

Appendix A. Development of a Three-Dimensional Hydrogeologic Framework Model

A three-dimensional hydrogeologic framework model was constructed using all available information. The foundation of the hydrogeologic framework model is a geologic framework model constructed from available surficial and structural geologic maps and geologic interpretations from 318 well logs (fig. 2) (Newcomb, 1969; Grady, 1983; Kienle, 1995; and Jervey, 1996). The following summarizes the technical aspects of the geologic modeling process and conversion of geologic model units to groundwater-flow model units (see Hydrogeologic Framework, figs. 3–5).

A.1—Motivation and Methods

The geologic framework modeling process was iterative (fig. A1), consisting of three interpretive steps: (1) creation of trend surfaces from compiled data, (2) building a 3-dimensional geologic model using the trend surfaces, and (3) analysis of the resulting model to evaluate how well the resulting geologic model matches the data. At the end of step 3, if the results are deemed inadequate, then the process is repeated with appropriate alterations to steps 1 and 2. Step 2 uses geologic and other physical principles, such as the geologic laws of superposition and original horizontality, to construct the distribution of geologic units from surfaces representing geologic unit tops and bottoms. More details of the motivation and methods used here are provided by Burns and others (2011).

Geologic unit tops were modeled as trend surfaces (fig. A1B), and it is assumed that the bottom of any unit is the top of the underlying unit. Trend surfaces were used for five reasons:

1. Well logs from which geologic picks were selected are of variable quality, with inherent inaccuracy in the estimates of ground-surface elevation and depth to contact;
2. Geologic picks from well logs from the previous studies were occasionally in conflict with each other, indicating that some picks are erroneous;
3. Geologic tops encountered in boreholes represent point samples of an undulating paleotopographic surface;
4. Mapped geologic contacts are smooth lines drawn across the current topography, providing artificial variability in estimated geologic unit top elevation; and

5. An understanding of the trend of the surface and local mismatch between data and the trend is deemed to be more informative about aquifer-system geometry than locally noisy fits acquired using exact interpolation of possibly erroneous data.

An example of using a trend to model a geologic surface is shown in the workflow of figure A1B, where mismatch between the trend surface and the data provides information about location and offset of a fault.

A.2—Geologic Model Assumptions and Implementation

Trend surface modeling was accomplished iteratively (fig. A1B); the first step was data compilation and confidence weighting. Because no data were obviously of lower quality, either initially or during the interpolation, all data received an equal weight. In addition to well data, the surficial geologic map compilation was also used. Where a geologic contact line represents the top of a unit at land surface, the line was sampled at a high frequency using points along the line. The elevation of the contact at each point was assigned the value from a digital elevation map of the land surface topography. Because the geologic map was constructed by drawing a smooth line across undulating terrain, the sampled geology also displayed this undulation. It was assumed that this elevation was correct on average, so points representing the local median were subsampled from the surficial geology points, providing a data reduction and estimates of the typical elevation of the contact.

The geologic map sample points were merged with the well data to provide sets of points representing each geologic model layer. Smooth trend surfaces were fit to data representing the top of each geologic unit (step 2 of fig. A1B). This was accomplished with a 2-dimensional local estimation regression method, LOESS, which was written in S for implementation in *S-Plus* (Cleveland and others, 1992). As implemented, LOESS performs a local linear fit to the data with an intended goal being a symmetrical distribution of the residuals around zero, where the residuals are defined as the difference between the measured value and the modeled surface. The LOESS algorithm has a variety of options, but all options were set to the default except for span and degree.

A.

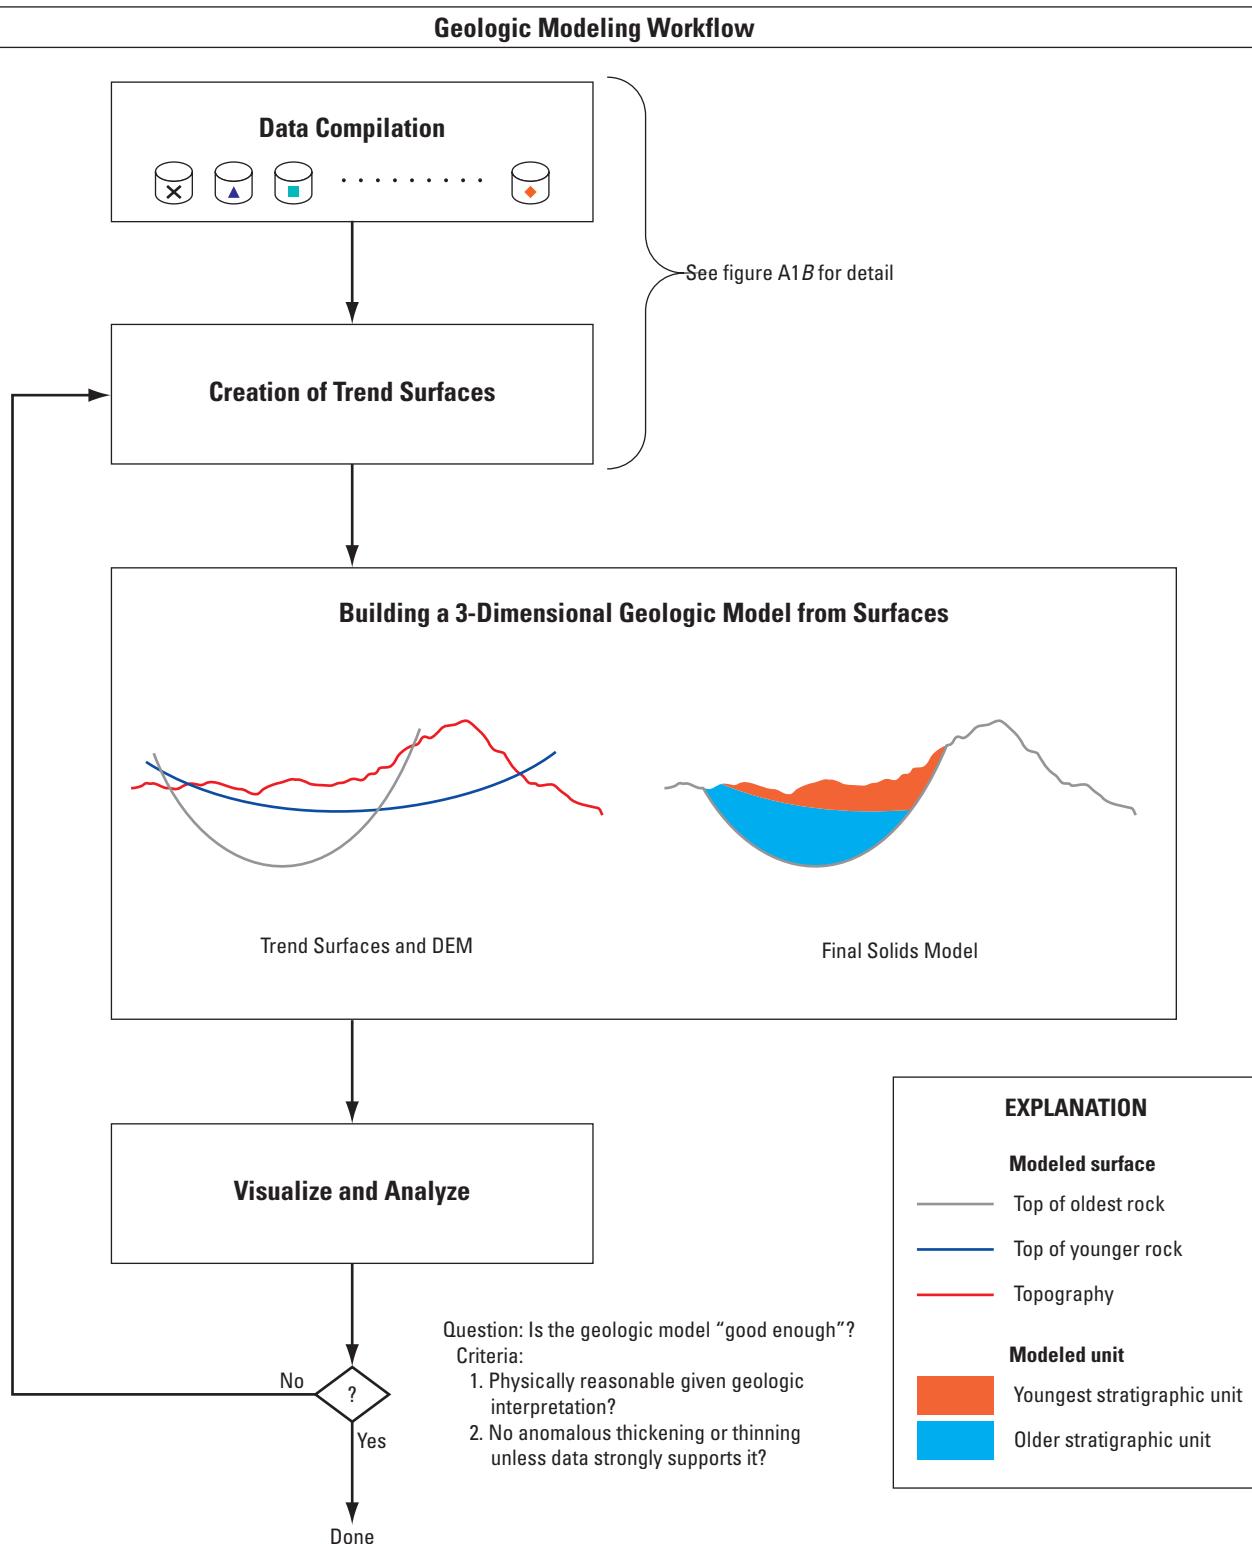

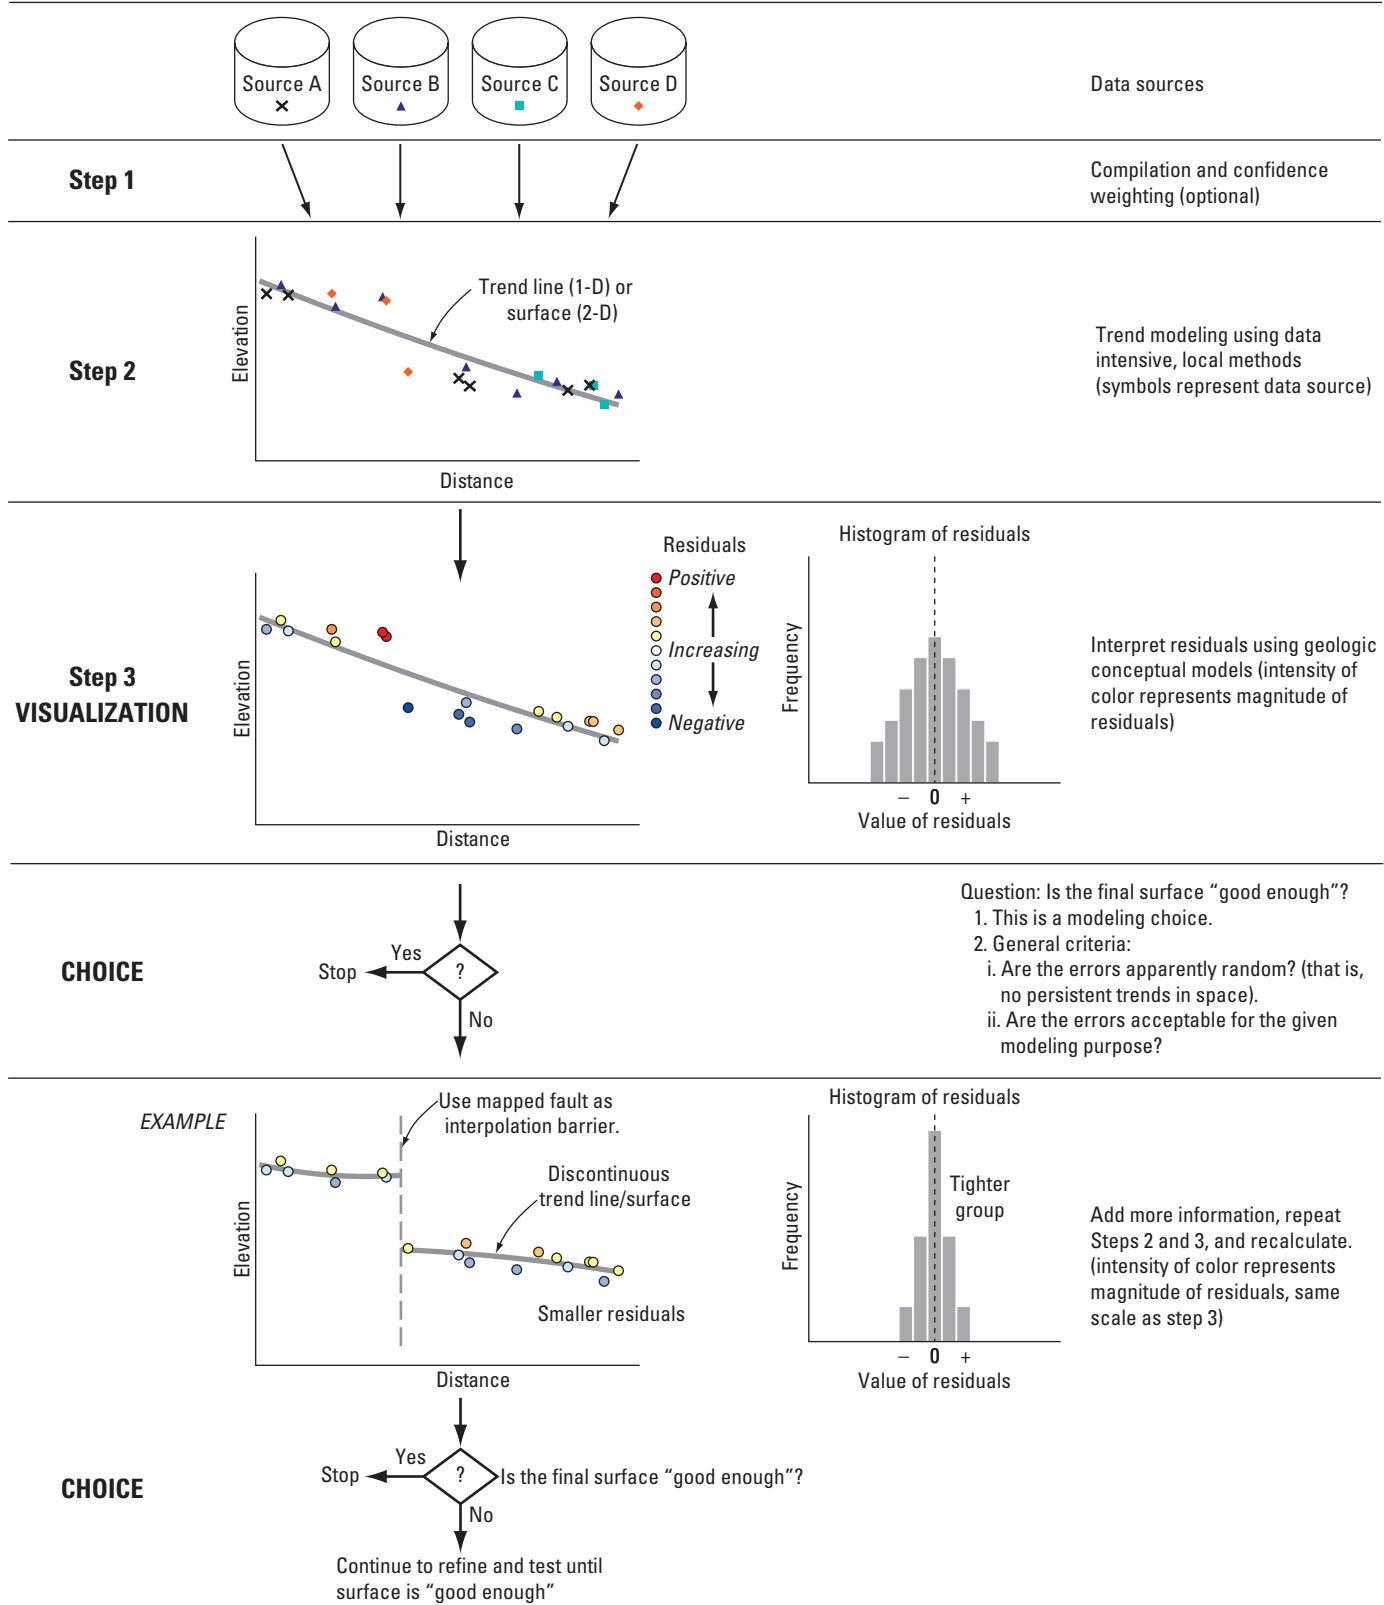

Figure A1. The geologic modeling process. (A) Geologic modeling workflow, (B) details of trend surface modeling.

B.**Details of Trend Surface Modeling****Figure A1.—Continued**

Degree controls whether the local fitting function is linear or quadratic, and in all cases, linear was selected here. Span controls the percentage of data that goes into the interpolation at any given data point, and data are locally weighted during interpolation using a tri-cube weighting function with heavier weight nearer the interpolation point. As a result, increasing the span uses more data for the local estimation, resulting in a smoother trend surface. If the span is small, only data close to the interpolation point are used, and the surface becomes irregular and numerical edge effects can occur. An edge effect is where an incorrect trend supported by only a few measurement points is continued past the data, resulting in substantially incorrect estimates of the surface in that direction. The “best” span is defined here as the largest span for which the residuals appear to be randomly distributed in space (the smoothest surface with no strong trend in the residuals when they are plotted on a map).

Iterative trend surface modeling revealed three distinct fault-bounded geologic modeling blocks (fig. A2). The associated faults had significant offsets (greater than 200 ft) across known faults or fault groups (fig. 2). The boundaries of the geologic modeling blocks represent the approximate location of the large offsets of the Rocky Prairie thrust fault and the Maupin wrench fault(s). The Maupin wrench fault has high offset to the south, with little or no offset to the north. The geometry of this fault to the north is uncertain because of low data density on the west side of the fault. The well data were insufficient to resolve offset on other mapped faults, so only these two faults are represented in the geologic model.

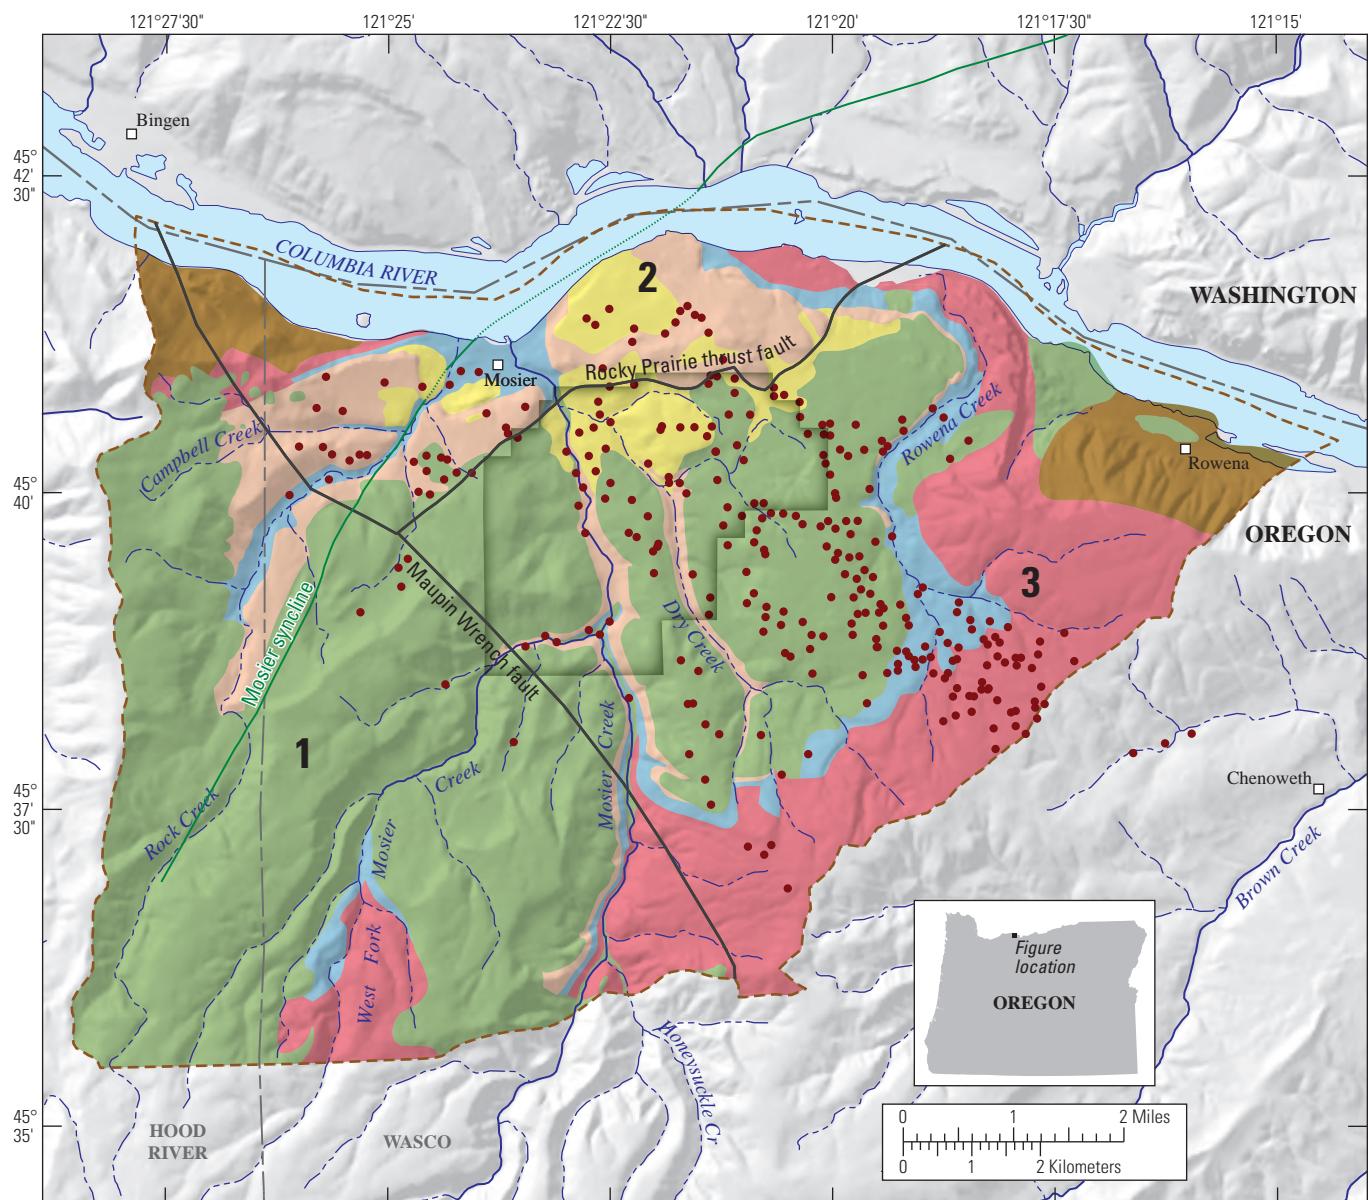

Because the angle of plunge of the Mosier syncline through geologic modeling block 1 is not known and there are little data available to constrain the geologic model, inferred control points were added to the interpolation for this block to represent the syncline as a gently plunging feature. The resulting geologic model has high uncertainty in this block, so calculations and estimates for this side of the model implicitly have higher uncertainty. However, the modeled geometry retains the necessary hydraulic character to route recharge in a manner consistent with the best available geologic understanding of the watershed.

Sufficient data existed to generate surfaces representing the tops of the overburden, the Pomona Basalt, the Priest Rapids Basalt, the Frenchman Springs Basalt, and the Grand Ronde Basalt (figs. 2, 3, and A2, and appendix A.5). The Selah and Quincy-Squaw Creek interbeds were less frequently identified in well logs, indicating that they possibly were not present or missed during drilling. Well log interpretation of the Priest Rapids Basalt was inconsistent, with some studies identifying the Lolo and Rosalia sub-units, whereas others only used the more generic Priest Rapids designation. Because insufficient data were available for the interbeds and the top of the lower Priest Rapids Basalt, the tops of these units were modeled as proportions of the distance between the overlying and underlying tops.

The distance between the top of the Pomona Basalt and the top of the Priest Rapids Basalt is partially filled by the Selah Interbed, which is overlain by the Pomona Basalt. The interbed represents the soil and alluvium that was accumulating on top of the Priest Rapids flows until the Pomona was deposited over it. Because the Pomona basalt flowed in through the valley bottoms and over the lower ridges of the paleo-Mosier valley, the thickest parts of the Selah correspond to the valley bottom deposits with thinner or non-existent deposits preserved in the topographically higher areas. Data coverage of the Selah Interbed is sparse with the thickest deposits estimated to be approximately 170 ft, but more commonly between 30 and 50 ft in the OWRD groundwater administrative area (Lite and Grondin, 1988). To generate a physically reasonable layer to represent the hydraulic character of the Selah Interbed, the interbed was modeled as a fraction of the distance between the underlying Priest Rapids and overlying Pomona basalt tops. The fraction was scaled to zero feet of thickness in the uplands where the Pomona basalt pinches out and to 40 ft of thickness in the administrative area to provide a simple linear relation that matches the data reasonably well (fig. A3). In plan view (not shown) measured thickness is highly variable over short distances, with relatively thin deposits of this confining unit occurring not far from thick deposits. So even though a better fit might be achieved using more complicated relations, the simplified relation is likely adequate for use in the flow model. This is because there is much more uncertainty in hydraulic conductivity of the interbeds than in interbed thickness through which groundwater flows.

The thickness between the tops of the Frenchman Springs Basalts and the Priest Rapids Basalts is filled with two individual Priest Rapids Basalt flows and the Quincy-Squaw Creek interbed directly overlying the Frenchman Springs unit. Twenty-one wells had data on interbed thickness, and the sedimentary interbed had no strong or persistent spatial trend in thickness (fig. A4). Reported thicknesses ranged from 10 to 53 ft with an average value of 24.7 ft and a median value of 20 ft. It is assumed that presence of the Priest Rapids Basalt will preserve interbed deposits, so the interbed was modeled wherever Priest Rapids Basalt was present. If total distance between top of Frenchman Springs and Top of Priest rapids was greater than or equal to 30 ft, a constant thickness of 20 ft was modeled as interbed. Below 30 ft, interbed thickness is modeled as two-thirds of the total thickness (fig. A4).

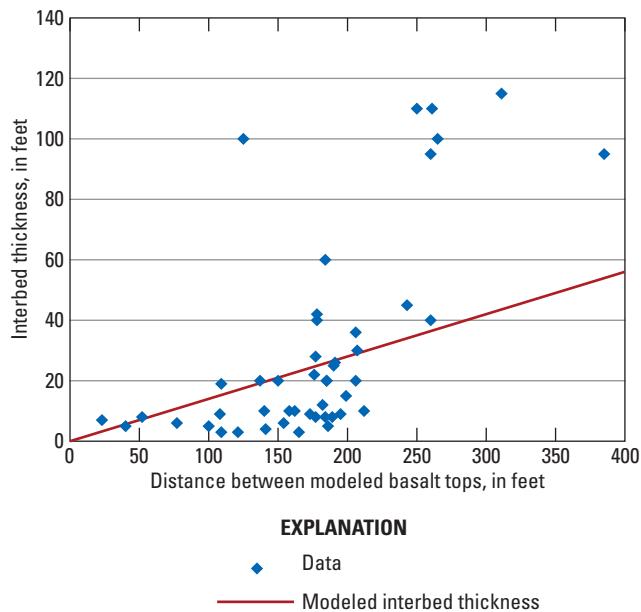

Many wells contained picks for either or both of the upper and lower Priest Rapids flows, but when modeling the top of the upper Priest Rapids flow, it became apparent that a pick for top of the Priest Rapids unit occasionally was in fact a pick for the top of the lower Priest Rapids flow.

EXPLANATION

Geologic model unit		OWRD Groundwater Administrative Area
Glaciofluvial Deposits		Modeled fault
Undifferentiated Overburden		Groundwater-flow model boundary
Pomona Basalt		Syncline
Priest Rapids Basalt		Syncline concealed
Frenchman Springs Basalt		Perennial stream
Grande Ronde Basalt		Ephemeral stream
		Stratigraphic control well

Figure A2. Simplified geology, wells with interpreted geology, and simulated faults corresponding to major structural features in the Mosier study area. Simulated faults were used to define separate geologic modeling blocks.

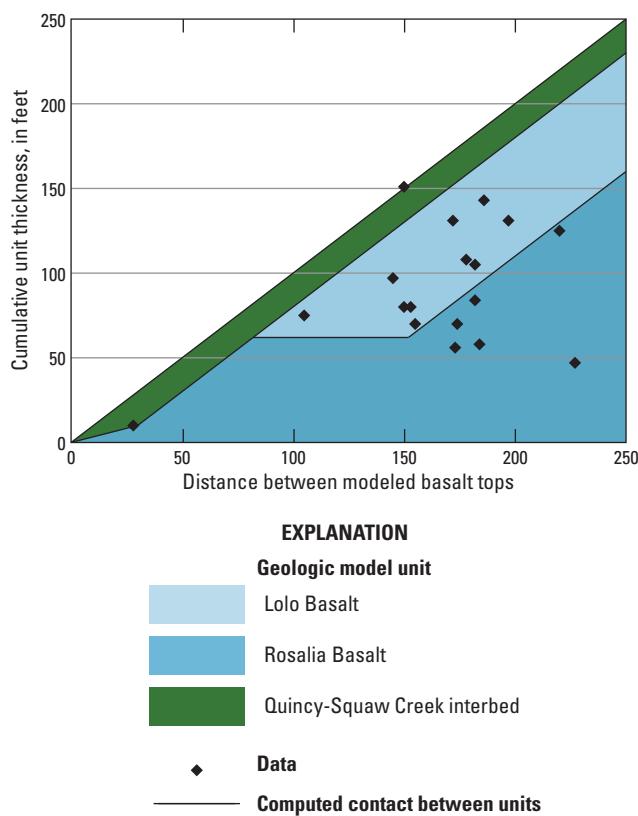

Figure A5. The relations between the thickness of the lower Priest Rapids units (Rosalia) and the total thickness of Priest Rapids Basalt and the Quincy-Squaw Creek interbed. The lines show the rules used to construct the Lolo and Rosalia geologic model units as a function of the available thickness.

Table A1. Summary statistics for well data residuals from the interpolation of each of the modeled basalt unit tops, Mosier, Oregon study area.

[Variance shown in units of square feet. All other quantities in units of feet. While including the surficial geology residuals would have a tendency to reduce variance and make the mean value closer to zero, the number of surficial geology points is a function of sampling methodology, so these data are not reported]

Unit top	Variance	Standard deviation	Number of points	Mean	Median	5th percentile	10th percentile	90th percentile	95th percentile
Pomona	2,404.0	49.0	165	13.8	10.6	-49.6	-36.2	78.9	106.5
Lolo	3,845.3	62.0	214	11.6	16.5	-107.9	-59.7	73.3	103.5
Rosalia	3,469.4	58.9	20	-12.7	-2.6	-96.8	-87.6	47.7	50.8
Frenchman Springs	3,986.9	63.1	240	-12.7	-3.8	-114.3	-79.8	51.9	65.6
Grande Ronde	11,589.7	107.7	39	-29.5	-37.2	-181.2	-162.6	119.6	124.9

This conceptual model merely requires that recharge into Frenchman Springs and Grande Ronde Basalts be transmitted toward the Columbia River through the deep flow system.

The residuals of well data for the final modeled surfaces are generally symmetrically distributed (fig. A6) and are random in map view, with typical magnitudes less than 50 ft (table A1). Generally, inclusion of surficial geology points used in trend surface estimation will result in smaller computed variances, mean values closer to zero, and a more symmetrical distribution of residuals. However, the number of geologic points used in the interpolation is arbitrary because surficial geology can be sampled at an arbitrary interval. Because the number of sample points affects the computed statistics, only well points were used when computing and displaying summary statistics that may be used to infer model error.

An illustrative example of the role of geologic map sample points on geologic model fit results are shown for the Frenchman Springs flow top in geologic model block 3 (figs. A7 and A8). Figure A8C is data shown in A6D that is for geologic model block 3. The asymmetry of the histogram for the surficial geology points (fig. A8B) indicates that the top of the Frenchman Springs unit in outcrop is consistently higher than the trend of the well picks, indicating there may be some bias in selection of the top of the Frenchman Springs unit using drillers' logs.

Figure A7. Distribution of residuals between both the geologic map and well data and the final trend surface for the top of the Frenchman Springs unit in geologic model block 3.

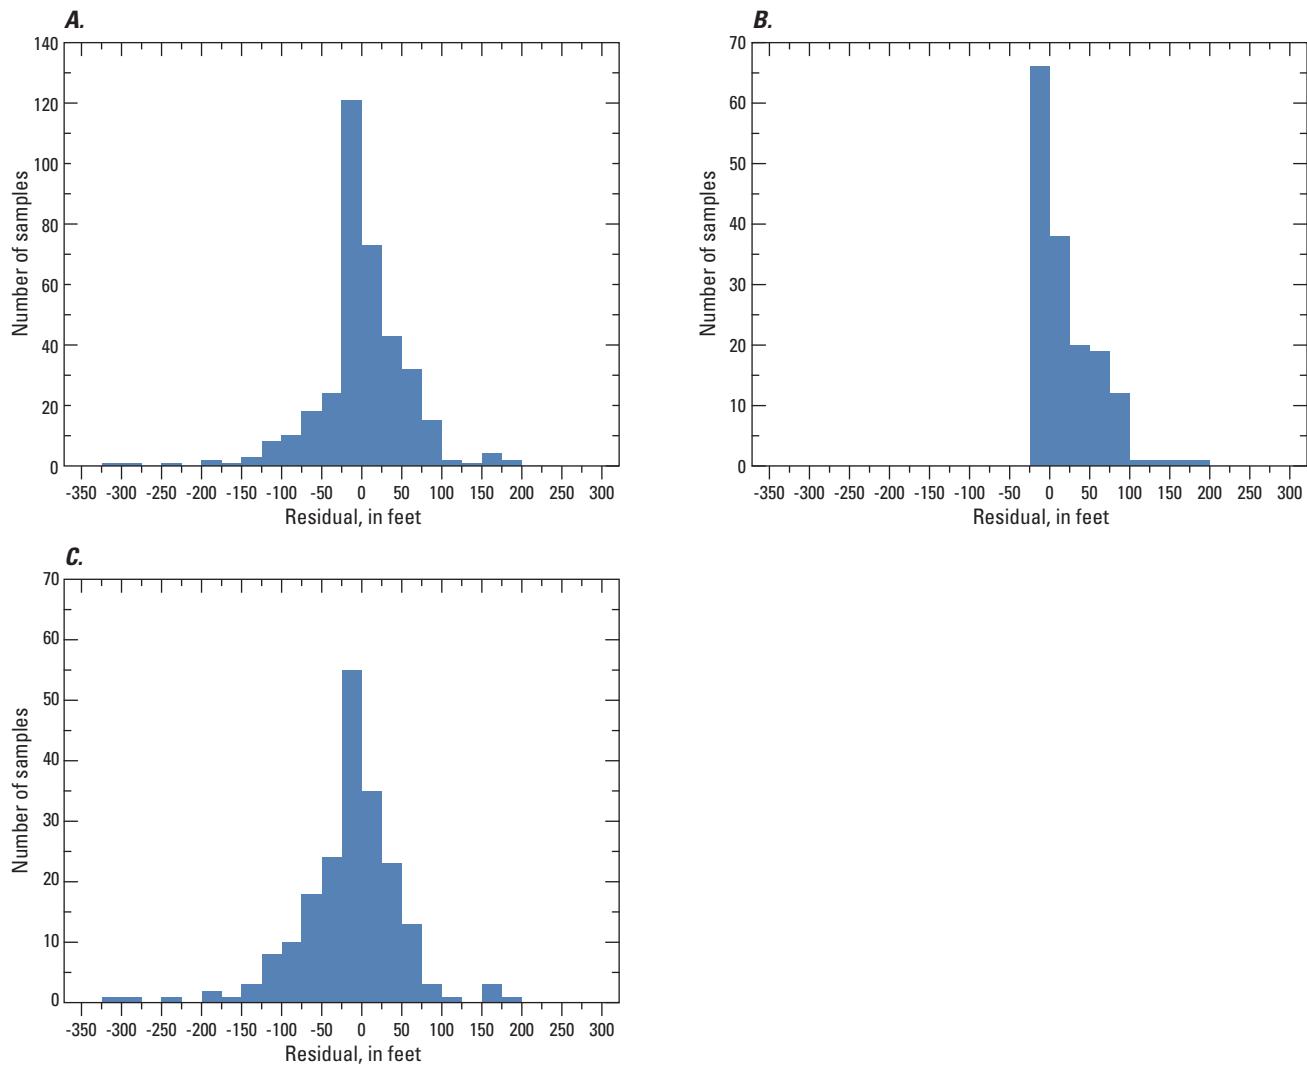

Figure A8. Residuals between both the geologic map and well data and the final trend surface for the top of the Frenchman Springs unit in geologic model block 3. Histograms are for three data groups: (A) surficial geology sample points and wells, (B) surficial geology sample points only, and (C) wells only. The composite histogram shows that the modeling criteria is satisfied overall, but the skew in the other histograms indicates that the other data are potentially not consistent, indicating possible error in some well data.

Recall that the best trend surface is defined as the smoothest surface that removes most spatial trends in residuals and for which the distribution of residuals is symmetric with mean value of about zero. Rather than removing possibly erroneous data from the dataset, all data are used in the analysis. A color scheme was applied to figure A7 to highlight the effect of data outliers. Generally, spatial trends in these extremes are random, but some trends are discernible. Of particular interest is the cluster of highly negative residuals to the south. These negative values indicate that the smooth trend surface is higher than the data here. Except for these outliers, a smooth trend in the area adequately explains the observations, matching well data to the north and outcrop data to the south.

There are various possible reasons for these outliers. It is possible that the data represent a flow top other than the top of the Frenchman Springs unit. Recall that the Frenchman Springs Basalt in the area likely comprises four distinct flows. It is possible that the geologist that classified the top correctly identified the top of one of the lower Frenchman Springs units. In general, geologic picks with high negative residuals tend to occur in topographically lower areas, so if depth was used to identify the top of the unit (instead of elevation) then a lower Frenchman Springs flow top may have been identified as the top. Another possibility is that there is a fault or other geologic structure between the outliers and the remaining data, but there are no continuous mapped structures in the area (fig. 2). The last possibility considered here is that the data represent a local steep-sided bowl-shaped depression in the top of the Frenchman Springs unit. This violates the assumption that the surface is a fairly simple, smoothly varying surface. Because of the likelihood of erroneous interpretation of strata at some locations, the assumption of a simple smoothly varying surface is retained in the model for parsimony given the support of the remaining data. Retention of the high residual data in the fit statistics identifies data that can require further examination in the future.

Examination of fig A8C shows that the picks with outlier high negative residuals wells are generally 200–300 ft lower than the trend surface (fig. A8). In fact, these few outliers contribute a significant part of the computed variance of the residuals (table A2) and skew the histogram of the surficial geology picks (fig. A8B). Combination of the residuals from each data source, figures A8C and A8B, into a single composite data histogram (fig. A8A) shows that the fit criteria of symmetrical residuals with mean zero is generally achieved for the composite dataset (table A2).

Surficial geology data points vary smoothly in space, so inclusion of these residuals with well residuals for computation of fit statistics tends to reduce measures of spread (table A2), indicating that summary statistics based only on well data provide relatively conservative estimates of model error. A typical value of standard deviation for well residuals for each layer except Grande Ronde is about 60 ft (table A1). This measure of geologic model error generally applies in areas where there is some data support to ensure the trend surface is near the true value. In areas with poor data support, such as geologic-modeling panel 1, the estimated surface has greater uncertainty, and far from supporting data, should be viewed as reflecting the conceptual geologic model. Near structurally complex areas, close to faults with significant offset and tight folds, uncertainty also is greater due to the inability of a smoothly varying trend model to capture small-scale spatial variability. This is illustrated by the larger residuals near the Rocky Prairie thrust fault (fig. A7). When considering the geometry of the geologic units to be described in Mosier, a local error of 100 ft compared to the typical about 3,000 ft of relief of the surface to be described, corresponds to about 3 percent error. Because the median and mean errors are close to zero and there are no significant trends in residuals, the model-generated surfaces are correct on average.

A.3—Groundwater-Flow Model Units

The digital geologic model units were converted into groundwater-flow simulation model units (fig. 3) using estimates of the fraction of each unit occupied by hydrogeologic units. Each permeable basalt unit flow top is estimated as 10 percent of total flow thickness. Because the Frenchman Springs Basalt unit consists of four or five distinct flows in the area with insufficient data to allow delineation of these individual flows, the flow tops are modeled as one unit, consisting of the upper 10 percent of the total thickness. Because few wells penetrate the upper part of the Grande Ronde Basalt in the study area, only the flow top is modeled and the flow interior is treated as a no flow boundary, precluding the need to model it explicitly in the geologic model. Flow top thicknesses of 10–20 ft are not uncommon for sheet flows, and because the Grande Ronde is assumed to be a sheet flow in the study area, the Grande Ronde flow top is assumed to be a uniform thickness of 20 ft.

In this study area, the only basalt flow with a documented laterally extensive, permeable flow bottom is the Pomona Basalt (Lite and Grondin, 1988). The permeable part of the flow bottom has a much smaller footprint than the flow itself. It is generally coincident with the thicker parts of the Selah Interbed and is postulated to have formed when the hot basalt flowed across the wet valley bottom deposits. The footprint of the permeable zone in geologic model block 3 has an estimated areal extent between 4 and 6 mi² immediately south of the Rocky Prairie thrust fault with a maximum thickness of about 20 ft (Lite and Grondin, 1988). Further, prior to development, this zone was hydraulically isolated from the underlying Priest Rapids flow top aquifer. Because the Pomona Basalt flow was thickest in valley bottoms, the thickness of this unit was used to estimate a reasonable distribution of permeable flow bottom. Whenever modeled Pomona thickness exceeds 155 ft, permeable flow bottom is assumed to exist, and the excess thickness is scaled linearly so that the maximum thickness of the flow bottom is 20 ft. The resulting modeled aquifer has several nice properties: (1) it is about 4 mi² in the area generally identified by Lite and Grondin (1988), and about 8 mi² over the entire area; and (2) the footprint is completely contained within the Selah Interbed footprint, ensuring the Selah can act as an confining unit as supported by early data. The modeled aquifer overly simplified, and exact geometry may be somewhat different, but supporting data indicate the geometry is a reasonable representation for use in the hydrogeologic flow simulation model.

In an idealized geologic model, flow tops would be modeled as 10 percent of the thickness before truncating the model with surficial topography. This would ensure that the flow top intersected erosional stream cuts at the appropriate elevation. This would result in the flow interior being exposed in a thin band along the stream-cut wall, much like is observed in reality. Instead, based on flow modeling considerations, this was not done here. The flow top is modeled here as 10 percent of the final computed thickness at all locations, even at stream cuts and other erosional features that may occur on topographic highs. This provides many properties that aid in stability of the numerical flow model, allowing for robust estimation of parameters during automated sensitivity and predictive runs, and that are consistent with physical and other modeling assumptions. The properties aiding stability include:

1. Because PRMS provides a recharge estimate that is uniformly distributed across a model hydrologic response unit, preferential recharge pathways into system aquifers are not represented in the recharge field. Rather than identifying focused recharge areas and redistributing PRMS estimated recharge to these zones, simulating the upper 10 percent of every basalt unit as aquifer allows the distributed recharge to enter the aquifers as distributed recharge. This prevents high model heads from occurring when flux into confining unit model cells is prescribed, preventing the need to alter the hydraulic conductivity of these cells to achieve physically reasonable simulation results.
2. Connectivity between basalts and streams and drains is highest where the flow top is present in reality, and diminishes as basalts thin erosionaly, providing a physically reasonable distribution of stream connection. This is especially true for the lumped Frenchman Springs Basalts, which is commonly about 400 ft thick consisting of multiple flows, but is modeled as a single flow top over a thick low permeability interior.

The overburden is laterally zoned into undifferentiated overburden and glaciofluvial deposits (fig. A2). Each zone is assumed to occupy the upper two groundwater-flow model layers (fig. 3). The Chenoweth Formation, which constitutes most of the undifferentiated overburden, is documented as generally having low permeability, as is expected of poorly sorted mud and ash deposits of volcanic origin. However, the base of this unit is occasionally coarse-grained and productive. Considering the morphology of debris flows, a gross oversimplification would be to conceptualize that the coarse, heavy deposits were funneled into the lowest path and to fall out much more rapidly than the finer deposits.

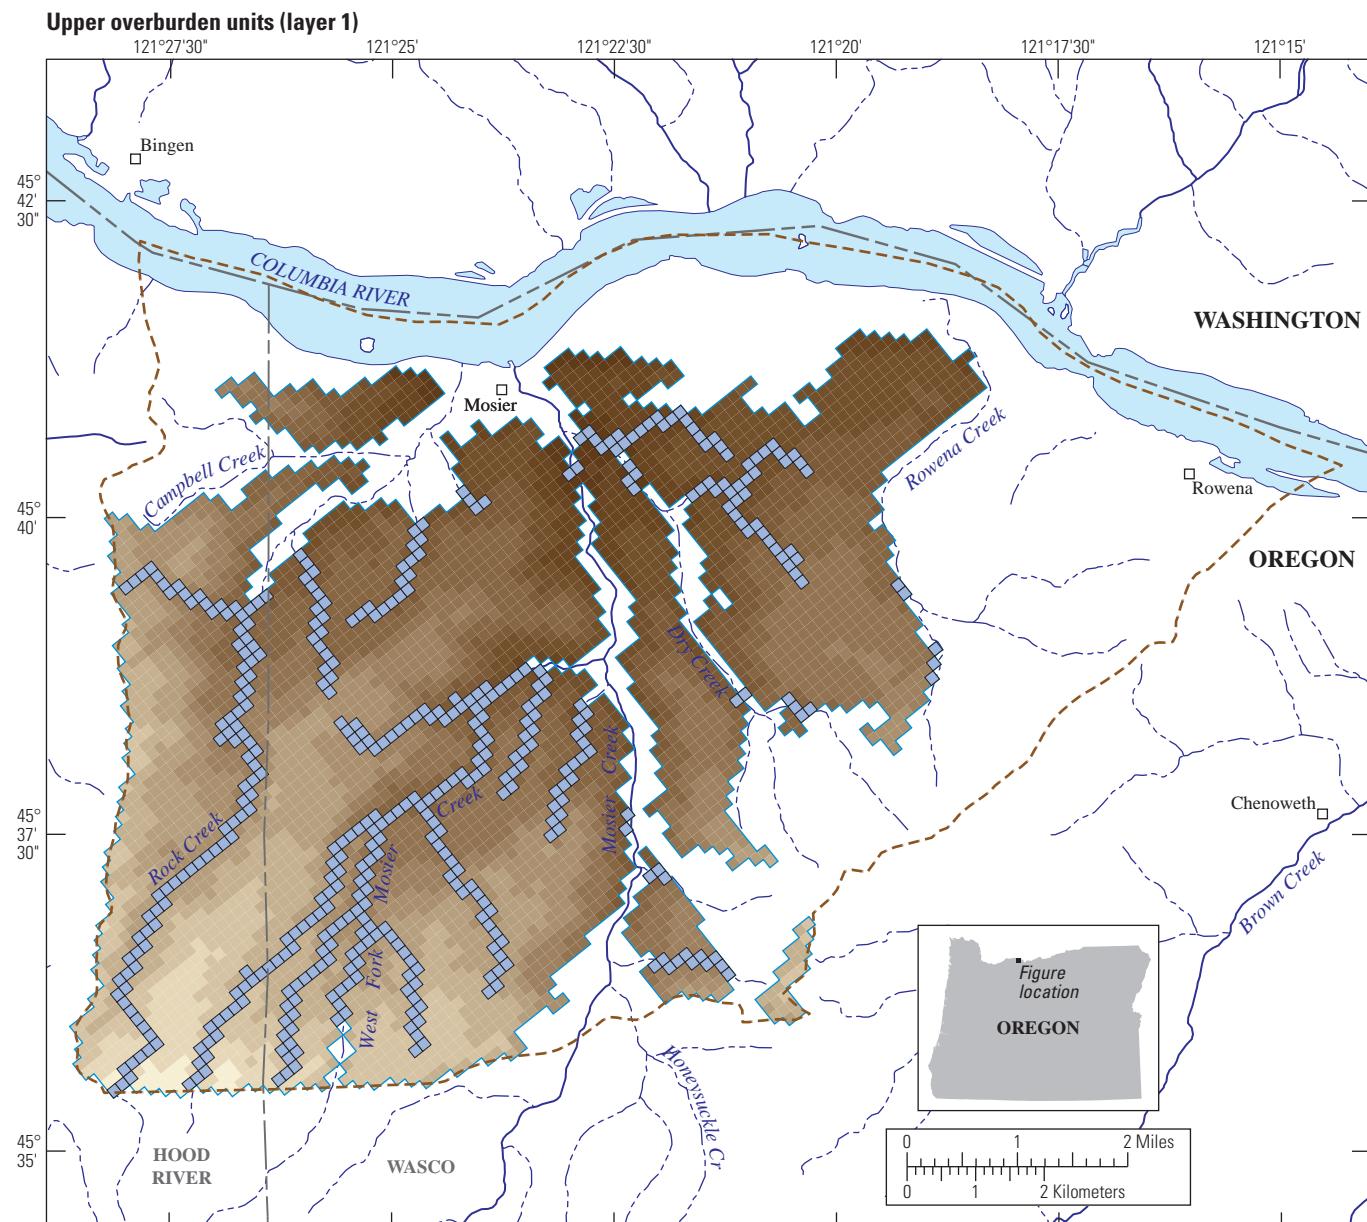

This gives a conceptual model of deposits that grade from fine to coarse from top down, and thicker sequences of coarse deposits in valley bottoms which also have thicker deposits overall. Accordingly, the overburden was divided into an upper 90 percent and lower 10 percent to allow for a relatively higher permeability base. Glaciofluvial deposits also retain the 90 to 10 percent split of groundwater-flow model layers, but because no data indicated that the upper and lower parts had dissimilar hydraulic properties, both groundwater-flow model layers were assigned the same hydraulic properties.

A.4—Groundwater-Flow Simulation Model Surfaces

Tops were computed for each of the groundwater-flow model units (fig. 3) at a 500 ft MODFLOW grid spacing (figs. A9–A22). The Grande Ronde aquifer unit is assumed to

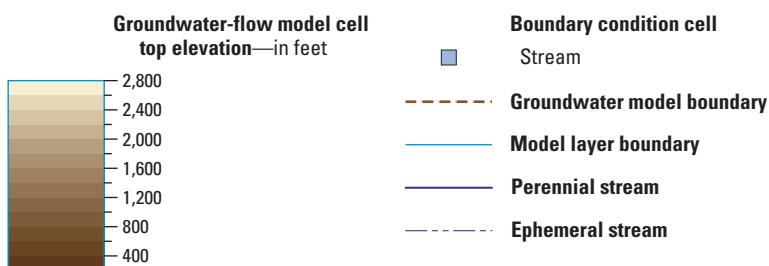

be 20 ft thick, defining the bottom of the flow model domain (20 ft below the surface shown in fig. A22). Each figure shows the extent of the MODFLOW model grid with cell color reflecting elevation and relevant boundary conditions displayed in appropriate cells. The set of lines from which the horizontal flow barriers are derived also is shown (figs. A11–A22).

For groundwater-flow simulation, model layers 3–11 have thin pseudo-cells that transmit water vertically between layers where hydrogeologic units have pinched out. These pseudo-cells are not shown on figures A11–A19, although they are a part of the active domain for groundwater-flow simulation. The reason for use of these cells is summarized in appendix E.3.

Perennial stream

Ephemeral stream

Figure A19. The extent, model layer top elevation, and model boundary conditions of the Quincy-Squaw Creek interbed unit [confining unit] (layer 11) in the Mosier, Oregon, groundwater-simulation model area.

Base modified from USGS and other digital data. Coordinate system: State Plane, Oregon North, FIPS 3601, North American Datum of 1927. Vertical coordinate information is referenced to the North American Vertical Datum of 1988 (NAVD88).

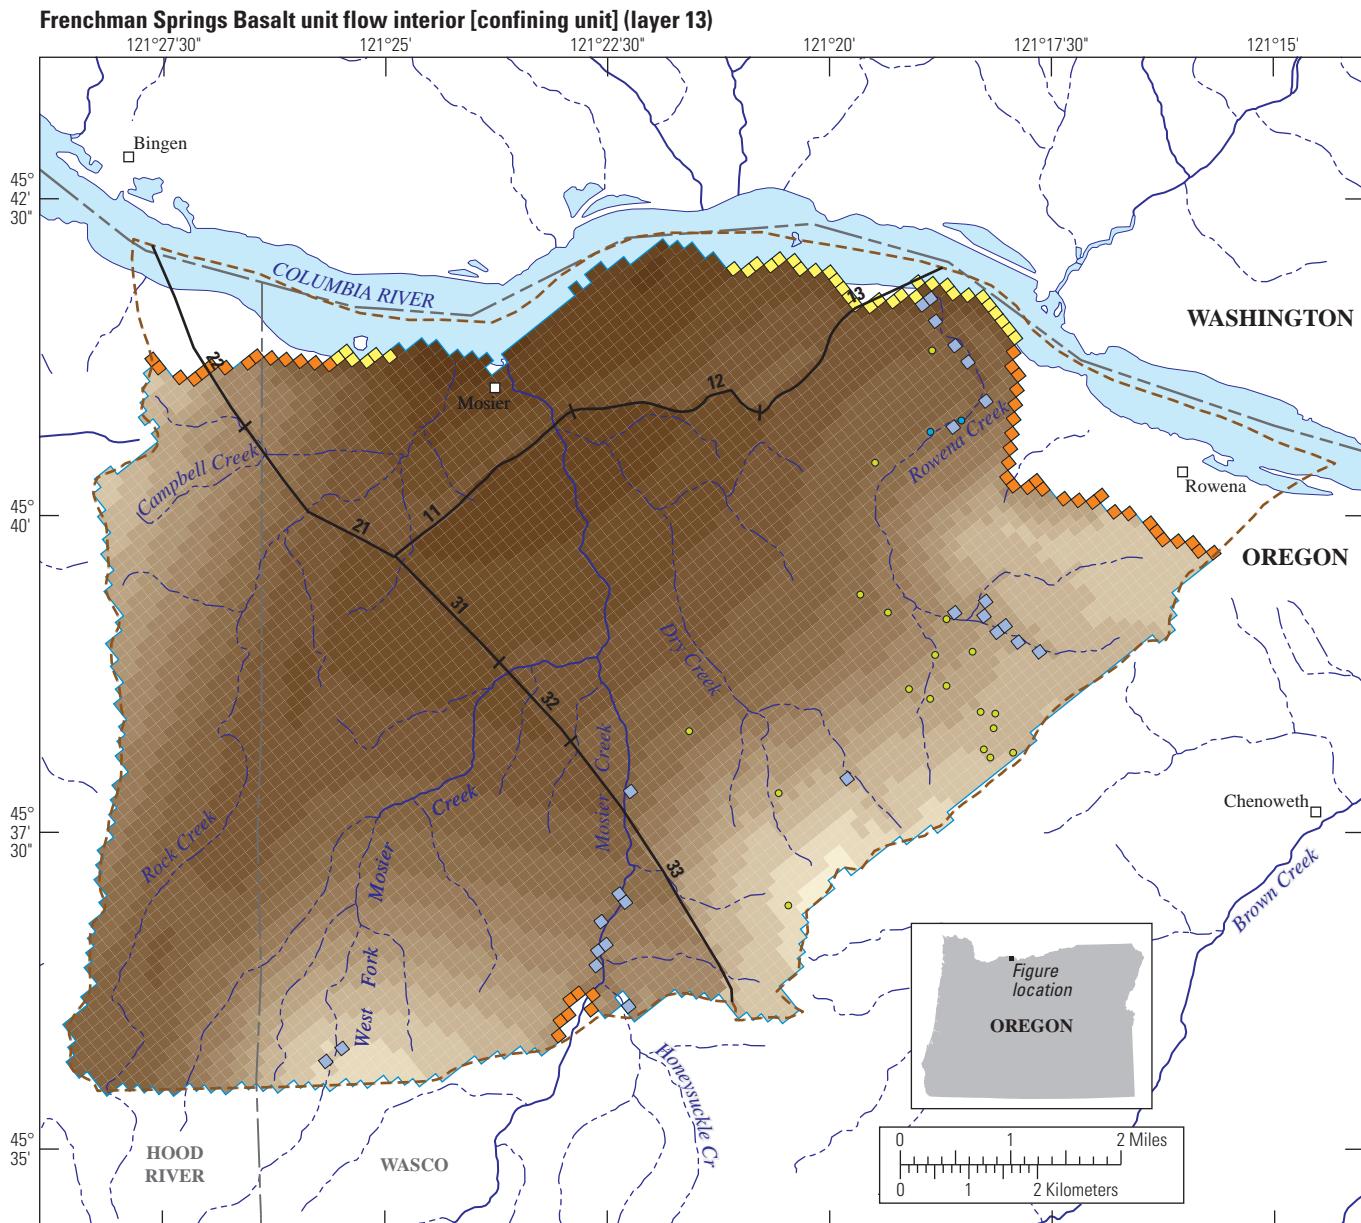

EXPLANATION

Groundwater-flow model cell top elevation—in feet	Boundary condition cell	Well, late
2,400	Drain	Single-aquifer completion
2,000	General head	Commingled
1,600	Stream	
1,200		
800		
400		
0		
-400		

Note: Range is -262 (minimum) to 2,332 (maximum).

Horizontal flow barrier and segment identification No.	Groundwater model boundary	Model layer boundary	Perennial stream	Ephemeral stream
11	Dashed brown line	Solid blue line	Solid blue line	Dashed blue line

Figure A20. The extent, model layer top elevation, and model boundary conditions of the Frenchman Springs Basalt unit flow top [aquifer] (layer 12) in the Mosier, Oregon, groundwater-simulation model area.

EXPLANATION

Groundwater-flow model cell top elevation—in feet	Boundary condition cell	Well, late
2,400	■ Drain	● Single-aquifer completion
2,000	■ General head	● Commingled
1,600	■ Stream	
1,200		
800		
400		
0		
-400		

Note: Range is -304 (minimum) to 2,282 (maximum).

11 Horizontal flow barrier and segment identification No.

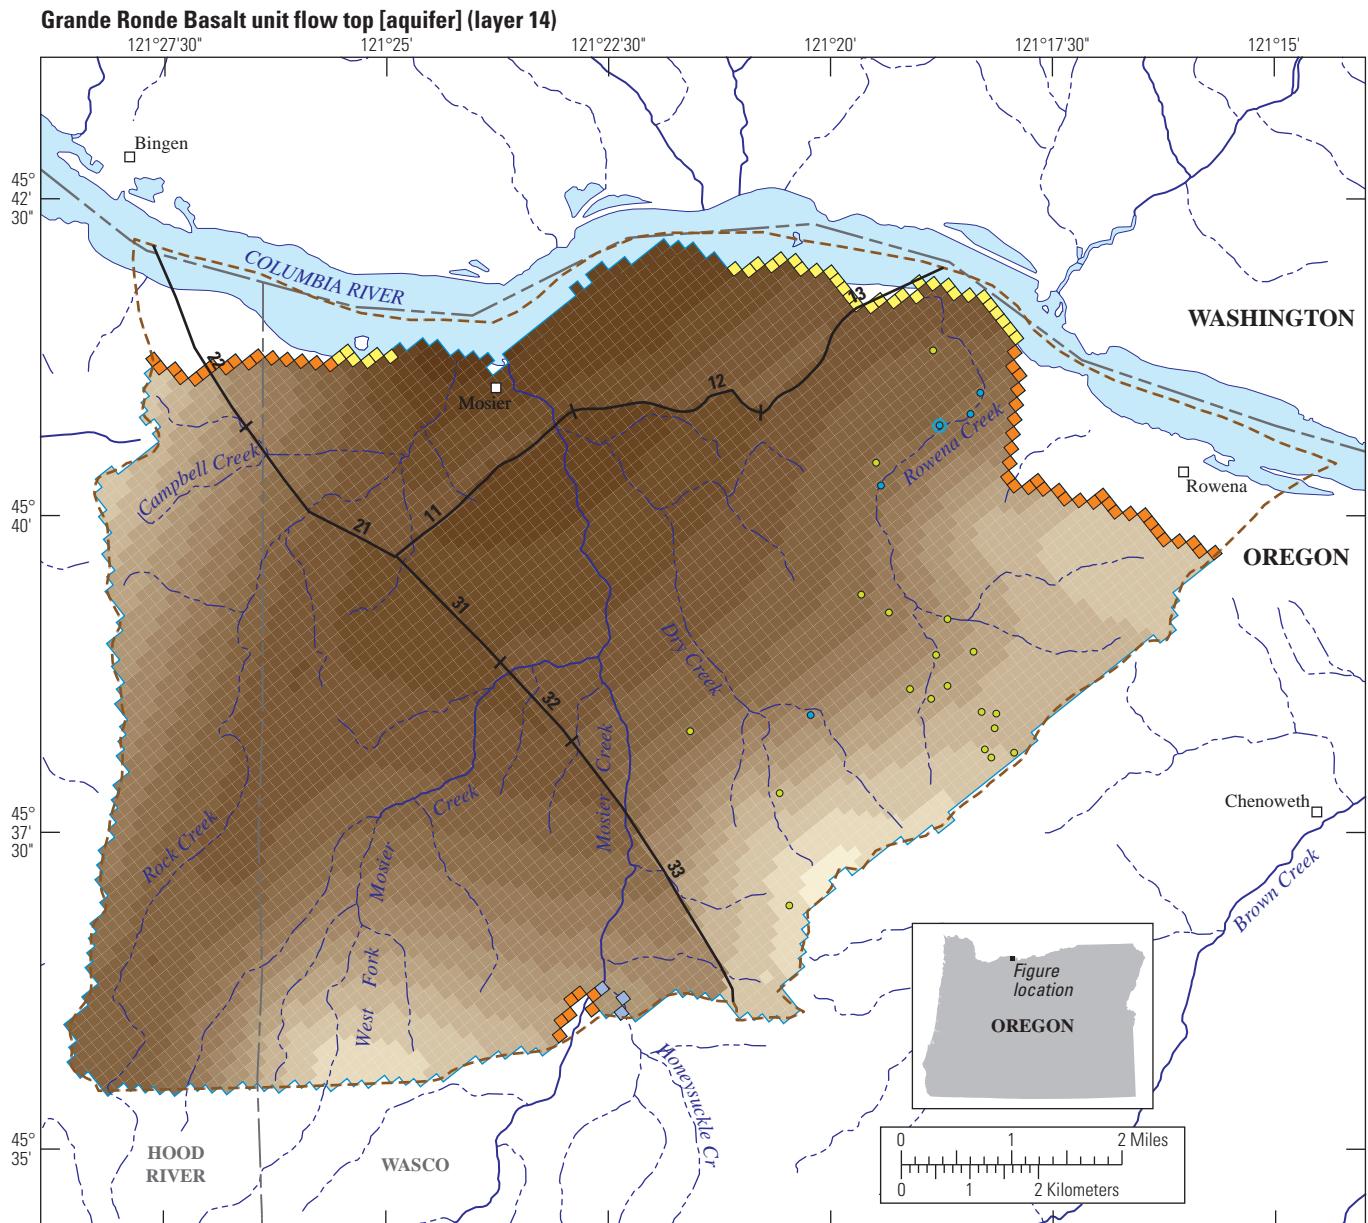

— Dashed line Groundwater model boundary

— Solid line Model layer boundary

— Thick solid line Perennial stream

— Dashed line Ephemeral stream

Figure A21. The extent, model layer top elevation, and model boundary conditions of the Frenchman Springs Basalt unit flow interior [confining unit] (layer 13) in the Mosier, Oregon, groundwater-simulation model area.

EXPLANATION

Groundwater-flow model cell top elevation—in feet	Boundary condition cell	Well, late
2,000	Drain	● Single-aquifer completion
1,600	General head	● Commingled
1,200	Stream	
800		
400		
0		
-400		
-800		

Note: Range is -682 (minimum) to 1,830 (maximum).

11	Horizontal flow barrier and segment identification No.	Well, early
	— Horizontal flow barrier	○ Single-aquifer completion
	— Groundwater model boundary	○ Commingled
	— Model layer boundary	
	— Perennial stream	
	— Ephemeral stream	

Figure A22. The extent, model layer top elevation, and model boundary conditions of the Grande Ronde Basalt unit flow top [aquifer] (layer 14) in the Mosier, Oregon, groundwater-simulation model area.

A.5—Elevation of Tops of Geologic Model Units in Wells in the Mosier, Oregon, Study Area

Table A3 contains all well log interpretations used to construct the geologic model and the source of the interpretation.

Table A3. Elevation of the tops of hydrogeologic units in wells in the Mosier, Oregon, study area.

[This table is available as a digital spreadsheet at <http://pubs.usgs.gov/sir/2012/5002>. **State plane:** State plane Oregon North (North American Datum of 1927) northing and easting coordinates (Kienle, 1995; Jersey, 1996). **Land-surface elevation:** Determined using state plane northing and easting coordinates (Kienle, 1995; Jersey, 1996) and USGS 10 meter digital elevation model (DEM). North American Vertical Datum of 1988 (NAVD 88). **Elevations:** Determined using well log stratigraphic interpretations (Kienle, 1995; Jersey, 1996) and land-surface elevation, NAVD 88. Grey italicized elevations have been interpreted below the drilled well depths using cross-sectional maps (Jersey, 1996). **Abbreviations:** USGS, U.S. Geological Survey; - no data]

Table A3. Elevation of the tops of hydrogeologic units in wells in the Mosier, Oregon, study area.—Continued

[This table is available as a digital spreadsheet at <http://pubs.usgs.gov/sir/2012/5002/>. **State plane:** State plane Oregon North (North American Datum of 1927) northing and easting coordinates (Kienle, 1995; Jersey, 1996). **Land-surface elevation:** Determined using state plane northing and easting coordinates (Kienle, 1995; Jersey, 1996) and USGS 10 meter digital elevation model (DEM), North American Vertical Datum of 1988 (NAVD 88). **Elevations:** Determined using well log stratigraphic interpretations (Kienle, 1995; Jersey, 1996) and land-surface elevation, NAVD 88. Grey italicized elevations have been interpreted below the drilled well depths using cross-sectional maps (Jervey, 1996). **Abbreviations:** USGS, U.S. Geological Survey; –, no data]

Table A3. Elevation of the tops of hydrogeologic units in wells in the Mosier, Oregon, study area.—Continued

[This table is available as a digital spreadsheet at <http://pubs.usgs.gov/sir/2012/5002>. **State plane:** State plane Oregon North (North American Datum of 1927) northing and easting coordinates (Kienle, 1995; Jersey, 1996). **Land-surface elevation:** Determined using state plane northing and easting coordinates (Kienle, 1995; Jersey, 1996) and USGS 10 meter digital elevation model (DEM), North American Vertical Datum of 1988 (NAVD 88). **Elevations:** Determined using well log stratigraphic interpretations (Kienle, 1995; Jersey, 1996) and land-surface elevation, NAVD 88. Grey italicized elevations have been interpreted below the drilled well depths using cross-sectional maps (Jersey, 1996). **Abbreviations:** USGS, U.S. Geological Survey; -, no data]
