples were similar (that is, separated by about 10 percent or less) at their optimal censoring thresholds (table 25). As examples, the concentration distributions in pre-landfall and post-landfall whole-sediment samples are shown for calcium and lead in figures 4I and 4J. Although calcium detection frequencies above the optimum censoring threshold were similar, at 67 to 68 percent, for pre-landfall and post-landfall samples, calcium concentrations appeared to be higher in post-landfall samples (fig. 4I). The opposite was true for lead, which had similar detection frequencies in both sampling periods, but higher concentrations during the pre-landfall period (fig. 4J). Because whole-sediment samples were collected from the swash zone and analyzed without pre-treatment, dried sea salt could have contributed to the sodium, potassium, calcium, and magnesium concentrations measured in whole-sediment samples.

Of nutrients, phosphorus was detected above 0.1 mg/kg in all pre-landfall and post-landfall whole-sediment samples (table 25), with the highest concentrations seen in two pre-landfall samples (fig. 4K). Total nitrogen was detected above its optimum threshold of 0.1 percent in 10 to 11 percent of both pre-landfall and post-landfall whole-sediment samples.

Comparison of Pre-Landfall to Post-Landfall Samples

Statistical comparison of trace- and major-element and nutrient concentrations in whole sediment was performed for 33 constituents, including total carbon and organic carbon. Six constituents showed a significant difference between pre-landfall and post-landfall samples in PPW tests ($p < 0.05$) after censoring each element to its specific optimal censoring threshold (table 27). Concentrations were higher in post-landfall samples for calcium (fig. 4I), total carbon, sodium, and strontium, and in pre-landfall samples for lead (fig. 4J) and mercury. Using lead in whole sediment as an example, figure 6C shows the difference in concentrations ($C_{\text{post}} - C_{\text{pre}}$) at each sampling site along the GOM coast, from west to east. Statistically higher lead concentrations in pre-landfall whole-sediment samples appear to be influenced in part by a negative difference value, showing higher pre-landfall concentrations, at three sites in Louisiana, one extreme site in Mississippi, and two sites in Florida (fig. 6C). Half of the sites (50 percent) had difference values ($C_{\text{post}} - C_{\text{pre}}$) that were negative and 23 percent had positive difference values; 27 percent had difference values that equaled or (if the difference value was a range) included zero, so they could not be classified as definitively positive or negative.

Because trace elements tend to be concentrated in the fine (less than 63- μm) fraction of sediment, it is possible that substantially different amounts of fine material in pre-landfall and post-landfall samples may have contributed to the few significant differences in trace- and major-element concentrations that were observed. Therefore, the PPW tests were also performed on trace- and major-element and nutrient concentrations measured in the less than 63- μm fraction of sediment (table 27). Of the six elements that showed significant differences between sampling periods in whole sediment, none were significant in the fine (less than 63- μm) sediment fraction. Several factors could contribute to the lack of significant relationships in the less than 63- μm sediment data. First, the sample size was much smaller for the less than 63- μm sediment fraction (15 to 16 sample pairs for nutrients and 21 to 35 for other elements) compared to whole sediment (35 sample pairs for nutrients and 44 to 48 for other elements), which reduced the power of the test. Also, any dried sea salt present on whole-sediment samples would not remain in the less than 63- μm sediment fraction because the sediment samples were rinsed with deionized water during the sieving process. This would affect salts of major ions such as calcium, sodium, and strontium. Finally, it is possible that significant differences in the constituent concentrations between post-landfall and pre-landfall samples also were influenced by differences in the amount of fine material in these samples.

Again using lead as an example, the difference in concentrations ($C_{\text{post}} - C_{\text{pre}}$) at individual sampling sites for the less than 63- μm sediment fraction (fig. 6D) can be compared to the difference for whole sediment (fig. 6C). First, the most extreme difference value for lead in whole sediment (MS-44, fig. 6C) was no longer extreme in the less than 63- μm sediment (fig. 6D). Both datasets had 50 percent of sites with a negative difference value ($C_{\text{post}} - C_{\text{pre}}$); however, the less than 63- μm sediment had a positive difference value at a higher proportion of sites (37 percent) compared to whole sediment (23 percent), with difference values indistinguishable from zero for the remaining sites (13 and 27 percent of sites for the <63- μm fraction and whole sediment, respectively). The smaller sample size of the less than 63- μm fraction also is illustrated in figures 6C and 6D. Fine sediment data were missing for several sites, especially in Florida and Alabama (fig. 6D), because the sediment samples collected at these sites had insufficient mass in the less than 63- μm fraction to run the trace-element analysis.

Overall, there was no significant difference in the percent of fine material (less than 63 μm) between pre-landfall and post-landfall samples (table 27). To test whether site-specific differences in the percent of fine material contributed to differences in contaminant concentrations, the differences in contaminant concentrations between post-landfall and pre-landfall samples ($C_{\text{post}} - C_{\text{pre}}$) were regressed against the difference in the percentage of sediment that was less than 63 μm (LT63) between post-landfall and pre-landfall samples ($\text{LT63}_{\text{post}} - \text{LT63}_{\text{pre}}$). For lead and mercury, which had significantly higher concentrations in pre-landfall samples than post-landfall samples, the difference in constituent concentrations ($C_{\text{post}} - C_{\text{pre}}$) was significantly ($p < 0.05$) related to the difference in fine material ($\text{LT63}_{\text{post}} - \text{LT63}_{\text{pre}}$). Although not conclusive, this supports the hypothesis that differences in the amount of fine material in sediment samples could have contributed to the significantly higher concentrations of lead and mercury in pre-landfall than post-landfall whole-sediment samples.

Comparison with Sediment-Quality Benchmarks and National Baseline Concentrations

About 18 trace elements have one or more empirical sediment-quality benchmarks for protection of benthic organisms. These apply to whole sediment. Of 143 whole (unsieved) sediment samples, 67 samples from 28 sites exceeded one or more upper screening values for trace elements (table 24B), putting these samples in the probable effect range; therefore, these samples have a high probability of adverse effects on benthic organisms. These samples included 33 of 83 pre-landfall samples (40 percent) and 34 of 60 post-landfall samples (57 percent). Eight samples, all pre-landfall, were in the

possible effect range. The remaining 68 samples were in the minimal effect range, so no adverse effects on benthic organisms would be expected. These results could be conservatively high estimates of potential toxicity because the present study measured total trace-element concentrations within the sediment matrix.

Those trace elements with one or more upper screening-level benchmark exceedances (with the number of whole-sediment samples with exceedances in parentheses) were barium (in 66 samples), aluminum (34), manganese (24), vanadium (17), cobalt (7), arsenic (2), and chromium (2). Trace-element concentrations exceeded one or more upper screening values in a substantial proportion of pre-landfall samples (40 percent), as well as post-landfall samples (57 percent). Fisher's exact test indicated no significant difference in benchmark exceedance frequencies between pre-landfall and post-landfall sampling periods for whole-sediment samples in the paired dataset. This was true for both upper and lower screening-value benchmarks.

There were no blank or matrix spike QC data available for trace elements in sediment. However, the QC replicate data indicate high variability in the concentrations of four elements: magnesium, mercury, sodium, and tin. Summary statistics and benchmark comparisons in tables 25 and 23, respectively, are footnoted accordingly.

Appendix table C-4 also lists trace and major elements for which enrichment was found, relative to national maximum baseline conditions, in the less than 63- μm sediment fraction. As noted previously, elements were considered to be enriched if their maximum baseline quotients exceeded 2 (for samples with less than 1 percent fine material) or 1 (for all other samples). About 20 samples with less than 1 percent fine material (less than 63- μm fraction) had insufficient material to do trace-element determinations. Of 124 samples analyzed for trace elements in the less than 63- μm fraction, 81 had less than 1 percent fine material (less than 63- μm fraction) and were compared to the quotient threshold of 2. Almost all samples (123 of 124) were enriched in at least one element.

The use of national baselines to assess anthropogenic enrichment is based on the observation by Horowitz and Stephens (2008) that upstream or underlying rock type had a minimal effect on trace- and major-element concentrations in streambed sediment nationally, compared to the effects of land use or population density. There are regional differences in soil composition, however, that likely affect trace- and major-element concentrations in fine (less than 63- μm) sediment from the present study. Gustavsson and others (2001) reported total concentrations of trace and major elements in fine (less than 75- μm) soil across the country. These authors observed much lower concentrations in fine (less than 75- μm) soil for many elements in the Gulf Atlantic-Coastal Flats, which includes the Florida sites from the present study, than in many other parts of the country; this was attributed to an abundance of quartz sand in surficial material combined with the wet climate, which causes leaching of many elements from the upper soil horizons. These elements include arsenic, chromium, copper, lead, manganese, nickel, vanadium, and zinc. On the basis of the soil distributions observed by Gustavsson and others (2001), we would expect concentrations of these elements to be lower at Florida sites, and some Alabama and Mississippi sites, from the present study than at sites in Texas and (especially) Louisiana. In fact, the concentrations of these elements reported by Gustavsson and others (2001) for most coastal soils in Florida, Alabama, and Mississippi were below the minimum baseline concentrations (i.e., below the range of natural geochemical variation) in U.S. river sediment from Horowitz and Stephens (2008). In contrast, Gustavsson and others (2001) reported that soils in the Mississippi River Alluvial Plain contained the same elements at concentrations within their national baseline ranges (i.e., within the range of natural geochemical variation) from Horowitz and Stephens (2008); this area corresponds to the Louisiana and Texas sites in the present study. This suggests that comparison with maximum

baseline concentrations will underestimate the degree of enrichment for our study sites in Florida, and parts of Alabama and Mississippi, but is generally appropriate for sites in Louisiana and Texas.

These baseline exceedance results can be considered together with upper screening-value benchmark exceedances, to identify samples that combine enrichment above baseline with potential for toxicity (table 24B, appendix table C-4). There were 122 sediment samples with trace-element data for both whole sediment and fine (less than 63- μ m) sediment. Of these, 19 samples (16 percent) exceeded upper screening-value benchmarks for, and were enriched in, one or more of these elements: barium (in 14 samples), vanadium (5), aluminum (3), manganese (3), arsenic (2), chromium (2), and cobalt (1). These samples were evenly divided between the pre-landfall (9 samples) and post-landfall (10 samples) periods, and were collected from a total of 11 sites located in Louisiana (8 sites) and Texas (3 sites).

Contaminant Concentrations at Sites with Macondo-1 Well Oil Fingerprint Evidence

As noted previously, sediment and tarballs sampled by the USGS at 49 post-landfall sites and 69 pre-landfall sites were analyzed for diagnostic geochemical biomarkers by Rosenbauer and others (2010, 2011). In the Rosenbauer study, extracts from sediment (subsamples of the same composite sediment samples analyzed in the present study) and tarballs were compared to the chemical “fingerprint” of BP M-1 oil. The identification of M-1 well oil in the extracts was based on a combination of an interpretation of compounds identified in the mass spectra of sample extracts and a multivariate statistical analysis of the biomarker ratios by using hierarchical cluster analyses and principal component analyses.

At pre-landfall sites, residues of oil (any oil) were found in sediment from 45 of 69 sites (65 percent of sites). However, none of the sediment samples correlated with the M-1 oil, although a tarball collected from site FL-18 (Coco Plum Beach near Marathon, Florida) was similar to M-1 oil (Rosenbauer and others, 2011). The pre-landfall sediment and tarball samples from site FL-18 were collected on May 24, which was six days after NOAA reported that a small tendrill of M-1 well oil had entered the loop current on May 18 (Lubchenco, 2010).

In post-landfall samples, at least a trace amount of oil was found at 44 of 49 sites (90 percent of sites), with evidence of M-1 oil in sediment, tarballs, or both, from 19 of the 49 sampled sites (39 percent; Rosenbauer and others, 2010). Of 20 tarballs collected from 19 sites, all but 2 contained M-1 oil. Five of the post-landfall sites likely contained a mixture of M-1 oil plus one or more other oils. These results indicate a high incidence of oil contamination at the post-landfall sites, with direct evidence of M-1 oil in sediment, tarballs, or both, at 19 sites. These 19 sites are identified in table 1 and figure 1.

When PPW tests were run for all contaminants on the “fingerprint-sample” dataset (that is, pre-landfall and post-landfall samples from only those 19 sites that had M-1 oil fingerprint evidence during the post-landfall period), the results were very similar to results for the paired-sample dataset. A few analytes with significant differences using the paired-sample dataset were no longer significant when the fingerprint-sample data subset was used. Specifically, toluene, calcium, and molybdenum in water, and calcium in sediment, were significantly higher in post-landfall samples from the paired-sample dataset, but not when the smaller fingerprint-sample dataset was used. Similarly, lead had significantly higher concentrations in sediment during the pre-landfall period using the paired-sample dataset, but not in the fingerprint-sample dataset. The loss of significance for some analytes could be a result of the much smaller sample size in the fingerprint-sample dataset (typically 14 to 18 sample pairs) compared to the entire dataset (typically 40 to 48 sample pairs). Although the 19 sites with direct evidence of M-1 oil landfall could be expected to show significantly higher contaminant concentrations in post-landfall samples for more analytes than in the full paired-sample dataset, this was not the case; however, the

small sample size of the fingerprint-sample dataset limits the power of the test. There are three analytes for which the post-landfall concentrations are significantly higher than pre-landfall concentrations in the fingerprint-sample dataset only, and not in the full paired-sample dataset: two alkylated PAHs (1-methylphenanthrene and C1-alkylated dibenzothiophenes) and sulfur in sediment. In terms of potential toxicity, the most important difference between the two datasets is that toluene is no longer significant at the subset of 19 sites in the fingerprint-sample dataset. The principal conclusion from the PPW analysis remains unchanged—concentrations of 20 PAHs, especially alkylated PAHs, were higher overall in post-landfall samples than pre-landfall sediment samples. Of the 19 post-landfall sites with M-1 oil, 5 sites had the largest difference in post-landfall minus pre-landfall concentrations of several PAHs: Grand Isle Beach at State Park, Louisiana (LA-31); Petit Bois Island Beach, Mississippi (MS-42); and BLM-1 (AL-8), BLM-2 (AL-9), and Fort Morgan BLM-3 (AL-10) in Alabama.

Data Issues, Data Censoring, and Quality Control

Because of the nature of this project—especially the emergency timing and the involvement of multiple agencies and organizations—there were a number of data issues that had to be resolved in order to do a technically sound analysis of the resulting data. This occurred because the pre-landfall sampling had to be done soon after the oil spill, before oil made landfall, and there were not yet recommendations in place as to what analytes should be targeted and what methods should be used. Later, between the pre-landfall and post-landfall sampling periods, changes were made to the target analyte list and chemical analysis methods used (Operational Science Advisory Team, 2010, appendix F), and these changes improved the information on contaminants for the post-landfall period. Data issues faced during the data analysis required for this report included large amounts of censored data, highly variable reporting levels for a given contaminant and sampling medium, duplicate analyses of the same sample (either verifications by the same laboratory or re-analysis by a different laboratory), systematic differences in reporting levels between pre-landfall and post-landfall sampling periods, and differences between the two sampling periods in the contaminants that were analyzed. The complexity of data types and sources also created difficulties for database management (for example, incomplete information on parameters, methods, and data precision from contract laboratories), which had to be solved before data analysis could proceed. The importance of database management cannot be overemphasized, and the expertise and efforts of the USGS database managers were essential to compiling a dataset of optimized and documented data quality. All of the data issues affecting this report were resolved, as detailed in the sections on data analysis and data censoring.

One primary tool for dealing with many of these issues was strategic data censoring, which was necessary so that the data coming from different sources and representing different sampling periods, sites, or laboratories were comparable and could be evaluated on equal grounds. Unfortunately, post-laboratory data censoring results in loss of information for some samples.

Consistency of methods. The fact that, for some contaminants, different laboratories were used to analyze different samples contributed to a number of data issues. Different laboratories can use different methods and often have different reporting levels for the same analyte. The latter was especially problematic when there were systematic differences in reporting levels between the two sampling periods, as occurred in this dataset for both organic contaminants and trace elements in water. To compare results from pre-landfall and post-landfall sampling periods, data had to be censored at a common threshold, which resulted in loss of information from the sampling period with the more sensitive method. Different laboratories also had different analyte lists, and all contaminants that were determined in only one of the sampling periods had to be dropped from the comparison between pre-landfall and post-landfall samples.

Quality control. Blank censoring was used to ensure that reported contaminant concentrations in environmental water samples were not affected by incidental contamination from sample collection, processing, or analysis. Because a limited number of blanks were collected during this study, a conservative approach had to be taken in censoring environmental-sample results on the basis of contamination in blanks. Detection of an analyte in any field or trip blank resulted in censoring of concentrations of that analyte in all environmental samples collected during the same sampling period. For some analytes (for example, ammonia plus organic nitrogen, and benzene in water), this resulted in the censoring of all quantified results from the post-landfall sampling period. If more blank samples had been collected, perhaps the potential for incidental contamination in an individual environmental sample could have been represented by the concentration in a single corresponding blank, and fewer samples would have been subject to blank censoring.

Target analytes. To obtain the most complete information on contaminant benchmark exceedances, water and sediment samples should be analyzed for trace elements and organic compounds, including PAHs, alkylated PAHs, and BTEX compounds. USEPA benchmarks for total PAH mixtures in water and sediment were designed to assess cumulative potential toxicity of 41 oil-related contaminants: 18 parent PAHs, 16 alkylated PAH groups, and 7 BTEX compounds (U.S. Environmental Protection Agency, 2011a,b). To obtain the most complete estimate of potential PAH toxicity, all 41 target analytes that go into this benchmark should be determined. In the present study, alkylated PAHs were not analyzed in water samples or (initially) in pre-landfall sediment samples. Although alkylated PAHs can be estimated from parent PAH concentrations using multipliers (USEPA, <http://www.epa.gov/bpspill/water/explanation-of-pah-benchmark-calculations-20100622.pdf>), this method can underestimate the total PAH benchmark toxic-unit value (\sum ESBTU or \sum TU) when parent PAHs are not detected. The Operational Science Advisory Team (2010; appendix table C-3) tested the efficacy of the multiplier-based estimation method by calculating toxic-unit benchmarks two ways for samples with a full suite of analytes measured; they compared the results obtained using data for 16 parent PAHs plus multipliers to the results using data for all 41 analytes. Although the toxic-unit benchmarks obtained these two ways were correlated positively with each other, the relationship was not statistically significant ($p > 0.05$). In the present study, this means that \sum TU benchmarks for total PAH mixtures in water could be underestimated. For organic compounds in sediment, this omission was corrected by reanalyzing pre-landfall sediment samples for all 34 parent and alkylated PAHs. A second target analyte omission in the present study is that BTEX compounds included in the \sum ESBTU benchmark were not analyzed in sediment, so \sum ESBTU values for sediment could be underestimated to some extent. At least for weathered oil, this low bias is likely to be minimal because the BTEX compounds are volatile and were not detected in weathered crude oil (State of Florida Oil Spill Academic Task Force, 2010).

These factors—use of different laboratories for pre-landfall and post-landfall sampling periods, highly variable reporting levels, missing data for analytes that should be included in benchmark calculations, and collection of only a limited number of blanks—led to difficulties in data analysis and interpretation. These are lessons learned that can be the basis for improvements in the agency response to future oil spills or similar environmental emergencies.

Summary and Conclusions

In response to the BP Deepwater Horizon M-1 oil spill on April 20, 2010, the USGS sampled beach water and sediment at 70 sites along the GOM coast during May 7 to July 7, 2010, in order to establish baseline contaminant levels in potentially vulnerable locations before the oil made landfall. After the oil made landfall, a subset of 48 sites was resampled during October 4 to 14, 2010, and one new site was sampled on August 23, 2010, to assess the existence of actionable levels of M-1 oil contamination after the extensive clean-up efforts of coastal areas by BP (Wilde and Skrobialowski, 2011). This report characterizes the water and sediment chemistry in pre-landfall and post-landfall samples, evaluates whether there were significant differences between the two sampling periods, and compares measured concentrations to applicable benchmarks for human health and aquatic life.

Organics in Water

For organic contaminants in water, detection frequencies and concentrations were generally low and similar in pre-landfall and post-landfall samples. Of the 11 compounds with enough quantified results to statistically compare pre-landfall and post-landfall samples, concentrations were significantly higher for only one organic contaminant—toluene—primarily as a result of detections in four post-landfall samples from Florida and one from Mississippi. No samples exceeded any human-health benchmarks for organic contaminants in water, which were available for 11 compounds. Aquatic-life benchmarks, which were available for 73 compounds or mixtures, were exceeded in only one water sample. The aquatic-life benchmark for PAHs and BTEX compounds was exceeded in the post-landfall sample from the Mississippi River at South Pass, Louisiana (site LA-35); no exceedance was observed in the corresponding pre-landfall sample for this site.

Organics in Sediment

Most PAHs and alkylated PAHs, and a few additional SVOCs, were detected in one or more samples during both pre-landfall and post-landfall periods. Nine alkylated PAHs and five parent PAHs were detected at concentrations greater than or equal to 1.5 $\mu\text{g}/\text{kg}$ in sediment at over 20 percent of sites during one or both sampling periods, despite very low organic carbon (median of 0.1 percent) in the sampled sediments.

Concentrations were significantly higher ($p < 0.05$) in post-landfall samples than pre-landfall samples for 20 analytes (3 PAHs and 17 alkylated PAH groups) of the 49 organic contaminants with enough quantified results to make statistical comparisons. Two analytes, naphthalene and oil and grease, had higher concentrations in pre-landfall than post-landfall samples. The same results were obtained when PAH concentrations were normalized by sediment-TOC, indicating that the significant differences observed were not caused simply by differences in sediment-organic carbon content between the two sampling periods.

Only one sample exceeded the chronic ESBTU benchmark for PAH mixtures—a pre-landfall sample from Trinity Bay near Beach City, Texas (site TX-52). This suggests that aggregate PAH concentrations were potentially toxic to benthic organisms at this site at the time of sampling. Because no post-landfall sample was collected at this site, no comparison can be made between sampling periods. Empirical benchmarks (upper screening values) for PAHs were exceeded in 45 sediment samples (27 percent), indicating a high probability of toxicity to benthic organisms at the time of sampling, although not necessarily due to PAHs. A higher percentage of post-landfall samples exceeded upper screening-value benchmarks (37 percent) than did pre-landfall samples (22 percent); however, there was no significant difference in the proportion of sediment samples that exceeded one or more

benchmarks for organic contaminants in sediment between paired pre-landfall and post-landfall samples. About 70 percent of all sediment samples were below all empirical sediment-quality benchmarks for organic contaminants, indicating that no adverse effects on benthic organisms would be expected. Sediment sampled in this study typically had low organic carbon content, which could affect bioavailability and potential toxicity.

For 15 of the 17 alkylated PAHs with statistically higher concentrations in post-landfall samples, 5 sites stood out as having among the largest concentration differences: Grand Isle Beach at State Park, Louisiana (LA-31); Petit Bois Island Beach, Mississippi (MS-42); and BLM-1, BLM-2, and Fort Morgan BLM-3 in Alabama (AL-8, AL-9, and AL-10). Combined with diagnostic geochemical evidence of M-1 oil in post-landfall sediment, tarballs, or both, from these sites (Rosenbauer and others, 2010), these results indicate that M-1 oil could have contributed to PAH concentrations measured in post-landfall samples at these five sites. In the nine pre-landfall samples that were collected from these five sites, the chronic \sum ESBTU values calculated for PAH mixtures were less than 0.005, and no empirical screening-value benchmarks were exceeded. For the seven post-landfall samples collected at these five sites, the chronic \sum ESBTU values calculated for PAH mixtures ranged from 0.2 to 0.3, and six samples, including at least one from each site, exceeded multiple upper screening-level benchmarks for total PAHs.

Trace and Major Elements and Nutrients in Water

Detection frequencies ranged from 0 to 100 percent, depending on the element or nutrient. It was essential to censor data to a common detection threshold prior to comparing concentrations and detection frequencies for different constituents or sampling periods because reporting levels varied by constituent and by laboratory. Of the 17 trace and major elements with enough quantified values to make statistical comparisons, concentrations in water were significantly higher ($p < 0.05$) in post-landfall samples for barium, calcium, magnesium, molybdenum, potassium, and sodium. These are all elements in seawater, and barium sulfate is a standard additive in drilling mud. Ammonia concentrations were significantly higher ($p < 0.05$) in pre-landfall samples.

Aquatic-life benchmarks were available for 18 trace elements in water. Acute and chronic benchmarks were exceeded in 1 percent and 29 percent, respectively, of pre-landfall water samples. Post-landfall water samples exceeded acute and chronic benchmarks in 21 percent and 93 percent of samples, respectively. The acute benchmarks exceeded in one or more water samples from either sampling period were for copper in 22 samples and zinc in 2 samples. The chronic benchmarks exceeded were for boron in 50 water samples, manganese in 30, copper in 24, cobalt in 19, nickel in 7, lead in 6, barium in 3, zinc in 2, and vanadium in 1 water sample. One or more exceedances occurred during the pre-landfall period in every state except Florida, and during the post-landfall period in all five states. Of the 56 post-landfall samples, 52 exceeded one or more chronic aquatic-life benchmarks for trace elements in water, with exceedances for boron in 48 post-landfall samples, copper in 22, manganese in 12, barium in 2, and lead, nickel, vanadium, and zinc in 1 post-landfall water sample each. Because of high and variable analytical reporting levels for trace elements in water, it was not possible to rigorously compare benchmark exceedances between the pre-landfall and post-landfall sampling periods. Overall, the frequency at which aquatic-life benchmarks for trace elements were exceeded in GOM water samples (47 percent) indicates there is potential for toxicity to aquatic life. Moreover, exceedance frequencies for several trace elements could be substantially underestimated because either the element was analyzed during only one sampling period or the analytical method had high and variable reporting levels. Aquatic-life benchmark exceedance could not be ascertained for at least 35 percent of samples within a sampling period for boron and vanadium in the pre-landfall period;

arsenic, cadmium, cobalt, lead, nickel, and silver in the post-landfall period; and copper in both sampling periods. Nickel and vanadium, which were specifically identified by U.S. Environmental Protection Agency (2011a) as relevant to the oil spill, were responsible for exceedances in only 1 of the 52 post-landfall samples with exceedances, although the results for nickel could be underestimated because of high reporting levels during the post-landfall period.

Trace and Major Elements and Nutrients in Sediment

Detection frequencies for trace and major elements and nutrients in whole sediment ranged from 0 to 100 percent, depending on the constituent, and they were similar for pre-landfall and post-landfall samples. Because sediment samples were subjected to strong acid digestion, concentrations represent total concentrations (greater than or equal to 95 percent of the amount present).

A few trace and major elements had significant differences in concentration in whole sediment between post-landfall and pre-landfall samples; however, these differences were insignificant when tests were run on the less than 63- μm sediment fraction. This is likely due, at least in part, to the smaller sample size of the less than 63- μm sediment-sample dataset, although other factors also could have contributed to the lack of significance in tests with the less than 63- μm fraction. Sample rinsing during sieving would have decreased concentrations of any dried sea salt present in the whole-sediment samples, which would affect calcium, sodium, and strontium. For lead and mercury, which were significantly higher in pre-landfall than post-landfall whole-sediment samples, differences in the quantity of fine material (less than 63- μm fraction) between the two sampling periods could have contributed to the significant difference observed for whole-sediment samples.

Empirical sediment-quality benchmarks were available for 18 trace elements in sediment. Overall, 47 percent of whole (unsieved) sediment samples exceeded one or more upper screening values for trace elements (table 24B), putting these samples in the probable effect range. These samples included 33 of 83 pre-landfall samples (40 percent) and 34 of 60 post-landfall samples (57 percent). These results could be conservatively high estimates of benchmark exceedance because they are based on measurements of total trace-element concentrations in sediment, including the sediment matrix. For trace elements in whole sediment, there was no significant difference in the proportion of samples exceeding one or more aquatic-life benchmarks between the pre-landfall and post-landfall sampling periods. Most fine-sediment (less than 63- μm) samples (123 of 124) were anthropogenically enriched, relative to national baseline values for U.S. streams (Horowitz and Stephens, 2008), in one or more trace or major elements. Sixteen percent of sediment samples exceeded upper screening-value benchmarks for, and were enriched in, one or more of these elements: barium in 14 samples, vanadium in 5, aluminum in 3, manganese in 3, arsenic in 2, chromium in 2, and cobalt in 1 sample. These samples were divided evenly between the pre-landfall (9 samples) and post-landfall (10 samples) periods, and were collected from a total of 11 sites located in Louisiana (8 sites) and Texas (3 sites). Because many trace elements have lower concentrations in Florida, Alabama, and Mississippi soils than in Louisiana and Texas (Gustavsson and others, 2001), however, the baseline comparison analysis probably underestimates the degree of enrichment in Florida, Alabama, and Mississippi sites.

Comparison of Pre-Landfall to Post-Landfall Samples

Considering all the information evaluated in this report, there were significant differences between post-landfall and pre-landfall samples for PAH concentrations in sediment. With a few exceptions, pre-landfall and post-landfall samples did not differ significantly in concentrations or benchmark exceedances for most organics in water or trace elements in sediment. For trace elements in water, aquatic-life benchmarks were exceeded in almost 50 percent of samples, but the high and variable analytical reporting levels precluded statistical comparison of benchmark exceedances between sampling periods. Twenty PAH compounds (3 parent PAHs and seventeen alkylated PAH groups) in sediment had significantly higher concentrations in post-landfall samples than in pre-landfall samples. Concentrations above the upper screening-value benchmarks put 37 percent of post-landfall samples and 22 percent of pre-landfall samples in the probable effect range. However, the proportion of samples exceeding empirical upper screening-value benchmarks for PAHs in sediment were not significantly different in paired post-landfall and pre-landfall samples.

For 15 of the 17 alkylated PAHs with statistically higher concentrations in post-landfall samples, 5 sites stood out as having among the largest concentration differences. These sites are Grand Isle Beach at State Park, Louisiana (LA-31); Petit Bois Island Beach, Mississippi (MS-42); and BLM-1, BLM-2, and Fort Morgan BLM-3 in Alabama (AL-8, AL-9, and AL-10). These results corroborate the results of Rosenbauer and others (2010), who found diagnostic geochemical evidence of Deepwater Horizon M-1 oil in post-landfall sediment and tarballs from these and other sites.

Acknowledgments

The USGS initiated the pre-landfall sampling and analytical study, and additional funding was later provided by the U.S. Coast Guard for both the pre-landfall and post-landfall work. We gratefully acknowledge the efforts of the staffs of the USGS Water Science Centers in Alabama, Florida, Georgia, Louisiana, Mississippi, and Texas in sample collection and processing. We thank Marge Davenport, Charles Demas, Yvonne Stoker, Donna Myers, and Terry Schertz for their coordination efforts; Franceska Wilde and Stan Skrobialowski for development of the sampling protocol and other assistance; and Gary Cottrell for his efforts in coordinating the laboratory contracts. We thank Arthur Horowitz, Geoffrey Plumlee, and Ruth Wolf for data and technical assistance. We also thank Robert Burgess, Christopher Ingersoll, Donald MacDonald, and David Mount for technical guidance on benchmarks. We are grateful to four anonymous reviewers for their thoughtful reviews of an earlier version of the manuscript that greatly improved this report. We thank David Strong and Gregory Wetherbee for their work on the map in this report. We also thank the USGS Tacoma Publishing Service Center, and Carol Sanchez and Robin Miller of the USGS Sacramento Publishing Service Center, for their support in the publication of this report.

Glossary

Censored data	A set of one or more censored values.
Censored value	An analytical result determined to be below a specified threshold concentration and reported as a less-than value (e.g., <3 when 3 is the threshold). (See Censoring.)
Censoring	Application of a threshold to data such that concentrations above that threshold are quantified values and concentrations below that threshold are reported as less-than values (e.g., <3, when 3 is the threshold). Censoring may be done (1) by the laboratory because of high uncertainty in quantifying concentrations near the method detection limit, in which case the threshold is a reporting level (for some methods, values that are below the reporting level but above the detection level might be quantified, but coded as estimates); (2) during data analysis because of blank contamination (to avoid interpreting incidental contamination in a sample as environmental contamination) or to eliminate bias when comparing data (such as due to different method sensitivities), in which cases the threshold is a censoring level. This report describes three kinds of censoring levels: raised censoring levels (applied to contaminants detected in quality control blank samples), optimum censoring thresholds (applied for comparison of pre-landfall and post-landfall sample groups) and common detection thresholds (applied for comparison among contaminants with different laboratory reporting levels).
Censoring level	A concentration threshold that is applied to data such that concentrations above that threshold are quantified values and concentrations below that threshold are reported as less-than values (e.g., <3).
Common detection threshold	A censoring level applied to a group of analytes for the purpose of comparing among the analytes. This eliminated bias due to differences in method sensitivities for different contaminants.
Detection level	A generic term for the lowest concentration that can be reliably quantified by a certain method at a certain laboratory.
Indeterminate sample	A sample with an indeterminate value for a specified analyte.
Indeterminate value	A censored value (i.e., reported as less than a specified reporting level) for which the reporting level is higher than the applied censoring threshold, so it cannot be classified as either a detection or nondetection at that threshold (e.g., an analyte concentration reported as less than 1 would be indeterminate at a censoring threshold of 0.2 because it is unknown whether the analyte is present at levels above 0.2).
Method detection limit	(MDL) The minimum concentration of a substance that can be measured and reported with 99-percent confidence that the value is greater than zero (40 CFR Part 136).
Optimal censoring threshold	The lowest censoring level that converts no more than 5 percent of results from censored to indeterminate values, maximizes the number of quantifiable detections, and if possible, also minimizes the number of indeterminate values. This was applied to concentrations of a given contaminant for the purpose of comparing pre-landfall and post-landfall sample groups.

Quantified value	An analytical result measured above the reporting level and reported as a specific concentration. For some methods (for example, those in which there is corroborative evidence of analyte presence in a mass spectrogram), an analytical result measured below the reporting level but above the detection level would be quantified, but coded as an estimate.
Parameter code	Code for parameters in the USGS National Water Information System database (http://nwis.waterdata.usgs.gov/usa/nwis/pmcodes); also called USGS parameter code.
Raised censoring level	A censoring level higher than the reporting level that is applied to censor data for selected contaminants (those detected in quality-control blanks) in selected environmental samples (those associated with the contaminated blanks). Typically, the raised censoring level is five times (or for common laboratory contaminants, 10 times) the maximum concentration determined in the applicable blanks.
Reporting level	The concentration, set by a laboratory, and used for reporting analytical results that are determined to be less than the detection level. This might be higher than the detection level because analytical results at or near the detection level can have high uncertainty. The reporting level can vary because of factors such as matrix interference, low sample mass, or sample dilution.

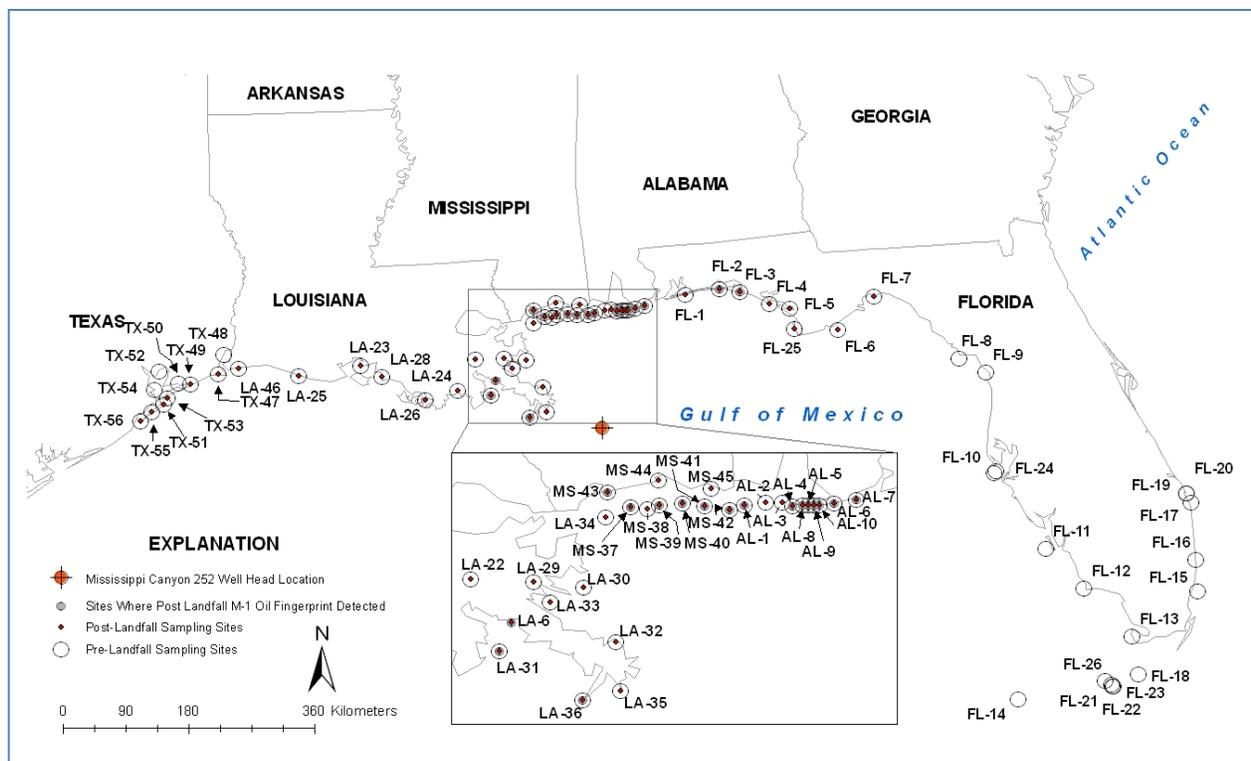

Figure 1. Map showing U.S. Geological Survey sites sampled in response to the Deepwater Horizon oil spill

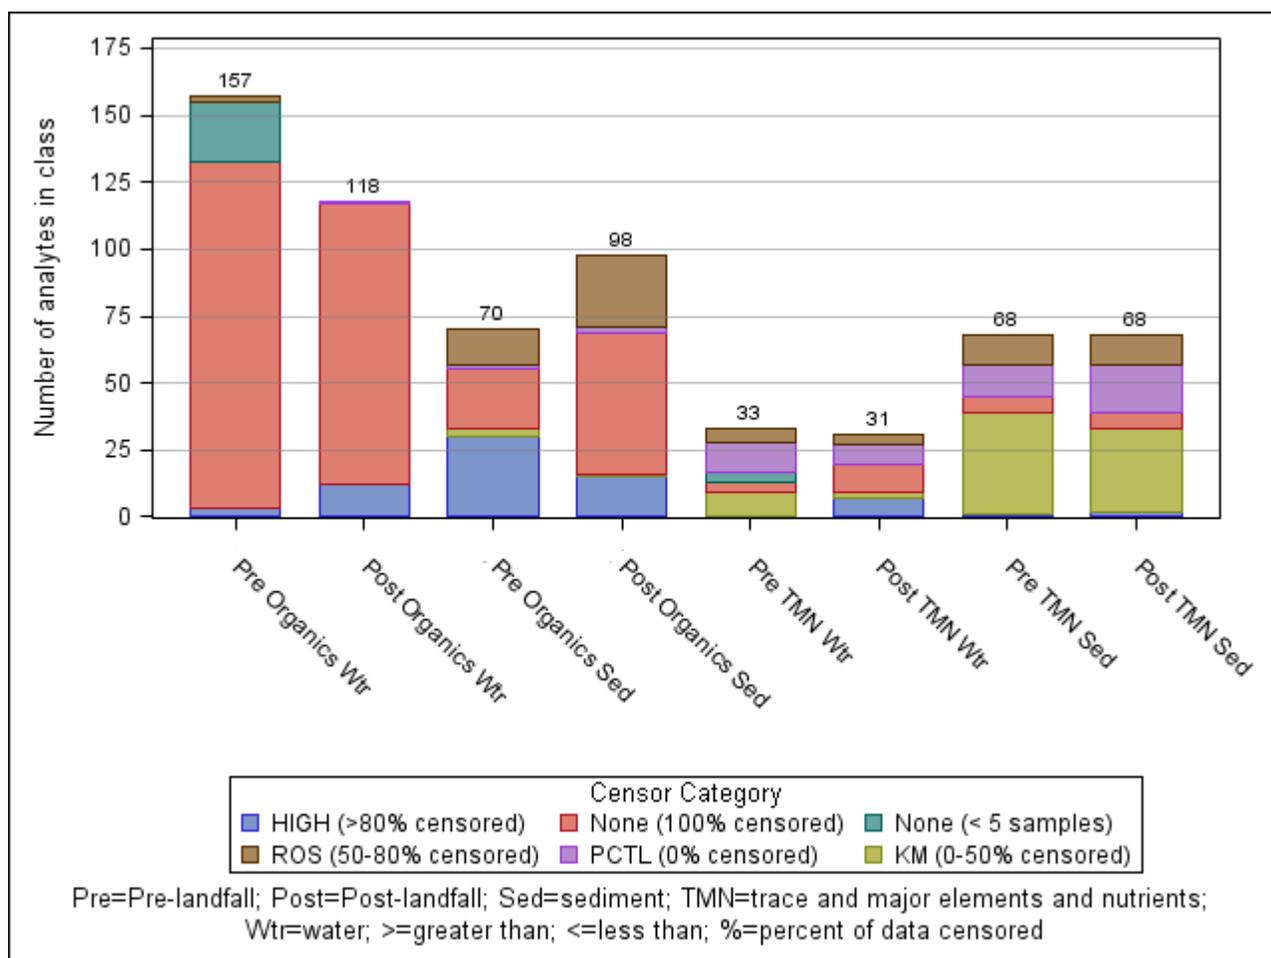

Figure 2. Number of analytes for which percentiles were determined by using four different methods, shown by contaminant class, sampling medium, and sampling period. The four methods are HIGH (only the 95th percentile was determined after censoring to a common detection threshold); KM (percentiles estimated using the Kaplan-Meier method); PCTL (percentiles calculated); and ROS (percentiles estimated using the Censored Data Regression on Order Statistics). “None” indicates that concentration percentiles could not be determined.

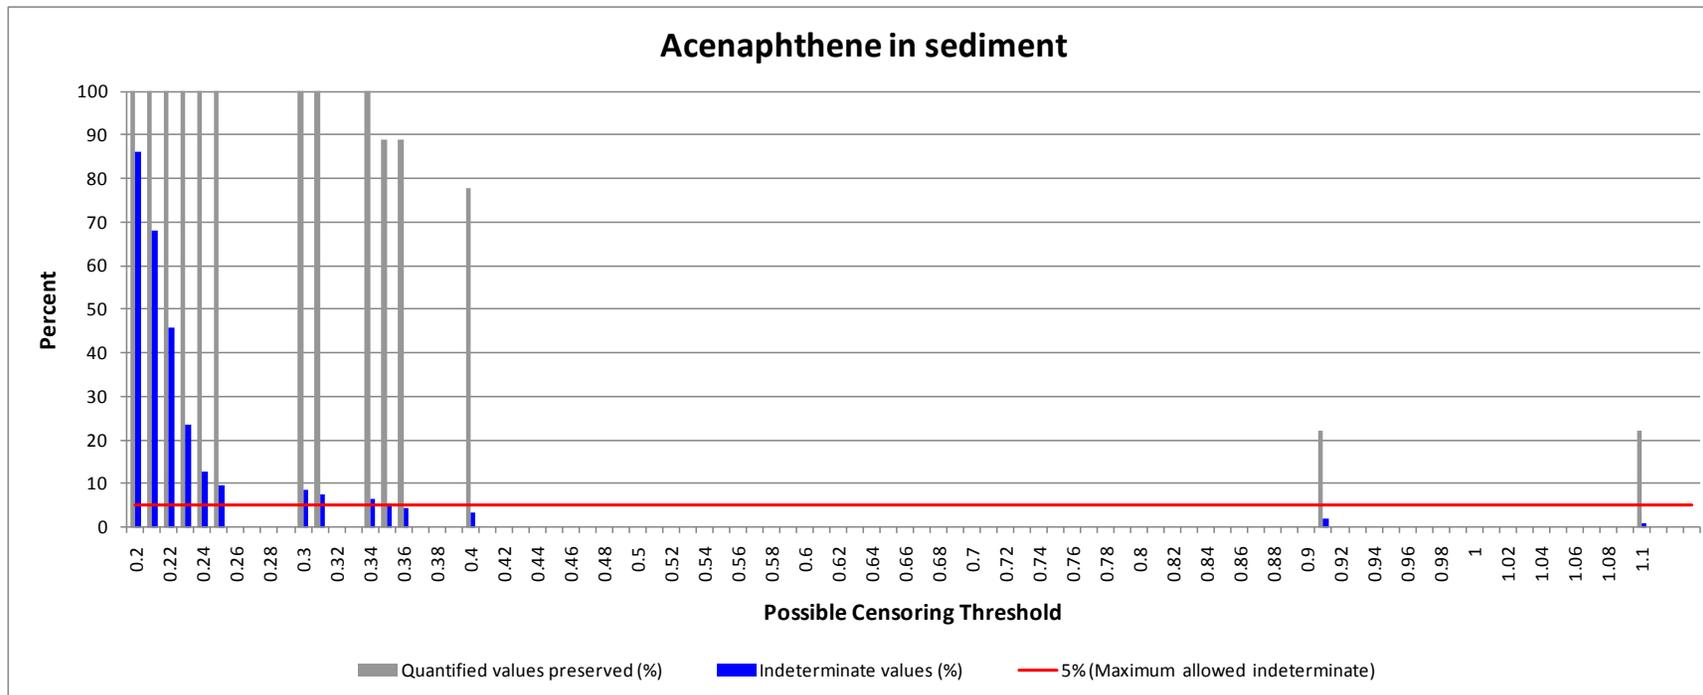

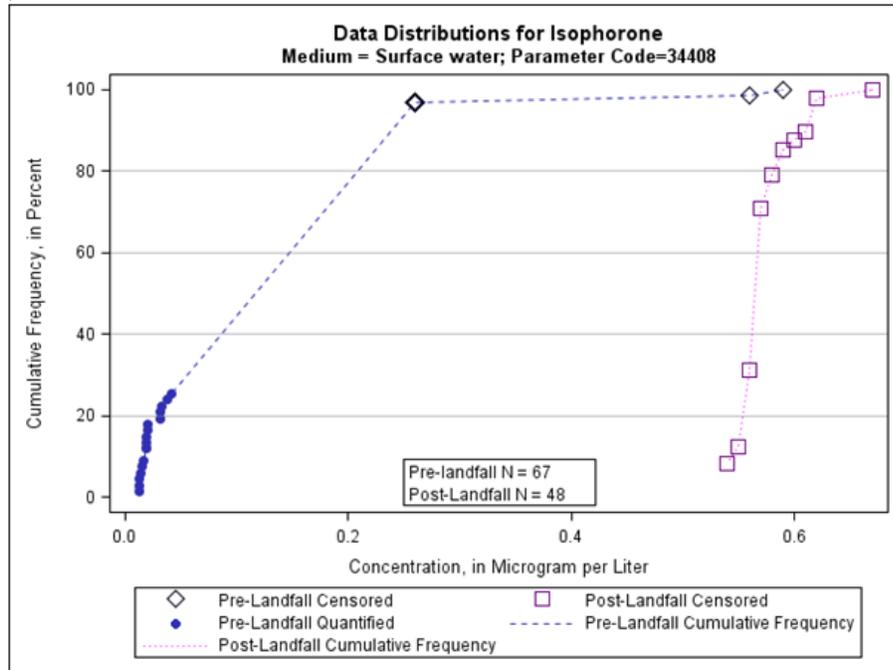

Figure 3. The effect of censoring threshold on the percentages of quantified values that are retained (gray bars) and indeterminate values (blue bars), shown for an example contaminant, acenaphthene in sediment. The maximum allowable missing data of 5 percent is also shown (red line). This illustrates the procedure used to determine the optimal censoring threshold, defined as the lowest censoring level that converts no more than 5 percent of results from censored to indeterminate values, maximizes the number of quantifiable detections, and (if possible) also minimizes the number of indeterminate values. Possible censoring thresholds are on the x-axis. For each censored data reporting level (i.e., each reporting level (RL) for which there are nondetections and which is reported as <RL), the gray bar shows the percentage of quantified values that would be preserved as “detections” if data were censored at that threshold concentration. The blue bars represent the percentage of samples that would be indeterminate at that threshold concentration because their RLs exceed the censoring threshold.

¹ Identified based on geochemical biomarkers by Rosenbauer and others (2010). Mix, likely mixture of oil with M-1 well oil, but cannot be conclusively verified; no, no M-1 fingerprint; yes, identified M-1 oil fingerprint; –, no post-landfall sample was collected.

² Pre-landfall sediment samples were analyzed for all sites except LA-36, but did not match the M-1 oil fingerprint. A tarball collected from FL-18 during the pre-landfall period was similar to M-1 oil.

³ Same result was obtained in replicate samples.

Table 2. Chemical analysis in water samples: laboratory, analytical methods, and sample treatment.

[BTEX, benzene, toluene, ethylbenzene, xylenes and related compounds; CVAA, cold vapor atomic absorption; FA, filter-acidify; g, gram; GC, gas chromatography; H₂SO₄, sulfuric acid; HCl, hydrochloric acid; HNO₃, nitric acid; ICP, inductively coupled plasma; L, liter; LAB, laboratory; mL, milliliter; MS, mass spectrometry; Na, sodium; NH₄, ammonium; NWQL, USGS National Water Quality Laboratory; OCRL, Organic Carbon Research Laboratory; oz, ounce; PAH, polycyclic aromatic hydrocarbon; poly, polypropylene plastic container; RA, raw acidified; SIM, selective ion monitoring; SVOC, semivolatile organic compound; TAL-CO, TestAmerica Laboratory in Arvada, Colorado; TAL-FL, TestAmerica Laboratory in Pensacola, Florida; TAL-VT, TestAmerica Laboratory in Burlington, Vermont; TKN, total Kjeldahl nitrogen; TP, total phosphorus; TPH-DRO, total petroleum hydrocarbons–diesel range organics; TPH-GRO, total petroleum hydrocarbons–gasoline range organics; USEPA, U.S. Environmental Protection Agency; USGS, U.S. Geological Survey; VOA, volatile organic analyses; VOC, volatile organic compounds; 1x, one of (or 2x means two of, etc.) the type of container that follows; °C, degrees Celsius; <, less than; µm, micrometer; %, percent.]

Table 5A. Benchmark values for organic contaminants: toxic-unit benchmarks ($\sum TU_i$) for PAH and BTEX compounds in water.

[Abbreviations: BP, British Petroleum; BTEX, benzene, toluene, ethylbenzene, xylenes and related compounds; CAS RN, Chemical Abstracts Service Registry Number; PAH, polycyclic aromatic hydrocarbons; TU, toxic unit; $\mu\text{g/L}$, microgram per liter; >, greater than)

Organic contaminant	CAS RN	Units	Acute divisor ¹ ($\mu\text{g/L}$)	Chronic divisor ¹ ($\mu\text{g/L}$)	Multiplier ²	Analyzed in this study
Benzene	71-43-2	$\mu\text{g/L}$	27000	5300	1	yes
Cyclohexane	110-82-7	$\mu\text{g/L}$	1900	374	1	yes
Ethylbenzene	100-41-4	$\mu\text{g/L}$	4020	790	1	yes
Isopropylbenzene (Cumene)	98-82-8	$\mu\text{g/L}$	2140	420	1	yes
Total xylene (<i>o</i> , <i>m</i> and/or <i>p</i>)	108-38-3	$\mu\text{g/L}$	3560	700	1	yes
Methylcyclohexane	108-87-2	$\mu\text{g/L}$	463	91.0	1	yes
Toluene	108-88-3	$\mu\text{g/L}$	8140	1600	1	yes
Naphthalene	91-20-3	$\mu\text{g/L}$	803	193	120	yes
Acenaphthylene	208-96-8	$\mu\text{g/L}$	1280	307	1	yes
Acenaphthene	83-32-9	$\mu\text{g/L}$	232	55.8	1	yes
Fluorene	86-73-7	$\mu\text{g/L}$	164	39.3	14	yes
Phenanthrene	85-01-8	$\mu\text{g/L}$	79.7	19.1	6.8	yes
Anthracene	120-12-7	$\mu\text{g/L}$	86.1	20.7	1	yes
Fluoranthene	206-44-0	$\mu\text{g/L}$	29.6	7.11	1	yes
Pyrene	129-00-0	$\mu\text{g/L}$	42.0	10.1	2.1	yes
Benz[a]anthracene	56-55-3	$\mu\text{g/L}$	9.28	2.23	1	yes
Chrysene	218-01-9	$\mu\text{g/L}$	8.49	2.04	5	yes
Perylene	198-55-0	$\mu\text{g/L}$	3.75	0.901	1	no
Benzo[b]fluoranthene	205-99-2	$\mu\text{g/L}$	2.82	0.677	1	yes
Benzo[k]fluoranthene	207-08-9	$\mu\text{g/L}$	2.67	0.642	1	yes
Benzo[e]pyrene	192-97-2	$\mu\text{g/L}$	3.75	0.901	1	no
Benzo[a]pyrene	50-32-8	$\mu\text{g/L}$	3.98	0.957	1	yes
Indeno[1,2,3-cd]pyrene	193-39-5	$\mu\text{g/L}$	1.14	0.275	1	yes
Dibenz[a,h]-anthracene	53-70-3	$\mu\text{g/L}$	1.17	0.282	1	yes
Benzo[g,h,i]perylene	191-24-2	$\mu\text{g/L}$	1.83	0.439	1	yes

¹ The Toxic Unit ($\sum TU_i$) benchmark is computed by dividing the concentration of each individual compound by its potency divisor (acute or chronic), then adding the ratios for all compounds in the sample to calculate the combined toxicity. A $\sum TU_i$ benchmark value > 1 indicates an exceedance.

² Because alkylated PAHs were not analyzed in water, their concentrations were estimated by applying a multiplier to the parent PAH concentration.

Table 5B. Benchmark values for organic contaminants: supplemental aquatic-life benchmarks for organic contaminants in water.

[ANZ, Australian and New Zealand guideline trigger value; BC, British Columbia water quality guideline for marine aquatic life; C, Value for chemical class; CA, Canadian water quality guideline for the protection of marine aquatic life; Eco, Ecotox threshold; LOEL, Lowest Observable Effect Level; p, proposed value; S, value for summation of isomers; USEPA, U.S. Environmental Protection Agency; µg/L, microgram per liter; <, less than; #, chronic value derived by division of acute value by 10; –, no benchmark]

Contaminant	Units	Marine acute ^{1,2}	Marine chronic ^{1,2}
1,1,1-Trichloroethane	µg/L	31,200 LOEL	3,120 #

PAHs, low MW	µg/L	300 C,LOEL	–
PAHs, total	µg/L	300 C,LOEL	–
Pentachlorophenol	µg/L	13	7.9
Phenanthrene	µg/L	7.7 p	4.6 p
Sum dichloroethenes	µg/L	224,000 S,LOEL	–
Tetrachloroethene (PCE)	µg/L	10,200 LOEL	450 LOEL
Tetrachloromethane	µg/L	50,000 LOEL	5,000 #
Toluene	µg/L	6,300 LOEL	215 CA
trans-1,2-Dichloroethene	µg/L	224,000 S,LOEL	–
trans-1,3-Dichloropropene	µg/L	790 S,LOEL	–
Trichlorobenzenes	µg/L	160 C,LOEL	<5.4 CA
Trichloroethene (TCE)	µg/L	2,000 LOEL	200 #
Trichlorofluoromethane	µg/L	12,000 C,LOEL	6,400 C,LOEL

¹ Guidelines are from Buchman (2008). Primary entry is from USEPA, either ambient water quality criterion or lowest of available guidelines (Tier II Species Acute Values, or LOELs), supplemented by lowest of available guidelines from other sources. Values were verified (except as noted) in the cited references.

² The following codes designate the type and original source of benchmark, as specified in Buchman (2008): ANZ, Australian and New Zealand guideline trigger value (Australian and New Zealand Environment and Conservation Council, 2000); BC, British Columbia water quality guideline for marine aquatic life (British Columbia Ministry of Environment, 2010; Nagpal and others, 2006); C, Value for chemical class; CA, Canadian water quality guideline for the protection of marine aquatic life (Canadian Council of Ministers of the Environment, 2011); Eco, Ecotox threshold (U.S. Environmental Protection Agency, 1996); LOEL, USEPA LOEL value (unverified) from Buchman (2008), who compiled LOELs previously published by USEPA; p, proposed value (unverified) from Buchman (2008); S, value for summation of isomers; #, chronic value derived by division of acute value by 10.

Table 5C. Benchmark values for organic contaminants: human-health benchmarks (recreational contact) for organic contaminants in water.

[C, cancer endpoint; CAS No., Chemical Abstracts Service Registry Number; HH, human health; NC, noncancer effects endpoint; µg/L, microgram per liter]

Organic contaminant	CAS No.	Units	HH benchmark (child swimmer)	Cancer/noncancer
Benzene	71-43-2	µg/L	380	C
Isopropylbenzene (Cumene)	98-82-8	µg/L	20,000	NC
Ethylbenzene	100-41-4	µg/L	610	C
Total xylene ¹	108-38-3	µg/L	18,000	NC
Toluene	108-88-3	µg/L	120,000	NC
2-Methylnaphthalene	91-57-6	µg/L	170	NC
Naphthalene	91-20-3	µg/L	1,800	NC
Acenaphthene	83-32-9	µg/L	2,500	NC
Fluorene	86-73-7	µg/L	12,000	NC
Anthracene	120-12-7	µg/L	22,000	NC
Pyrene	129-00-0	µg/L	4,100	NC

¹ Analyzed in this study as total xylene in some samples, and as the summed concentrations of *ortho*, *meta*, and *para* isomers in other samples

Table 5D. Benchmark values for organic contaminants: equilibrium-partitioning sediment benchmark toxic units (Σ ESBTU_i) for PAH and BTEX compounds in sediment.

[BTEX, benzene, toluene, ethylbenzene, xylenes, and related compounds; ESBTU, equilibrium-partitioning sediment benchmark toxic unit; BP, British Petroleum; CAS RN, Chemical Abstracts Service Registry Number; PAH, polycyclic aromatic hydrocarbons; $\mu\text{g}/\text{kg-oc}$, microgram per kilogram of sediment organic carbon; >, greater than; –, not applicable]

Organic contaminant	CAS RN	Units	Acute divisor ¹ ($\mu\text{g}/\text{kg-oc}$)	Chronic divisor ¹ ($\mu\text{g}/\text{kg-oc}$)	Multiplier ²	Analyzed in this study
Benzene	71-43-2	$\mu\text{g}/\text{kg-oc}$	3,360,000	660,000	1	No
Cyclohexane	110-82-7	$\mu\text{g}/\text{kg-oc}$	4,000,000	786,000	1	No
Ethylbenzene	100-41-4	$\mu\text{g}/\text{kg-oc}$	4,930,000	970,000	1	No
Isopropylbenzene (Cumene)	98-82-8	$\mu\text{g}/\text{kg-oc}$	5,750,000	1,130,000	1	No
Total xylene	108-38-3	$\mu\text{g}/\text{kg-oc}$	4,980,000	980,000	1	No
Methylcyclohexane	108-87-2	$\mu\text{g}/\text{kg-oc}$	4,960,000	976,000	1	No
Toluene	108-88-3	$\mu\text{g}/\text{kg-oc}$	4,120,000	810,000	1	No

¹ The Σ ESBTU benchmark is computed by dividing the sediment organic carbon-normalized concentration of each individual compound by its potency divisor (acute or chronic), then adding the ratios for all compounds to calculate the combined toxicity. An Σ ESBTU benchmark value > 1 indicates an exceedance.

² For samples with no data available for alkylated PAHs, their concentrations were estimated by applying a multiplier to the parent PAH concentration.

¹ EqP, Equilibrium partitioning sediment benchmark, which is mechanistically based and derived from equilibrium-partitioning theory; Lower SV, empirical screening value, below which adverse effects are not expected; Upper SV, empirical screening value above which there is a high probability of adverse effects.

² From Long and others (1995).

³ Except as noted, values are common to both Canada (Canadian Council of Ministers of the Environment, 2002) and Florida Department of Environmental Protection (MacDonald and others, 1996).

⁴ From MacDonald and others (2000).

⁵ From Field and others (2002).

⁶ From Buchman (2008). Value shown is the lowest reliable AET value among available tests, as determined by Buchman (2008). Some values also appear in Barrick and others (1998) or Gries and Waldow (1994). Abbreviations indicate types of bioassays, and are defined in the table headnote.

⁷ EqP, Equilibrium partitioning sediment benchmark for either acute or chronic effects on benthic organisms from U.S. Environmental Protection Agency (2004)

⁸ Value applies to Florida only (not Canada).

⁹ Benchmark applies to *para* isomer.

Table 6A. Benchmark values for trace and major elements: aquatic-life benchmarks for trace elements in water.

¹ Values are USEPA ambient water quality criteria supplemented by the lowest of Tier II Species Acute Values or other guidelines, as selected by Buchman (2008). Values were verified (except as noted) in the cited references.

² ANZ, Australian and New Zealand Environment and Conservation Council (2000); BC, British Columbia Ministry of Environment (2010); NOAA, Buchman (2008); USEPA WQC, water quality criteria from U.S. Environmental Protection Agency (2009); USEPA response, USEPA Response to British Petroleum Spill in the Gulf of Mexico from U.S. Environmental Protection Agency (2011a)

³ p, proposed values from Buchman (2008)

⁴ Detected in 1 of 4 field blanks for post-landfall samples, so data were censored prior to comparison with benchmarks. (See "Censoring Based on Quality Control Results" in text.)

⁵ The criterion maximum concentration (CMC, which is USEPA's acute water quality criterion) was halved to correspond to the 1985 guideline derivation (Buchman, 2008)

⁶ USEPA's LOEL; values (unverified) are from Buchman (2008), who compiled LOELs previously published by USEPA

Table 6B. Benchmark values for trace and major elements: human-health benchmarks (recreational contact) for trace elements in water.

[Abbreviations: C, cancer endpoint; HH, human health; NC, noncancer effects endpoint; µg/L, micrograms per liter]

¹ Lower SV, empirical screening value below which adverse effects are not expected; Upper SV, empirical screening value above which there is a high probability of adverse effects.

² From Long and others (1995).

³ Except as noted, values are common to both Canada (Canadian Council of Ministers of the Environment, 2002) and Florida Department of Environmental Protection (MacDonald and others, 1996).

⁴ From MacDonald and others (2000).

⁵ From Field and others (2002).

⁶ From Buchman (2008). Value shown is the lowest reliable AET value among available tests, as determined by Buchman (2008). Some values also appear in Barrick and others (1998) or Gries and Waldow (1994). Abbreviations indicate types of bioassays, and are defined in the table headnote.

⁷ Based on Screening Level Concentration approach using sensitive species, HC5 (hazardous concentration for 5 percent of species). From Leung and others (2005)

⁸ Value applies to Florida only (not Canada)

⁹ Based on equilibrium partitioning approach using the current criterion continuous concentration (CCC, USEPA's chronic ambient water quality criterion). From Buchman (2008)

Table 6D. Benchmark values for trace and major elements: national baseline concentrations for trace and major elements in fine (<63- μm fraction) sediment.

¹ Baseline Median, median concentration associated with sites (1) that were predominantly agricultural or undeveloped, (2) where urban land use was $\leq 5\%$, and (3) where population densities were ≤ 27 people per square kilometer, calculated from 450 bed sediment samples collected from streams across the U.S. The Baseline Minimum and Baseline Maximum values are equivalent to the Median Baseline $\pm 30\%$ median absolute deviation. From Horowitz and Stephens (2008).

Table 7. Analytes with quantified results (detections) in field blanks collected during the pre-landfall sampling period.¹

¹ For contaminants detected in one or more laboratory, field or trip blank samples, reported concentrations were censored at 5 times the concentration in the corresponding laboratory blank, or at 5 times the maximum concentration detected in field or trip blanks for that sampling period. F(x), field blank affected all samples collected during period x, where x = "pre" or "post" for pre-landfall or post-landfall; L, laboratory blank; T(x), trip blank affected all samples collected during period x; –, contaminant was not detected in any blank samples.

² Lowest censoring level that maximizes the number of quantifiable detections, minimizes the number of indeterminate samples, and for which the percent indeterminate samples is no more than 5 to 8% (depending on sample size). nc, not censored at optimal censoring threshold because no quantified detections remained after blank-censoring

³ Indeterminate samples are censored data for which the reporting level (e.g., <1) is higher than the applied censoring threshold (e.g., 0.2), so it cannot be classified as either a detection or nondetection at that threshold (e.g., it is unknown whether the contaminant is present at levels above 0.2).

⁴ Yes, paired Prentice-Wilcoxon (PPW) test was performed to compare pre-landfall to post-landfall samples; no, PPW test was not performed.

⁵ A, constituent was analyzed in samples from only one sampling period; B, constituent was not detected in any samples after blank-censoring; C, constituent was not detected in paired sample dataset, D, constituent was not detected in any samples after optimal censoring threshold was applied. Blank indicates that PPW test was performed.

Table 16B. Optimal censoring thresholds and sample counts: organic contaminants in whole sediment.

[CARB, carbon, including petroleum hydrocarbons and hexane-extractable oil and grease; L, laboratory; No., number; PAH, polycyclic aromatic hydrocarbon; PPW, paired Prentice-Wilcoxon; SVOC, semi-volatile organic compound (excluding PAHs); µg/kg, microgram per kilogram; mg/kg, milligram per kilogram; %, percent; –, not detected in any blanks; <, less than]

TOTAL ALL	119	253	1		118	165	116	4	45	

¹ The total number of water samples includes field replicate samples, and counts separately samples sent to different laboratories for analysis. About 70% of water samples were analyzed for PAHs and BTEX compounds, and 30% were analyzed for BTEX compounds at a different laboratory. Samples typically were collected from a given site on the same date.

² Organic contaminants in water were compared to aquatic-life benchmarks in tables 5A and 5B, and human-health benchmarks in table 5C.

³ The total number of sediment samples includes field replicate samples. Samples were analyzed for PAHs, alkylated PAHs, and a few additional semivolatile organic compounds. Samples typically were collected from a given site on the same date.

⁴ All constituent concentrations were below all applicable benchmarks (table 6C); there is no indication of adverse effects on benthic organisms within this range.

⁵ One or more constituents exceeded a lower SV benchmark, but no elements exceeded an upper SV benchmark; adverse biological effects occasionally occur within this range.

⁶ One or more constituents exceeded an upper SV benchmark; adverse biological effects frequently occur within this range.

⁷ Organic contaminants in sediment were compared to sediment-quality benchmarks in tables 5D and 5E.

Table 20. Summary statistics for organic contaminants in sediment.

Table 20 is a Microsoft® Excel file that can be downloaded at <http://pubs.usgs.gov/of/2011/1271/>.

Pyrene	µg/kg	0.24	45.5	0.1712	ns	µg/g-oc	0.48	47	0.2265	ns

¹ Lowest detection threshold at which the percentage of indeterminate samples is less than or equal to 5%. Separate optimal threshold determinations were made for dry weight and organic-carbon normalized concentrations.

² Number of Pre-landfall and Post-landfall sample pairs in PPW test; Non-integer indicates one or more incomplete sample pairs (data missing for one sampling period).

³ p-value, from 2-sided test. The alternative hypothesis is: Post-landfall sample concentration minus the Pre-landfall sample concentration is not equal to zero. Significant p-values are shaded bright yellow (p<0.01) or pale orange (p<0.05).

⁴ Sampling period with significantly higher concentrations (p<0.05).

⁵ Normalized contaminant concentrations (in µg/g-oc) were calculated by dividing the censored contaminant concentration (µg/kg) by the sediment organic carbon concentration (g/kg).

⁶ No detections remained after censoring at optimal censoring threshold.

⁷ Organic carbon data is not available for a sufficient number of pre-landfall samples to determine an optimal censoring threshold or run PPW test on organic carbon-normalized data.

Table 22. Summary statistics for trace and major elements and nutrients in water.

Table 22 is a Microsoft® Excel file that can be downloaded at <http://pubs.usgs.gov/of/2011/1271/>.

Table 23. Statistical comparisons of contaminant concentrations in pre-landfall samples to those in post-landfall samples: trace and major elements and nutrients in water.

[N, nitrogen; n, number of sample pairs; ns, not significant at 0.05 level; P, phosphorus; PPW, paired Prentice-Wilcoxon; µg/L, micrograms per liter; mg/L, milligrams per liter; –, PPW test was not run.]

¹ Lowest detection threshold that maximizes the number of quantifiable detections, minimizes the number of indeterminate samples, and has ≤7% indeterminate samples.

² Number of Pre-landfall and Post-landfall sample pairs. Non-integer indicates one or more incomplete sample pairs (data missing for one sampling period).

³ p-value from 2-sided PPW test. The alternative hypothesis is: Post-landfall sample concentration minus the Pre-landfall sample concentration is not equal to zero. Significant p-values are shaded bright yellow (p<0.01) or pale orange (p<0.05).

⁴ Sampling period with significantly higher concentrations (p<0.05).

⁵ A, No quantified detections remain above censoring threshold; B, no quantified detections remain after blank-censoring. Blank indicates that PPW test was performed.

⁶ Data not censored because constituent was detected in all samples.

⁷ Optimal censoring threshold was not applied because no quantified detections remained after blank-censoring.

Table 24A. Summary of benchmark and baseline exceedances for trace and major elements: benchmark exceedances in water.

[AL, Alabama; B, boron; Ba, barium; Co, cobalt; Cu, copper; FL, Florida; LA, Louisiana; Mn, manganese; MS, Mississippi; Ni, nickel; no., number; Pb, lead; POST, post-landfall samples; PRE, pre-landfall samples; TX, Texas; V, vanadium; Zn, zinc; <, less than.]

TOTAL (ALL)		119	143	68	8	67	19	

¹ The total number of samples includes field replicate samples.

² All constituent concentrations were below all applicable benchmarks (table 6C); there is no indication of adverse effects on benthic organisms within this range.

³ One or more constituents exceeded a lower SV benchmark, but no elements exceeded an upper SV benchmark; adverse biological effects occasionally occur within this range.

⁴ One or more constituents exceeded an upper SV benchmark; adverse biological effects frequently occur within this range.

⁵ The listed elements exceeded one or more of their respective upper SV benchmarks (table 6C) in whole sediment, and also were enriched relative to national baseline concentrations from Horowitz and Stephens (2008; table 6D).

Table 27. Statistical comparisons of contaminant concentrations in pre-landfall samples to those in post-landfall samples: trace and major elements and nutrients in whole and fine (<63- μ m fraction) sediment.

[n, number of pre-landfall and post-landfall sample pairs; na, not applicable; nc, optimum censoring threshold was not applied; ns, not significant at 0.05 level; Post, post-landfall period; PPW, paired Prentice-Wilcoxon; Pre, pre-landfall period; μ m, micrometer; mg/kg, milligram per kilogram; %, percent; <, less than]

Constituent	Symbol	Units	Whole Sediment					Fine (<63- μ m) Sediment				
			Optimal censoring threshold ¹	Paired Prentice-Wilcoxon test			Reason no PPW test was run ⁴	Optimal censoring threshold ¹	Paired Prentice-Wilcoxon test			Reason no PPW test was run ⁴
				² n	p-value ³	Period with higher concentration ⁴			² n	p-value ³	Period with higher concentration ⁴	
Vanadium	V	mg/kg	1	47	0.6394	ns	nc ⁶	35	0.5479	ns		
Zinc	Zn	mg/kg	1	47	0.116	ns	nc ⁶	35	0.3091	ns		
Percent less than 63 μ m	PLT63	%	1	46.5	0.8166	ns	na	na	na	na	na	

¹ Lowest detection threshold that maximizes the number of quantifiable detections, minimizes the number of indeterminate samples, and results in a percent indeterminate samples of no more than 5% (for whole sediment) or 7% (for <63- μ m sediment).

² Number of sample pairs with data for this constituent. Non-integer value indicates missing data for member of one sample pair).

³ p-value, from 2-sided test. The alternative hypothesis is: Post-landfall sample concentration minus the Pre-landfall sample concentration is not equal to zero. Significant p-values are shaded bright yellow (p<0.01) or pale orange (p<0.05).

⁴ Sampling period with significantly higher concentrations.

⁵ A, Not detected in any samples; B, Not detected at the optimal censoring threshold in any samples. Blank indicates that PPW test was run.

⁶ Detected in every sample, so no censoring was necessary.

⁷ Sample size is low because there was a large number of samples with missing data.

⁸ Not detected in any sample, so no censoring was necessary.
