channel and ascending the opposite slope he catches more than one glimpse of a coarse buff dolomite (the Galena, or lead-bearing limestone) with the light blue clay of the overlying Maquoketa shales, and both quickly followed by the cherty Niagara) for all these formations are thin in the north; and while he finds the lower hills rugged, and occasional flat topped mesas or precipitous bluffs at higher levels for a mile, he soon leaves all this behind him and passes upon the bowlder-dotted drift plain.

Could he now put himself once more in the place of the pioneer, he would see before him only smooth prairie land stretching to an unbroken horizon, without tree, bush, or shrub, save for the narrow belts of fire-stunted forest along the larger water courses, with never a hill, or valley, or other topographic form save the plain, and that plain smooth, level, ill drained, and bounded only by the limits of vision save where diversified now and then by a low mound of unknown origin (Pl. XII). But man has made his mark on the face of the land, and the vision of the tourist is obscured by artificial groves, by houses and barns dotting the surface and not concealed by its slight irregularities for a score of miles in either direction; his course is constrained by the barbed wire fences of the lanes into

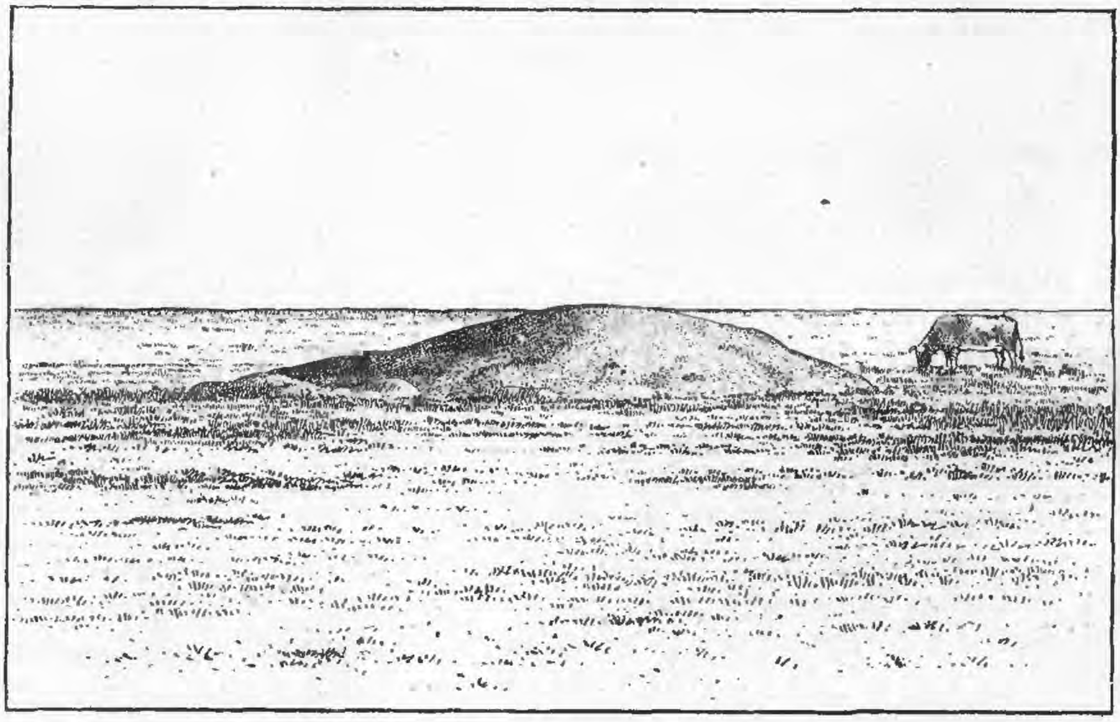

FIG. 1.—Drift bowlder of granite.

roads running upon the land lines, stretching straight as arrows to west and south for scores of miles with no hill too steep to be crossed without grading nor valley so deep as to require embankments; and he finds the smaller bowlders sown in myriads by the ice-king gathered in lines along the fences, heaped up by the roadside, and built into foundations of houses and barns, though many of the larger—

true that there are a few loess ridges and a few moraine-like hillocks over the divides between the rivers; it is true that sometimes the drift is thin, with glacier-rounded bosses of limestone (generally the light buff or gray argillaceous limestones of the Devonian) cropping out; but it is also true that throughout these counties the surface is so smooth that the roads run on the land lines with neither cutting nor filling for dozens of miles, and that the engineer locates his railway with far less reference to the topographic configuration than to the township tax and village bonus, crossing summits without cuts and building embankments only to approach bridges.

Let the tourist now begin another journey across the territory, and if he desires to examine the southern extremity of the driftless area, and at the same time to see the drift plain diversified in a unique and anomalous manner, he may well travel in a course nearly parallel with his last; and he can do no better than cross the "Father of Waters" at the pioneer city of the State, one time the "Key City" to the entire Northwest—Dubuque.

Here he finds the great river hemmed between high bluffs but a mile apart, with its eastern waters laving the base of a precipice of brownish gray Galena limestone 160 feet high, with slopes rising from its verge for another hundred feet to rounded summits crowned with the tumuli, temples, and effigies of a prehistoric people; crossing the swift flowing river he sees it ever swirling and eddying over a rough and often rocky bottom under a 4-mile current, and occupying but half its cañon bottom; and on the west he finds a strip of flood plain rising quickly into steep but round topped limestone bluffs 250 feet high, with the city straggling along the narrow shelf at their base for 2 or 3 miles. Recalling the uplands of Allamakee County, where the Trenton limestone caps the highest summits 600

FIG. 2.—Bluffs and bottoms of the Mississippi at Dubuque, looking southeastward. The nearer bluffs are Galena limestone and those in background are Niagara limestone.

feet above the level of the Mississippi, he is surprised to find the same rocks here exposed in the river bottom and only at low water; and his next surprise comes with the discovery that the 20-foot bed of

Galena limestone seen on the upper Turkey River has multiplied in thickness, and forms the whole of the 250-foot cañon walls.

Journeying westward once more, he finds cross-country roads radiating in all directions from the Key City, over hills and through ravines, yet seldom on the land lines; for he soon discovers that

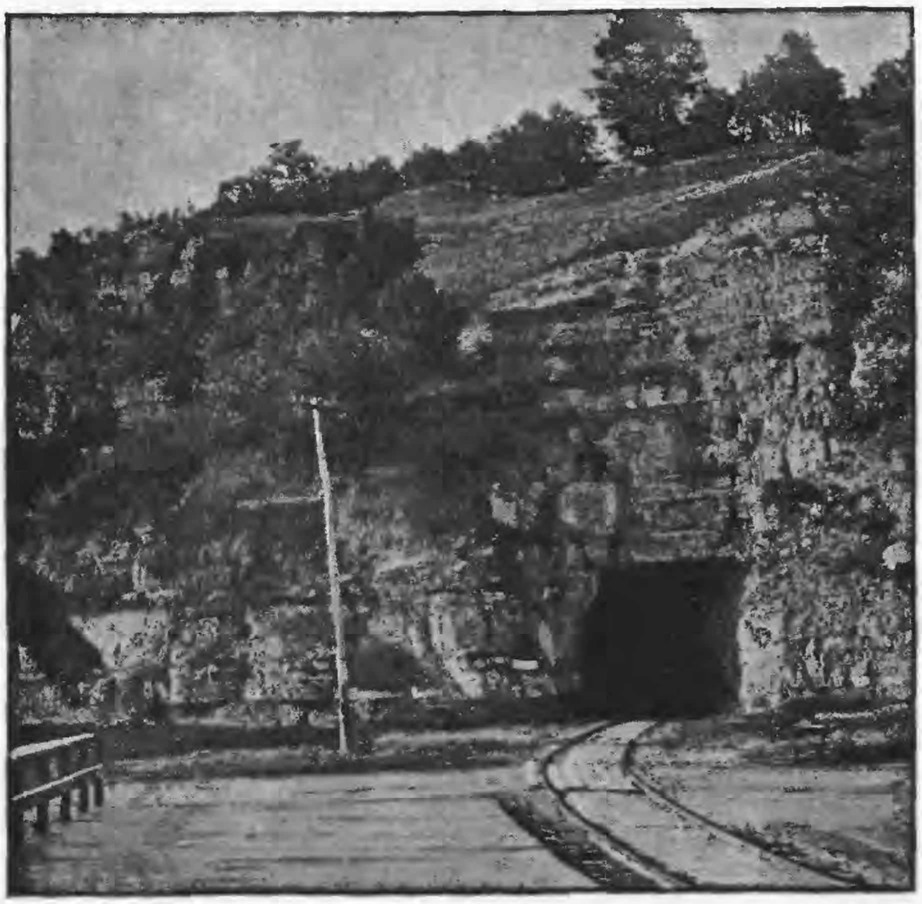

FIG. 3.—Bluff of Galena limestone opposite Dubuque. Aboriginal tumuli crown the grassy swell rising from the verge of the cliff.

although the ravines are as steep sided and labyrinthine and the hills as round topped and many sided, the cañons are but half as deep and the hills but half as high as in the extreme northeast, so that while the roads cross hill and valley alike they are adjusted to the easiest slopes and shortest distances. From the verge of the cañon wall he scans an area of five miles radius, all round topped hills defined by cañon-like ravines; he perceives that the summits of these hills, both at his feet and beyond the rock-bound gorge of the great river, rise to a common plane, and at a second glance sees that the plane is at first gently inclined southwestward, and then rises more rapidly in the same direction in a series of smoothly rounded slopes, unbroken by pinnacle or precipice, to a line of cliffs, salients, and isolated crests, higher and more conspicuous than the immediate bluffs of the Mississippi, though 600 feet higher and half a dozen miles distant from its waters—he looks upon the deeply dissected plain of the rugged Galena limestone, rising through the gentle slopes formed by the clays of the Maquoketa shales (here 125 feet thick) into the bold escarpment of the Niagara limestone, the most conspicuous topographic feature of the State.

As he climbs the river bluffs through Julien avenue or Miners' avenue, which connect the cañon-bound city with the adjacent upland, the tourist finds the massive ledges of Galena limestone on

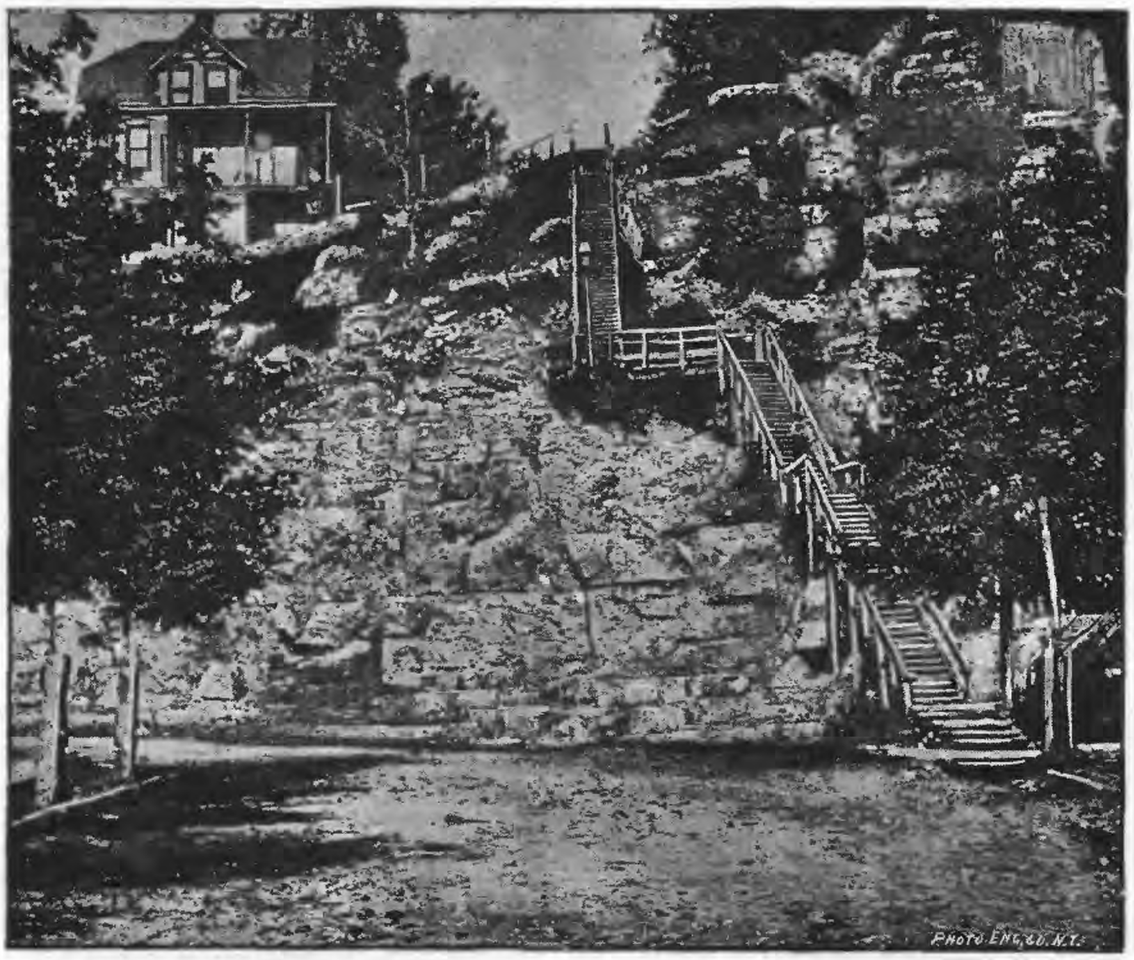

FIG. 4.—A typical bluff of Galena limestone at Dubuque.

either side overlain, first by red brown loam like that above the Trenton limestone in the northeast (and here as there a residuum of rock decomposition), and next by a heavy bed of yellowish buff loam with an underlying gravel bed, sometimes thick and again inconspicuous; and over the uplands to the very base of the Niagara escarpment he notes the same residuary loam and the same loess sheet maintaining the same relation save that the intervening gravel bed thickens westward and that over the gentle slopes of the Maquoketa shales the residuary loam becomes a tenacious red or gray clay. Over all he finds numerous and generally well kept meandering roads, flanked by comfortable and even elegant farmhouses, with church or schoolhouse for every mile: he finds flourishing young apple orchards, and vineyards in plenty despite the rigorous climate, and the hazel, crab apple, cherry, and even the oak, the hickory, the walnut, and other hard-wood trees springing up in every neglected nook and fence row; and he might justly infer from the luxuriance of the arborescent growth and the wealth of the cultivated produce that the land once supported a luxuriant forest long since felled as the eager tiller of the soil wrested the acres from nature's prodigal dominion.

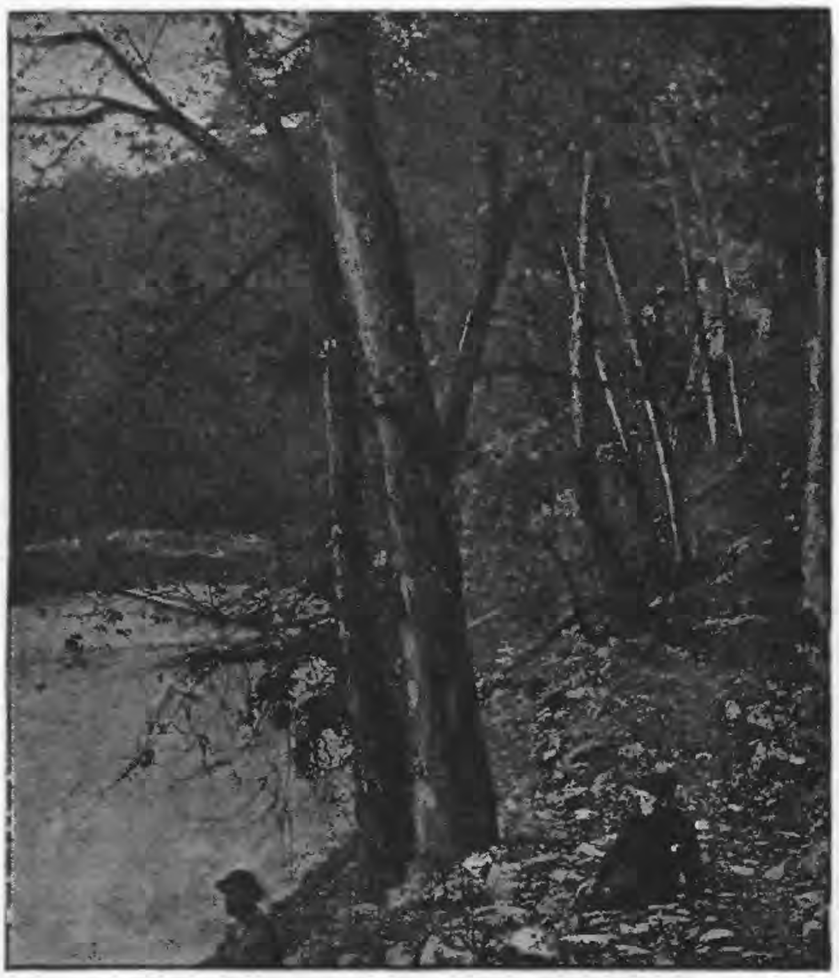

FIG. 5.—Base of a wooded bluff of Galena limestone on Little Maquoketa River.

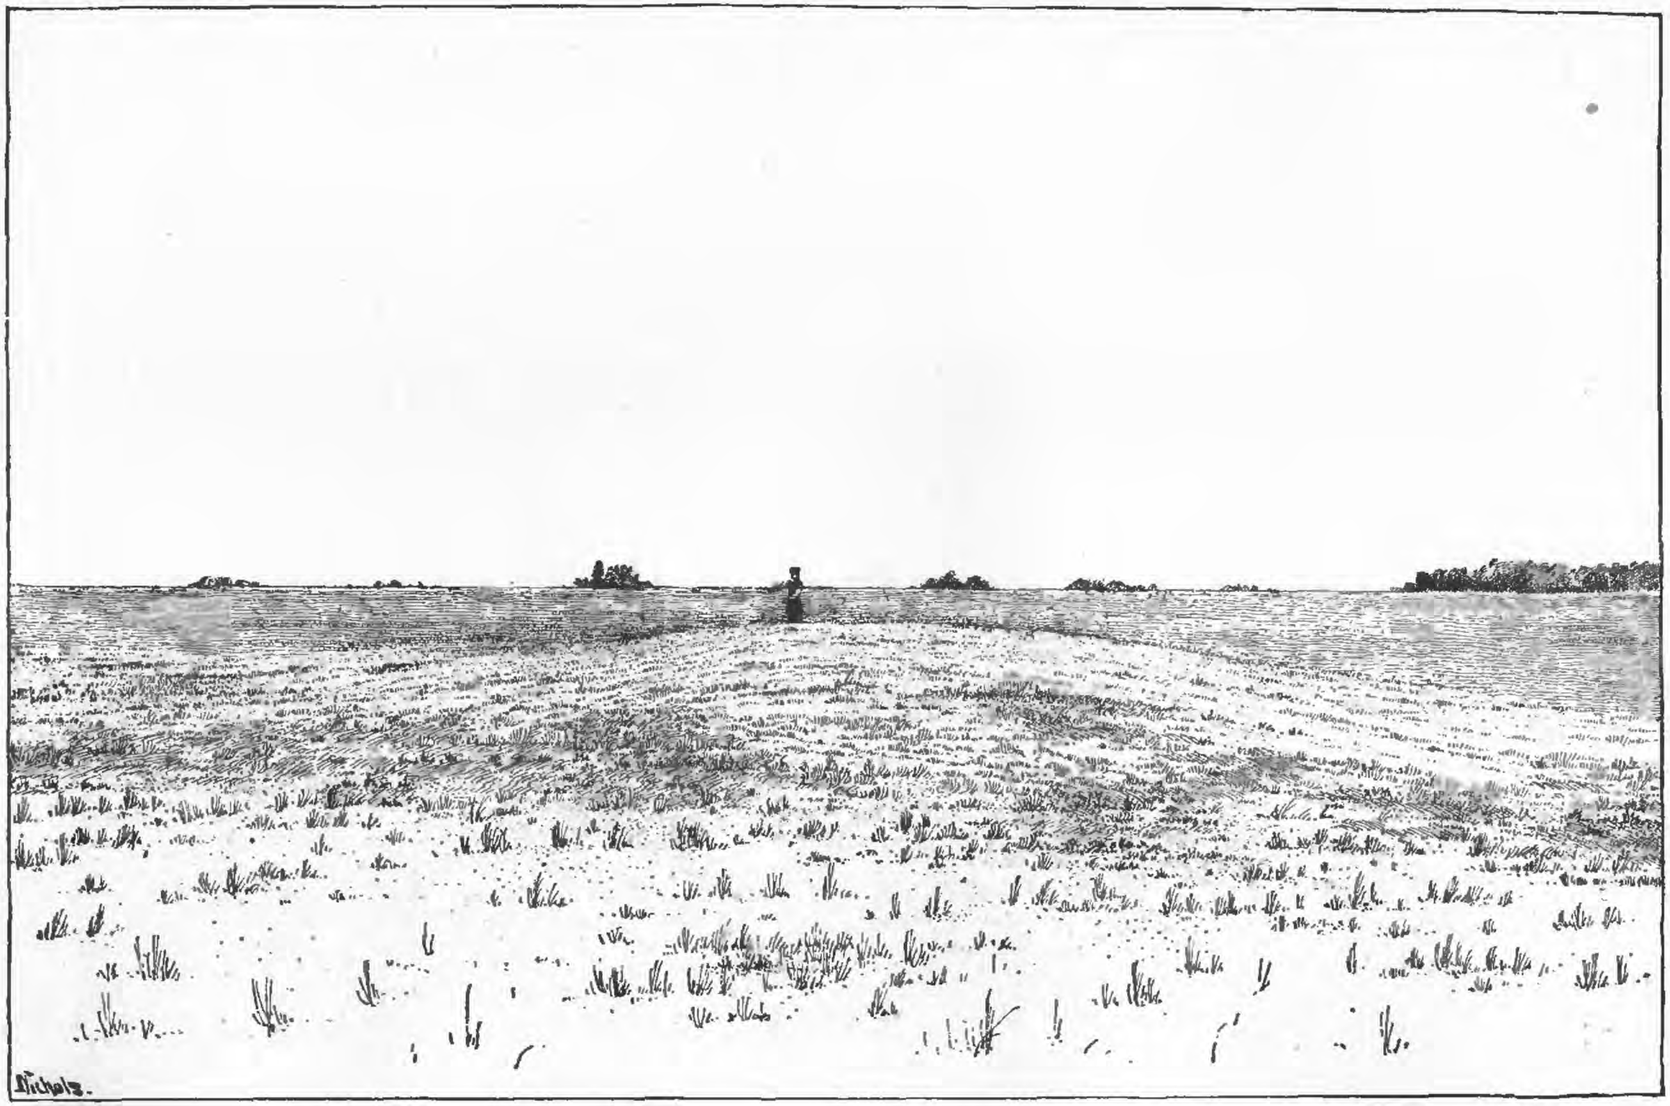
In traversing the region about the Key City the eye of the stranger can not fail to fall upon odd conical mounds and craters of red earth and stones, dotting the slopes and crowning the crests of the hills, sometimes sparsely scattered, but again a dozen to the acre; wherever he turns, these débris heaps—giant ant hills in form—meet his eye, many old and grass-grown, some fresher, and a few scarcely touched by the weather; and he perceives that they are artificial, and represent an enormous expenditure of human energy. When he stops to inquire of the resident he finds that these are the "diggings" of the lead miner, and that the hills are literally honeycombed by his shafts and drifts; for in the early days, when the Mississippi and Dubuque were the ultima thule of the Northwest, the mining craze ran riot here, and despite recent discoveries in the new West it has not yet entirely subsided. The memory of



PRAIRIE LANDSCAPE, WITH NATURAL (?) MOUND IN FOREGROUND.

her prestige as a mining town is yet vivid in Dubuque. The rude wooden stockade and stone heap erected over the grave of the pioneer miner, old Julien Du Buque, have indeed fallen before the vandal; but he has more lasting monuments in the names of the city and its principal avenue of outlet, as well as of a neighboring village; and the far famed Indian beauty who lured him to the lead

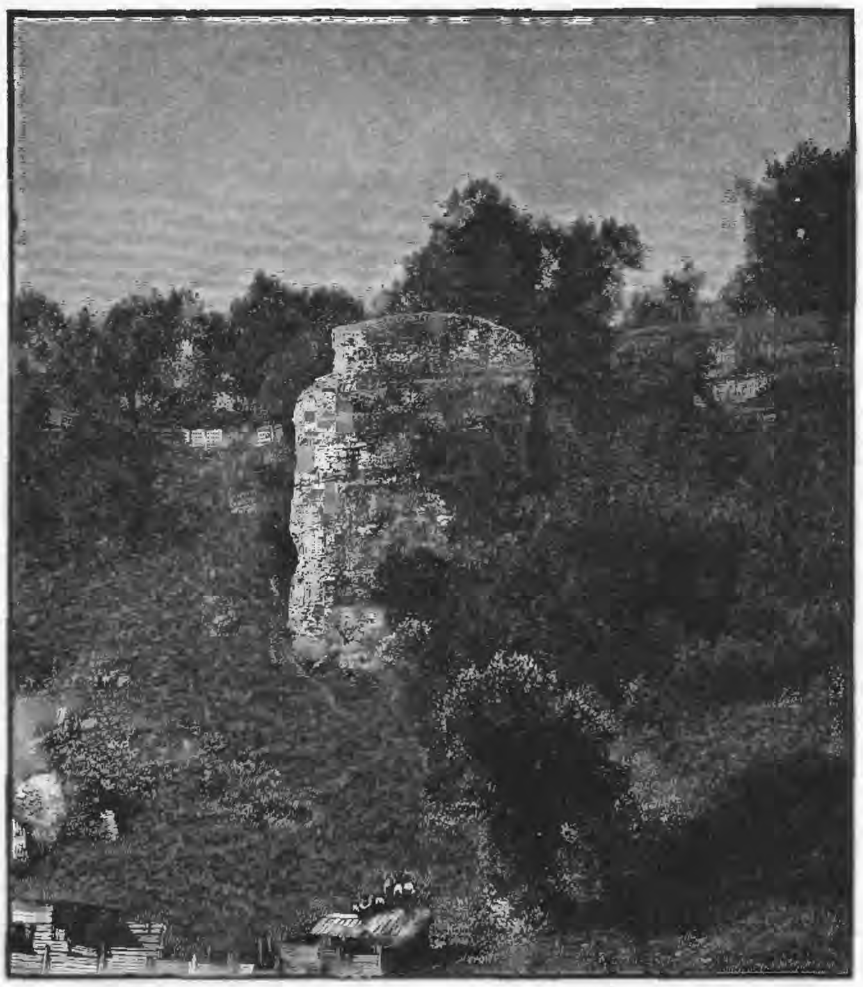


FIG. 6.—A typical erosion form of the Mississippi bluffs about Dubuque.

region is commemorated in the name of a charming lakelet, Peosta, and of another neighboring village. And, just as for decades the ruins of pumps, windlasses, smelting machinery, and other relics of the mining plant will lie along the streams, so for generations the snow-white stalactites and the fantastic stalagmites extracted from the mines will adorn the verandas and lawns of the Dubuquer; and so, too, for centuries the Titanic ant heaps and burrows will mar the smooth crests of the hills.

Wending his way westward. the tourist ascends by a circuitous route the steep slope of the Niagara escarpment, gaining its crest near Centralia, and, turning about, sees before him perhaps the grandest prospect of "The Plains." At his feet lies an embossed

A RECLAIMED SWAMP.

almost upon the verge of the escarpment. Facing westward he surveys the drift lobe stretching west-northwestward to the North Maquoketa, where it is nearly cut off by the loess hills and sand dunes, as well as the belt of hard wood forest, skirting that stream; and

FIG. 7.—Middle latitude prairie landscape—Farley. Drift plain in foreground; loess ridge in right background; with lower swells of loess in left background.

through the vistas of clearing in the forest belt he sees the drift lobe expand quickly into the broad prairie land already traversed a hundred miles northwestward. Turning to the southward, he scans a stretch of loess hills cleft by steep sided but flat bottomed ravines—the hills hidden beneath luxuriant crops and crowned by ample homesteads, and the ravines lined with sward through which many bowlders peep—inclining to the southward to, and again beyond, the North Maquoketa. And if he tarried long and wandered far in this section of the State, he would find that these landscapes, with their mingling of low-lying drift lobes, loess ridges, and broad loess uplands cut through to the drift by wide branching ravine systems, represent fairly considerable portions of Fayette, Clayton, Delaware, Dubuque, Jackson, Jones, Linn, Cedar and Clinton Counties.

Continuing his journey southwestward from Farley, the tourist finds the ravine-cut loess tract extending to the North Maquoketa near the village of Rockville. Here he finds the stream confined in a narrow gorge of Niagara limestone rising in precipitous walls 40 or 50 feet, and then in gentle slopes to the loess-crowned upper bluffs 150 feet above its waters; and on reaching the crest of the farther bluffs he sees before him a landscape, common enough in Northeastern Iowa, but unlike any that he might find beyond the limits of that territory—a relation between river and upland without parallel elsewhere on the globe. Glancing north and south he perceives that the river skirts the flanks of a rock-ribbed, loess-mantled, and forest-covered plateau, generally keeping within it, but occasionally breaking through its crenulate escarpment to the lowland beyond, only to reenter the upland within a mile; to the westward he sees a level, bowlder-dotted prairie (broken by occasional rounded bosses of Ni-

DEVIL'S TOLL GATE NEAR BUENA VISTA.

clining gently away from it to the bases of the Iowa bluffs, a mile distant. He finds the village connected with the higher lands toward the west by a wagon-road causeway a mile long and by lines of trestle work for the railways, with the depot set on stilts, 20 feet above ground in autumn, but just above the floods of spring; and he finds the western bluffs a single mural precipice of heavy bedded Niagara limestone 150 feet high and stretching north and south along the river for 5 miles, with stunted cedars clinging in its crevices and at its base a steep, wooded talus occasionally breached by a spring-formed amphitheater exposing in its sides the blue shales and clays of the Maquoketa. As he ascends to the verge of the bluffs through some narrow defile, he finds them capped with just such earthy brown loess as that developed on the east side of the river; and as he surveys the upland he observes that the same deposit mantles hill and dale everywhere save along erosion lines, and that it bears a scant pebble bed at its base.

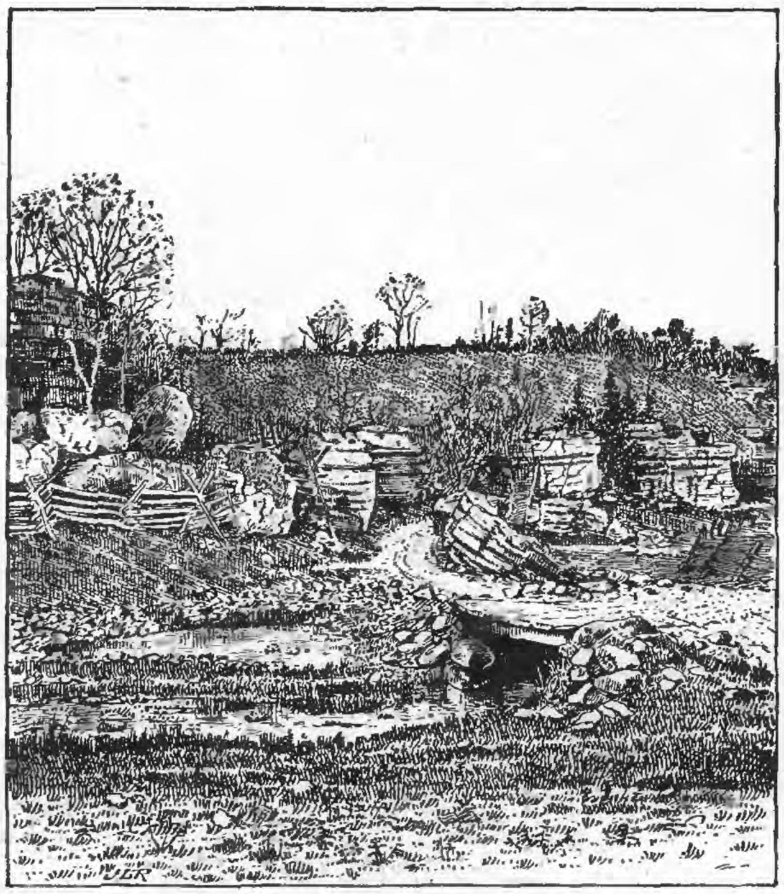

FIG. 8.—Typical landscape of the drift margin, showing rounded summits and precipitous bases of hills.

Four or five miles west-southwest of Sabula the tourist finds himself upon a strongly undulating plain cleft by tortuous ravines, once wooded but now transformed into fairly fertile fields, reminding him of the country west of Dubuque and in eastern Allamakee County, though the relief is lower. But looking west and southwest he notices that the hilltops become more and more smooth and grace-

THE FORMATION OF RIVER TERRACES.

Three theories of terrace formation, all applicable in the regions in which they were developed, have been prominently advocated by American geologists—by the elder Hitchcock,[1] Dana,[2] and Gilbert.[3]

The first of these relates to the terraces developed about drift-lined estuaries and lakes upon land surfaces just emerging from the waters, and upon which the rivers are newly born and the drainage systems are yet in process of growth. In such estuaries and lakes the débris gathered up by the rivers is supposed to accumulate, the coarser materials below, and the farther-transported and hence finer materials in newer strata, all successively laid down in the form of deltas and littoral shoals; and each grade of detritus is supposed to constitute a subaqueous shelf fringing the shores of the lakes and estuaries about the mouths of the rivers. In such a system each terrace is newer than the next higher member, and its materials are finer. The ideal section of such a system is reproduced in Fig. 9.

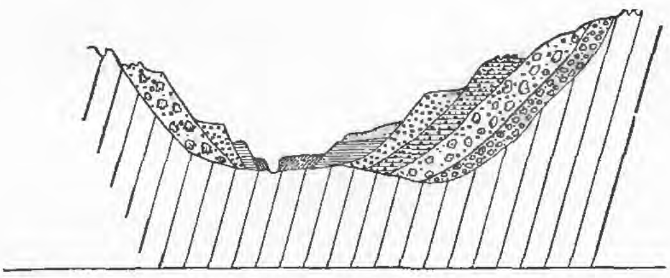

FIG. 9.—Hitchcock's ideal section of river terraces.

This may be called the deposition theory of terrace formation, and the products of the processes contemplated may be called *terraces of deposition*.

In the explanation of the terraces of the second class, there is postulated an ancient valley, completely clogged with sediments, and subsequently partially cleared by a secularly constant or progressively shrinking stream during either paroxysmal or uniform continental elevation, which may have been either uniform or more rapid inland, the excavation being effected by the gradual lowering of the flood plain, and the terraces constituting remnants of successive flood plains. In such a system of terraces each bench is indeed newer than the next higher member, but its materials are older, since each is a simple outcrop of partially eroded beds laid down in the natural order. All of the terraces are incomplete, and the degree of comminution of the deposits of each is determined solely by the condi-

[1] Illustrations of Surface Geology, Smith. Contr. to Knowledge, No. 90, vol. 9, p. 5 et seq., Pl. XII, Fig. 1.

Sci. 3d Ser., vol. 1, 1871, pp. 1-125; Ibid., vol. 2, p. 144; Ibid., vol. 5, 1873, p. 198, note, and 208-211; Ibid., vol. 10, 1875, pp. 409-438, 503-508; Manual of Geology, 1875, pp. 558-559, 644, fig. 944; and elsewhere.

[3] Geology of the Henry Mountains, 1877, p. 132.

tions of antecedent deposition and not at all by the agencies or conditions of the terracing per se. The ideal section of such a system of terraces is shown in Fig. 10.

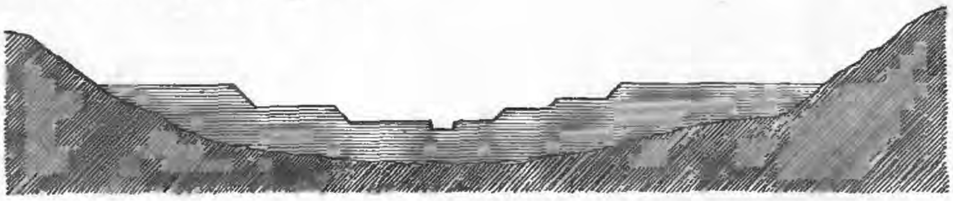

FIG. 10.—Dana's ideal section of river terraces.

Terraces of this character may be designated *terraces of reexcavation.*

In the production of the terraces of the third class there is required a water way (with its flood plain) lying not upon a sheet of drift, nor upon the débris clogging an ancient channel, but upon the normal terrane of the region; and the altitude is required to be such that the surface is progressively lowered by secular degradation, yet so slowly that a considerable part of the energy of the stream is expended in lateral corrasion. The remnants of successively parallel flood plains, perhaps covered with unconsolidated débris, constitute the terraces, which are thus "carved out and not built up." The ideal section through a system of terraces of this kind is reproduced in Fig. 11.

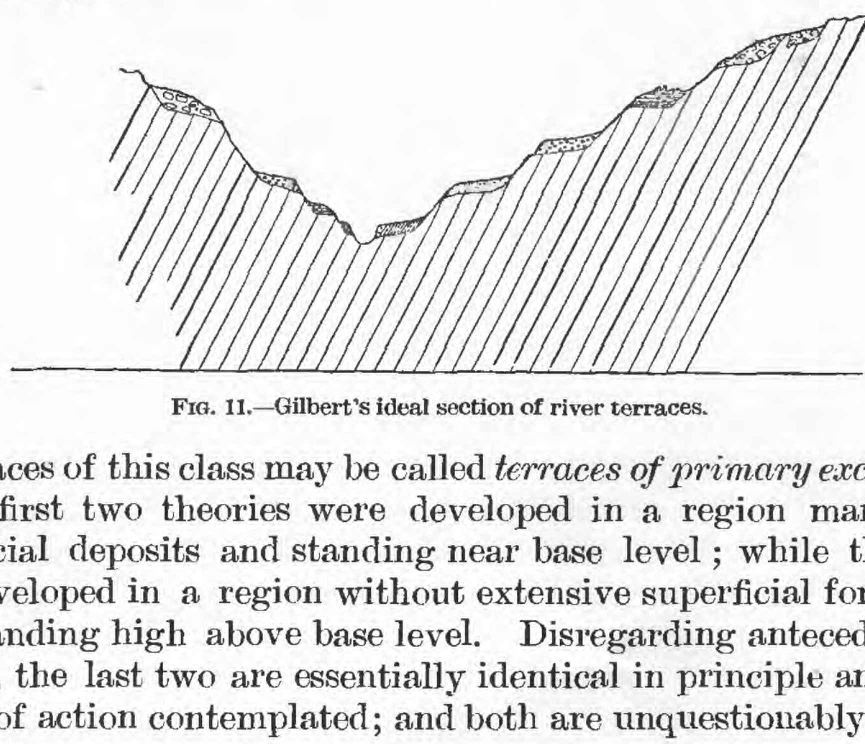

FIG. 11.—Gilbert's ideal section of river terraces.

Terraces of this class may be called *terraces of primary excavation.*

The first two theories were developed in a region mantled by superficial deposits and standing near base level; while the third was developed in a region without extensive superficial formations and standing high above base level. Disregarding antecedent conditions, the last two are essentially identical in principle and in the modes of action contemplated; and both are unquestionably valid.

Now, the river terraces of Northeastern Iowa may be thrown into two classes defined by structural characteristics: (1) In the larger valleys and about the confluences of the principal tributaries with the Mississippi there are extensive terraces, little affected by erosion, whose scarps are steep and built of coarser material than the bodies

(5) Diminishing stream volume with low land.

In this case lateral corrasion will remain predominant, and while the diminished energy and contracted width of the stream will conjointly reduce the probability of degradation of the strath remnants, this disposition will be antagonized and perhaps more than counterbalanced by the cumulatively increased wandering resulting from loss of velocity going with the diminution of volume; and the low terraces possibly formed during given cycles will be buried beneath the accumulating detritus of the enfeebled stream during succeeding cycles, and the channel will be clogged and a "drowned river" formed.

(6) Diminishing stream volume with high or rising land.

In this case the element antagonistic to the formation of terraces will be eliminated if the declivity remains, such that the stream continues to attack the bed-rock as each strath is channeled. Lateral corrasion will be reduced by contraction of the stream and concomitant loss of absolute energy, while the corrasive energy will be relatively but slightly augmented by the increase of friction and of differential flow going with reduction in volume; and if the terrane is such that vertical corrasion remains far in excess of the concurrent recession of the cañon walls through sapping, the strath remnants formed and the rock surface carved out during successive

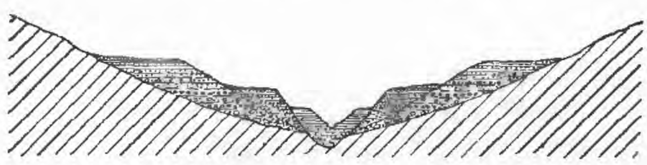

FIG. 13.—An ideal section of river terraces.

cycles in the vertical and horizontal wanderings of the stream may exceed in width and continuity, if not in number and height, those developed during any other case.

The last case is that of the rivers of Northeastern Iowa. As proved by a large body of cumulative evidence, the land stood low when burdened by the weight of the Pleistocene ice sheet, while with the recession of the ice the swollen rivers shrank and the land rose toward its present altitude; and it was concurrently with the shrinking of the streams and the rising of the land that the older terraces of the Oneota, the Turkey, the Maquoketa, the Wapsipinnicon, and several other rivers were formed. In structure these terraces are sheets of stratified débris, finer above and coarser below, and finer in the newer (and inner) terraces than in the older, slightly inclined, as to both surface and structure lines, in the direction of stream flow. A section which is at the same time a generalization of observation upon the later Pleistocene terraces of Northeastern Iowa and

CONTACT BETWEEN DEVONIAN AND SILURIAN LIMESTONES, FAYETTE.

Conformity.

2. Variable beds of rapidly weathering limestone, somewhat argillaceous, and either laminated or brecciated, the lamination and brecciation being best displayed in alternating layers. The laminated portions are poorly fossiliferous.................. 15′ ±

No marked unconformity.

3. Argillaceous limestone, extensively brecciated. The fragments are finely laminated, as are the few nonbrecciated portions. Rare fossils alike in fragments and matrix .... 12′ ±

Apparent unconformity.

4. Heterogeneous whitish limestone, generally argillaceous and laminated, sometimes magnesian and massive or heavy bedded, such portions being commonly lenticular with inclosing laminæ; unfossiliferous........... 10′ ±

NATURAL EXPOSURE.

1. Regularly bedded and uniformly jointed compact subcrystalline limestone with occasional fossils (quarried near by)................... 12′ ±

Contact not exposed.

2. Slope interrupted by ledges of much weathered limestone, yielding no fossils. The limestone is argillaceous, but its structure does not appear in the imperfect exposures.... 15′ or 18′

Contact not well exposed.

3. Much weathered argillaceous limestone forming a steep slope, inconspicuously brecciated, the fragments and at least part of the matrix being laminated..................... 10′ or 12′

Contact not exposed.

4. Thin bedded or laminated argillaceous limestone, exhibiting moderately regular bedding below, but becoming shaly above; unfossiliferous above, poorly fossiliferous below... 12′ or 14′

Unconformity?

5. Heterogeneous, silty and cherty brown magnesian limestone in a single ledge.......................... 3′

Conformity?

6. Heavily bedded, light brown magnesian limestone with fossil casts..... 12′ ±

Counties, and have been noted as drift bowlders in all of these and in some other counties of Northeastern Iowa. The brecciation appears to be practically coextensive with the Cedar Valley terrane.

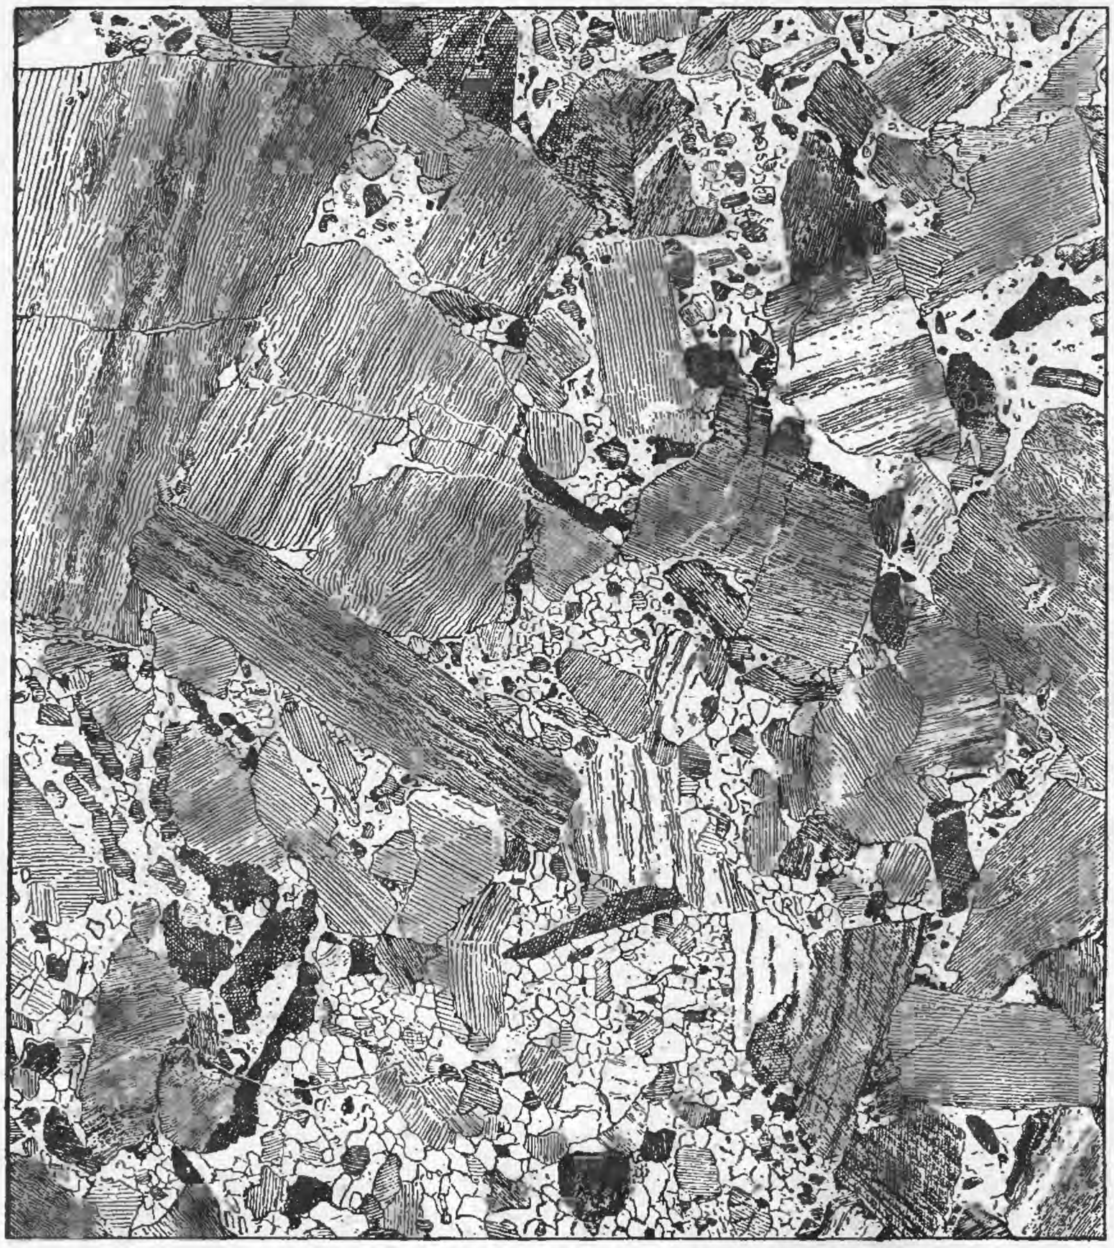

FIG. 15.—Devonian breccia. Natural size.

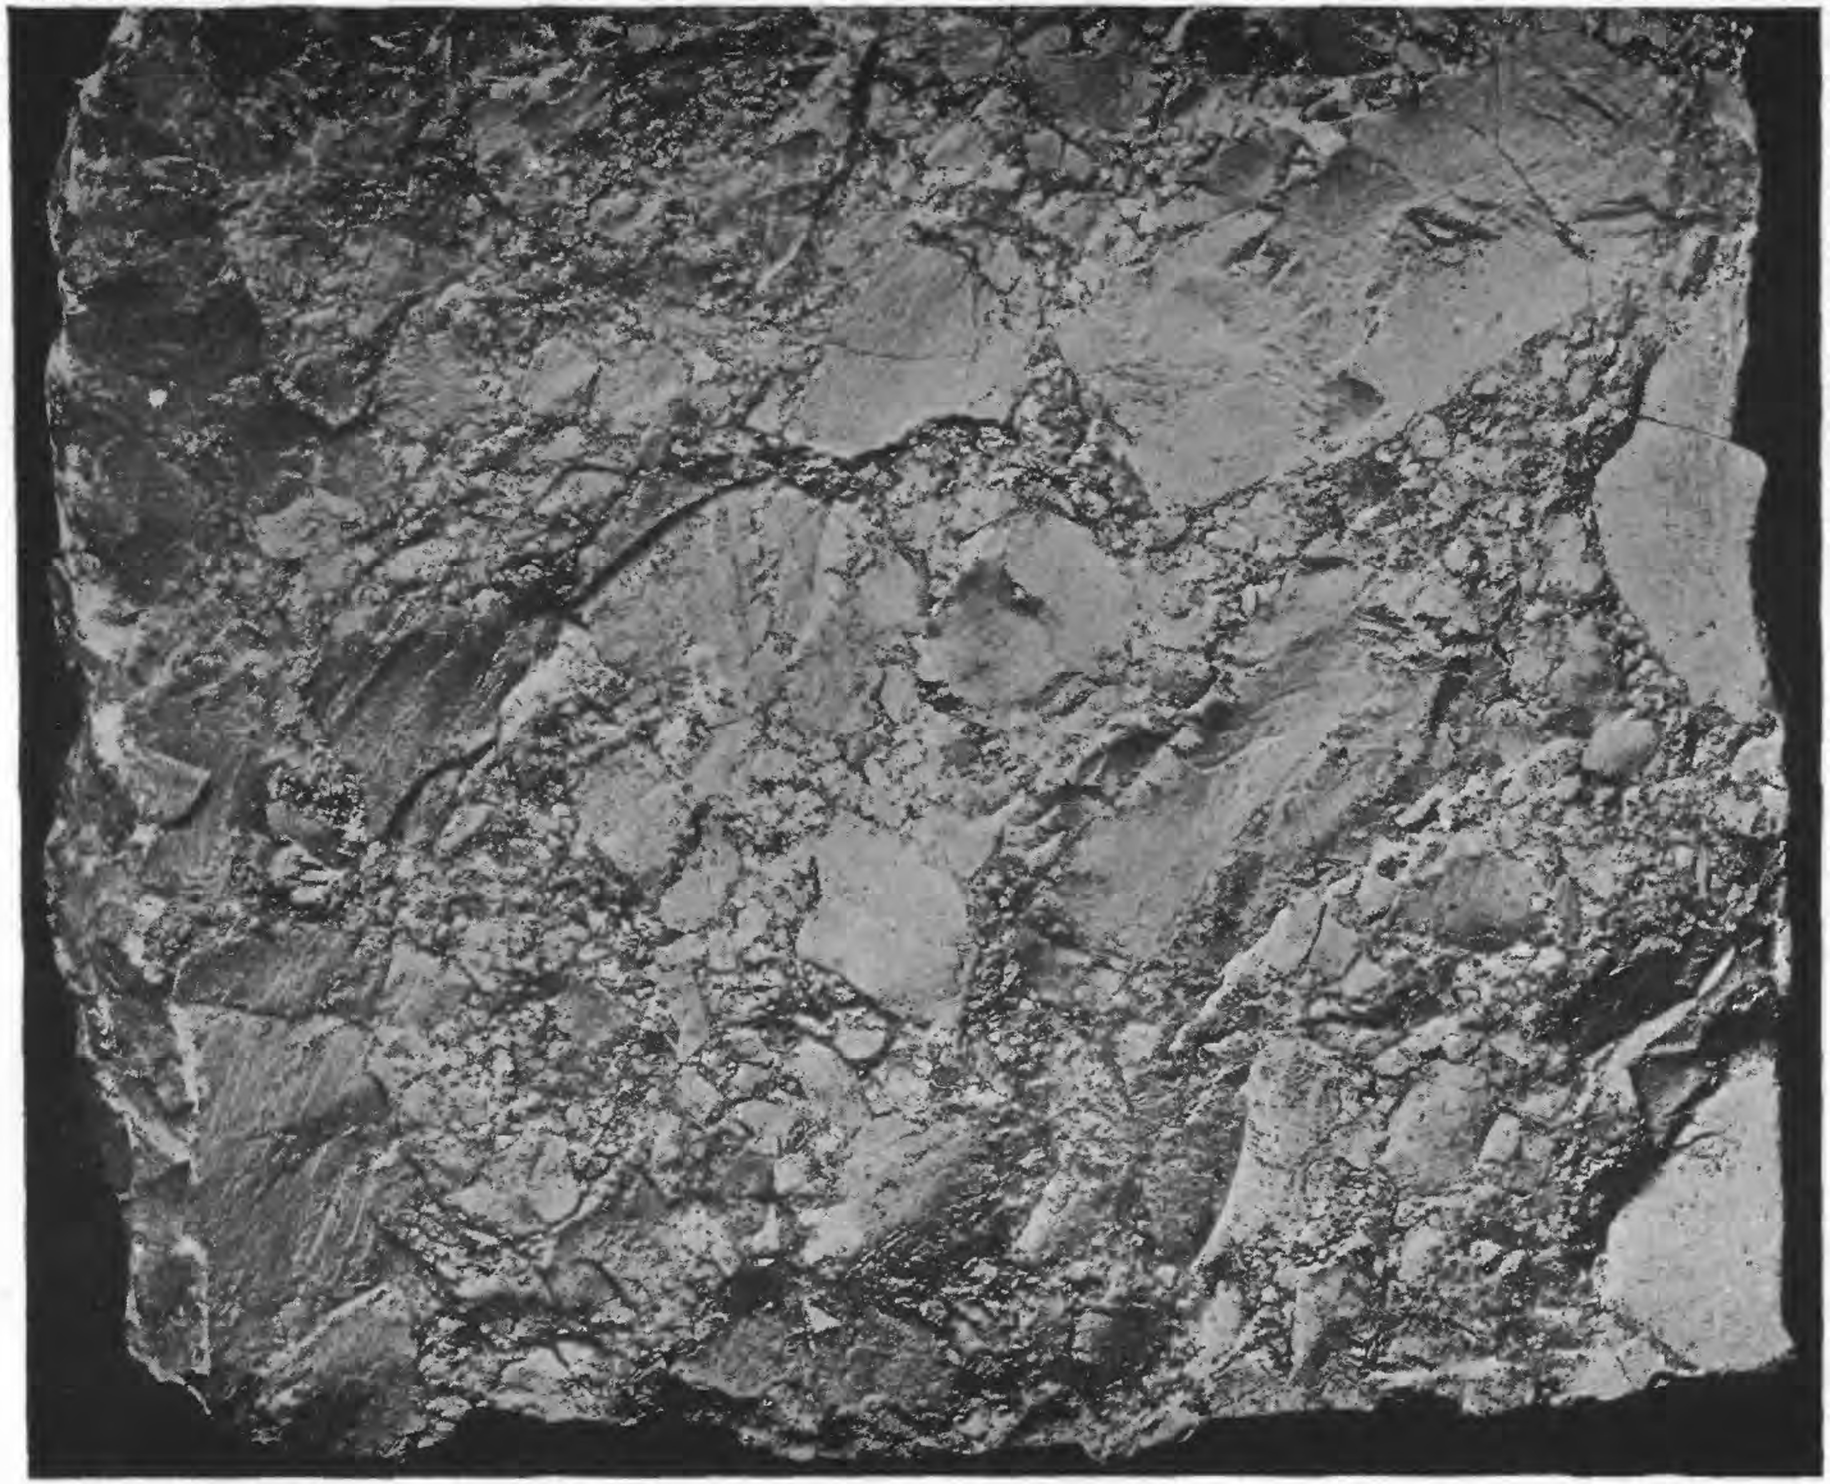
The Independence Shale.—This formation, named by Calvin in 1878,[1] is overlapped by the Cedar Valley limestone and probably has no natural outcrop. It is a dark carbonaceous shale, about 25 feet in maximum known thickness, characterized by an abundant and distinctive fauna closely allied to that of the Hackberry shale. It was first found in a shaft at Independence, and has since been brought to light at several localities in the Wapsipinnicon and Cedar valleys, notably at Marion and a few miles east of Toddville. Its

[1] Am. Jour. Sci., 3d ser., vol. 15, p. 460; and elsewhere.



DEVONIAN BRECCIA.

relation to the Cedar Valley limestones above and to the Niagara below are shown in the accompanying section, Fig. 17.

As a whole the Devonian rock-mass has a gentle southwestward inclination and thickens southwestward. Its terrane narrows and its mass apparently thins materially to the southeastward, yet its thickness at the Mississippi River, in Scott County, probably exceeds 400 feet;[1] and its thickness in the northern part of the terrane may

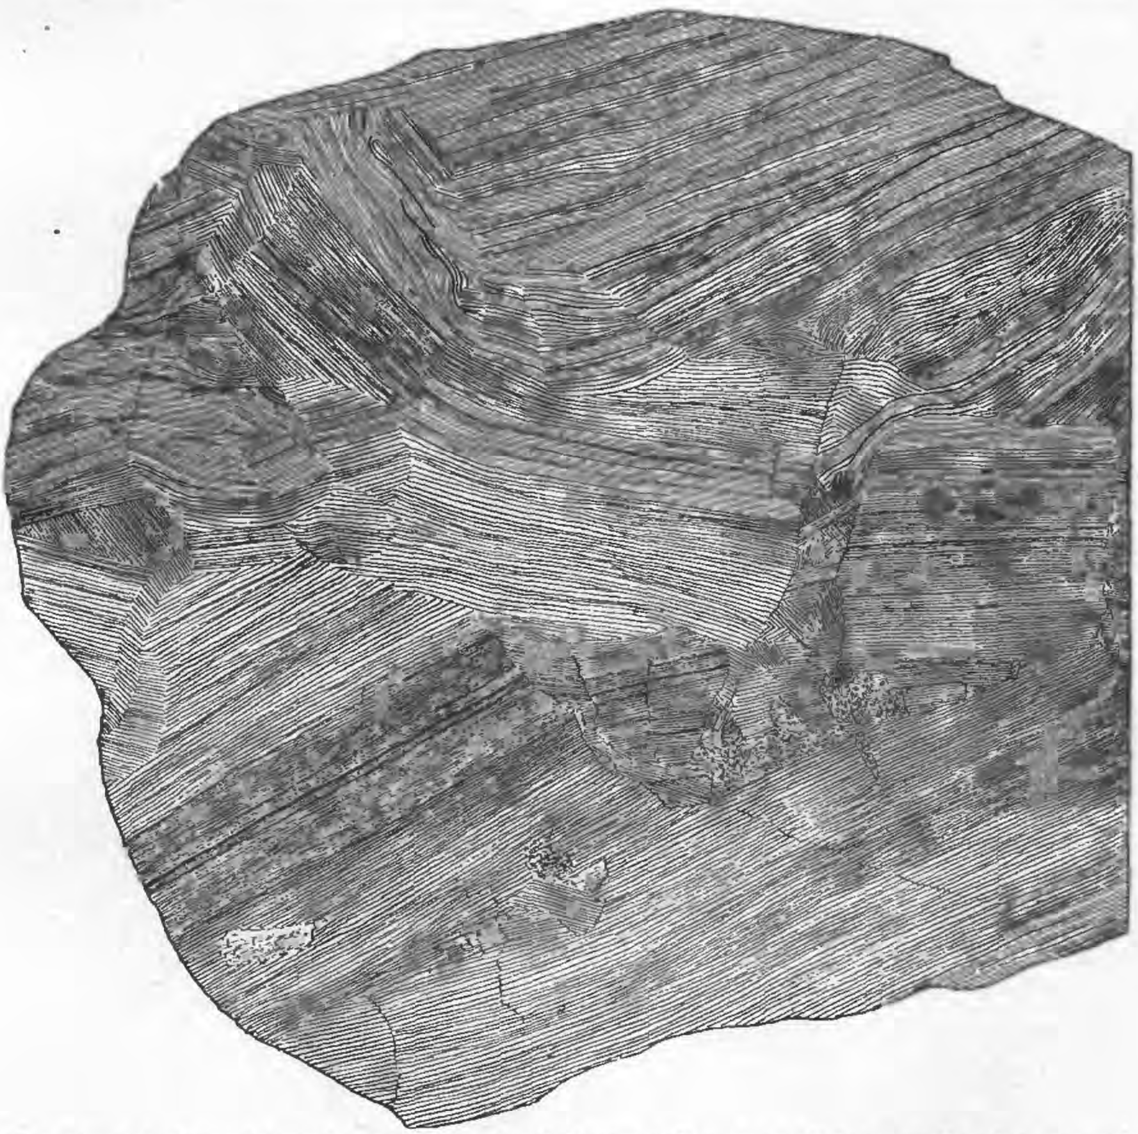


FIG. 16.—Relations of breccia to non-brecciated Devonian limestone, slightly smaller than natural size.

be roughly estimated at 300 to 600 feet. Neither the Hackberry shales nor the Independence shales are known in the south (unless the former are represented by the yellow sandstones at Buffalo); yet the great mass of the formation in the north consists of more or less pure limestones with some dolomites (the shales being relatively thin), while to the southward the limestones are argillaceous, shale-parted, and sometimes sandy, with some clean sandstones. So the mass as

[1] According to Tiffany, there are 390 feet of Corniferous and 80 feet of Lower Helderberg ("Le Claire") at Davenport. Am. Geol., 1889, vol. 3, p. 117.

a whole is predominantly calcareous in the north and largely argillaceous and arenaceous in the south—the distribution of mechanical and chemico-mechanical materials respectively agreeing with that exhibited by the Subcarboniferous formations.

The greater part of the Devonian strata are made up either of finely comminuted sediments or precipitates such as are commonly regarded as deep-water deposits. Yet the northeastern shore of the Devonian sea could not have been far away. No outliers like the conspicuous "mounds" of Niagara limestone occur beyond the principal terrane; none of its silicified fossils or rare cherty nodules have ever been found among the residuary materials of the driftless area, as are the residua of the Devonian and Carboniferous formations of central Kentucky upon the lower Silurian floor; there is not throughout the Silurian terranes of Iowa, Illinois, and Wisconsin, either an outlying Devonian knob or a residuary pebble, so far as known; and

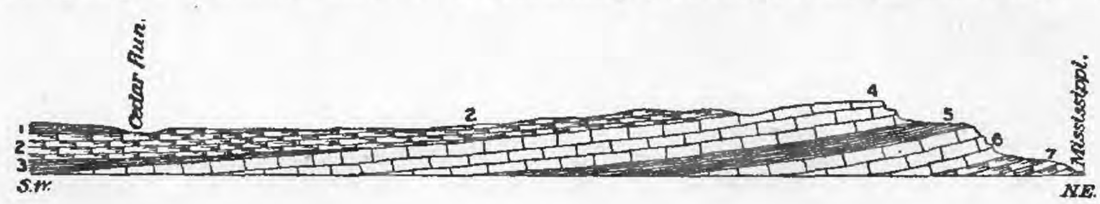

FIG. 17.—General stratigraphy of the Devonian and Silurian in Northeastern Iowa: (1) Hackberry shale; (2) Cedar Valley limestone; (3) Independence shale; (4) Niagara limestone; 5) Maquoketa shale; (6) Galena limestone; (7) Trenton limestone.

still more decisively, there is not a hill nor a valley in the region which exhibits form or relation certainly inherited from any newer terrane than the Niagara limestone. The greatly eroded Niagara has left its impress on every hill and valley of the region, but no topographic feature can be ascribed to the Devonian. Chamberlin has indeed hypothetically located the Devonian shore line near the present course of the Mississippi between Iowa and Wisconsin;[1] and while there are reasons for believing that the course of the Mississippi was not finally chosen until long after the post-Devonian elevation, it is probable that this location is approximately right.

From the general section forming Fig. 17, it will be seen that the southwestward inclination of the Devonian strata is less than that of the Niagara; that the lower division of the Devonian rock-mass laps but a little way upon the Niagara, and falls short of the deeper water limestones; that there is a hiatus between the Independence shale and the Niagara limestone, probably representing in part or in whole the Corniferous, the Schoharie, the Cauda Galli, the Oriskany sandstone, the Lower Helderberg, and the Salina series of New York, whose equivalents may exist (perhaps greatly attenuated) beneath the Independence shale farther to the southwestward; that the successive beds of the Cedar Valley limestone fail below, and thus that the Devonian and Silurian rocks are unconformable in a large way, despite the close accord in dip at the points of contact; and it will

[1] Geology of Wisconsin, 1883, vol. 1, pl. 3, pp. 202, 252, 253.

Niagara, and the steep-sided cañons of the Mississippi and its tributaries are carved within it; but in Winneshiek County it has little topographic expression.

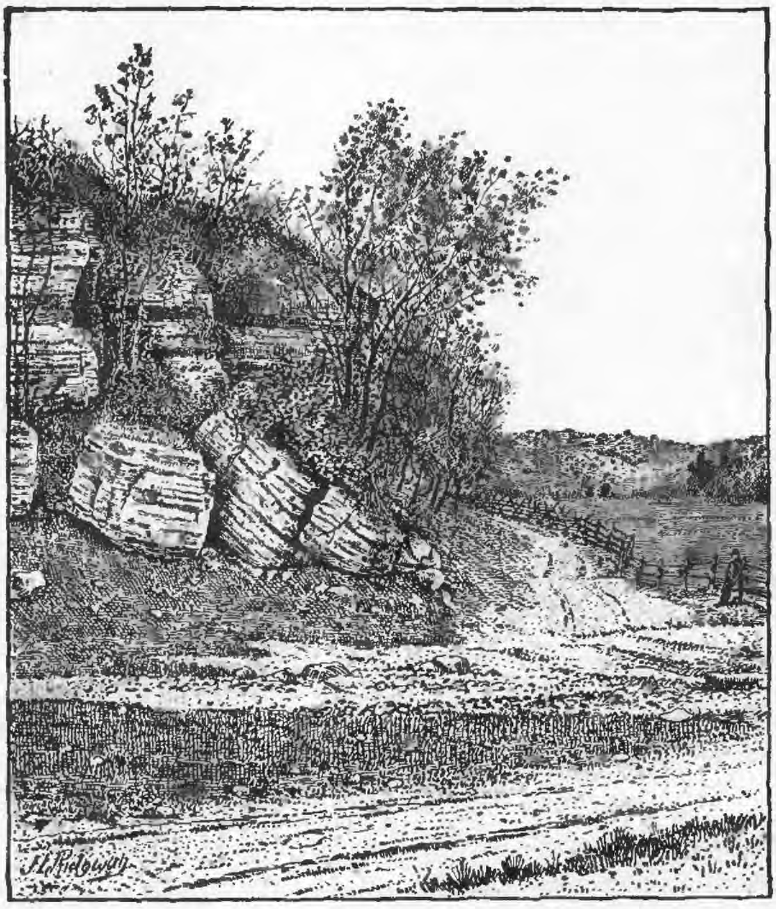

FIG. 18.—Truncated bluff of Galena limestone at Eagle Point (near Dubuque).

TYPICAL CLIFFS OF ONEOTA LIMESTONE, IOWA BLUFF FROM THE EAST.

different part of the outcrops and also in the different formations); but these inconsistencies are inconsiderable, and the mean inclination is is not far from S. 45° W.

This general inclination of the strata was determined by the conditions of growth of the nascent continent, and forms an intelligible record of these conditions and of the mode of growth.

THE IRREGULAR DEFORMATIONS.

Throughout its terrane the Cedar Valley strata are frequently flexed into low anticlinals, synclinals, and monoclinals. The dips range from almost nothing to 5° or 6°, in some case 10°, and rarely 15°. The axes of inclination are various, but generally coincide approximately with the strike. Inconsiderable faults are sometimes connected with these flexures. An example of the flexing with a fault associated is shown in Fig. 20.

The folds are every where of small amplitude, both vertical and horizontal. The anticlinals and synclinals are seldom more than 50 to 100 yards across, and a complete monoclinal flexure may be confined within 10 yards; and the vertical deformation seldom exceeds 10 feet. Yet these slight irregularities of structure are so widely distributed that, in the numberless exposures occurring in nearly all parts of the terrane, the strata are more frequently distorted than in the sensibly horizontal normal attitude. Whether these irregular deformations of the strata affect the formations below and formerly affected those above the rock-mass of which they are characteristic is uncertain; but certainly such deformations are never seen in the older Niagara limestone, nor are they at all common in the newer Subcarboniferous strata within Northeastern Iowa; and it is noteworthy that in some cases the distortion is evidently confined to a limited thickness of strata.

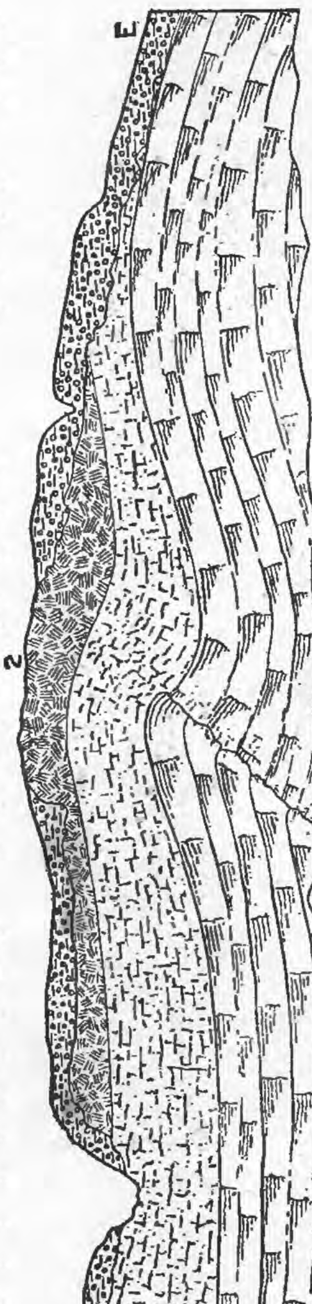

FIG. 20.—Fault and flexure in Devonian strata at Roberts's Ferry, Johnson County: (1) Glacial drift; (2) Brecciated limestone; (3) Irregularly bedded argillaceous limestone; (4) "State House quarry" rock—heavy bedded limestone made up largely of comminuted molluscan shells. Height of exposure 16 feet.

It has already been stated that throughout much of its terrane

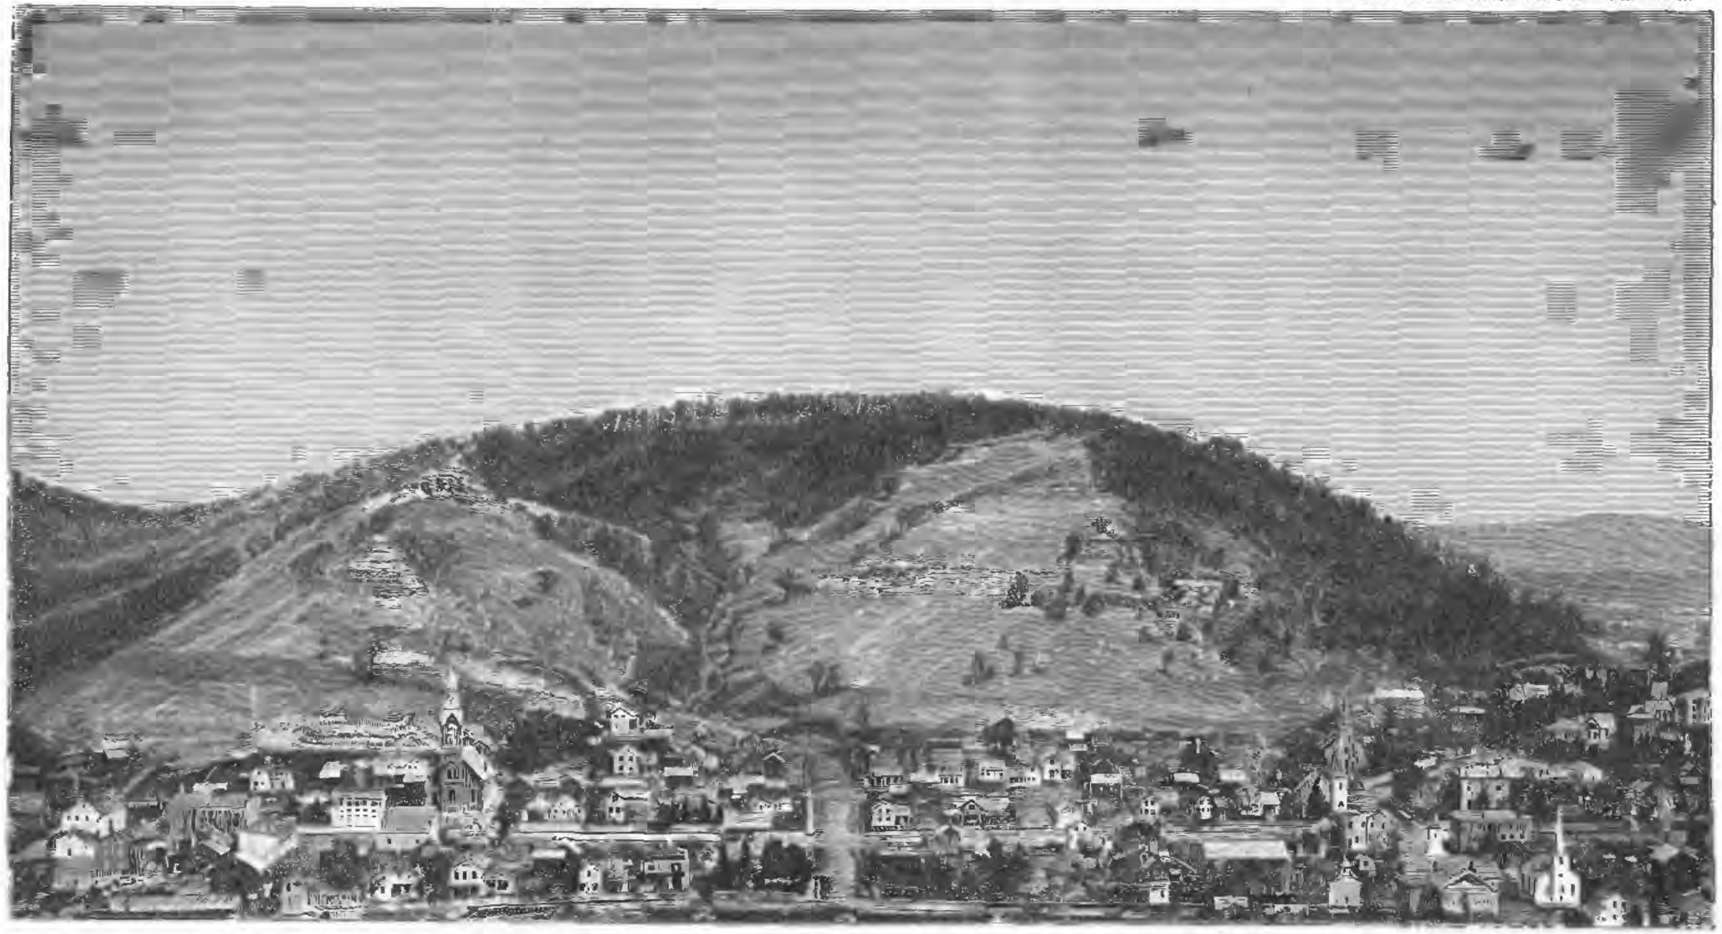
GORGE OF THE MISSISSIPPI ABOVE LANSING.

line of isolated buttes, now round-topped, again crowned with a fillet of precipitous rock, and always forest clad on the north slopes but grassed toward the sun. Yet viewed from one of their own summits, the sentry-like bluffs are seen not as buttes but as salients —the extremities of divides stretching and rising far into the interior of the strongly undulating plain forming the driftless area. At the same time, too, the interspaces are found to be but broad reentrants or amphitheaters, bounded by the converging sides of the salients, themselves sculptured into lines of bluffs as high and steep as those overlooking the river channel. Yet now and then there may be seen mural precipices nearly as steep as the Palisades of the Hudson, and continuous perhaps for two, three, or even five miles.

FIG. 21.—Truncated salients. Below Lansing.

The tourist who views the cañon walls of the upper Mississippi from the deck of one of the packets plying between St. Louis and St. Paul can not fail to note two distinct aspects in the bluff faces. The prevailing cañon wall is a line of gracefully rounded bluffs whose slopes are either continuous from base to summit or broken by one or more sensibly horizontal ledges of hard rock cropping out now in narrow precipices and again in nearly continuous vertical faces 10 to 100 feet high. In Allamakee County the principal outcropping ledge by which the bluff faces are broken is the Oneota dolomite. In the northern part of the county and in the lower bluffs, the ledge simply crowns the eminences and converts their summits into mesas; but in the southern part of the county and in the higher bluffs the limestone face skirts the palisades, winds in and out about the reentrants and around the salients composing the cañon-wall, and in the reentrants often forms cascades over which brooklets leap 100 feet before they are dashed into spray upon the rugged talus below; and the steep slopes above and below the vertical face of the ledge are of débris formed from its disintegration and from the disintegration of the rocks of the summit, and represent the angle of stability of such materials. In the northern part of Clayton County two conspicuous ledges score the



BUTTE-LIKE BLUFF, LANSING.

face and interrupt the slopes of the rounded river bluffs, the lower representing the Oneota dolomite and the upper the Trenton limestone; but toward the mouth of Turkey River the lower ledge disappears

FIG. 22.—Cañon wall of Mississippi, opposite Buena Vista. Rounded bluffs of Galena limestone with precipitous faces of Trenton limestone half concealed by flood plain forests.

beneath the Mississippi alluvium, and thence southward there is a single cliff line diminishing in altitude to the southern end of the cañon at the lower extremity of the driftless area. Moreover, while

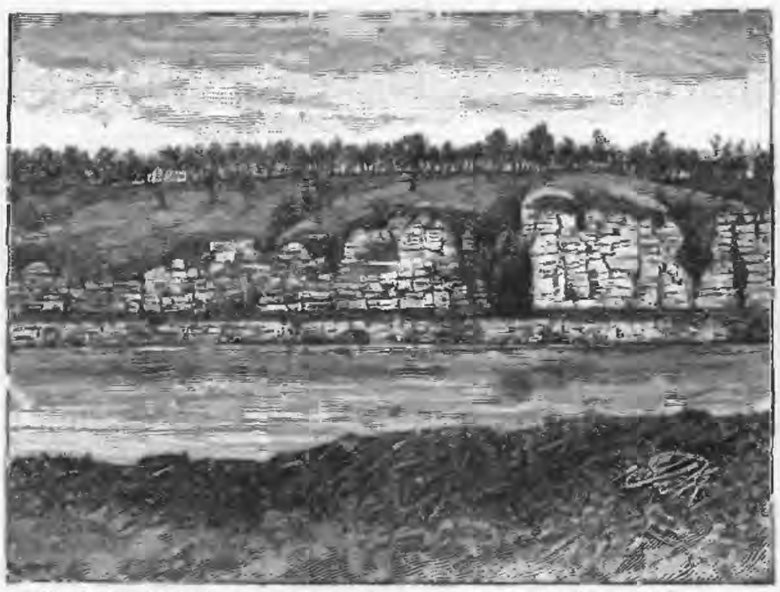


FIG. 23.—Cañon wall of Mississippi, opposite Dubuque. Mural precipice of Galena limestone with the prevailing rounded uplands of the driftless area rising from the cliff crest.

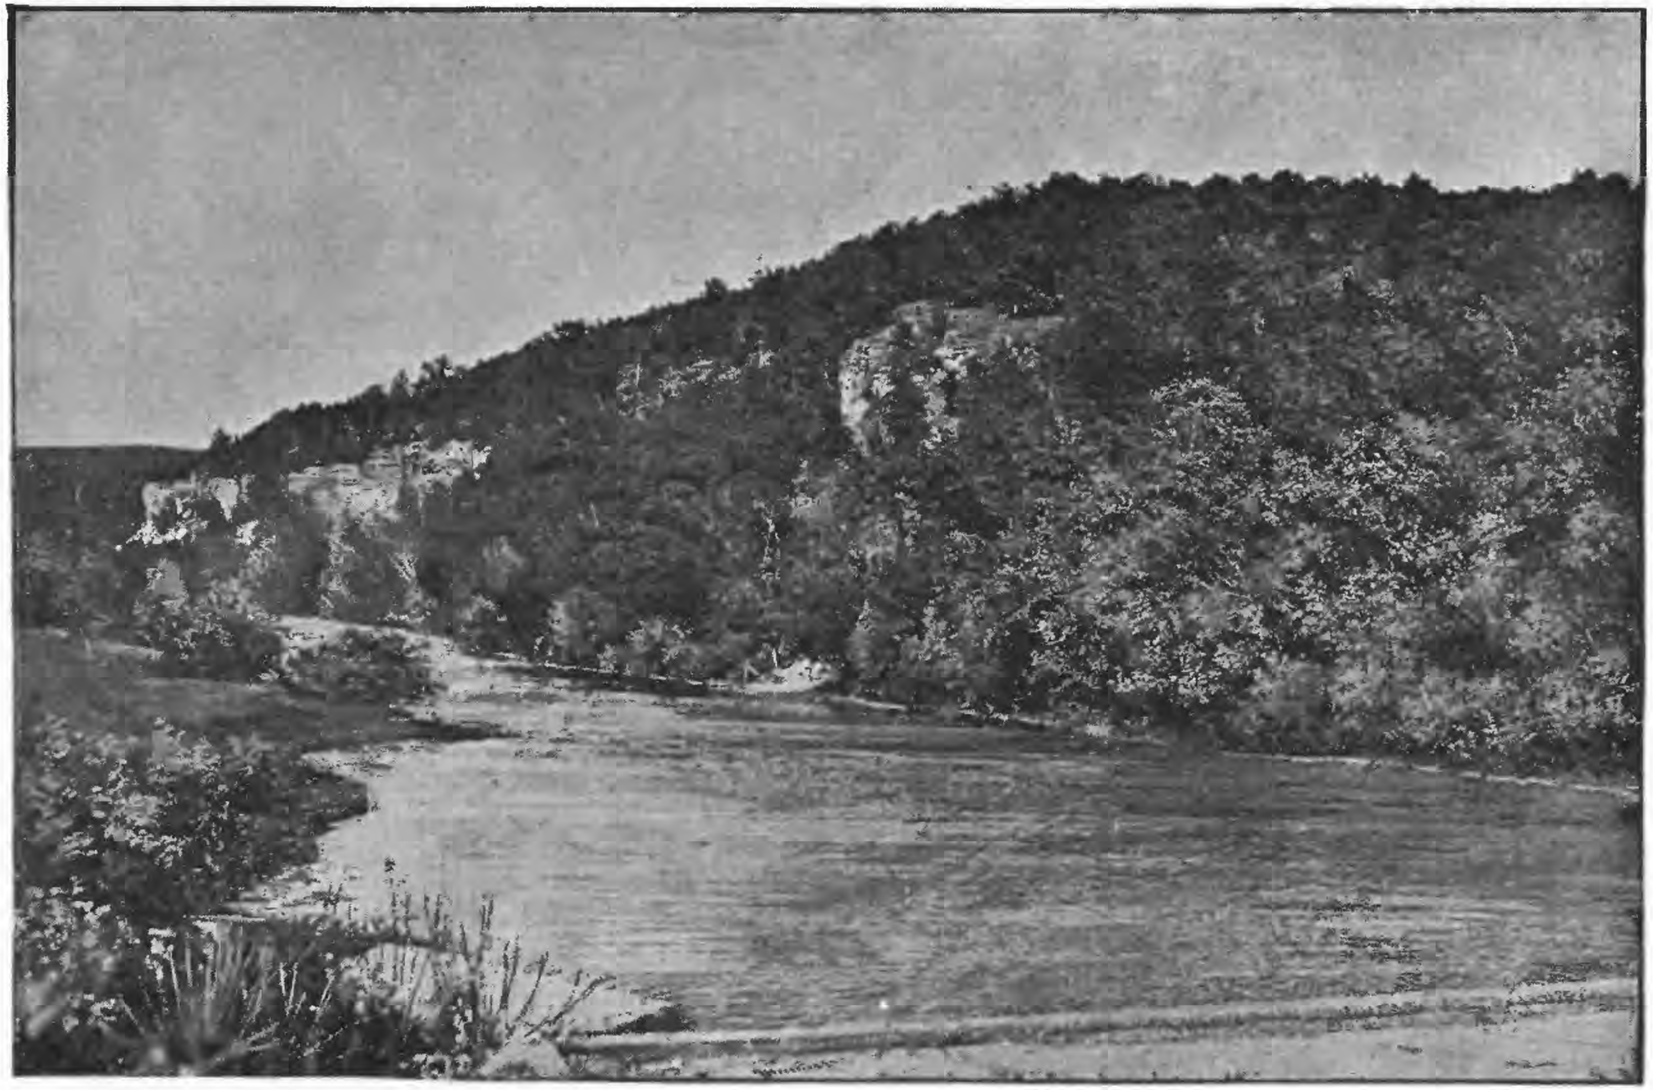
the gracefully rounded contours of the first aspect of bluff faces continue, and while the eminences diminish in height, the cañon walls are steeper and more rugged south of the Turkey than toward the Oneota; for the Trenton and Galena limestones are more homogeneous and more obdurate than the alternating calcareous and arenaceous beds of the subjacent formations so well developed in the extreme northeastern corner of the State. These rounded bluffs have been subjected to erosion for a long period; they are mature forms.

The less common form of bluff bounding the cañon of the upper Mississippi is a precipitous cliff or mural face extending from summit to base of the cañon wall, perhaps cumbered by a talus below, and exposing the more friable as well as the more obdurate ledges from the St. Peter above to the Potsdam below in a buttressed wall so steep that no shrub finds place for its rootlets in the ledges of solid rock, and no less hardy tree than the dwarfed but vigorous

FIG. 24.—Typical truncated bluffs. Near Dubuque. Illustrating topographic youth in the cliffs, topographic maturity in the gentler slopes.

cedar takes root in the crevices and crannies between them. Generally these precipitous cliffs pass suddenly at their extremities into the more characteristic bluffs of gentler slopes; and generally they are found at the extremities of salients which elsewhere take the prevailing rounded contours. Sometimes, indeed, a completely



PLYMOUTH ROCK, ONEOTA RIVER.

isolated butte of the soft contoured aspect appears to have been cleft in twain, leaving a vertical face overlooking the area where once stood half its base. The precipitous bluffs are young.

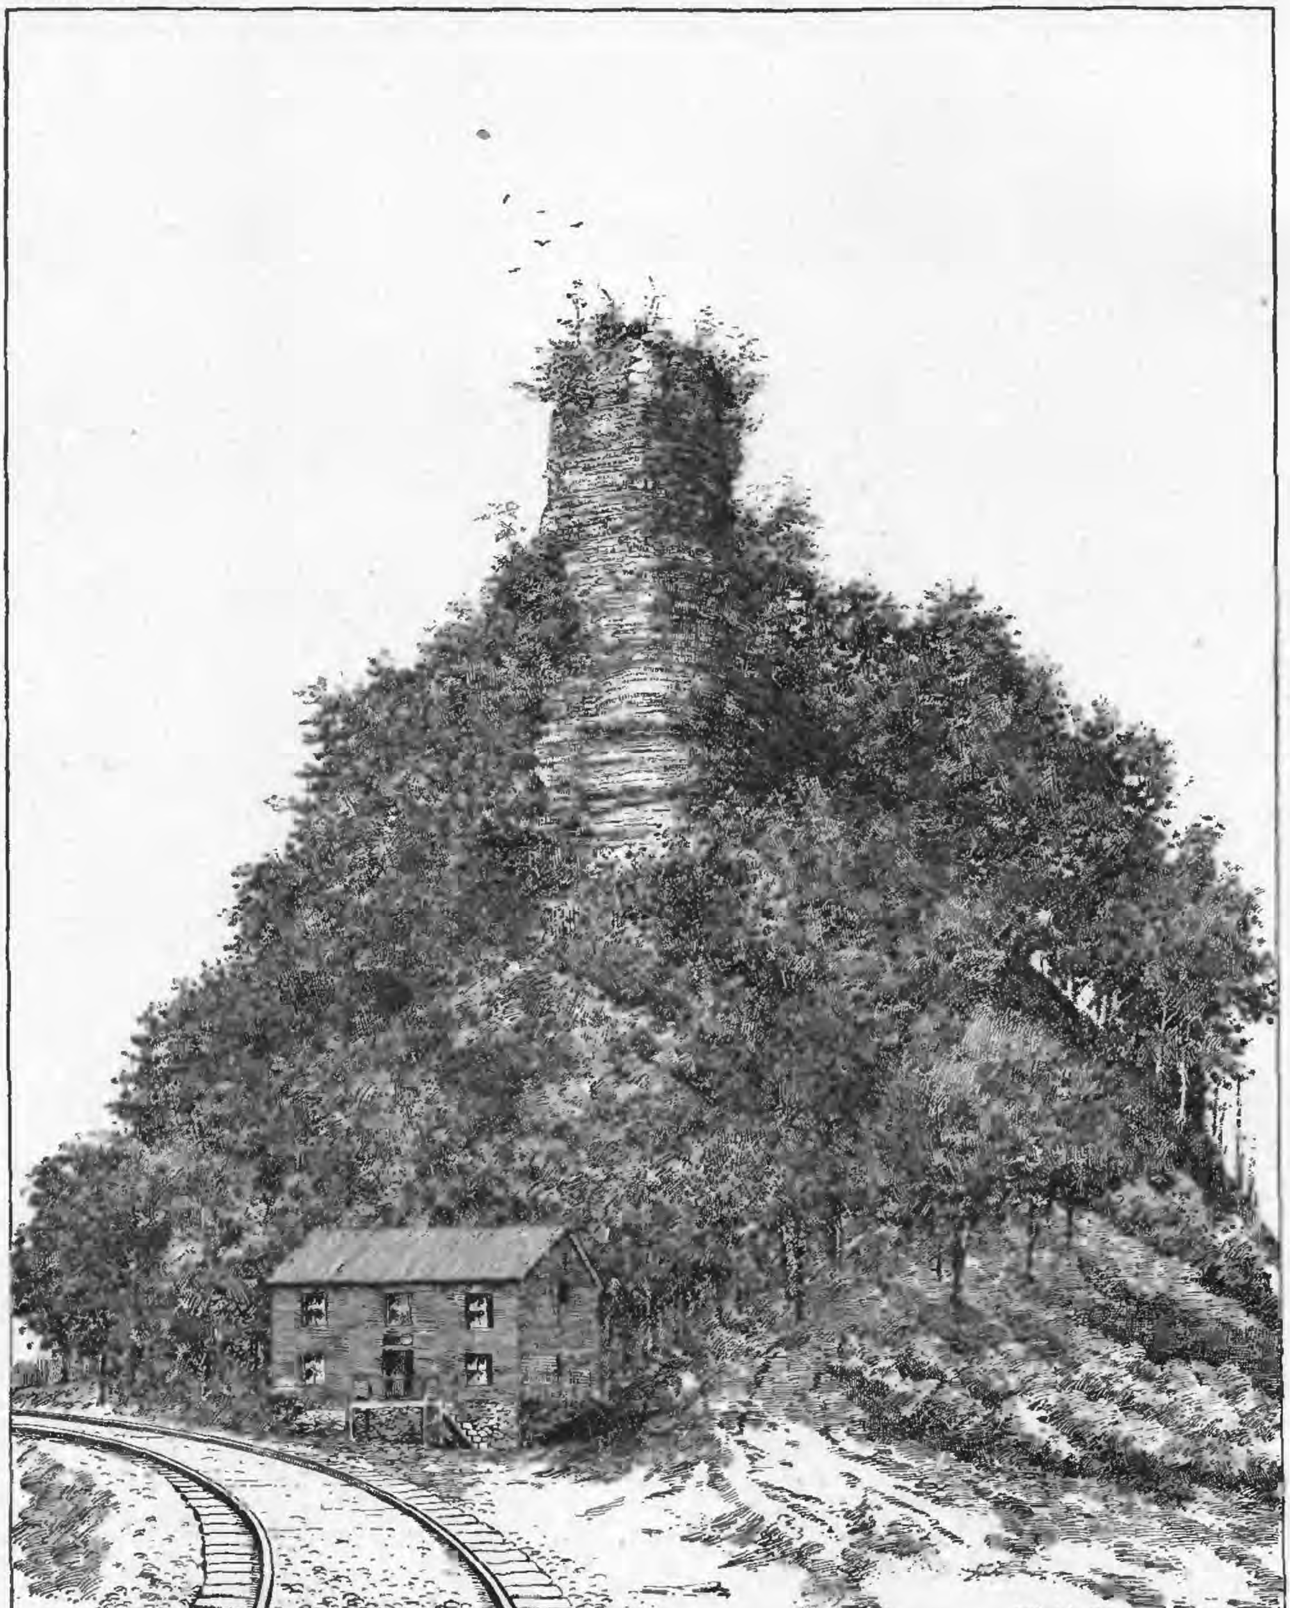
The rounded bluff overlooking Lansing (shown in Pl. XXXIII) illustrates the common aspect of the bluffs, and represents topographic maturity; the cañon walls of the Mississippi opposite Buena Vista and Dubuque (Figs. 22 and 23) represent respectively topographic youth and infancy; the sharply truncated salients just below Lansing and near Dubuque, shown in Figs. 21 and 24 illustrate the steeper cañon wall, and lie between the two extremes in topographic development; and the curious isolated knobs, evidently once symmetrically

FIG. 25.—"Sugar Loaf," near Winona, Minnesota. An almost exact image of this "Sugar Loaf" occurs a few miles below Lansing, Iowa.

rounded but now cleft in twain, like Sugar Loaf near Winona and its homologue near Lansing (Fig. 25), and like Barn Bluff at Red Wing, illustrate the diverse contours of the two stages.[1]

The reason for the diversity in form of the bluffs overlooking the Mississippi gorge is evident from a casual inspection of the cañon itself, or indeed of the illustrations representing it. The rivers, the valleys, and the hills are all of the autogenetic type, and were evidently fashioned by the progenitors of the present streams during a vast period of constant base-level, perhaps somewhat lower than now; but latterly the base-level has been disturbed, the Father of Waters has silted up his bed, and in his wanderings from side to side has

[1] Figs. 25 and 26 are from Chamberlin and Salisbury, 6th Annual Rep. U. S. Geol. Survey, pp. 233 and 235.



ESTELL POINT, NORTH OF TURKEY RIVER.

house-like blocks to rubble, then from rubble to angular gravel, next from angular gravel to earthy sand, and finally from earthy sand to the rich red loam or residuary clays prevailing over the driftless area uplands; and the upland itself is simply a maze of minor divides meandering this way and that and converging toward the principal divide, all forming a billowy plain, itself rising and falling in broad and gentle undulations. The plain is not without accentuation, it is true; the escarpment of the Oneota limestone recedes from the rivers and breaks the plain about the confluence of the Oneota with the Mississippi; the Trenton escarpment is a noteworthy feature and generally easily traceable across Allamakee County and part of Clayton; and while the prevailing surface materials are the characteristic residuary clays which never interrupt but really emphasize the distinctive autogenetic topography, the rock configuration of the southwestern margin of the driftless area tract is sometimes masked by the marginal deposits of the loess, which mantles the valleys more deeply than the hills.

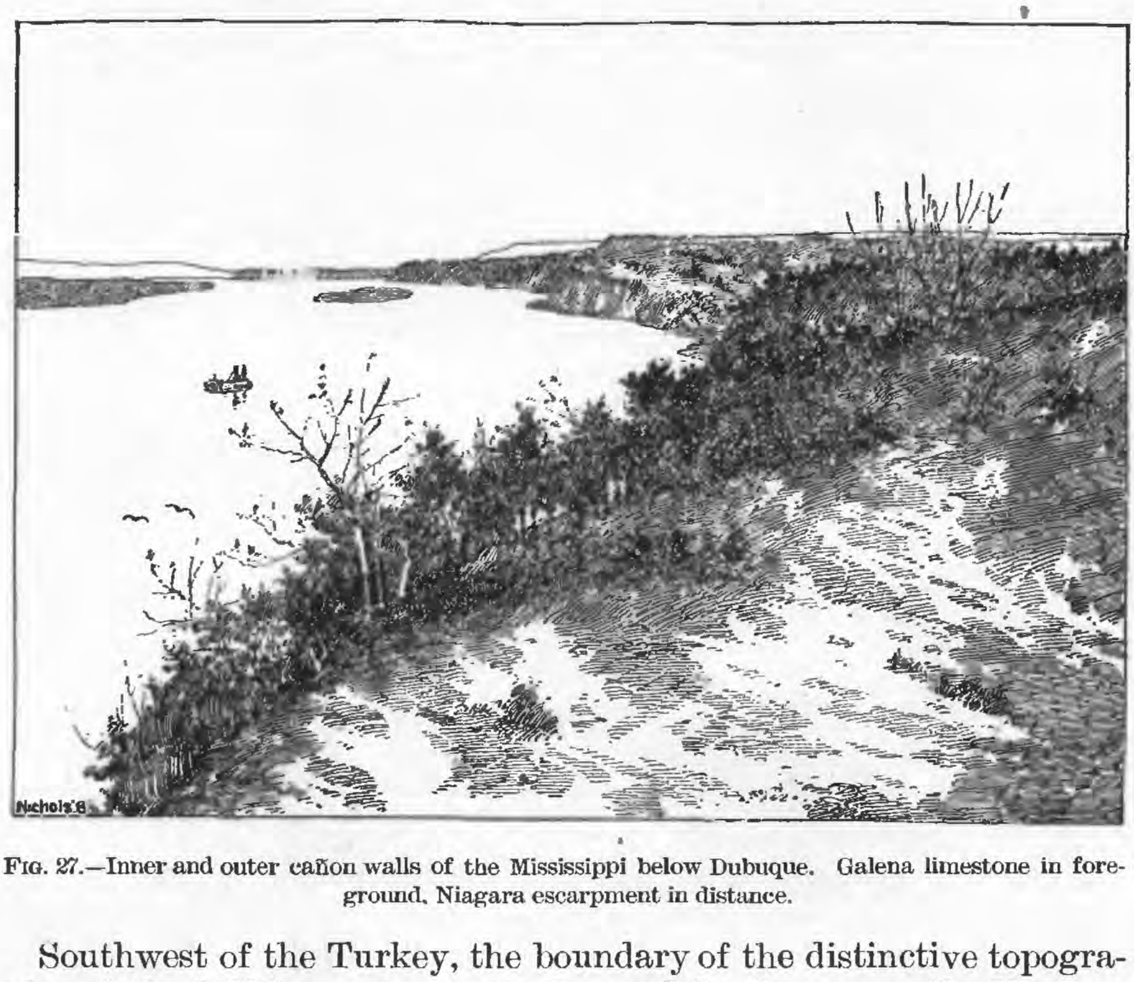


FIG. 27.—Inner and outer cañon walls of the Mississippi below Dubuque. Galena limestone in foreground, Niagara escarpment in distance.

Southwest of the Turkey, the boundary of the distinctive topography of the driftless area approaches and finally crosses the Niagara escarpment; for, although both ice sheets stretched eastward to that escarpment in this part of the State, their action was feeble and their effect upon the topography insignificant. So the prominent line of cliffs, spurs, and knobs forming the escarpment is a conspicuous feature of the southwestern part of the driftless area. Thus the Little Maquoketa and the Tête des Morts rise among rock-bound but

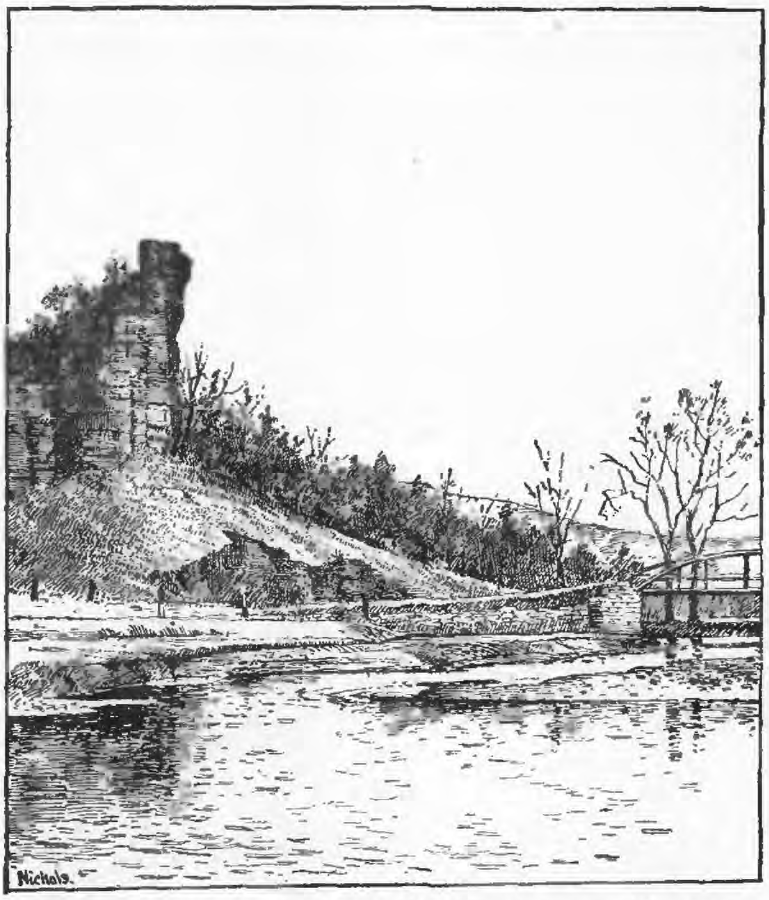

FIG. 28.—Erosion tower on the Little Maquoketa, near Durango.

rounded hills, as do Village Creek and Snymagil, and like them flow in narrow V-shaped gorges gradually increasing in depth and

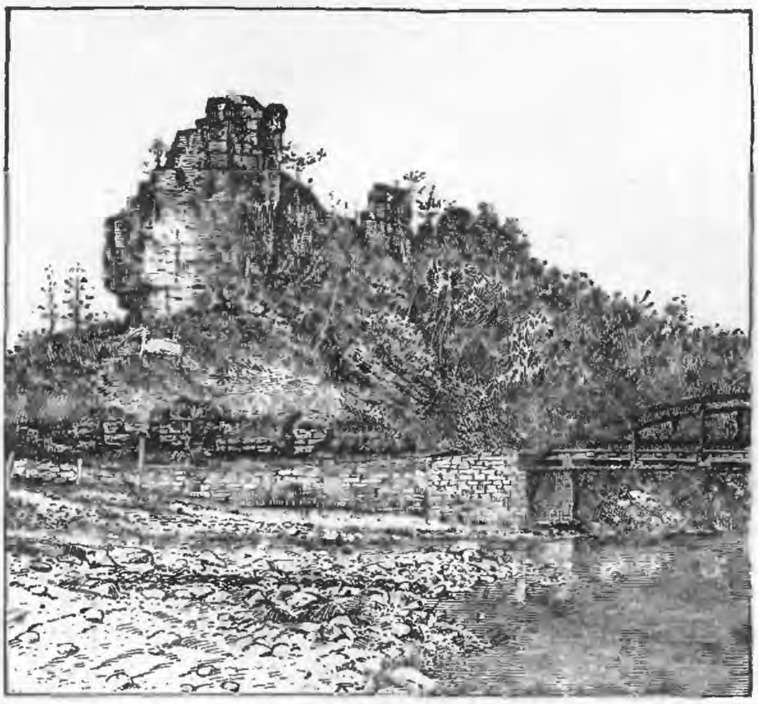

FIG. 29.—Salient on the Little Maquoketa, near Thompson's Mill, 4 miles northwest of Dubuque.

in the ruggedness of their sides; but half way to its mouth the cañon walls of the Little Maquoketa withdraw, the gorge first becomes U-shaped and then flat-bottomed, and at length its channel deepens into an inner gorge incised into the Galena limestone; and in this inner gorge, which exhibits all of the characteristic features of those of other driftless area rivers, it once found its way directly into the Mississippi. Then the mouth of the stream was just above the present position of Dubuque. But during some ante-Pleistocene shift of the great river the western bluffs were cut away, and the channels, greater and smaller, anastomosed some miles above the original confluence; when the larger stream withdrew, the smaller followed, building a delta plain like that of the Turkey, which has not since been invaded; and the channel between the old confluence and

FIG. 30.—Niagara limestone cliffs at headwaters of Catfish Creek, near Julien.

the new is a deep, rock-walled gorge, broad enough for a river, though occupied only by a spring-fed brooklet. This was "la coulée" of Julien Du Buque and his compatriots, and is "The Cooley" of the present; while the course of the brooklet is followed by "Couler" Avenue.

The headwaters of the Catfish gather on the Niagara terrane, but they accumulate so near the escarpment that they soon leap down to the smoother surface of the subjacent Maquoketa shale in a series of cascades; and the Tête des Morts, like the Maquoketa, has a double cañon, the outer carved in Niagara limestone, and the inner in the Galena limestone. The south-flowing tributaries of the Maquoketa occupy the homogeneous Niagara terrane alone, and the varying aspects of each, from source to embouchure, are identical with those of streams of corresponding size in Allamakee County, save that here the declivity is less and the slopes proportionately lower, while the valleys are more completely clogged with Pleistocene deposits.

The Niagara escarpment is a far more conspicuous topographic feature than those of the Trenton and Oneota formations, despite the higher local relief where the latter are best developed. The line

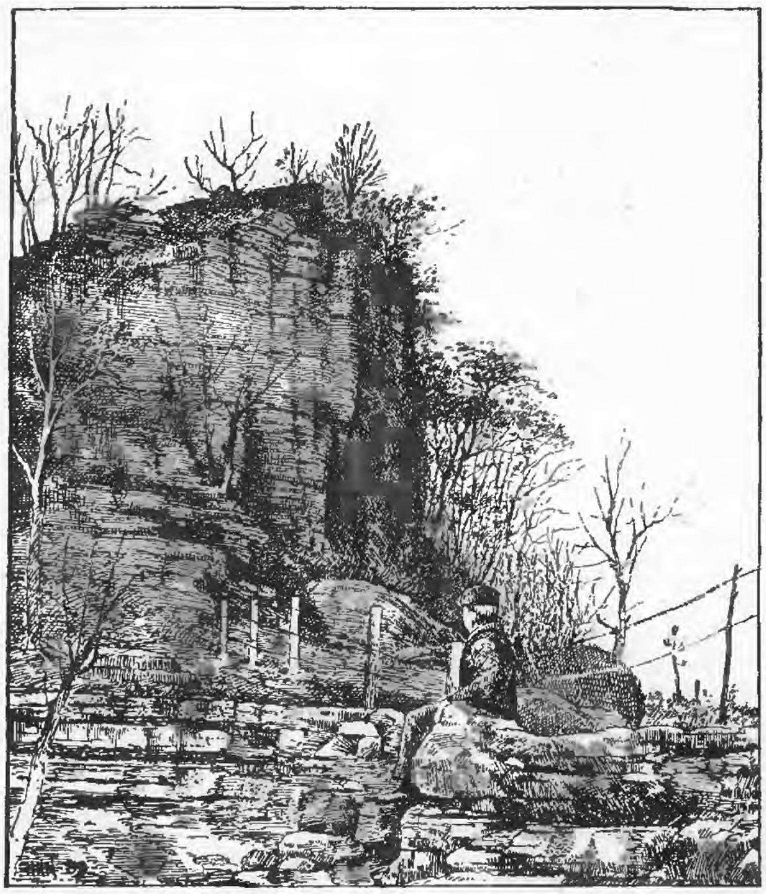

FIG. 31.—The hill where Julien Du Buque was buried—a typical cliff of Galena limestone near the mouth of Catfish Creek.

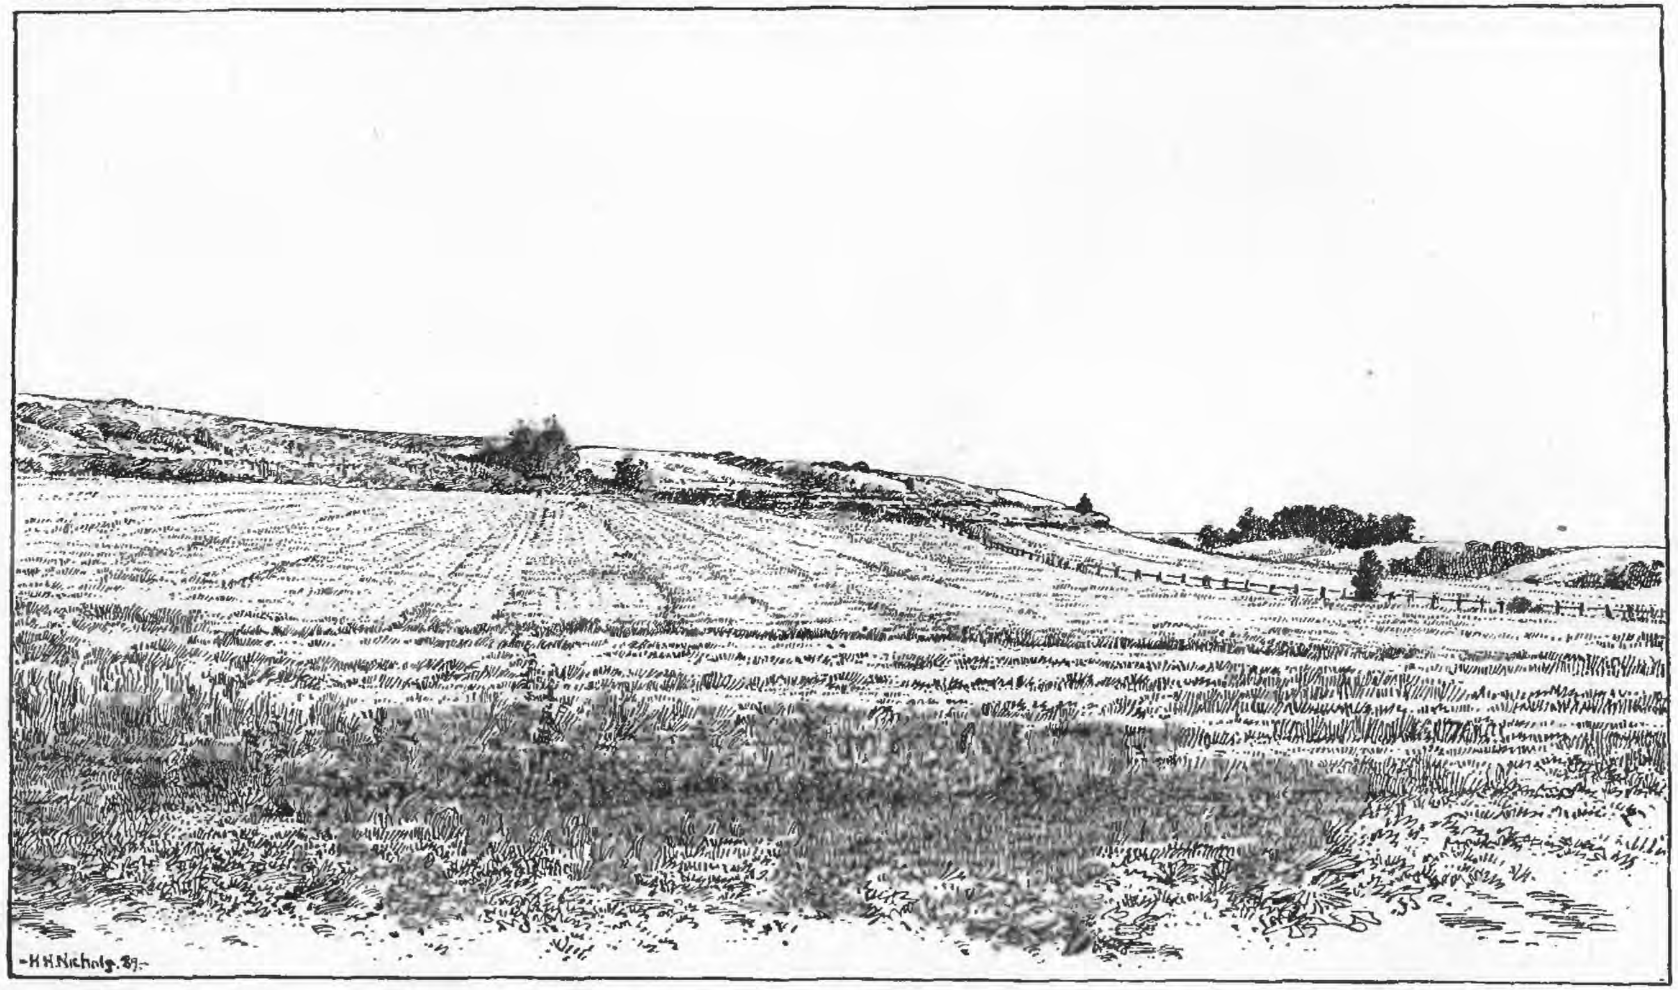
of bluffs and cliffs bounding the Niagara terrane on the northeast is everywhere conspicuous; the greater streams break through it in narrow gorges; the smaller streams generally leap down the precipitous ledges in cascades or at least in rapids; and even along the divides the slopes are too steep for travel and traffic, and the wagon roads wind here and there in ascending and descending them, while railways never cross the Niagara line save through the stream gorges. And not only is this escarpment exceedingly sinuous, stretching out in long salients on the divides and receding in deep dells excavated by the streams, but in the progressive recession of its cliffs it has left numerous outliers, some completely isolated from the main body of



WATER-CARVED VALLEY, WITH ICE-MOLDED RIMS, NEAR PRESTON.

the narrow gaps leading into the gorges of the North Maquoketa and the Little Maquoketa respectively. A similar drift basin stretches eastward from Worthington, and drains through its southern rim into two widely separated tributaries of the North Maquoketa. A third, which is of considerable dimensions and especially notable by reason of the great width of loess by which it is separated from the continuous drift plain, lies in the southern part of Dubuque County. It is simply an isolated bit of drift plain, as level, uniform, and abundantly dotted with bowlders as any portion of the great drift area in the northwestern part of the territory, but completely encircled by loess hills rising 30 to 80 feet above its level; it is a divide between two considerable streams (Prairie Creek and Lytle's Creek), and the gaps connecting with these deep-gorged streams have been so far lowered that the basin is fairly drained; its margin is digitate, and the usual lenticular loess hills jut into it from the west and rise from its surface and pass into the bounding wall on the east; and on the north the basin is flanked by an exceptionally prominent loess-capped ridge.

In the 20 miles of its southerly course, coinciding roughly with the boundary between Delaware and Dubuque Counties, the North Maquoketa well exemplifies the paradoxical behavior of the streams of this tract of topographic paradoxes. The principal branch of the river originates almost at the verge of the Niagara escarpment, within sight of the Mississippi bluffs and within sound of the blast of the passing packet. At first it flows directly down the dip of the limestone beds in the direction of the steepest general surface slope of the entire territory; in 10 miles it diverges from this general slope, and for the 20 miles of southerly course it flows at right angles to the local development of that slope in such manner that it

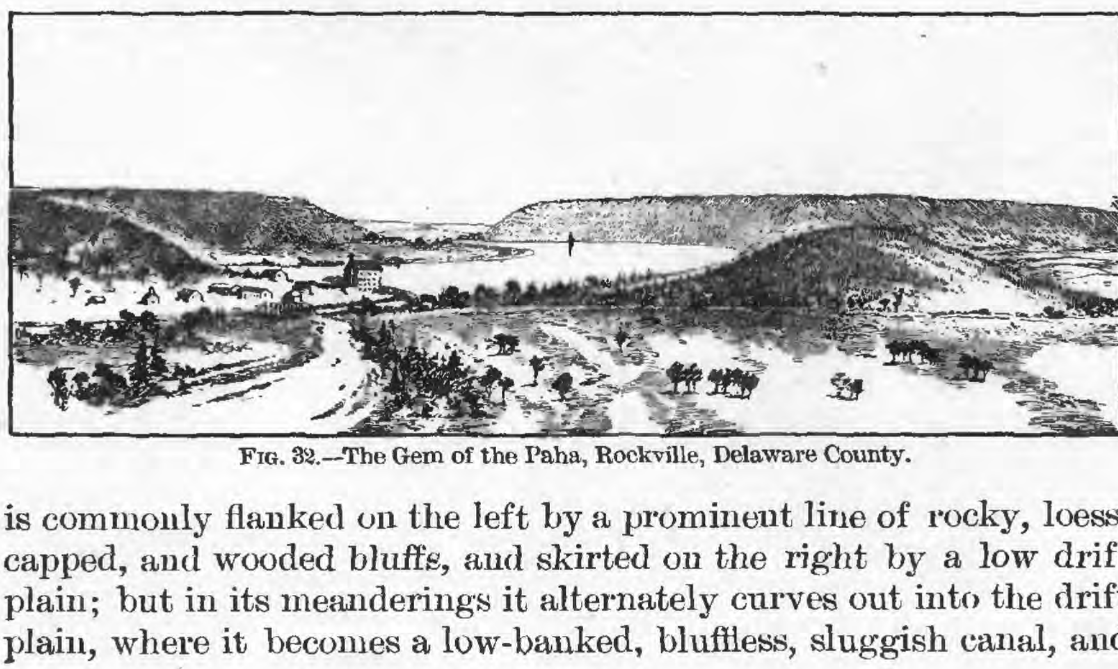


FIG. 32.—The Gem of the Paha, Rockville, Delaware County.

is commonly flanked on the left by a prominent line of rocky, loess-capped, and wooded bluffs, and skirted on the right by a low drift plain; but in its meanderings it alternately curves out into the drift plain, where it becomes a low-banked, bluffless, sluggish canal, and

WATER-CARVED VALLEY IN ICE-MOLDED REGION, NEAR PRESTON.

cuts into the rugged edge of the plateau, where it ripples over a rocky bottom between precipitous rock-bound walls 50 to 150 feet high.

At Rockville the incurving stream slices from the upland border a miniature plateau a mile or two across, and this isolated fragment of upland is rich in significant features. It is in itself a typical illustration of the paradoxical stream behavior and topography of the territory; it is partly crowned by a remnant of the probably Cretaceous Rockville conglomerate, the only one known within 100 miles; and a ravine in the isolated plateau leads down toward a small but wonderfully symmetric and graceful mound of loess—the Gem of the Paha, illustrated in Figs. 32 and 33,—and the relations between

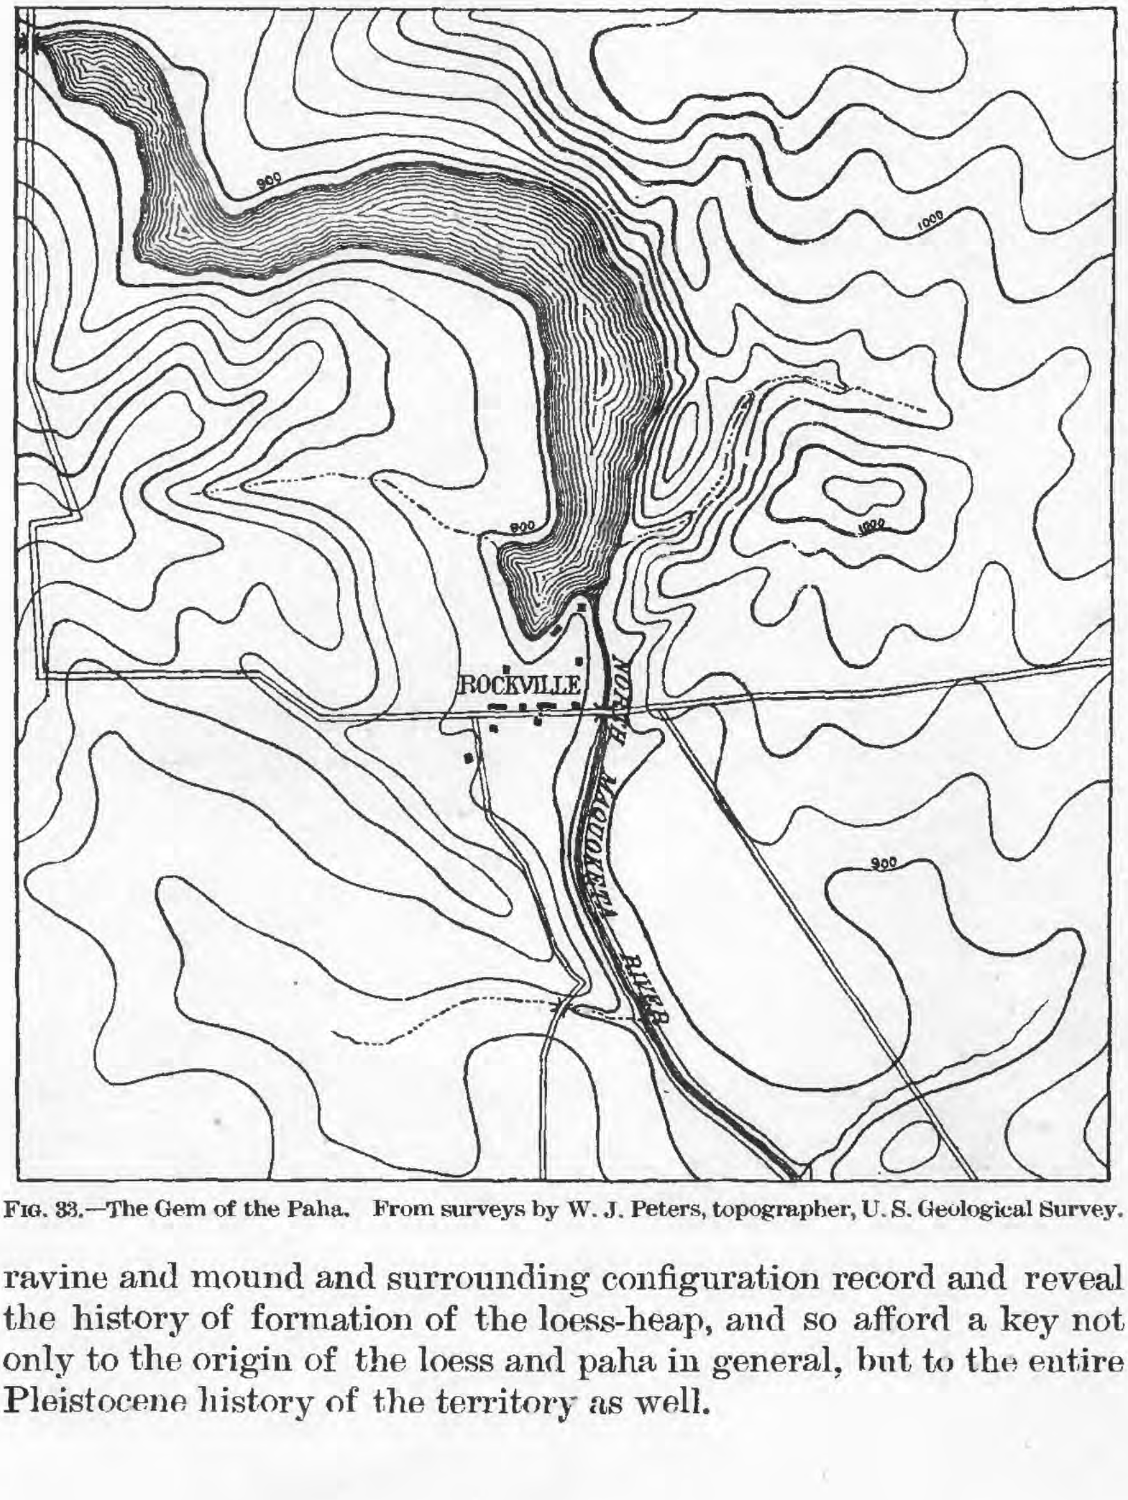

FIG. 33.—The Gem of the Paha. From surveys by W. J. Peters, topographer, U. S. Geological Survey.

ravine and mound and surrounding configuration record and reveal the history of formation of the loess-heap, and so afford a key not only to the origin of the loess and paha in general, but to the entire Pleistocene history of the territory as well.

LATE PLEISTOCENE CHANNEL OF THE MISSISSIPPI, NEAR GOOSE LAKE.

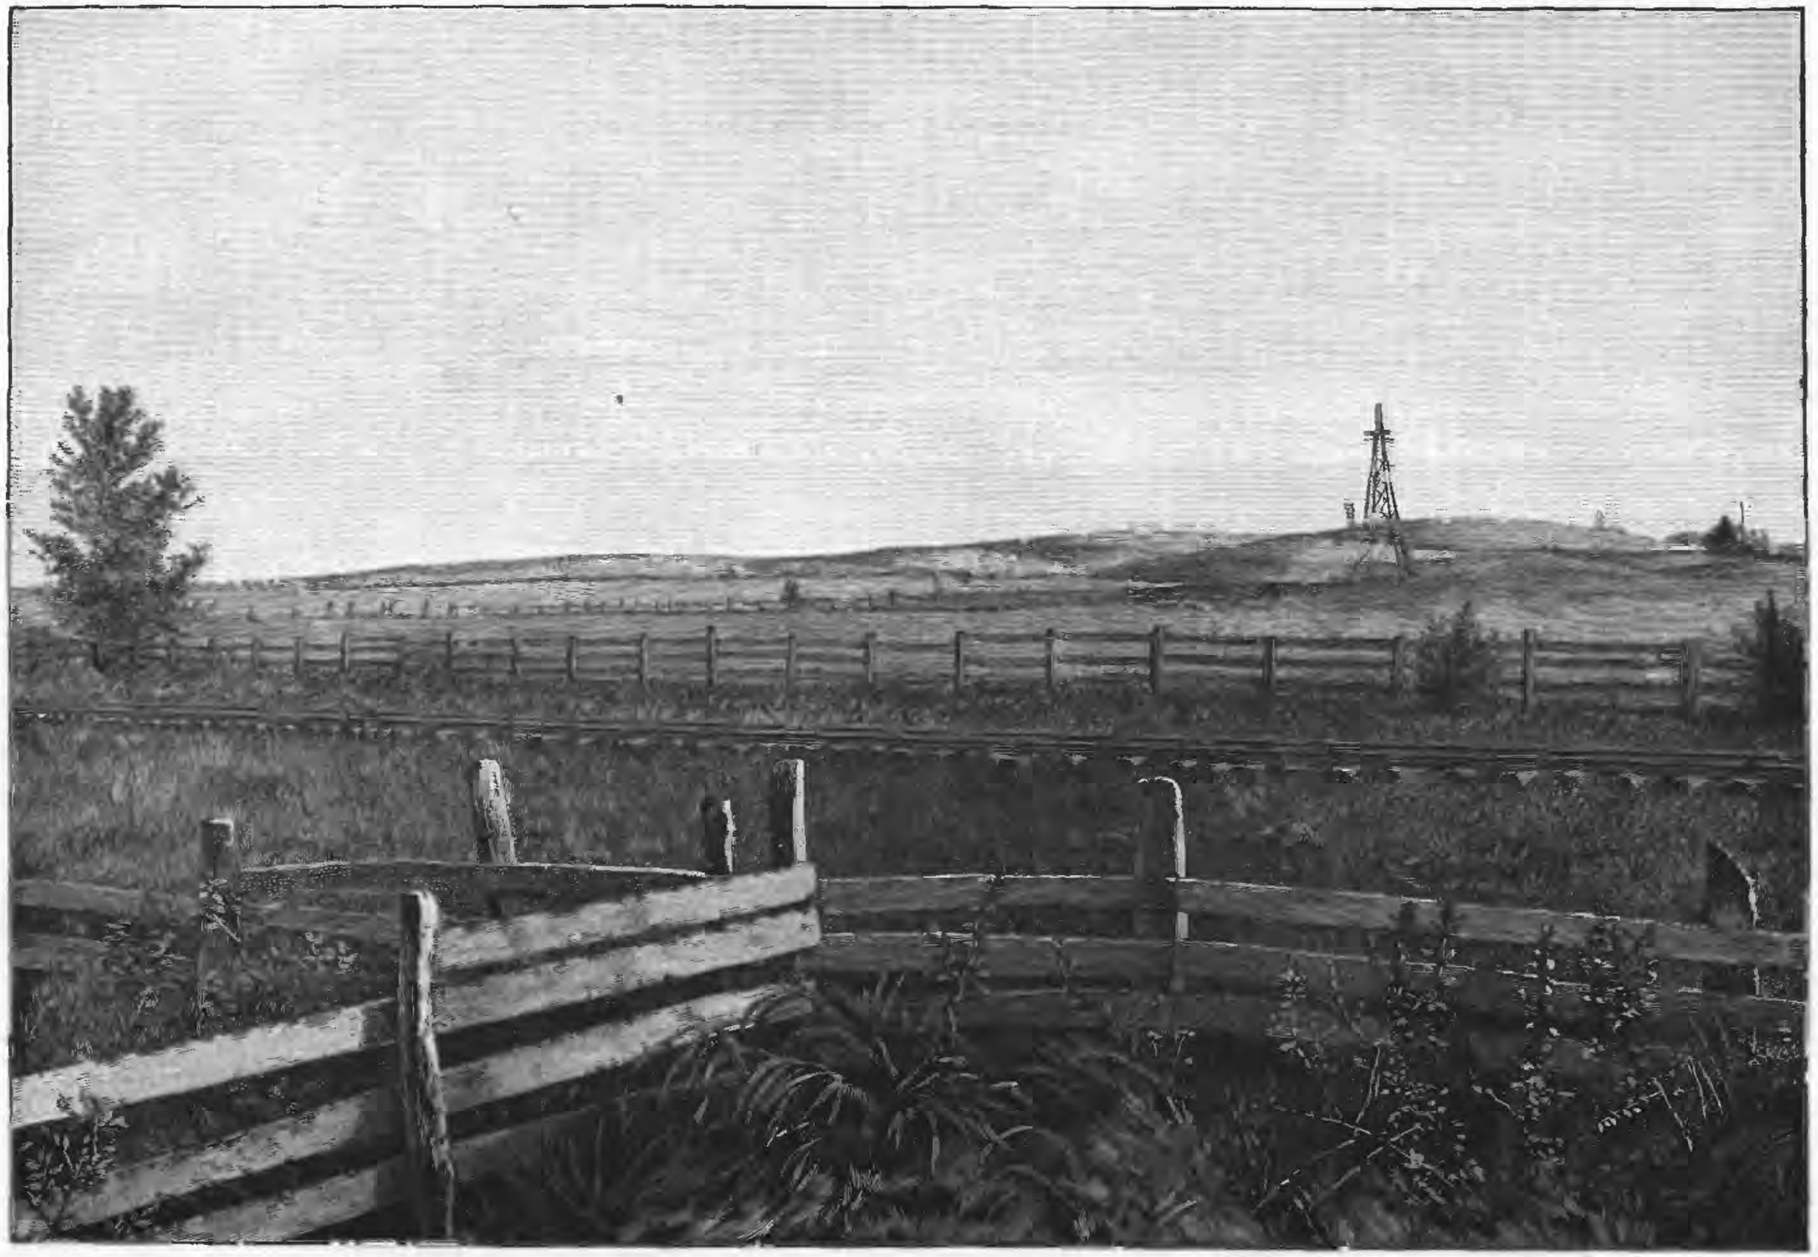
This hybrid configuration is one of the most striking phenomena of Northeastern Iowa. Its eems anomalous, incongruous, almost incredible, that the hilltops should be molded into the long and gracefully rounded swells of rock turned out from the ice-mill, and that in the

FIG. 34.—Hybrid topography near Spragueville. Water-sculptured cliffs in foreground, ice-molded uplands in background.

same vicinity the older valley bottoms should exhibit the rugose aspect of water sculpture; but the fact is patent to any observer, and indeed forms the conspicuous topographic feature of the drift border region.

Another unique feature is developed in this part of the drift border area. From its elbow near Goose Lake to its mouth at Spragueville, Deep Creek occupies a disproportionately large cañon, which is lined with alluvium and flanked by precipitous bluffs of Niagara limestone 100 to 200 feet high. That the occupation of this gorge by Deep Creek is fortuitous is shown by the fact that the gorge continues southward to Goose Lake and thence across the Maquoketa-Wapsipinnicon divide and down the farther slope to the Wapsipinnicon River 8 miles above its mouth. About the water-parting this broad, flat-bottomed gorge is undrained, and Goose Lake itself

LATE PLEISTOCENE CHANNEL OF THE MISSISSIPPI, NEAR GOOSE LAKE.



THE MONTICELLO PAHA.

and there the Niagara limestone crops out at the extremities of the ridges, or at the bases of the hills in precipitous cliffs. Near Monticello the plain is smoother for a space; but a few miles below, the river abandons a lowlying drift plain and swerves more and more to the left into a wooded upland stretching off toward and nearly to the Mississippi; and the sluggish prairie stream becomes a swift-flowing, cliff-bound river.

Below Monticello, the divide between the Maquoketas is generally loess-mantled; but now and then its axis sinks into a flat bottomed, bowlder-dotted drift basin surrounded by loess hills save at the narrow gates through which it is drained. Such an upland basin was Bowen's Prairie of early days—the Bowen of to-day.

West of Monticello on the Maquoketa-Wapsipinnicon divide, long paha stretch far southeastward, but fall short of the Maquoketa; for they are cut off by the indefinite trough connecting the Turkey and the Cedar, as are the loess ridges jutting from the Plum Creek belt a score of miles northward. Low these ridges may be, so that the railroad cuts through them and the farmer plows over them, but smooth and gracefully rounded are they always, so that the tourist discriminates them, the artist enjoys them, the topographer is impressed by them, and the geologist hastes to delve into their hearts.

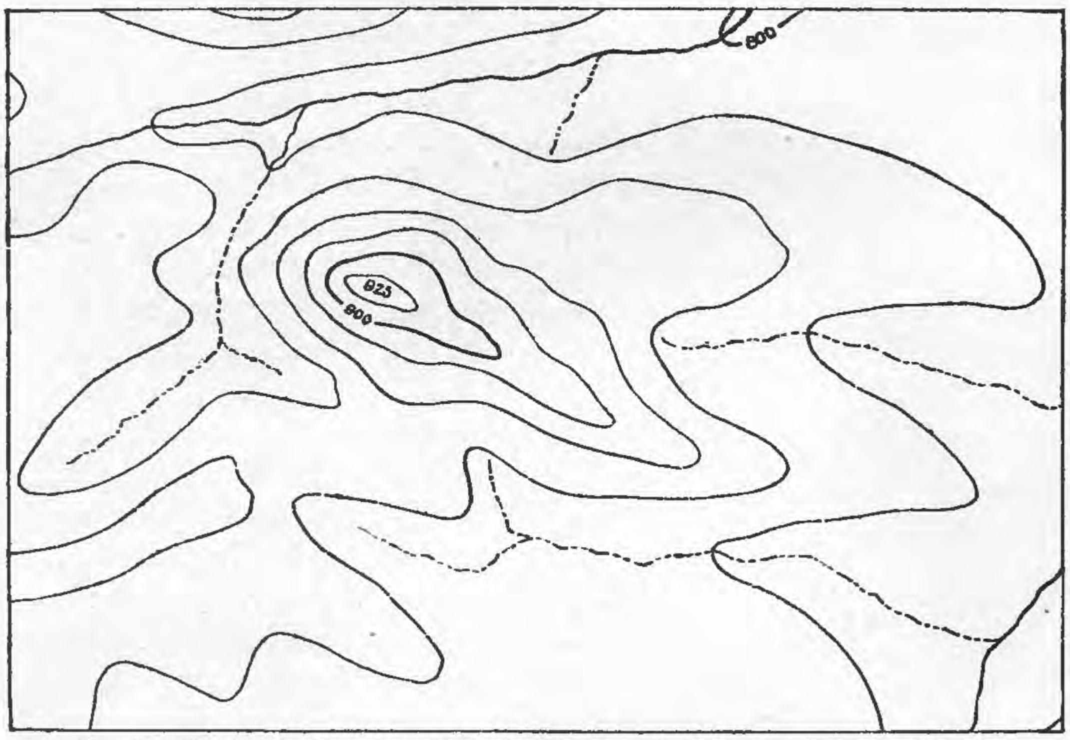


FIG. 35.—The Monticello paha. Scale, 3 inches=1 mile;[1] Contour interval=20 feet.

Their ever changing but always characteristic contours are illustrated in the triple paha three miles southwest of Monticello, shown in the contoured map constructed from minute surveys forming Fig. 35, and also in Pl. XL.

[1] This paha, with the contiguous country, is represented on a scale of 1:62,500 with 20 foot contours on the Monticello sheet of the Topographic Atlas of the U. S. Geological Survey.

CONTRACTED GORGE OF THE MISSISSIPPI AT DAVENPORT AND ROCK ISLAND.

of its yellowish loams and sands; but this late Pleistocene terrace is not beyond the reach of modern waters, for great freshets have occurred since the mounds were built, and deposited a layer of sands and dark brown loams of the modern alluvium about the bases of the mounds on the lower part of the bench, half burying some of their number.

Over the flood plain proper the river has repeatedly wandered and is still wandering, and its abandoned courses are amply marked by sloughs forming minor channels through which a part of the current passes; by meandering moats clogged with alluvial sands at one or both ends; by crescentic lakes completely dissevered from the main and minor channels; and by irregular depressions and morasses scattered here and there over its expanse. That these are the tracks left by the wandering river is shown by the observations of the river-pilot as well as by the inferences of the geologist. When the channel is first diverted during some great flood, a part of the waters flow for a time through the old channel; but the new was selected because offering a lower level or a shorter course, and so the new channel gains on the old until its volume is the greater; the new passage is

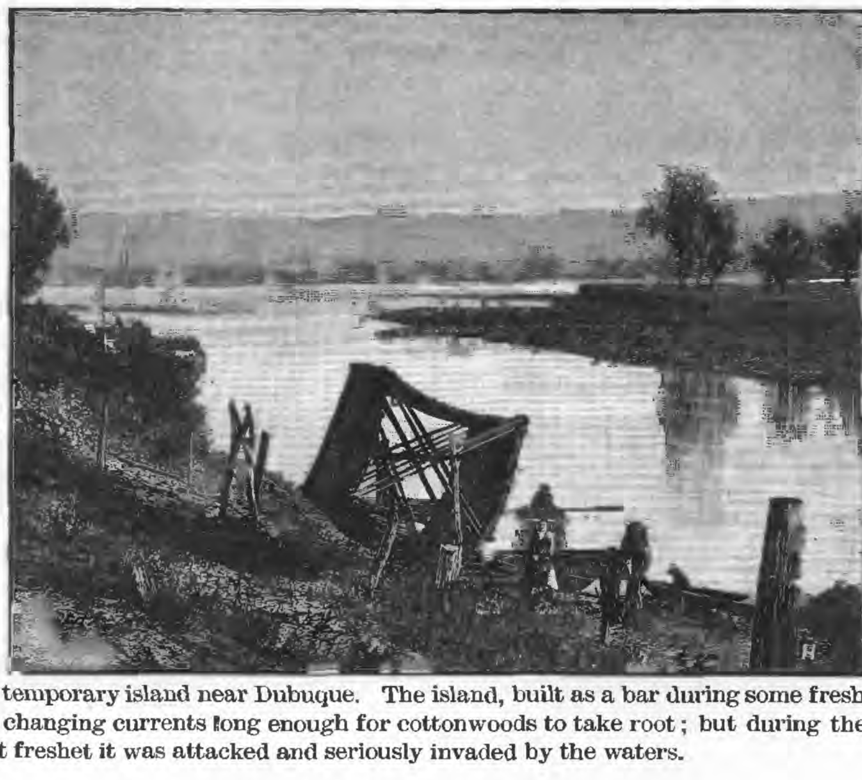

FIG. 36.—A temporary island near Dubuque. The island, built as a bar during some freshet, has withstood the changing currents long enough for cottonwoods to take root; but during the subsidence of the last freshet it was attacked and seriously invaded by the waters.

rapidly widened by the swift current, while the current grows sluggish and the idle waters drop sand and silt in the old. So the channel becomes a slough. Then, during some freshet, the shifting currents build a bar across an extremity of the old channel, and it is finally abandoned save during the highest floods; and as time goes on the other extremity is dammed, and the slough becomes a moat. Next, the ever wandering river shifts far upon its plain, and perhaps

buque the valley bifurcates, embracing between its arms the upland known as Eagle Point, and about the bifurcation (north of Thompson's Mill) the principal terrace expands to half a mile in width. It here rises about 55 feet above the ordinary water level, and its materials consist of fine sand and loam, similar to that of the loess by which the bounding hills are mantled.

Catfish Creek.—Toward the embouchure of this stream there are extensive deposits of stratified sand and loam, finest above and rising to a moderately uniform surface. Extensive exposures have been

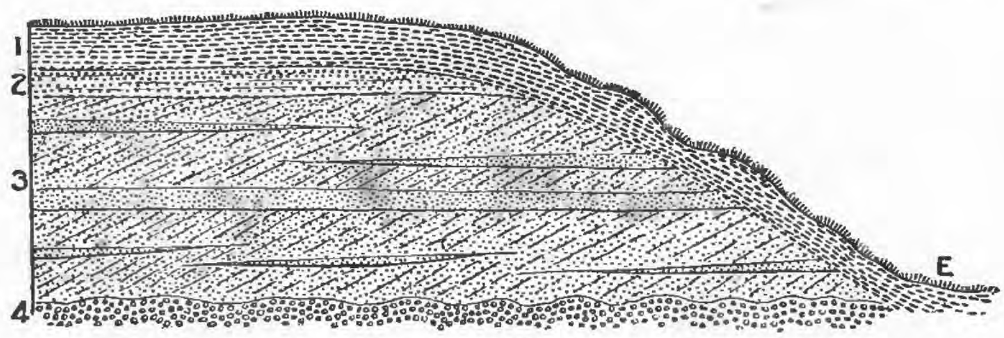

FIG. 37.—Structure of terrace on Catfish Creek, near Rockdale: (1) Sandy loam, without definite structure. (2) Horizontally bedded loam, loess like in color and appearance, but somewhat sandy. (3) Cross-bedded sand, generally fine, with intercalated sheets and lenses of fine, structureless sand. (4) Fine gravel, structureless or obscurely stratified, locally separated from the sand by a definite line, but elsewhere merging into it.

made in excavating the deposits for use as road material and building sand. The excavations display 10 to 30 feet of the loams and sands, the structure of which is illustrated in Fig. 37, and elsewhere the mass is probably 50 or 60 feet in thickness. The configuration of the deposit indicates that the gorge of the Catfish was once completely clogged, and that the stream has excavated an inner gorge within the old; and the composition of the deposit indicates that it grades into the practically continuous mantle of loess overspreading the whole of the region save the bottoms of the deeper cañons. The materials are generally cross laminated fine sand, with intercalated sheets either of fine gravel or loam.

The phenomena of the Catfish are duplicated in the Tête des Morts, Mill Creek, Pleasant Creek, and the lesser affluents of the Mississippi between the two Maquoketas.

The Maquoketa.—Terraces are not characteristic of this stream. Above Manchester it meanders through a broad bottom land which passes into a drift plain; in its lower course it flows through a cañon apparently too small for so considerable a stream, in which appear scant remnants of high-level terraces, something like those of the Oneota and Turkey; and even in the middle part of its course the terraces are generally narrow and inconspicuous.

Perhaps the best development is near Delhi and Hopkinton, where a considerable terrace rises some 50 feet above water level. Its

tion appears to depend upon weathering. In fresh excavations only broad stains may appear, but these gradually contract in area and harden in texture until, in long-weathered exposures, the concretions are firm; and solid concretions exposed in natural gullies are found on examination to gradually expand and become friable within a foot or less beneath the surface.

The materials of the deposit are commonly fine and easily reduced to impalpable powder between the fingers; and, wherever the usual clayey consistency prevails, to such a degree is it compacted by pressure that when freshly turned over by the polished plowshare or compressed in the roads beneath steel-shod hoofs and wheels the smooth surface reflects the rays of the sun like planished metal and dazzles the eyes of the beholder. Yet coarser particles, either concretionary or of crystalline rock, sometimes occur, and perhaps once in each week's examination a pebble or small bowlder, like those in the basal pebble-bed, may be found within the deposit.

By reason of its habit of crumbling and breaking down into talus slopes on weathering, good exposures, revealing the deposit from base to summit, are rare. Artificial excavations are commonly unsatisfactory, too, since the minuter characteristics of the deposit are obscure during the life of an evanescent exposure and become conspicuous only when brought out and emphasized by moderate weathering, so that a mass really abounding in significant detail may long appear uniform and homogeneous throughout. The most satisfactory exposures are found in roadside gullies, in the sides of storm-washed ravines, and in the precipitous falls formed at the heads of the smallest ravines by rain-born rills; for in such outcrops the minutest features are commonly revealed, and what the single cutting lacks in depth is made up in the multitude of cuttings at all horizons.

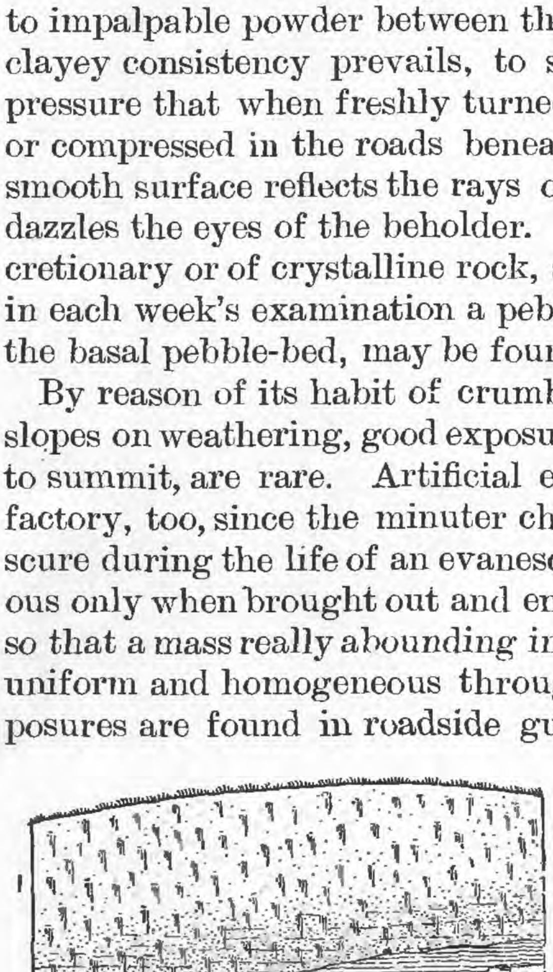

FIG. 38.—Relation of the loess to subjacent deposits in Winneshiek County: (1) Loess, somewhat clayey, homogeneous, and free from coarse material save sparsely disseminated sand grains in its upper portion, becoming decidedly sandy and somewhat pebbly at base, 12 feet. (2) Plastic red clay (geest), granular in texture, containing a few fragments and nodules of chert, with a dark line at base, 1½ feet. (3) Trenton limestone.

An exceptionally complete exposure in the extreme north is that displayed in a deep roadside cutting in the NE. ¼ NE. ¼ Sec. 26, T. 98 N., R. 8 W., Winneshiek County. Here the conditions of drainage are such that the compact residuary clay and the sandy or pebbly base of the loess are carried away by storm floods much more rapidly than the loess recedes by crumbling; and so the cliff is sapped and falls down in vertical slabs a few inches thick, perhaps 3 or 4 feet wide, and 12 feet high. Frequently these slabs cleave off without toppling over, and are gradually let down by the erosion of their bases. The loess in this exposure is, for its latitude, exceptionally rich in lime and poor in clay.

In the deeper sections the northern loess, like that of the other Iowa areas, exhibits an obscurely banded or stratified appearance after some exposure, particularly on the gradual drying of the surface in spring or after a rainstorm. Commonly no difference in the composition or texture of the bands can be detected, and they even disappear if an inch or two of the face be removed. The banding appears simply to betray a slight difference in porosity of successive strata; but sometimes the drier and lighter colored layers are found under the glass to be made up of groups or floccules of particles, while the particles of the wetter layers are not so arranged; and the hygroscopic inequality of the successive bands appears to be due to inequality in degree of flocculation. The phenomenon thus appears to illustrate the effects of the flocculation of fine particles, first recognized by Hilgard.[1] Analogous phenomena have already been noted by Todd in southwestern Iowa.[2] Commonly the darker bands are the thinner in the ratio of 1 to 2 or 1 to 3, and range from 8 inches in thickness downward; and commonly the thickness of the bands is uniform and the attitude sensibly horizontal or slightly inclined toward adjacent lowlands throughout each exposure, as illustrated in Fig. 40; but now and then the bands are curiously contorted. One of the best examples of such contortion (represented in Fig. 39) was observed in a deep roadside gully in the SW. ¼ NE. ¼ Sec. 36, T. 95 N., R. 9 W., in Fayette County. Such contortion has never been observed save on slopes. It is probably due to simple settling of the deposit, accompanied by both compression and slight slipping in the direction of the slope, as in the case of the much more profoundly contorted laminæ of the lower members of the Albany clays on the banks of the Hudson. Contorted laminæ of this character are not confined to the northern loess, but occur occasionally in the deposit throughout the territory.

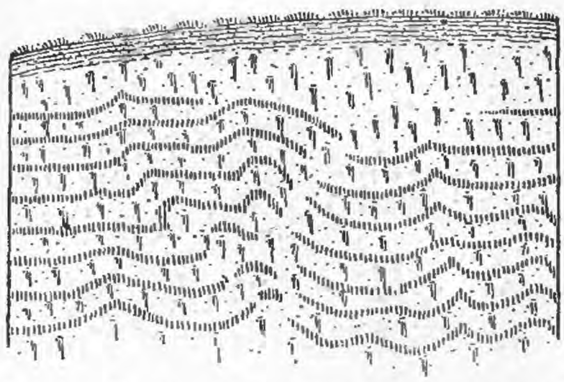

FIG. 39.—Hygroscopic banding and contortion of the loess, Fayette County.

Definite stratification of the deposit is uncommon, and practically confined to the basal portion in a few localities and to the high level terraces into which the loess appears to grade.

It has already been shown that no constant demarkation in altitude, geographic position, or time can be drawn between the Pleistocene and post-Pleistocene deposits in Northeastern Iowa; and the loess

[1] Amer. Jour. Sci., 3d ser., vol. 17, pp. 205 et seq.; ibid. vol 18, p. 110.
[2] Proc. Am. Assoc. Adv. Sci., 1877, vol. 26, pp. 287, 288.

of late Pleistocene terraces sometimes grades up into or is overlain by alluvium, as in the cutting in the SW. ¼, Sec. 14, T. 93 N., R. 5 W., Clayton County, illustrated in Fig. 40. The horizontal banding is

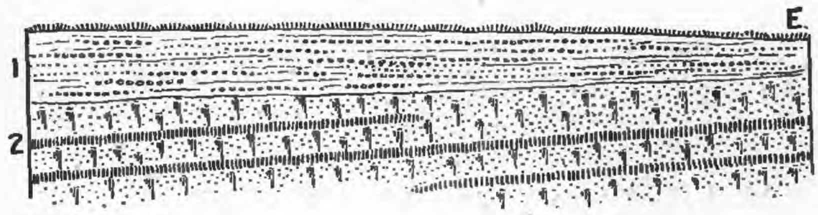

FIG. 40.—Hygroscopic banding of loess and superposition of alluvium, Clayton County: (1) coarse sandy and pebbly loam, irregularly bedded, 4 feet; (2) exceptionally calcareous loess, fine and generally homogeneous, but horizontally banded.

much like that displayed at Muscatine and illustrated in plates XLVIII, and XLIX. This section exhibits the structure of a broad strath, perhaps a square mile in extent, overlooking Turkey River just north of Elkader. The strath is nearly circumscribed by precipitous bluffs of Galena limestone; and although 60 feet above the river level, or about the average height of the upper terraces of this part of the stream, the enfeebled drainage of post-glacial times has apparently been unable to commence the destruction of this part of the terrace, and has indeed only buried it beneath débris gathered from the bounding bluffs.

Everywhere beyond the Niagara escarpment and the coincident drift margin, the northern loess appears to be made up in part of the residuary clays which formed the surface deposit during the ante-Pleistocene time. This intermingling of deposits is shown in various ways: (1) The element of clay in the loess varies inversely with the extent of residuary clays in its vicinity. Thus in the north, where its volume is slight in proportion to the volume of subjacent residuary clays, the loess is especially rich in clay; the clay element increases from the drift margin eastward toward the interior of the driftless area under each parallel; and the same element diminishes under each meridian southwestward from the interior of the driftless area until it becomes inconspicuous in Jones and Clinton Counties. (2) The incorporation of geest within the northern loess is indicated by the high proportion of iron found in the deposit; for the residuary clays are always ferruginous, and most of the other components of the loess are non-ferruginous. The distribution of the iron in this as in other deposits is determined by various conditions, one of the most important of which is weathering; so a ferruginous band is frequently found a few feet beneath the surface of the deposit within the driftless area. Commonly this band is parallel with the surface, as in the accompanying section (Fig. 41) observed in a roadside gully in the SW. ¼ NW. ¼ Sec. 3, T. 90 N., R. 2 W., Dubuque County. Here the incorporation of residuary products is indicated not only by the prevalently argillaceous character and the pronounced ferruginous staining, but by the presence of two rounded pebbles of jointed red clay identical with that of the prevailing mantle of the rocks within the

FIG. 41.—Ferruginous banding of the loess, Dubuque County: (1) Somewhat incoherent loess, brownish drab in color, 2 feet; (2) brownish red band, partially indurated, 3 inches; (3) clayey loess of the usual aspect, containing two rounded lumps of dark red plastic clay, similar to residua of Niagara limestone exposed a few rods away, 5 feet.

driftless area. Sometimes, however, the ferruginous banding is not parallel to the surface but approximately horizontal, and probably coincides with the hygroscopic banding already noticed, as shown in Fig. 42 (roadside gully in NW. ¼ SE. ¼ Sec. 28, T. 91 N., R. 2 W.,

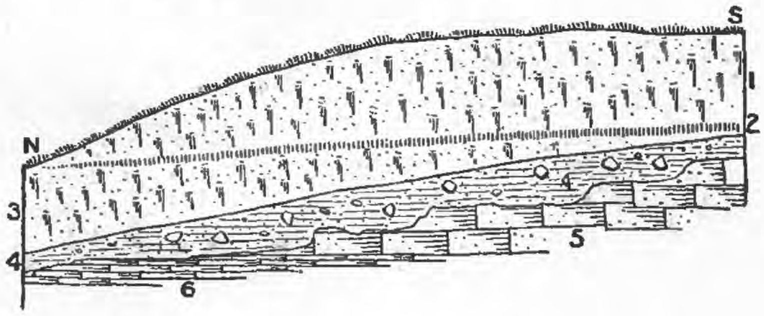

FIG. 42.—Ferruginous banding of the loess, Clayton County: (1) Brownish drab loess, 6 feet; (2) partially cemented ocherous band 3 inches; (3) homogenous loess with small cylindrical concretions, 3 feet; (4) brownish red clay, compact, tenacious, with a few fragments of local chert and erratic pebbles, 1 foot; (5) Niagara limestone; (6) Maquoketa shale.

Clayton County). More rarely the ferruginous staining is irregular, and associated with firm nodular concretions like those of the drift. This case is illustrated in Fig. 43, observed in the NW. ¼ SW. ¼ Sec. 33,

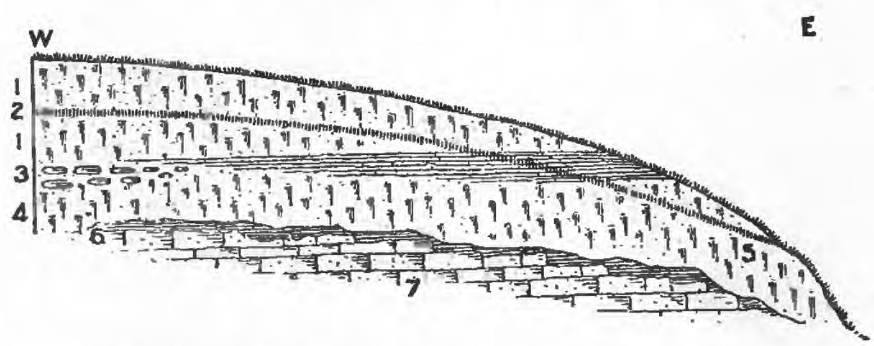

FIG. 43.—Ferruginous banding of the loess, Clayton County: (1) Loess, homogeneous, light drab in color, 7 feet; (2) ferruginous band; (3) loess, homogeneous, somewhat silty and unusually light colored and calcareous, thinning westward and giving place to a bed abounding in loess-kindchen and large calcareous concretions, 2 feet; (4) somewhat silty loess with a bluish tinge, containing loess-kindchen and branching tubules of lime carbonate, 4 feet; (5) the same with the calcareous concretions replaced by cylindrical ferruginous concretions and irregular ferruginous nodules, 4 feet; (6) unctuous red clay; (7) Galena limestone.

T. 92 N., R. 4 W., in Clayton County. The exposure is of additional interest in that it is the northernmost in which loess-kindchen have

loess invariably grades, sometimes so rapidly as to suggest unconformity, but generally by imperceptible transition or interlamination; and it reposes unconformably alike upon the Paleozoic rocks, the residuary clays derived from them, the older drift sheet where it extends beyond the newer in the northern counties, and (generally) the newer drift sheet in the central and more southerly counties. In structure the deposit is distinct from the loess, yet the two intergrade; in distribution they are conterminous; in composition they are indeed diverse, but the diversity is chiefly in degree of comminution; in time of formation they are evidently immediately successive; and in genesis they are unquestionably related.

So prevalent is the basal pebble bed that it appears in greater or less volume in nearly every section exposing the base of the loess. In Fig. 44 (well, in NE. ¼ SW. ¼, Sec. 31, T. 89 N., R. 1 W., Dubuque County) it is bitartite, the lower portion consisting mainly of local chert irregularly disseminated throughout an unstratified reddish yellow, sandy clay, while the upper portion consists of erratic bowlders and pebbles closely packed in a similar matrix. In this section the erratics are large, sub-angular, and rounded, comprising granite of two or three varieties, hornblende schist, hematite, quartzite, etc., 2 feet and less in diameter, none distinctly striated, but one polished; and a similar bowlder bed is exposed in an adjacent road-cutting as shown in Fig. 65. Here the loess, with its basal pebble bed, rests upon the newer drift sheet.

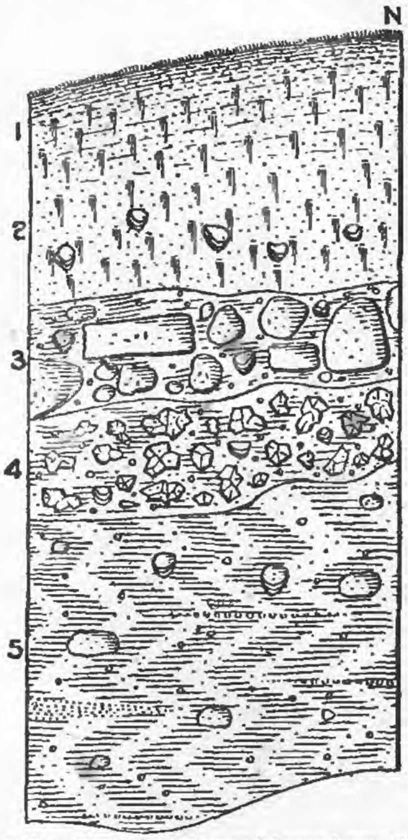

FIG. 44.—Bowlder-charged loess-base, Dubuque County: (1) black surface soil; (2) loess, stained dark blue; (3) yellow sandy clay with great numbers of erratic bowlders (the larger of which are drawn to scale) and a few cherty fragments; (4) similar clay packed with nodules and fragments of chert; (5) unstratified yellow clay with a few small bowlders and striated pebbles. Exposure, 10 feet.

Quite beyond the drift margin the relations are similar. In a specific case the basal deposit consisted of sandy and gravelly yellow clay containing numerous erratic pebbles and bowlders, including one of brown quartzite, sub-spheroidal but unworn, 18 inches in mean diameter; one of hornblende slate, angular and unworn, 8 by 15 by 30 inches; one of coarse-grained hornblende granite, angular, 6 by 8 by 10 inches; and several of smaller sizes. The whole reposed unconformably upon obscurely laminated blue plastic clay, containing a few small local pebbles at its base. This exposure was observed some miles from the Niagara escarpment and within the driftless area proper, in the SE. ¼ NW. ¼, Sec. 12, T. 88 N., R. 2 E., Dubuque County. It is, however, exceptional to find the included bowlders so largely erratic in the interior of the driftless area—indeed, outside the drift margin the pebbles are smaller and more largely local in most cases than those of the subjacent drift; and within the driftless area they are still smaller and more largely local.

While in general the pebble bed is more or less distinctly separable from the newer drift sheet, this relation is not invariable; for, as in the section represented in Fig. 45 (observed in the NE. ¼, Sec. 20,

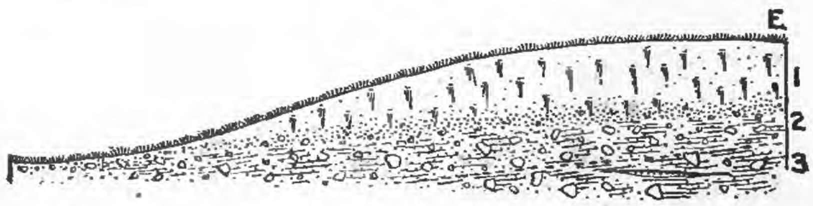

FIG. 45.—Relation of loess to basal pebble bed, Dubuque County; (1) brownish drab loess, 6 feet; (2) yellowish brown loam, charged with fine gravel and larger pebbles, both local and erratic, 5 feet; (3) brownish yellow clay with worn erratic bowlders (some polished) and lenses of sand and gravel, 4 feet.

T. 90 N., R. 2 W., in Dubuque County), no other than an arbitrary line can be drawn between the deposits, though the bowlders decrease in size and increase in number and degree of rounding upward. Despite the rapid and complete change in appearance between loess and drift displayed in this section, there is no indication of unconformity, no mark of erosion, no oxidation, no ancient soil, no ferruginous stain; and in some cases intergradation is evident. A natural gully in the SE. ¼ of the SW. ¼, Sec. 5, T. 87 N., Dubuque County, displays distinctive loess above and distinctive drift below, separated by a bed of composite character, into which the former

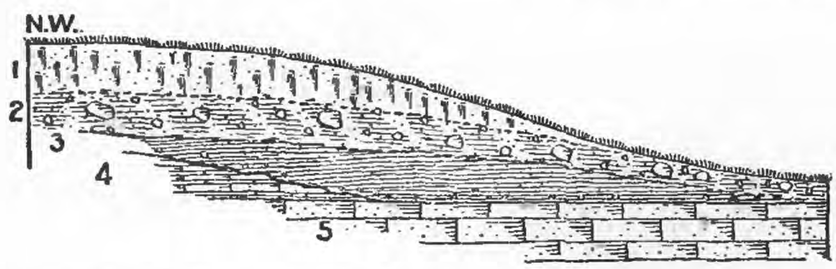

FIG. 46.—Relation of loess to basal pebble bed, Dubuque County: (1) loess: (2) stony, sandy, and gravelly yellow clay; (3) plastic blue clay; (4) Maquoketa shale; (5) Galena limestone. Mean exposure, 10 feet.

grades by imperceptible stages, while the demarkation from the latter is even less easily found. In a neighboring gully the pebble bed is fairly distinct from the loess, and sharply demarked from the subjacent blue clays representing the marginal and superior phase of the older drift sheet (Fig. 46).

The basal bed of the loess is protean in composition as in structural relations. Sometimes pebbles are altogether absent, and the loess simply becomes sandy toward the base, as in the section forming Fig. 47 (observed half a mile south of Cascade, within a few yards

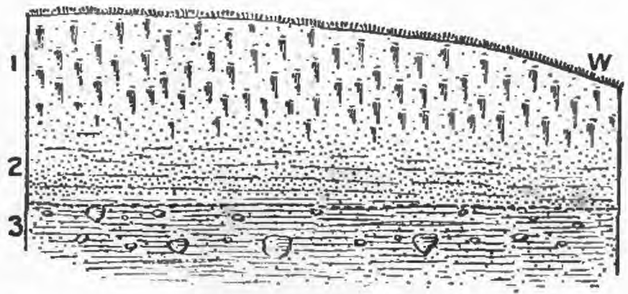

FIG. 47.—Transition of loess to sand, Jones County; (1) Loess, slightly silty above, grading into sand below, 12 feet; (2) obscurely stratified sand, fine above, coarser below, 5 feet; (3) dense, tenacious blue clay, with ferruginous nodules above and sparsely disseminated greenstone pebbles below, 5 feet.

of the Dubuque-Jones County line). Here the newer drift sheet is absent, and the loess rests unconformably upon an old soil representing the interglacial forest bed, and at lower levels upon a bed of gravel representing the older drift sheet.

The basal member of the northern loess is as variable in thickness as in the degree of comminution of its materials. In a railway cutting through one of the characteristic narrow divides of the area (in

FIG. 48.—Relation of loess to basal pebble bed, Dubuque County; (1) Loess; (2) brownish yellow, pebbly sand and clay with erratic bowlders; (3) yellow drift clay containing large erratic bowlders. Maximum exposure, 20 feet.

SW. ¼ NW. ¼, Sec. 9, T. 88 N., R. 1 E., Dubuque County) exhibited in Fig. 48, both members of the deposit mantle a still narrower ridge of drift, attenuating over its crest and thickening along its flanks, save where reduced by degradation.

All the foregoing variations in the basal member of the northern loess occur within a radius of 10 miles. They exhibit well its leading features and its protean character; for little greater or little different variations can be found within the entire area.

While the loess with its attendant pebble bed forms a nearly continuous mantle over the driftless area and the adjacent drift margin, and while its surface is (save in the minor features due to post-Pleistocene erosion) conformable in a general way to the older surface upon which its rests, there are a few cases in which the old surface and the new are discordant, and in which the relations of the deposit betray slight geographic changes, usually the abandonment of old and the selection of new waterways. An example of such geographic change is illustrated in Fig. 49, observed in the SW. ¼, Sec. 27, T. 88 N., R. 1 E., Dubuque County. It is noteworthy, too, that here, as well as farther southwestward, the loess displays a

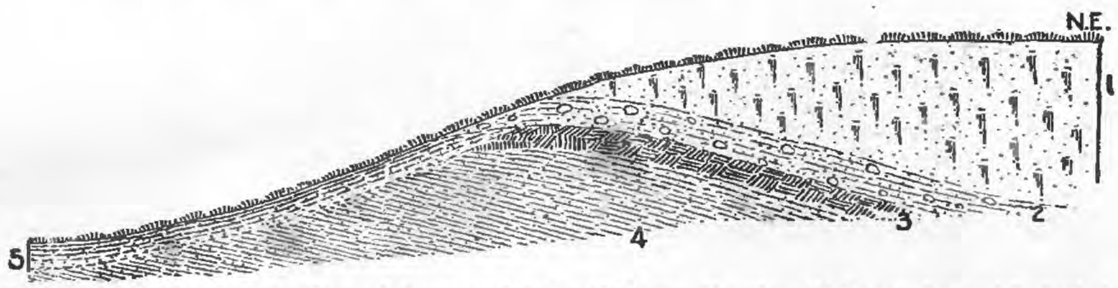

FIG. 49.—Discordant deposition of loess and drift, Dubuque County: (1) Loess, brownish drab in color, 6 feet: (2) obscurely stratified sand and pebbly clay, 1 foot; (3) dark brown friable earth with ferruginous nodules and traces of wood (forest bed), 1 foot; (4) clean, finely laminated plastic blue clay, weathering whitish drab (lower till), 5 feet.

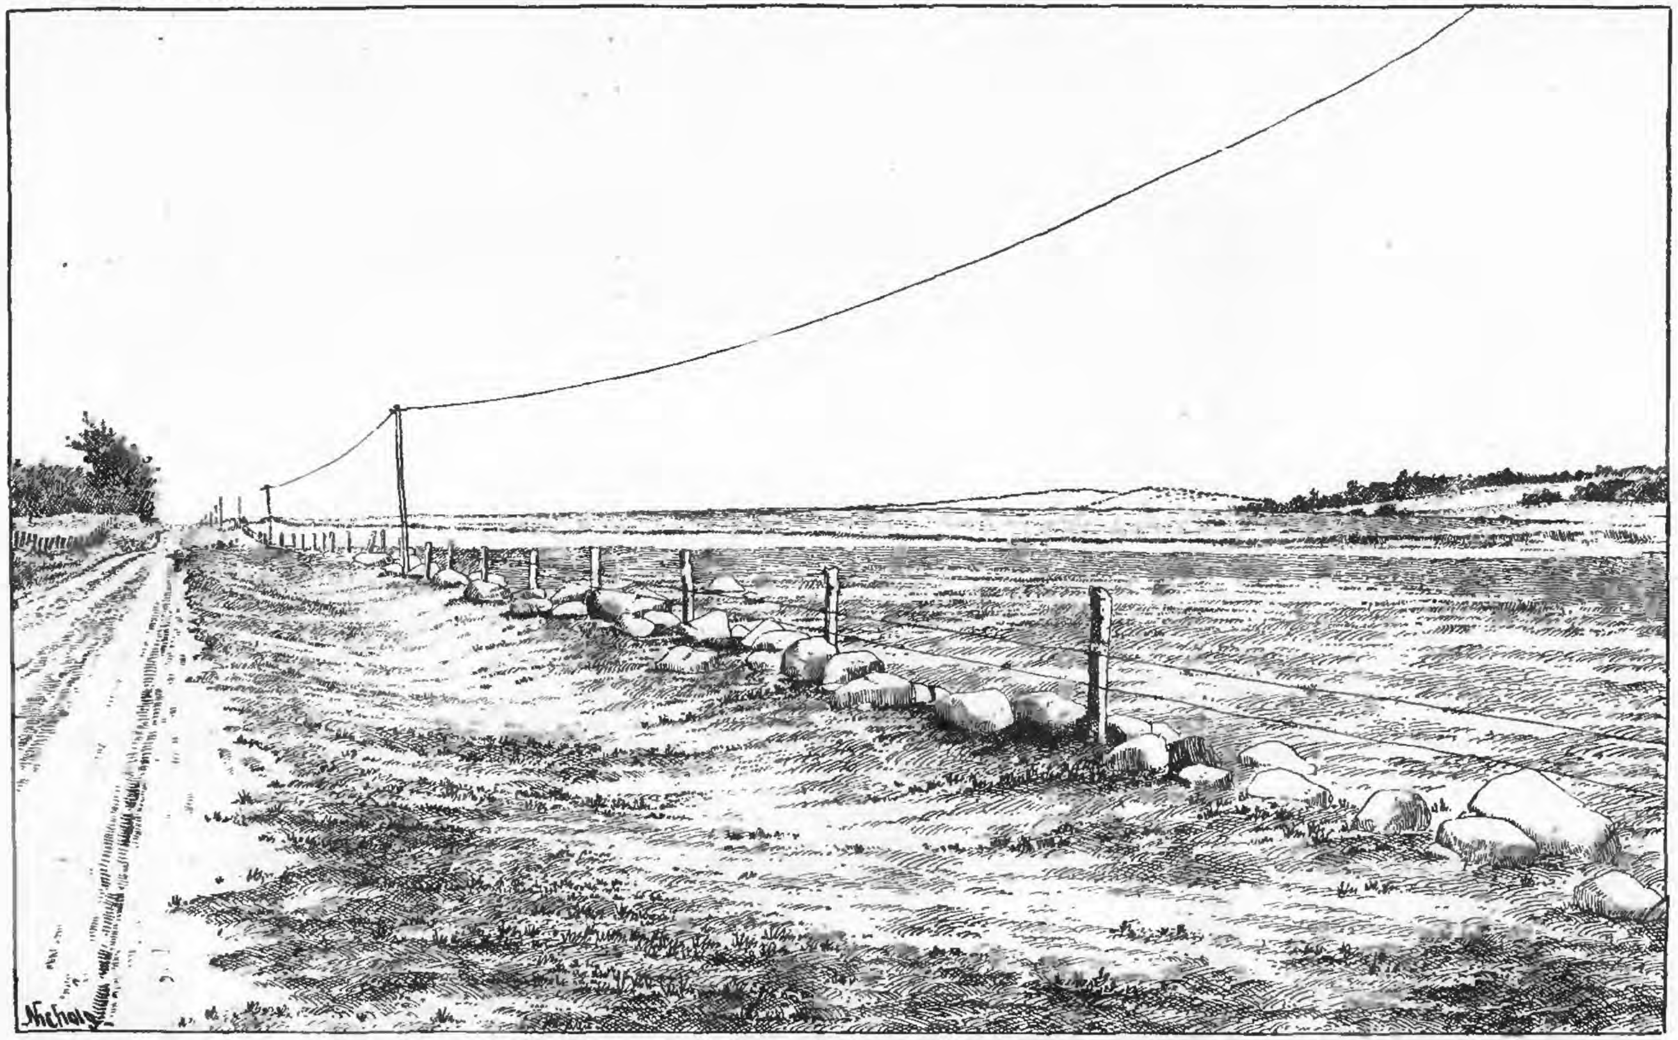
tendency to accumulate on southerly slopes of summits and on northerly slopes in valley bottoms; but this tendency is best marked among the paha.

In brief, while the basal pebble-bed is protean, it is a (if not *the*) distinctive feature of the northern loess; yet it is, perhaps, not altogether superfluous to point out that the feature is not wholly unique. Throughout Northeastern Iowa the loess everywhere grades downward into (1) a bed of water-laid sand and gravel like that exhibited in most of the foregoing sections; (2) stratified sand, like that exhibited in Fig. 47; or (3) modified glacial drift. The same proposition is true of the loess of the Missouri and the Mississippi Rivers generally. About Sioux City the loess is sandy below, and the sand frequently passes into a pebble bed; in southwestern Iowa the drift thins as the loess thickens toward the Missouri River (as shown by White and St. John), and at Council Bluffs and Omaha beds of sand and pebbles occur near its base. At St. Joseph the city is supplied with sand taken from the lower part of the loess; no line can be drawn between the homogeneous deposit above and the sand below, and the same fossils run through both. The deeper excavations at St. Louis generally reveal a bed of sand and pebbles or both at the base of the loess, and the two classes of materials intergrade; and the prevailing relation holds still farther southward. The relation between the homogeneous upper member and the heterogeneous lower member of the loess, not only in Northeastern Iowa but throughout the upper Mississippi Valley, is identical with that existing between the homologous (but probably much older) members of the early Pleistocene Columbia formation of eastern and southeastern United States.

Perhaps the most striking attribute of the northern loess is the great altitude at which it occurs. The highest lands in Northeastern Iowa are found in the neighborhood of the Niagara escarpment. The Paleozoic terrane here is commonly covered with the ground moraine



A TYPICAL LOESS MARGIN, FAYETTE COUNTY.

of the Pleistocene glacier, and the land is thus further elevated; but over the obdurate Paleozoic strata, over the dense tenacious drift sheet, up to and over the culminating summits and crests of the entire territory of 16,500 square miles, the fine, friable, readily pulverulent materials of the loess are heaped; and the real altitude is emphasized and exaggerated by the nearly universal forest covering. Along its southwestern boundary the deposit, in its main body and in its digitate spurs, and outliers as well, invariably overlooks the contiguous drift plain; and isolated basins of drift are sometimes found along the loess margin, or even miles within the loess area. The most notable of these completely isolated drift basins is that of southern Dubuque County, between Fillmore and Bernard; but the nearly isolated basin in the western part of the same county, between Dyersville and Epworth, is nearly as striking. The intermediate village of Farley is located on a drift plain, smooth, level and bowlder-dotted as those of 50 miles northwestward; and this drift plain is overlooked from north and south, and less prominently from east and west, by the elevated rim of loess hills, which is barely broken eastward and westward by streams leading respectively into the Little Maquoketa and the North Maquoketa. The hypsographic relations of loess and drift in the southern rim of this basin are shown in Fig. 7 (p. 218); and a profile through it forms Fig. 50. Another noteworthy drift basin is that lying east of Lima, in eastern Fayette County, where the drift floor represents the lower till.

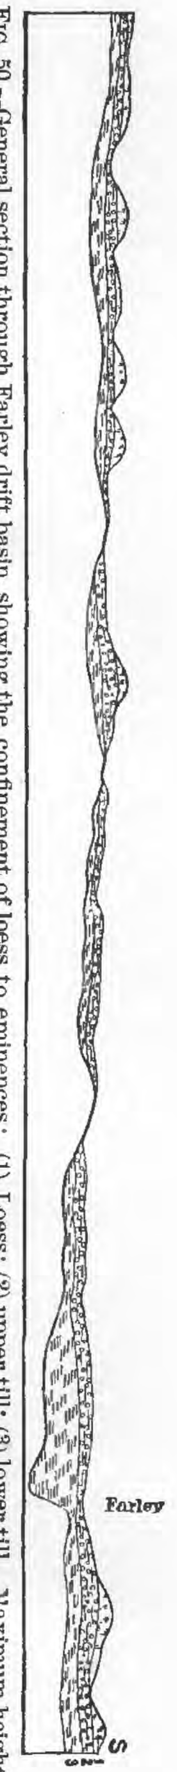


FIG. 50.—General section through Farley drift basin, showing the confinement of loess to eminences: (1) Loess; (2) upper till; (3) lower till. Maximum height from base line, 200 feet; length, 6 miles.

Viewed as a unit, the northern loess varies notably from the well defined margin skirting the drift border belt to the vaguely defined eastern margin traversing the interior of the driftless area a few miles beyond the Mississippi. On the west the deposit maintains its thickness to its very verge, crowns the highest crest within scores if not hundreds of miles in scarcely diminished thickness, and overlooks the drift plain in a prominent scarp; while northeastward the deposit thins rapidly to and still more rapidly beyond the Mississippi, becoming in Wisconsin a sediment-like mantle, thickest in valleys and thinnest over divides, failing or blending with the subjacent residua over the greater eminences and dying out so gradually that its margin can

STRIATED BOWLDER FROM LOESS OF THE NORWAY PAHA.

of the loess coincide with depressions in subjacent drift or rock (indicating that the deposit forms a mantle of approximately uni-

trated in Fig. 53, observed immediately above the bridge of the Chicago, Milwaukee and St. Paul railway over the Wapsipinnicon

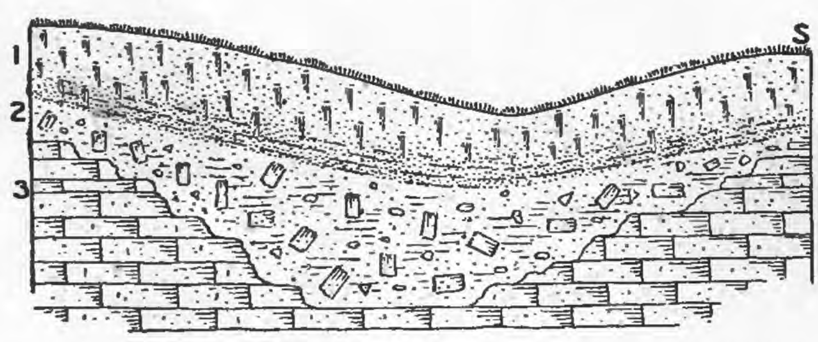

FIG. 53.—Discordance between loess surface and rock surface, Stone City: (1) Homogeneous loess, slightly silty but standing long in vertical walls, light drab, fossiliferous, passing into stratified fine sand, with fragments of *Unio* shells, 10–15 feet; (2) brown and yellow clay and loam containing angular fragments of Niagara limestone like that of immediately adjacent exposures, 1–20 feet; (3) Niagara limestone.

River at Stone City. The section is of additional interest in that the loess grades downward into stratified sand in the manner common to this region; also, in that no erratic deposits appear between the stratified sand and the rock below, although the locality is well within the glaciated area, the mass of clay above the limestone simulating the glacial talus described elsewhere; and moreover, in that, while the homogeneous upper part of the loess here yields only the characteristic pulmoniferous mollusca—*Succinea*, *Pupa*, etc.—in slightly depauperate condition, the subjacent sands contain decomposed shells of undetermined species of the freshwater genus *Unio*.

The behavior under weathering of the loess faces formed by artificial excavation, the relations of the homogeneous upper member

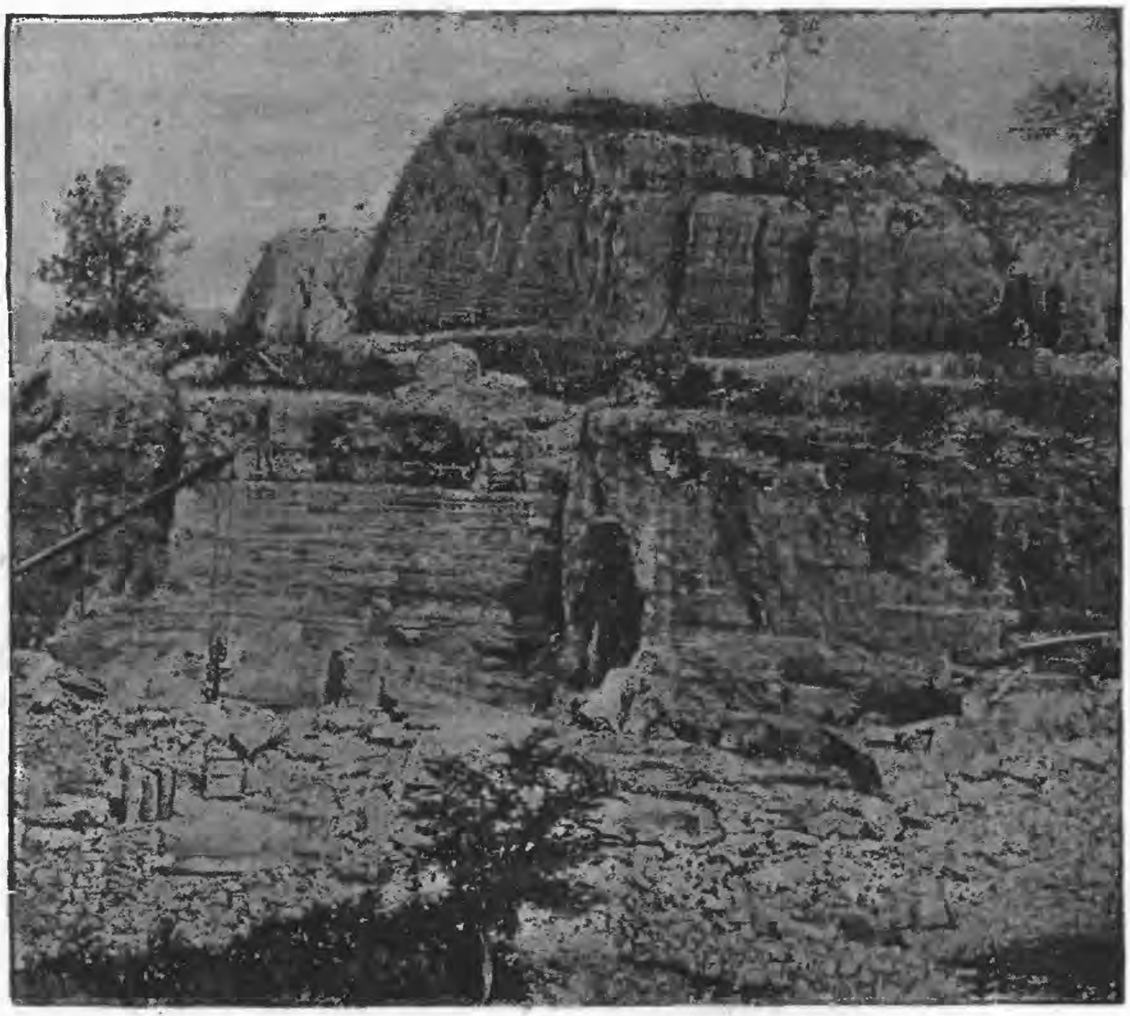

FIG. 54.—Relation of loess to basal sands and subjacent limestone, J. A. Green's quarry, Stone City.

to the stratified lower part, and the relations of both to the subjacent Niagara limestone at Stone City are illustrated in the photograph reproduced in Fig. 54. Here the loess is generally destitute of loess kindchen, though there are scattered throughout it indurated lumps made up of its own materials cemented by carbonate of lime, ranging from a quarter of an inch to 2 or 3 inches in diameter. Calcareous tubules also occur occasionally, particularly between 5 and 10 feet beneath the surface.

The prevailing relations between loess and drift in the region of river ridges and paha are exhibited graphically in the section extending from Onslow northward to the Maquoketa River, forming Fig. 55. Onslow is situated at the south side of one of the most extensive drift lobes extending into the loess area. This lobe is fully 35 miles in length from the drift plain near Prairieburg to its eastern termination near Monmouth. It is nearly isolated by the river ridges flanking the Maquoketa at Monticello and the Wapsipinnicon at Anamosa, and by a series of paha originating on the divide; but east of Langworthy its average width is 3 or 4 miles. On both margins the loess rises in a scarp, sometimes continuous for miles, as in the vicinity of Onslow, but again sinuous and digitate, as in the vicinity of Scotch Grove, ranging from 10 to fully 100 feet in height. The basin is imperfectly drained northward and eastward by streams originating within it, which break through the prominent loess rim into the Maquoketa, and in the days of the pioneer much of it was marshy. Its surface is a uniform plain, dotted with bowlders and destitute of trees, so level that the fences can be followed by the eye for many miles from any part of the bounding loess rim.

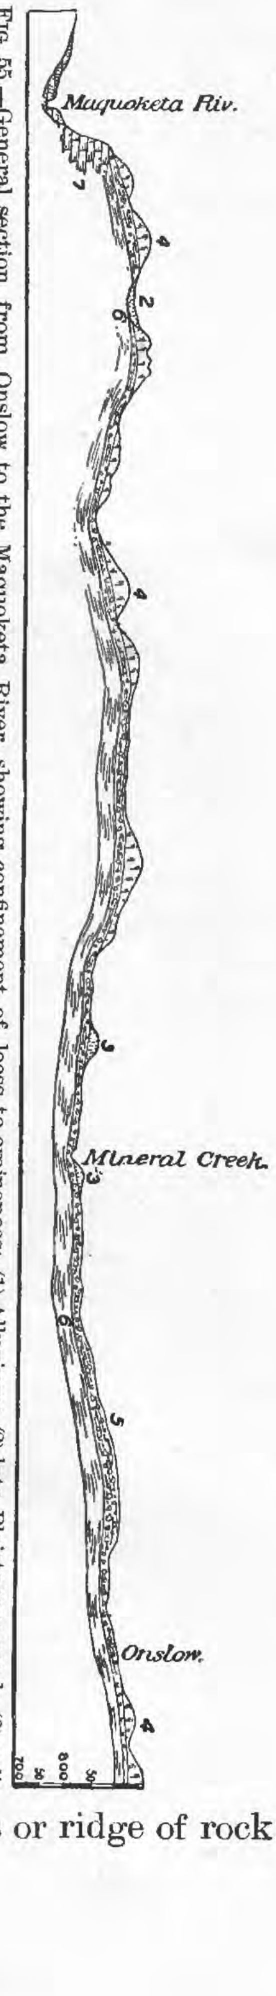

FIG. 55.—General section from Onslow to the Maquoketa River, showing confinement of loess to eminences: (1) Alluvium; (2) late Pleistocene sand; (3) eolic accumulations of sand from base of loess where removed by erosion; (4) loess; (5) upper till; (6) lower till; (7) Niagara limestone.

It frequently happens that the bluffs and ridges of the loess of the middle region have nuclei of rock rising well toward their summits. This relation is exhibited by nearly all of the ridges cleft by rivers. On the Maquoketa between Delhi and Hopkinton, and again north of Onslow; on the Wapsipinnicon at Quasqueton, and near Anamosa; on the Cedar at Osage, below Vinton, and near Moscow; and on the Iowa at its great elbow, and in many other localities, the indurated rocks of the Paleozoic subterrane rise not only to unusual heights, but even above the level of the drift-plain surface on either side of the ridge. So, in a general way, the cross section through a paha exhibits at the base a boss or ridge of rock; next in order a local thickening of the glacial drift; and finally a nearly coincident cap of loess, fine and homogeneous above, sandy and stratified below, and thinning out and quickly disappearing laterally. But in longitudinal section the boss or ridge of rock

abundant; while on the lower Wapsipinnicon and Cedar Rivers in the south the deposit approaches that of the Missouri River in texture, structure, composition, and habit of weathering.

The thickness of the sheet of loess crowning the river ridges and paha ranges from a veneer just sufficient to give character to the soil to 50 or 75 or even (about the great elbow of the Iowa River) 100

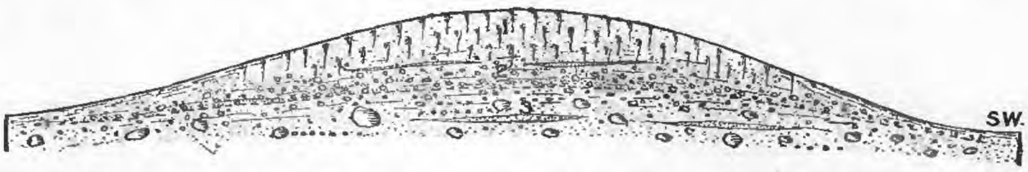

FIG. 56.—Relation of loess to drift in paha, generalized section: (1) Loess, perhaps sandy; (2) laminated sand, sometimes containing pebbles and lenses of gravel; (3) upper till.

feet. The mean thickness within its actual area is, despite the enormous local accumulation, probably less than 10 feet; for while the deposit rises in conspicuous ridges and plateaus 20 to 200 feet in height, it does not form but simply coats or only veneers most of the eminences to which it gives character. The relations are semi-ideally illustrated in Fig. 56.

The loess of the river ridges and paha is fossiliferous throughout the greater part of its extent. The northernmost locality at which fossils have been found, in the loess of this phase and of the territory as well, is the Waverly Plateau, in the SW. ¼ NW. ¼ Sec. 27, T. 91 N., R. 13 W., where it yields *Helicodiscus lineatus* and *Succinea avara*, as already noted. Abundant fossils occur also immediately above the Palisades overlooking the Cedar River south of Mount Vernon; fossils may be found in most good exposures over the Iowa-Cedar divide in northwestern Johnson and western Cedar Counties; and they are especially abundant about the elbow of the Iowa, north and northwest from Iowa City. At Stone City fragile bits of shells of *Unio* or *Anodonta* have been found. With this exception the facies of the entire fauna of the deposit is represented by that described at Iowa City by Shimek.[1]

The Iowa City fauna is as follows:

Succinea avara, quite abundant; unlike the living form.
Succinea vermeta, quite abundant; larger than the living form.
Succinea obliqua, abundant; somewhat unlike living forms.
Pupa muscorum, common; now extinct.
Pupa blandi, common; now extinct.
Pupa armifera, rare; like the modern form.
Patula striatella, quite abundant; like the recent form.
Patula strigosa, quite rare; now extinct.
Vallonia pulchella, quite abundant; larger than the recent forms.
Helicina occulta, abundant; smaller than the recent form.
Physa, sp. und.; exceedingly rare.

[1] Am. Geol., 1888, vol. 1, pp. 149 to 152.

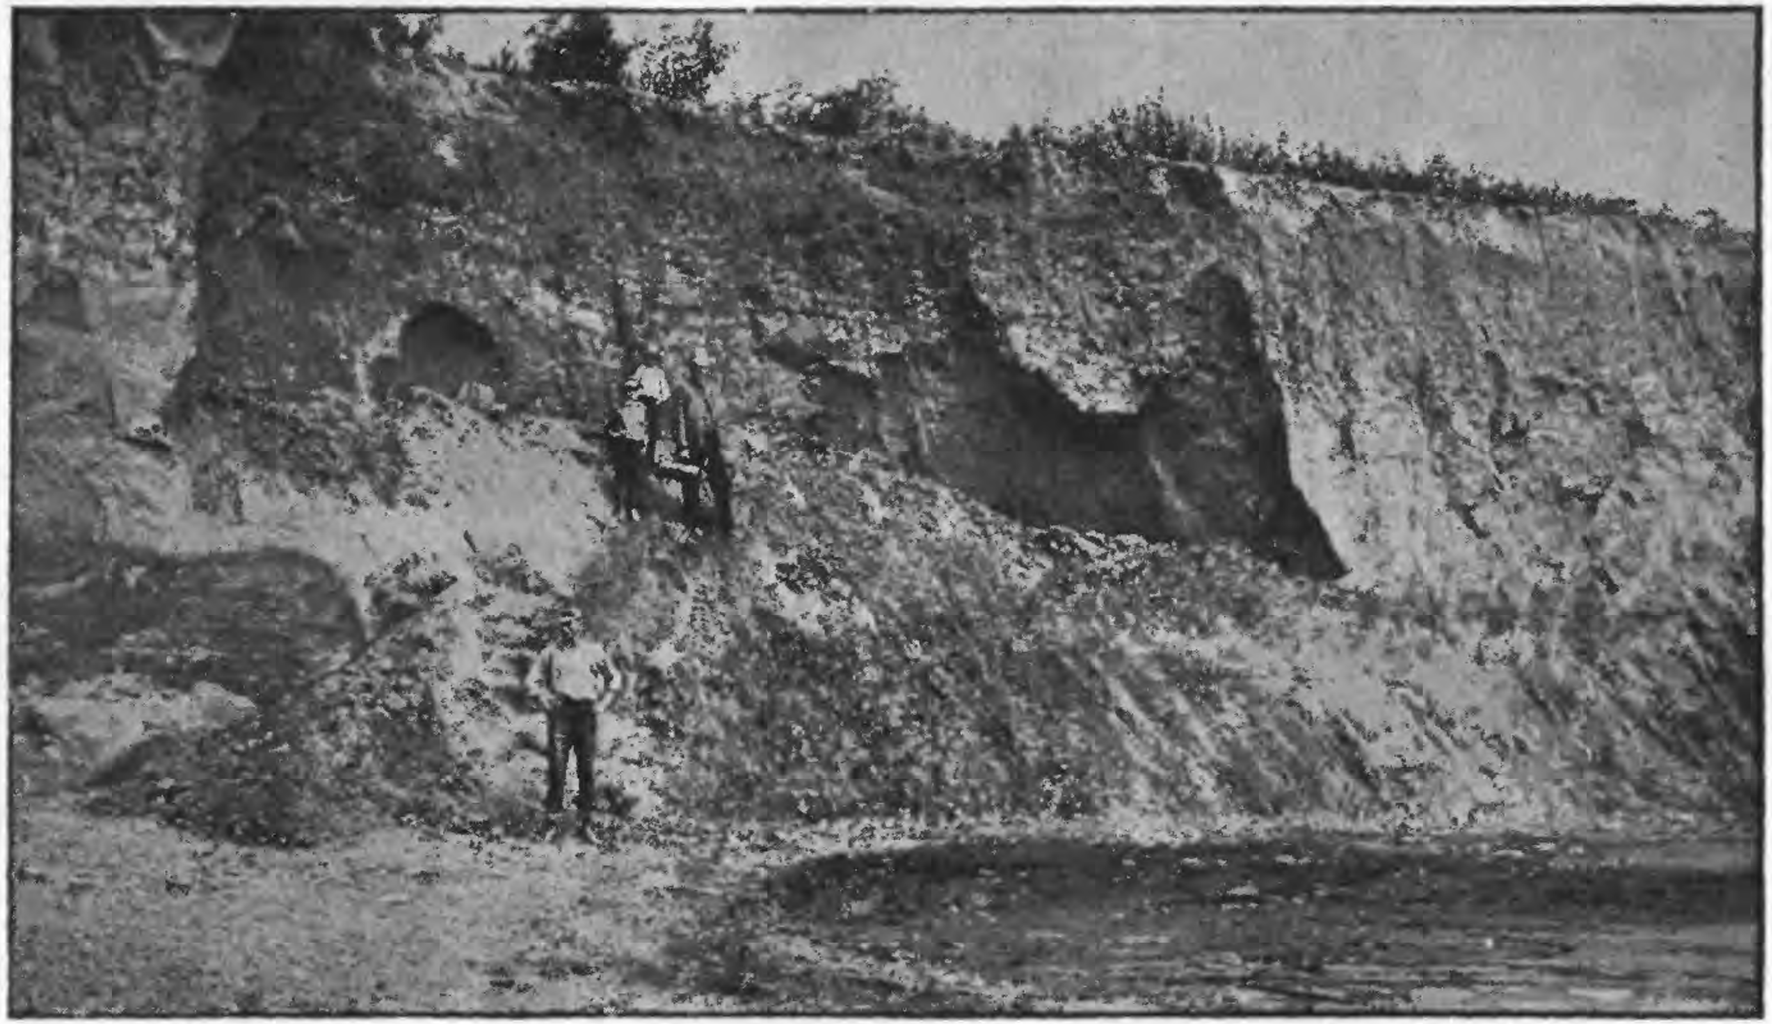
by dendritic drainage, and rises into ridges—i. e., the sensibly horizontal plains have their northern edges tilted in such manner that their margins form low, smooth scarps as seen from within, and high and steep scarps as seen from the waterway without. This feature is illustrated in the general section from the Mississippi to the Wapsipinnicon, through Scott County, forming Fig. 57. Now, in all these upturned northern edges, the loess grades downward into stratified and cross-laminated sand, sometimes of great thickness; and by the erosion of the marginal loess these basal sands are exposed, and along the Iowa and the Wapsipinnicon they are blown into dunes and drifts interspersed with ponds; and in some cases the loess fossils extend well down into the stratified sands—e. g., in the SW. ¼ NE. ¼, Sec. 29, T. 80 N., R. 5 E., in Scott County. The principal eolic deposits of the southern counties, indeed, are derived from the basal sands of the upturned and ravine-scarred northern margins of the southern loess fields.

Fig. 57.—General section through Davenport from the Mississippi to the Wapsipinnicon, showing surface planes of the loess, etc; (1) Loess; (2) upper till; (3) lower till.

There are two drift sheets in Northeastern Iowa, slightly different in composition, notably different in area, and widely different in age, yet so similar in certain characters that they may hardly be distinguished, save when well exposed in natural juxtaposition with the forest bed between. The southern margin of the upper drift sheet lies not far from the southern limits of the territory; and about its margin this drift sheet is sometimes discontinuous. So the loess may rest upon the older drift sheet, perhaps with the forest bed between. Such is the case in the classic Davenport locality, where a buried soil—an ancient land surface mantled by moss and other vegetal matter—separates the drift-like base of the loess from the older drift sheet.[1] Such is the case, too, in many other localities.

In the exposure 3 miles northwest of Muscatine, illustrated in Pl. L, the loess (which is here accumulated in the form of a paha) becomes stratified and sandy below and rests upon an ancient soil 4 or 5 feet thick, which in turn passes into the lower drift sheet. In northeastern Muscatine, in the first spur beyond Mad Creek, the following strata are exposed in the bluff face:

[1]Proc. Dav. Acad. Sci., 1876, vol. 1, Pl. XXXII.



A TYPICAL EXPOSURE OF SOUTHERN LOESS, MUSCATINE.

ties. The nearest approach to the ideal type of the deposit displayed on the Missouri River, e. g., at Council Bluffs, is found crowning the eminence known as "The Hill" in southern Muscatine. The deposit here is practically homogeneous throughout a thickness of 30 to 50 feet; it abounds in fossils from summit to base, and not only the tiny and fragile shells of land snails, but even the minute and exceedingly fragile eggs of one of their species are preserved; the characteristic loess-kindchen occur in moderate abundance; irregularly ramifying tubules penetrate and agglutinate the mass in all parts; and the vertical faces formed in street-grading display the marks of the implements by which they were cut for months and stand intact for years.

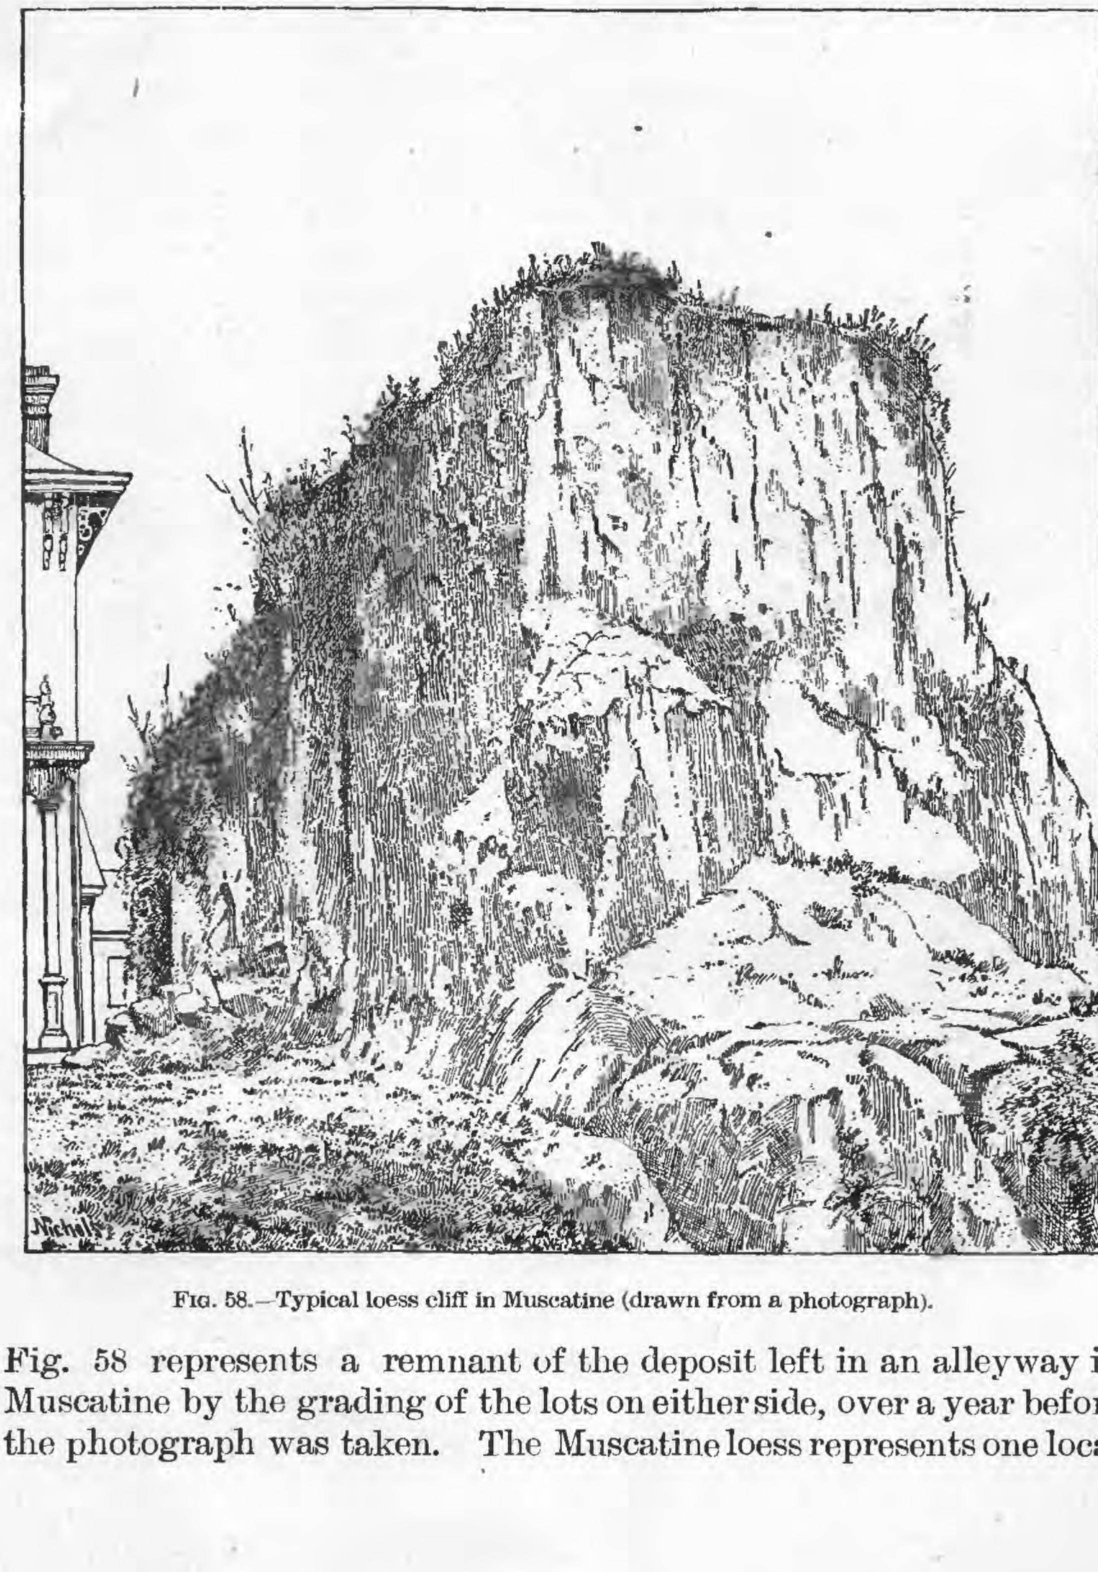


FIG. 58.—Typical loess cliff in Muscatine (drawn from a photograph).

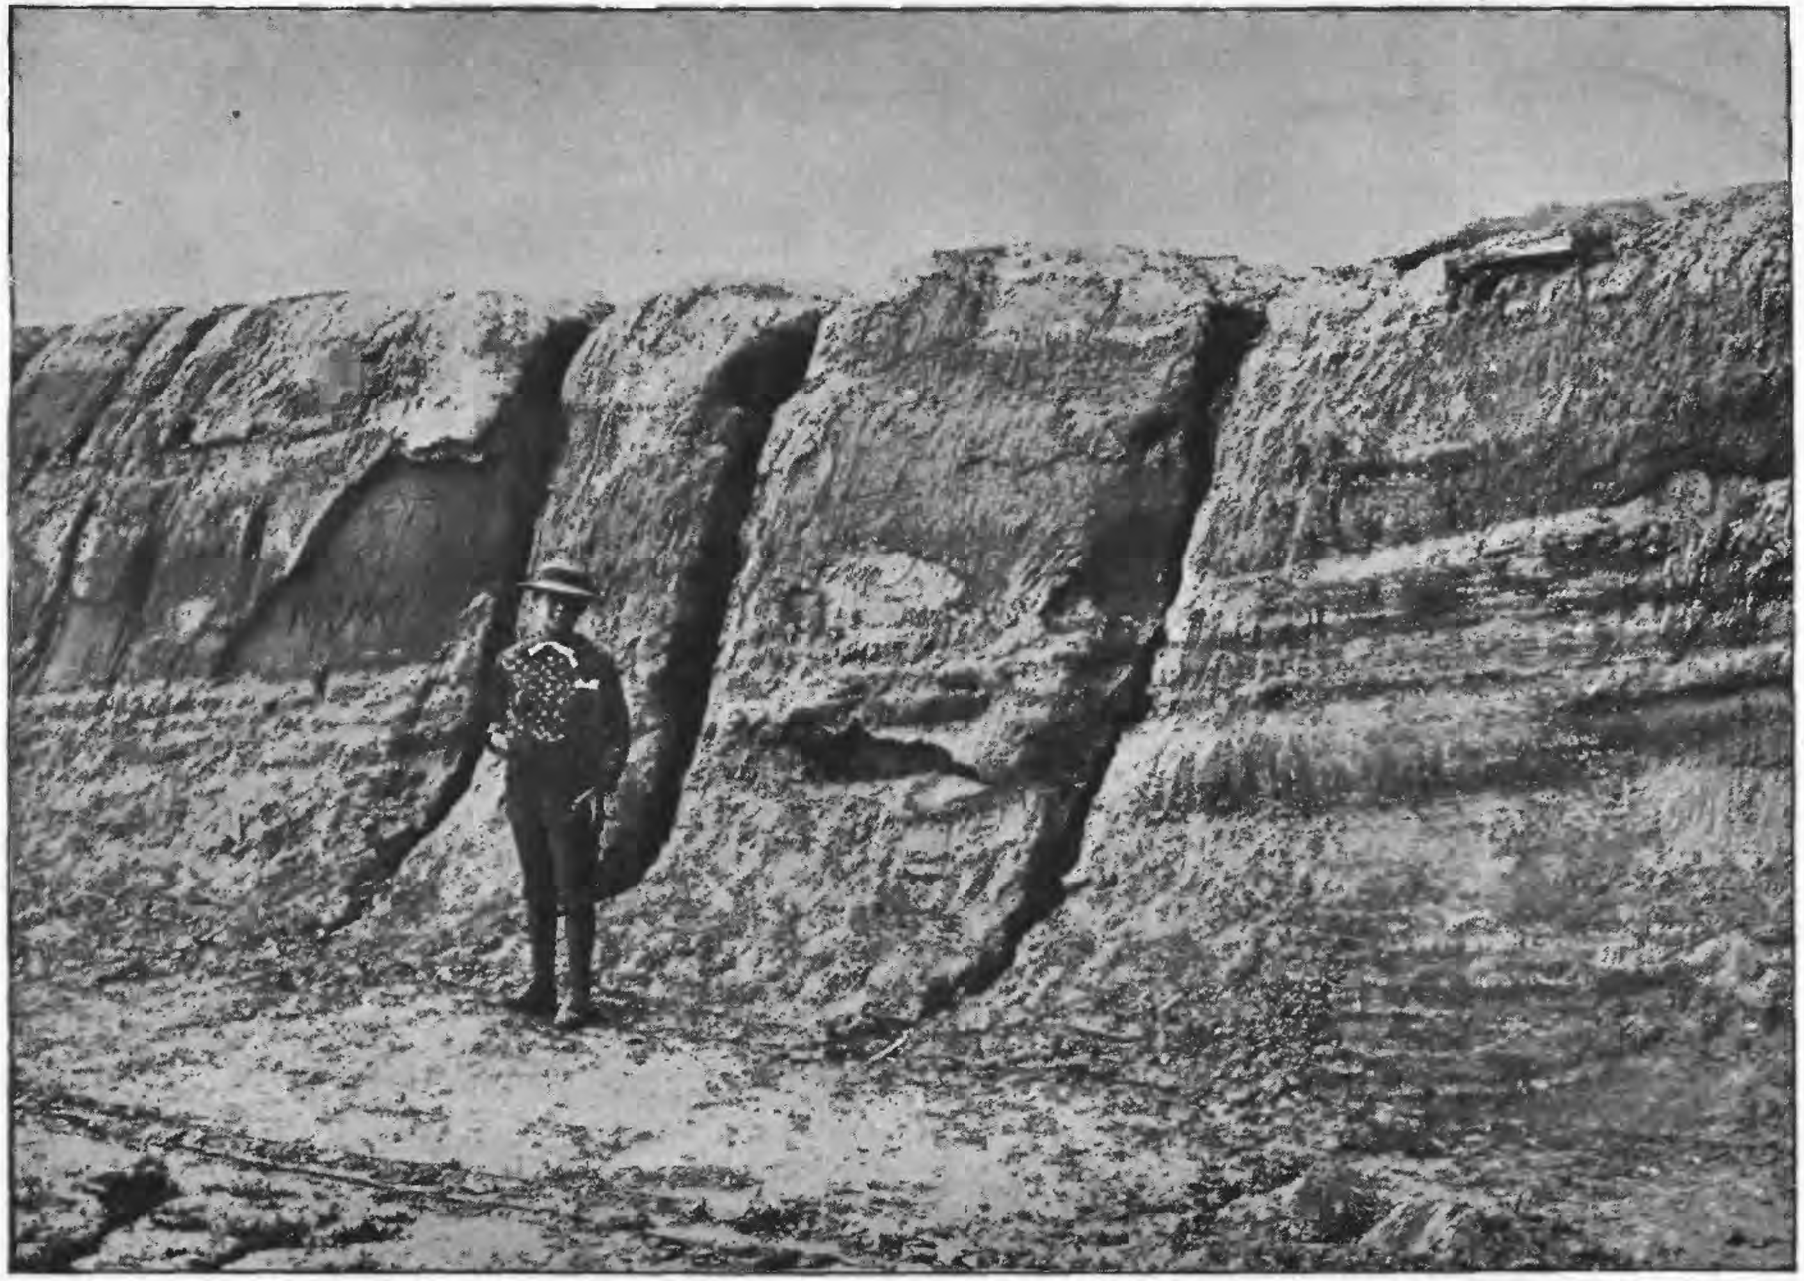
Fig. 58 represents a remnant of the deposit left in an alleyway in Muscatine by the grading of the lots on either side, over a year before the photograph was taken. The Muscatine loess represents one local



STRUCTURE OF LOESS, MUSCATINE.

phase of the deposit; the clayey veneer concealing the drift on Deer Creek, in Tama County, represents another extreme; but all possible intermediate phases are represented in different parts of the area.

The stratigraphic variation is no less notable. Plate XLVII illustrates the transition from the homogeneous upper portion to the obscurely stratified medial portion of the deposit in Muscatine; and a parallel transition is exhibited in every considerable exposure within the southern era. The deposit is always more homogeneous above and becomes more heterogeneous below either by stratification or by the intermingling of pebbles or other coarse material.

In the southern counties as in the northern the loess is stratified or banded, perhaps by layers of unequal wetness; and this banding is most conspicuous about mid depth of the deposit between the homogeneous upper portion and the stratified or promiscuous lower portion. Plates XLVIII and XLIX, reproduced from photographs, illustrate this banding at Muscatine. As in the north the banding is horizontal or slightly inclined in the direction of the slope; and sometimes the bands are contorted. A good example of such contortion in the basal and sandy portion of the deposit, occurring in the northern part of Muscatine, is illustrated in Fig. 59. The visible

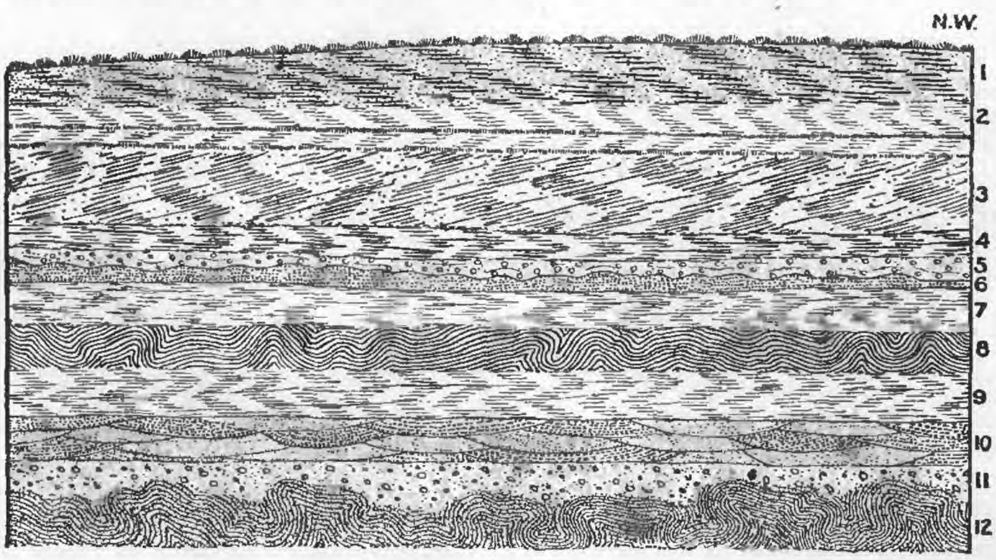


FIG. 59.—Stratification and contortion of loess base, Muscatine: (1) Surface soil and loam; (2) marly loam with a double carbonaceous line at base; (3) obliquely, laminated arenaceous silty clay; (4) fine silty clay horizontally laminated; (5) brown gravel partly cemented with iron oxide, apparently unconformable to subjacent layer; (6) brown and red horizontally laminated sand; (7) regularly laminated white silty clay; (8) laminated buff silty loam, contorted as shown; (9) regularly laminated white and light buff silty clay; (10) coarse red, brown, and buff sand, cross-stratified and laminated; (11) sand, gravel, and coarse pebbles, generally resting in and on the corrugations of the lower member; (12) laminated marly sand, contorted as shown. Total exposure, 20 feet.

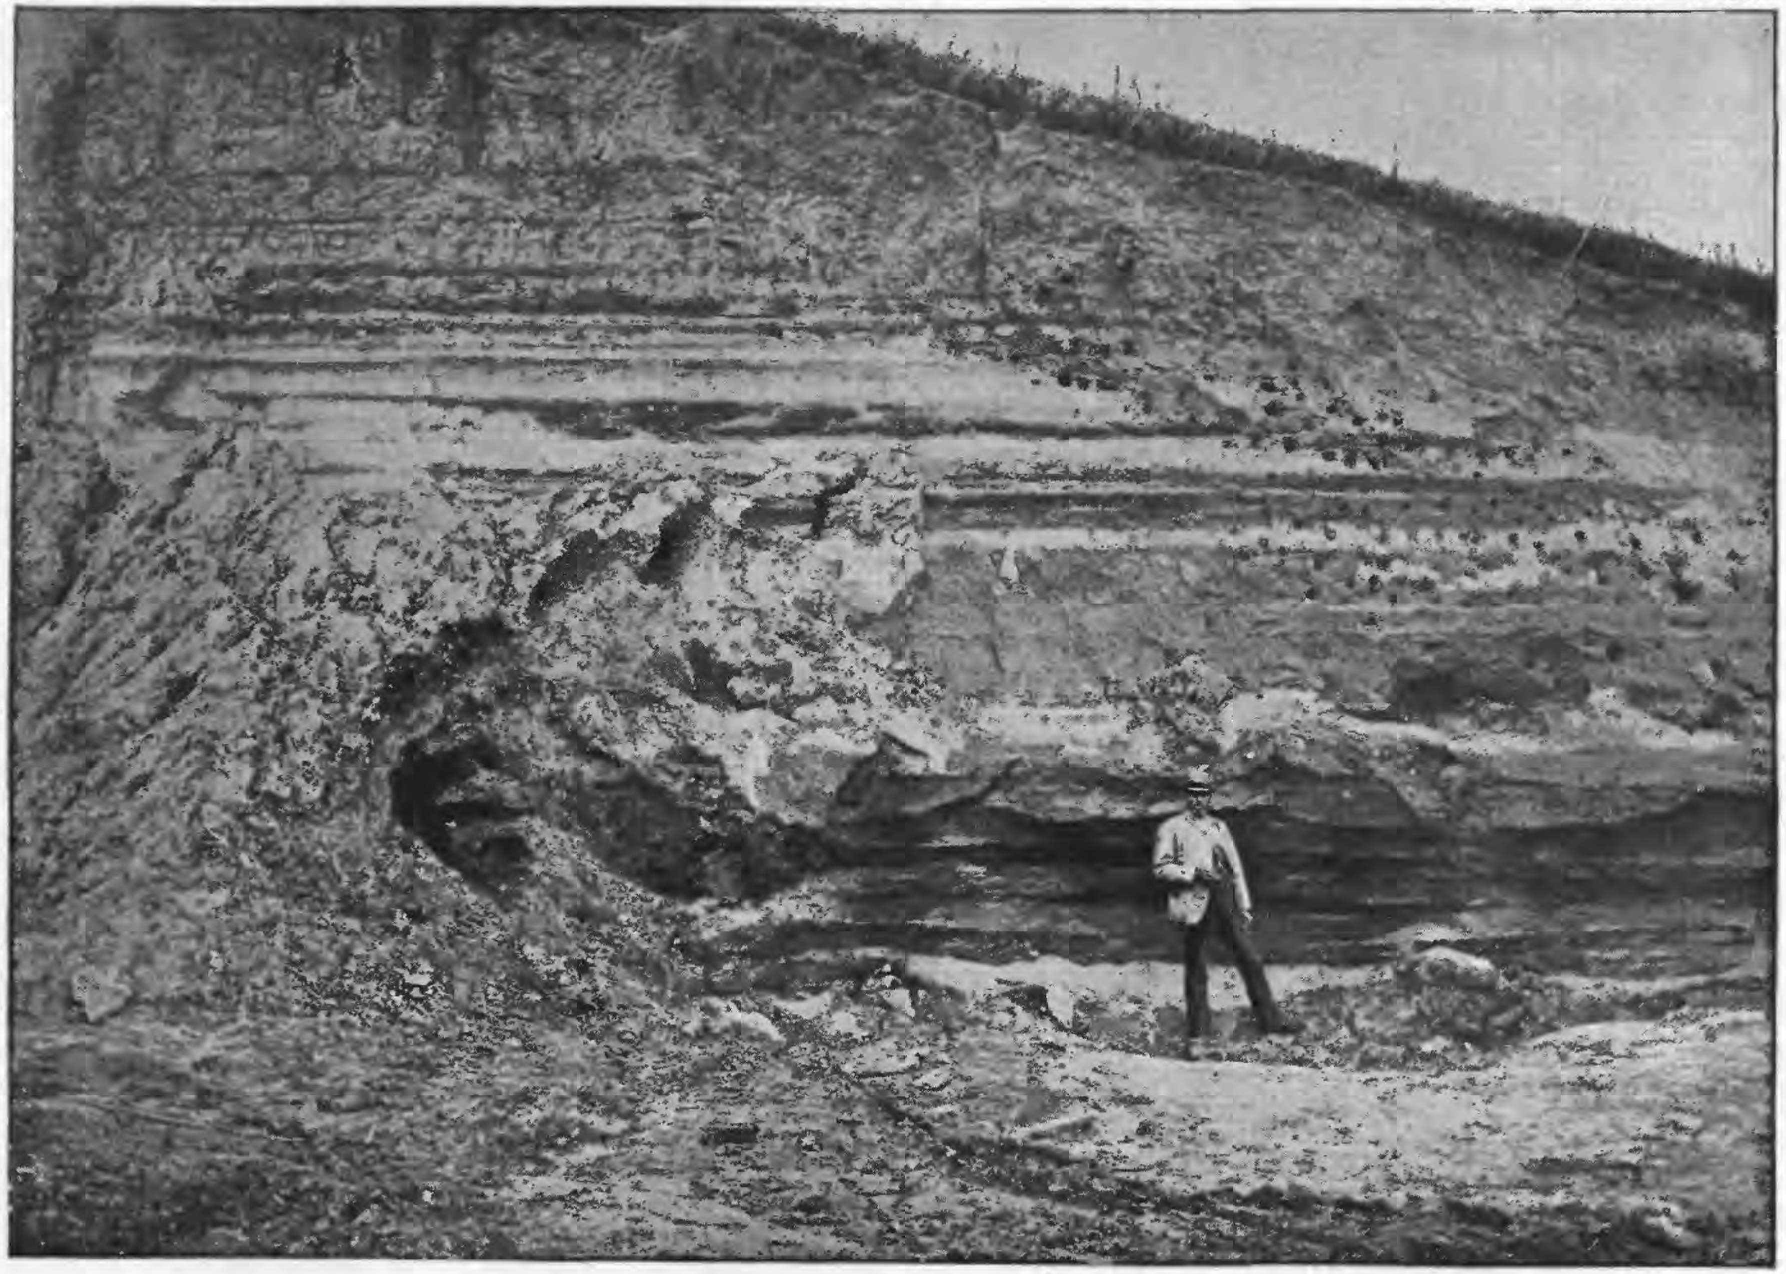
deformation here is confined to certain horizontally laminated and exceptionally plastic strata, suggesting not only that the contortion was produced by inequipotential slipping of the mass, but also that the slipping was confined to the most readily yielding beds.

In hypsographic distribution the southern loess is allied to the northern phase, in that it sometimes seeks eminences and avoids de-



STRUCTURE OF LOESS, MUSCATINE.

of the deposits are compared, which strikes the comparative student more forcibly than that heterogeneity in the small way which is prominent when a single exposure of small extent is studied. Let the term homogeneity for present purposes express the idea of homogeneity in this large way. Then, throughout the northern portion of the territory, the upper till is commonly homogeneous in both horizontal and vertical directions; in the horizontal direction it remains essentially the same from mile to mile, and in the vertical direction it is fairly homogeneous from yard to yard of its thickness, and from the low hilltops to the shallow valley bottoms of the gently undulating plains formed by its surface. But this homogeneity is sometimes interrupted by far traveled bowlders whose diameter may exceed the thickness of the deposit; it is also interrupted where the sheet is exceptionally thin and where the Paleozoic subterrane or the older till have, by reason of local conditions, contributed in unusual amount to its materials. Moreover, gradual change in composition may be observed in passing from the interior of the drift field toward the drift margin in the great crest overlooking the Mississippi; and a still more gradual change supervenes in traversing the territory from north to south.

The thickness of the sheet is variable. Along the margin of the driftless area it is usually denuded and, overlain as it generally is by loess, becomes inconspicuous. Along this line and north of Dubuque County it commonly rests upon the lower till or modified representatives of that deposit, though occasionally the older deposit has been removed and the newer lies in part upon ice-worn contours of the lower till and in part upon rock, as shown in Fig. 60, representing a section observed in a road cutting in NE. ¼ SE. ¼ Sec. 15, T. 90 N., R. 3 W., Delaware County.

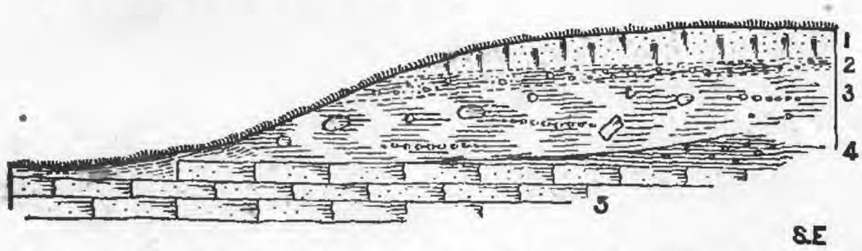


FIG. 60.—Partial removal of lower till by later ice work, Delaware County: (1) Loess; (2) yellow sandy and gravelly clay, irregularly stratified; (3) unstratified yellow clay with local and erratic bowlders and pebbles; (4) dark laminated clay with fragments of chert and small erratic pebbles; (5) Niagara limestone. Mean exposure, 10 feet.

No morainic accumulations appear along the eastern margin of the upper till save in two localities: (1) Between West Union and Fayette the marginal drift rises into an irregular series of steep, rounded knobs, sometimes loess-capped, but more frequently exposing gravel with numerous rounded pebbles and bowlders on their weathered summits. Many of these are high and conspicuous. One in particular, 3 miles southeast of West Union (locally known as Jones Hill), is a prominent landmark. Though in general form, distribution, and association with ponds and dry basins these knobs are decidedly moraine-like, they are confined to an area of only a few square miles; there is no general thickening of the drift in their vicinity, and the loess capping and elongated form of many of the isolated knobs distinguish them from true terminal moraines like that found 80 miles farther westward. (2) Again, between Rockville and Sand Spring, in eastern Delaware County, particularly 3 miles southwest of Worthington, there is a congeries of isolated knobs, sometimes loess-covered, but again built of bowlder-charged drift to their very summits, which are of decidedly morainic aspect; but they are fewer in number than those of Fayette County, and at least a part of them pass into paha.

The range in thickness of the till is increased by these anomalous deposits, yet the thickness probably nowhere exceeds, if it reaches, 100 feet; in general it is not more than 20 feet; over considerable areas it ranges from 5 to 10 feet; and toward the Niagara escarpment in northeastern Howard and northwestern Winneshiek Counties, west and south of Fort Atkinson, for some miles around Brush Creek, over the divide between Plum Creek and the North Maquoketa in eastern Delaware County, and in many more restricted areas, its thickness is less than 5 feet; and it frequently disappears completely, leaving tors of Niagara limestone wholly uncovered or only dotted with erratic pebbles and bowlders.

There is a progressive increase in thickness of the till westward from its eastern margin to the western limit of the territory, yet here and there it attenuates locally and sometimes forms but a trifling mantle over the subjacent Paleozoic strata—e. g., over the divide between Flood Creek and the Cedar in Floyd County, where an interesting relation between configuration and drift accumulation is displayed. This relation is roughly illustrated in the generalized section across Floyd County from west to east a mile south of Rockford and Charles City (Fig. 61), constructed from

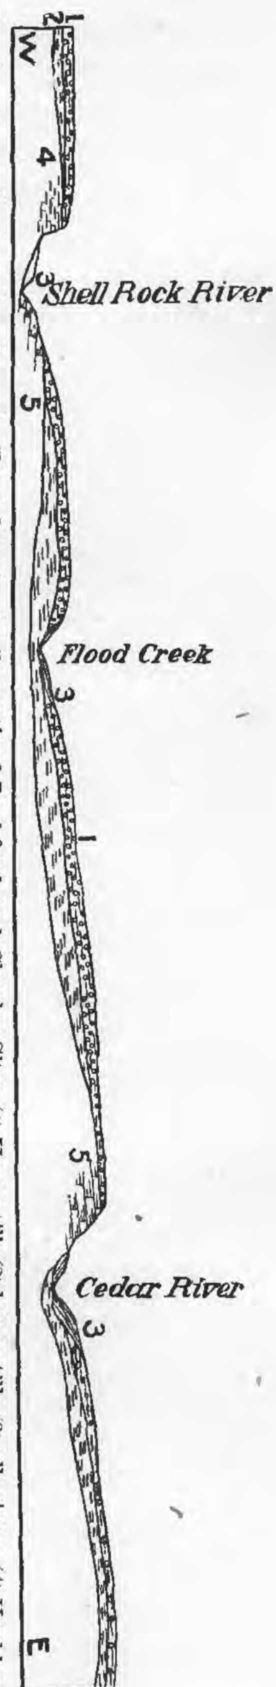

FIG. 61.—Generalized section through Floyd County, 1 mile south of Rockford and Charles City: (1) Upper till; (2) lower till; (3) alluvium; (4) Hackberry shale; (5) Cedar Valley limestone. Relief, 200 ± feet; length of section, 24 miles.

data collected by observations upon the surface and examination of natural and artificial exposures at various points. The same relation is illustrated in greater detail in the section reproduced in Fig. 62, constructed from surface observations and study of well excavations in southeastern Floyd County.[1] From these sections it will be apparent that the upper till tends to attenuate over crests and thicken in depressions (though certain exceptions to this law appear), that the lower till displays the same tendency in a much more decided way, and (from Fig. 62) that the forest bed fails in exceptionally exposed situations and is deeply buried in exceptionally protected situations—in short, it is apparent that in this part of the territory the ice sheet was both constructive and destructive in its operation, its special agency being determined by local conditions.

FIG. 62.—General section in Floyd County: (1) Upper till; (2) compact dark clays of lower till; (3) gravel and sand (water bed) of lower till; (4) Cedar Valley limestone; dark shading—forest bed. Relief, 50 feet; length of section, one-half mile.

The maximum thickness attained by the upper till in the northwestern part of the territory can be confidently estimated to probably reach and perhaps exceed 80 feet, and the mean thickness in the northern half of its extent may be roughly estimated at 20 feet.

The usual relations of the upper till to older deposits are illustrated in many of the well sections represented in Pl. LI. Its relations to older and newer Pleistocene deposits and to the Paleozoic strata about the margin of the driftless area are more clearly illustrated in Fig. 63,[2] representing general sections extending from Farley to Dubuque. The sections represent also the relation between the till and the Niagara escarpment; for it is a significant fact that for a hundred miles the glacial deposit extends with unbroken continuity over gentle slopes to the very verge of an exceedingly sinuous and deeply crenulate escarpment, to there suddenly cease entirely or suffer transformation into a bed of water-sorted sand, gravel, and bowlders. Here as elsewhere along the great Niagara escarpment the unmodified glacial deposit extends only to the verge, and its limits in the valleys thus fall far short of those reached on the hills. So about the driftless area

[1] The wells indicated are represented on a larger scale in Pl. LI, and described in section V of this chapter under the following numbers: I = 15; II = 13; III = 11; IV = 10; V = 16; VI = 12, and VII = 14.

[2] This figure represents three sections, the uppermost along the principal wagon road (the "old Delhi road"), the intermediate one along the line of the Illinois Central Railway, and the lower along the line of the Dubuque and Dakota Railway.

margin the unmodified upper till may be traced to the extremity of a salient, and no representative of the deposit may be found for miles beyond; but if the line of examination be so projected as to cross another salient, howsoever long, narrow, and curved, the till is nearly sure to reappear on its crest, as in the case a mile north of Lattner's, illustrated in Fig. 64. Viewed by itself such a section would naturally be interpreted as a record of erosion since the deposition of the till; but there is abundant evidence that the complex configuration of the Niagara escarpment has been little changed since the advent of northern ice. In some cases the upper till, or a modified representative of that deposit, may be found in completely isolated patches crowning uplands (commonly beneath a mantle of loess) completely divided from the general drift area by drift-free transverse valleys, as about Preston and Goose Lake.

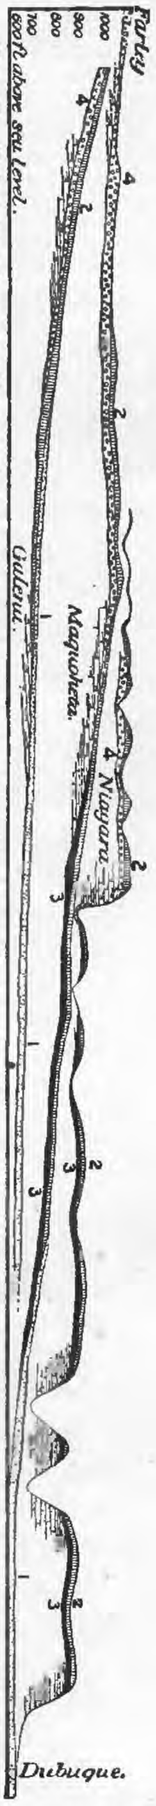

FIG. 63.—Relations of upper till toward its eastern margin; general section from Farley to Dubuque: (1) Alluvium; (2) loess; (3) geest; (4) upper drift clay.

The principal material of the upper till is a mixture of finely comminuted rock débris, exhibiting the consistency and commonly taking the name of clay. This fine material, however, can only be arbitrarily separated from sand, which in turn can be separated only in the same way from gravel, that from pebbles, and these from cobbles and bowlders; so that the dimensions of the component particles of the drift sheet here, as commonly elsewhere, represent an unbroken series from the finest to the coarsest. The finest particles, like the coarser, are found under the microscope to consist mainly of rock fragments, and beneath the reach of weathering this rock débris usually effervesces freely under acid, indicating that the particles have not been exposed to the air or to free percolation of water since the original trituration beneath the ice field.

The prevailing color of the upper till is yellow or buff, running into gray, and rarely into reds and browns; i. e., it is commonly stained by hydroferric oxide. Exceptions to this prevalent coloration frequently occur, however, particularly in ill drained sloughs, where there are considerable accumulations of iron in the form of bog ore, either in nodules or in films incrusting pebbles and bowlders, and in which the deposit frequently assumes the blue color given by the ferrous oxide which commonly characterizes the lower till.

This unusual coloration sometimes extends several feet into the newer till, but never, so far as yet seen, to the junction with its older homologue.

It is significant that other conditions leading to decomposition of organic matter than slow maceration in sloughs are equally potent. It has frequently been observed that beneath barnyards and in all similar situations the upper till assumes a blue color undistinguishable from that of the lower; and in a known instance the change was effected within a few months. The section exposed in the shallow well represented in Fig. 44, and again with associated phenomena in Fig. 65, is of interest in this connection; for although the alteration in color is mainly confined to the loess, it extends some distance into and similarly affects the upper till. The well was excavated in a barnyard which had been in use for a year or less. In this case deeper extension of the blue color may have been prevented by the more porous pebbly stratum below.

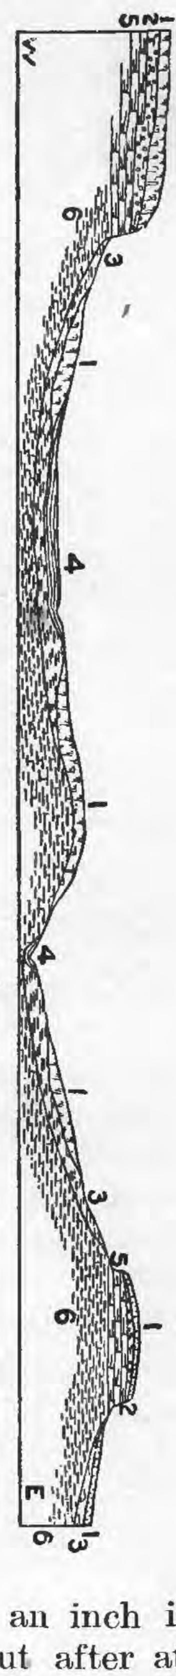

Fig. 64.—Relations of upper till toward its eastern margin; general section near Lattner's, Dubuque County: (1) Loess; (2) upper till; (3) water laid beds of local and erratic débris and residuary clays; (4) alluvium; (5) Niagara limestone; (6) Maquoketa shale. Relief, 300 feet; length of section, 3 miles.

This section is of interest, too, in that it illustrates the relation between change in coloration and the formation of ferruginous nodules, and indeed exhibits the precise mode of formation of such nodules; for nodules in all stages, from simple, indefinite staining to the complete form, were displayed. The process appears to be as follows: At a point where several minute fissures or jointage planes intersect in such manner as to form a solid angle projecting downward, but from which no openings extend in such direction as to drain the fissures at the point of intersection, a slight accumulation of the iron carried downward through the fissures takes place. At the same time the clayey material appears to undergo some condensation, so that the fissures are enlarged; and from a thin film of ferric oxide staining the surface the deposit increases until it forms a deep brown, incoherent shell, resembling ocher in composition, perhaps a tenth of an inch in thickness. Thus far the shell remains open above; but after attaining a thickness of from a tenth to a fifth of an inch (the thickness attained varying directly with the size) the process of nodulation proper commences, and the shell grows upward and inward, at first simply as a dark stain cutting off the downward projecting angle of clay; and along the rudely spherical surface so marked out, segregation proceeds, the stain is converted into a shell or crust, and a fissure is gradually formed about its periphery. Accretion from without seems to practically cease with the completion of the nodular shell; but as this becomes indurated, segregation takes place from

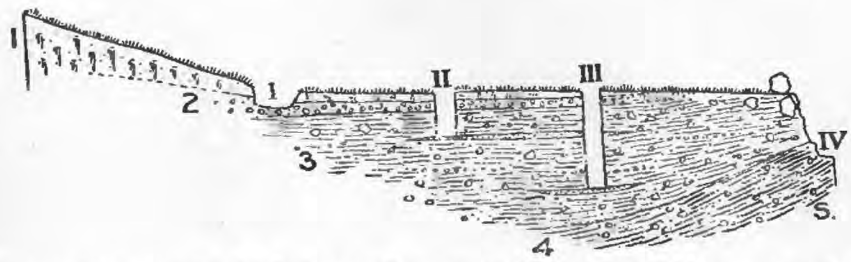

FIG. 65.—Representative section in Dubuque County: (1) Loess; (2) pebbly stratum (loess base); (3) coarse yellow pebbly clay, unstratified, but with a few irregular horizontal sand veins; (4) lower till. I is a road cutting; II is the shallow well illustrated in Fig. 44; III is a well yielding a large supply of water; the space between III and IV was in early days a quaking bog during much of the year; IV is a natural gully, with springs formerly flowing from the summit of the lower till. The bowlders near IV reach 5 feet in diameter. The striated pebbles illustrated in Fig. 68 came from the well at III. Location, near the center of Sec. 31, T. 89 N., R. 1 W.

within, and the inclosed nucleus of clay becomes bleachedand perhaps indurated. The nodules formed in this manner commonly have at first an angle projecting downward and a rounded surface above; but like other forms of limonite they are exceedingly unstable in configuration, and the original attitudes and dimensions may become greatly changed.

Next to the mass of rock débris commonly called clay, the most abundant material of the upper till is sand. A considerable proportion of this sand is quartzic and more or less sharply angular; but grains of like size of all the rock materials represented in the coarser particles, and perhaps more besides, occur also. Commonly the sand is intermixed with finer material so uniformly as to form a loam varying somewhat in composition from place to place; but in some cases there is more or less assortment of materials, and certain limited beds are made up mainly of sand, sometimes stratified and even crossbedded. Sand grains run in dimensions all the way from the finest visible or palpable particles to gravel grains; but the larger dimensions are, in general, and in nearly every local section as well, progressively rarer with increase in size.

Next to sand and the gravel into which it runs, pebbles are important as an element of the upper till; and they, like the bowlders, tell something of their own original homes and of the agencies to which they have been subjected in transportation. And pebbles and bowlders alike reveal the significant facts, (1) that by far the greater part of the coarser drift material of Northeastern Iowa is erratic, and (2) that much of it has been transported from distances of many hun-

To the tourist traveling over the surface, the bowlders form the most conspicuous element of the upper till. Everywhere within an area of several thousand square miles in the northwestern portion, they are so numerous that a dozen or a score are always in sight,

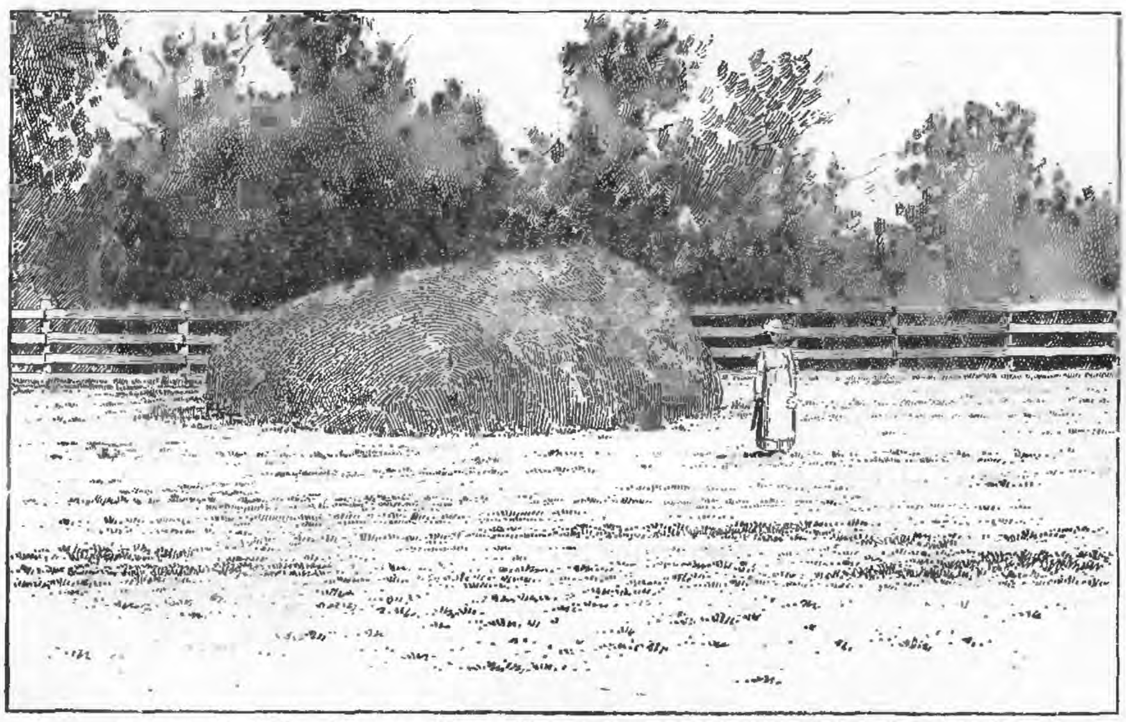

FIG. 66.—Drift bowlder, 1½ miles northwest of Maynard, 18 by 23 feet, 7 feet high.

and so large that they rise above the drift surface as high as houses or haystacks, and give character to every landscape. They culminate in abundance and size in Butler, Bremer, Black Hawk, and Buchanan

Counties, and they are quite as large, though barely so abundant in Mitchell, Floyd, Chickasaw, and western Howard Counties. The largest measured lies 2½ miles north of Sumner. At the time of measurement its diameters at the surface were 25 by 40 feet and its height above the surface 11 feet; but enough of it had been quarried to form foundations for two or three houses, and the larger portion appeared to be buried in the drift. Scores of others rise higher than this, reaching 15 to 18 feet above the surface, and hundreds of others measure more than 20 feet in mean diameter at the drift surface. Most of them are incorporated in the drift sheet and only peep out from its mass; but many others lie mainly or wholly upon the surface.

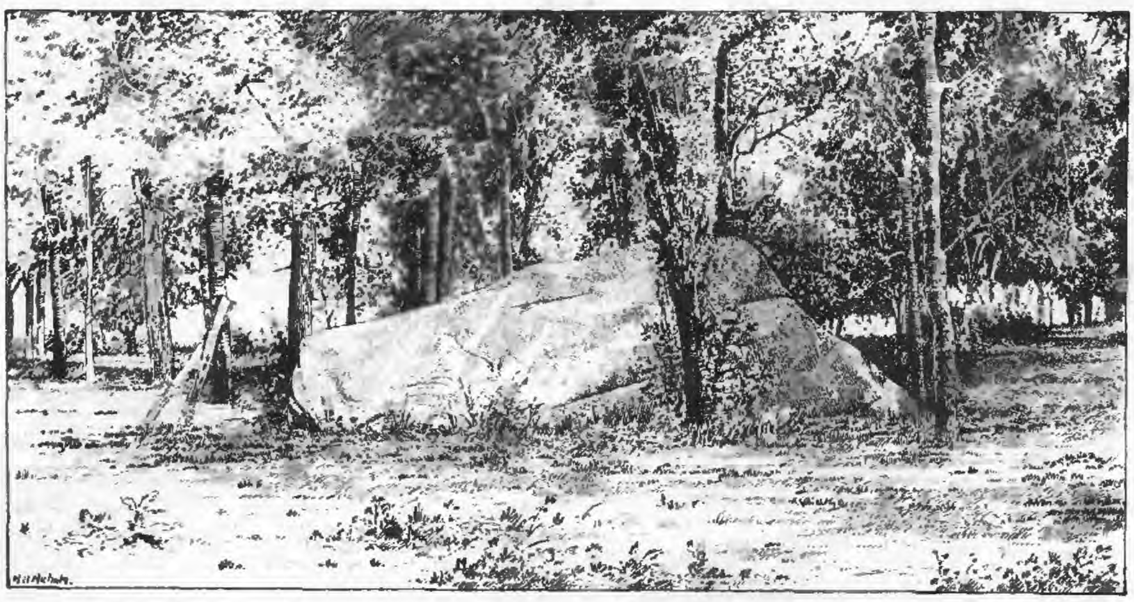

FIG. 67.—Drift bowlder in Buchanan County (NE. ¼ NE. ¼, Sec. 18, T. 89 N., R. 7 W.), 25 by 32 feet, 9 feet high.

In the southern part of the territory the surface bowlders are smaller and rarer. The southernmost observed bowlder of large dimensions lies in Duck Creek, in the southwestern part of Sec. 21, T. 78 N., R. 4 E. Its mean diameter is about 12 feet. Another notable bowlder, 16 by 21 feet measured at the ground, and rising 11 feet above the surface yet mostly buried, occurs 2 miles northeast of Massillon, in the NE. ¼ SE. ¼ Sec. 1, T. 82 N., R. 1 W. Another, of beautifully variegated syenite, was nearly buried beneath the drift of the SE. ¼ SW. ¼, Sec. 4, T. 81 N., R. 9 W., in Iowa County. Its least dimension was 11 feet, and on breaking up it yielded material for the walls of a house, the foundations of a barn and other outbuildings, and the lining for a well.

The greater part of the larger bowlders are of coarse feldspathic granite of firm texture. A coarse-textured syenite in which large crystals of feldspar predominate and in which hornblende is conspicuous is also common. None of the larger bowlders have been observed to be striated; but those commonly seen have been long exposed to weathering, and their angles are more or less rounded by exfoliation.

Although so conspicuous, the great bowlders of a thousand cubic feet or more are far less numerous than those of smaller sizes, ranging down (in increasing numbers) to cobblestones. These sometimes dot the surface and charge the drift beneath in vast numbers; those lying so near the surface as to interfere with the plow are either more deeply buried by the agriculturist or dragged away, a score or possibly a hundred from an acre, until the lanes are lined with rod-wide ranks of bowlders sometimes piled two or three deep; and now and then they are so abundant in certain lots of land as to discourage agriculture and the lot is given over to grazing. But this abundance of bowlders is local, and apparently confined to spots subjected to exceptional wash during the melting of the ice sheet.

Many of the smaller bowlders are striated; and still larger numbers of the cobbles and pebbles are similarly marked—the dimensions most frequently exhibiting striæ probably lying between one-fifth and three-fifths of an inch. The striæ on small pebbles are not, however, so regular as those upon large. Their character is illustrated in Fig. 68, representing three such pebbles, of the natural size.

FIG. 68.—Striated pebbles; natural size.

The striæ and other markings exhibited by the bowlders and pebbles of Northeastern Iowa are in no way specially distinctive, but closely similar to those displayed by ice-fashioned bowlders throughout the drift-covered portion of North America, and in the moraines at the termini of the Alpine and other living glaciers as well—they simply represent one of the most interesting and instructive features of the trail of the ice monster. Indeed the proportion of striated bowlders, particularly of the larger sizes, is considerably less than that commonly observed east of the Mississippi. One of the best illustrations of bowlder striation observed in the territory is that afforded by the limestone bowlder represented (one-half natural size) in Pl. XLVI; and a curious illustration of the effect of ice wear upon a previously water worn pebble is shown in Figs. 69–71. It was taken from unmodified upper till in a well in NW. ¼ SE. ¼ Sec. 1, T. 88 N., R. 1 W., Dubuque County.

There are several less important but significant elements locally found in the upper till. One of these is Cretaceous fossils (chiefly fish teeth) occasionally found in the northern part of the territory.

Another comprises pebbles and bowlders, sometimes well worn but again little affected by the agencies of transportation, of ferruginous pudding-stone evidently representing the meagerly developed Cretaceous formation of the territory—the Rockville conglomerate.

FIG. 69—Ice-worn pebble; natural size.

Still another element of the upper till is wood, commonly in the form of battered and broken logs, sticks, and smaller fragments of coniferous wood similar to that found in the forest bed. This material was notably abundant in the railway cuttings between Fayette and Brush Creek, and between Maynard and Oelwein, in Fayette County. The same railway cuttings expose to view many examples of another highly interesting element of the upper till, i. e., ferruginous nodules such as frequently abound in the lower till associated with the forest bed. These nodules are sometimes intact, but again battered and broken, and occasionally striated and polished like the erratic pebbles with which they are commingled. Similar striated concretions, evidently derived from the lower till, have been found, also, in the lower part of the upper till in the cutting of the Chicago, Milwaukee and St. Paul Railroad, 3 miles east of Lawler. These nodules evidently represent the period of ferrugination and soil formation represented more decisively by the forest bed; and it is evident that they were completely formed and indurated as firmly as to-day before the advent of the later ice sheet by which they were dislodged and incorporated in the newer deposit and impressed with the unmistakable seal of the Ice King.

FIG. 70—Ice-worn pebble; natural size.

FIG. 71—Ice-worn pebble; natural size.

Of related interest and significance are the bowlders of clay and sand sometimes incorporated in the upper till. These may represent either the red residuary clays of the drift margin or the pebbly deposits of the lower till; and the included masses may be either true bowlders, rounded or subangular, or flattened, elongated, or otherwise modified masses. In the case illustrated in Fig. 72 (ob-

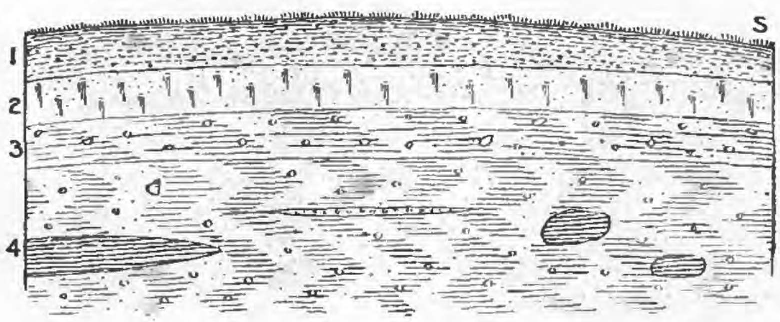

FIG. 72.—Bowlders of lower till incorporated in upper till, Linn County: (1) alluvium, 3 feet; (2) loess, perhaps rearranged, 2 feet; (3) yellow pebbly and sandy clay, obscurely stratified, 2 feet; (4) unstratified yellow clay with local and erratic pebbles, with a 5-foot bowlder near by, containing lumps and an elongated band of blue clay, 8 feet.

served in a railway cutting between Paralta and Springville, Linn County) the two smaller masses are simply rounded bowlders, while the largest body was apparently washed and compressed in such manner as to simulate an intercalated stratum. A remarkable example observed in a natural exposure on Mad Creek, 1½ miles north of Muscatine, is represented in Fig. 73. Here

FIG. 73.—Clay bowlder embedded in sand bowlder, near Muscatine: (1) Soil and débris; (2) loess, fossiliferous above, sandy below, passing into stratified sand; (3) stratified sand, fine above, coarse and somewhat gravelly below; (4) fine stratified sand containing a mass of structureless sand in which is embedded a rounded bowlder of pebbly clay, the stratification of the bed being horizontal save in the neighborhood of the sand bowlder, to which the stratification is adjusted; (5) somewhat sandy yellow clay containing erratic pebbles, grading into the sand beds between which it lies; (6) stratified sand containing lines of gravel, resting on an irregular surface of distinct material, somewhat ferruginated at base; (7) tenacious blue clay with disseminated erratic pebbles and with carbonaceous spots and streaks above. Exposure, 30 feet.

a rounded bowlder of tenacious pebbly clay, undistinguishable from that of the lower till in the base of the same section, is embedded in a mass of structureless sand, which is itself incorporated in a bed of coarser and distinctly stratified sand—the two merging to some extent laterally, though the sides of the bowlder are clearly defined above and sharply distinct below. This is near the margin of the upper till.

Yet another locally developed element appears, but thus far only in the southern portion of the territory, in the form of calcareous

place. The section illustrated in Fig. 74, revealed in a railway cutting 2 miles southeast of Fayette (SW. ¼ NE. ¼, Sec. 3, T. 92 N., R. 8 W.) is exposed in the margin of a paha veneered with loess though chiefly

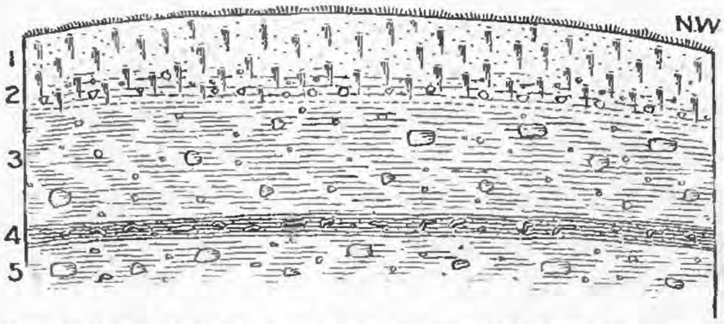

FIG. 74.—Intercalation of forest bed below s mmit of lower till, near Fayette. (1) Loess; (2) sandy, gravelly, and pebbly yellow clay passing into the loess; (3) plastic clay, yellow above, blue below, with a few pebbles and small greenstone bowlders, as well as crushed fragments of wood; (4) dark blue and black friable loamy earth and clay, with rootlets, fragments of wood and ferruginous nodules passing into the subjacent clay; (5) compact unstratified blue clay with striated pebbles. Total exposure, 22 feet.

formed of upper till. Here the soil and its arborescent products are broken up and intermingled with débris apparently derived largely from the lower till but redeposited by the later ice sheet. This rearranged portion of the lower till contains crushed fragments of coniferous wood at various levels, and is less compact than the undisturbed deposit below. Rootlets and much decayed fragments of wood are found in the dark soil represented in the section, the rootlets apparently in part in situ. A large quantity of wood (estimated at 50 to 75 cubic feet) was thrown out from this cutting. Most of it was apparently cedar, several specimens resembled pine, a few pieces appeared to be elm, and some fragments were not identified. Several striated ferruginous nodules were found associated

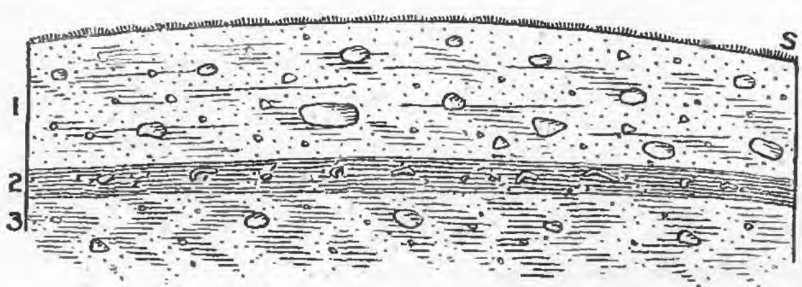

FIG. 75.—Normal position of forest bed, Fayette County: (1) Unstratified yellow clay with sand and gravel irregularly disseminated, with local and erratic (mainly the latter) pebbles and bowlders, in part striated, and with two or three rudely spherical bowlders of lower till, 8 feet; (2) dark friable and crumbling earth with crushed and twisted fragments of wood, rootlets apparently in situ passing into the subjacent member, ferruginous nodules (one striated), etc., 1 foot; (3) compact blue clay, jointed above, with striated pebbles chiefly of greenstone, and a few small bowlders, 3 feet.

with the wood. A similar section in which the forest bed materials were even more profoundly disturbed and nearer to the surface is exposed on the same railway (the Chicago, Milwaukee and St. Paul) half a mile nearer Fayette.

In the sections illustrated in Figs. 75 and 76 the forest bed was observed at what appears to be its normal horizon. The former is exposed in a cutting on the Burlington, Cedar Rapids and Northern Railway, a mile south of Maynard, Fayette County, on the divide between the Turkey and Wapsipinnicon basins. The upper till here contains numerous and large superficial bowlders, one within a few yards of the section reaching a diameter of 18 feet. The section is noteworthy by reason of the occurrence within the upper till of rounded masses of pebbly clay evidently derived from the older glacial deposit. There was also found in this section, intimately associated with the wood of the forest bed (identified as cedar and ash, the former greatly predominating), three sections of a partly silicified tree trunk 7 inches in diameter, two of which bore marks of glacial action. An analogous exposure is displayed on the same railway a mile north of Oelwein. The section illustrated in Fig. 76 was exposed in a well in the SW. ¼ SE. ¼, Sec. 15, T. 89 N., R. 9 W., Buchanan County, under the most favorable conditions, i. e., just as the excavation was completed. It is in the region of huge superficial bowlders, and a dozen or more measuring from 15 to 25 feet in diameter lie within rifle shot. The unstratified mass of the upper till is here overlain by a stratum of irregular sandy material, which extends from this point to the Wapsipinnicon River and represents the puzzling series of deposits connecting the Pleistocene drift sheet with the modern alluvium all over the northwestern part of the territory; and the drift mass is divided by a fissure, filled with similar sand, trending southeasterly and northwesterly and cutting entirely through the newer glacial deposit. The forest soil was apparently but slightly disturbed, though only a single fragment of wood was found.

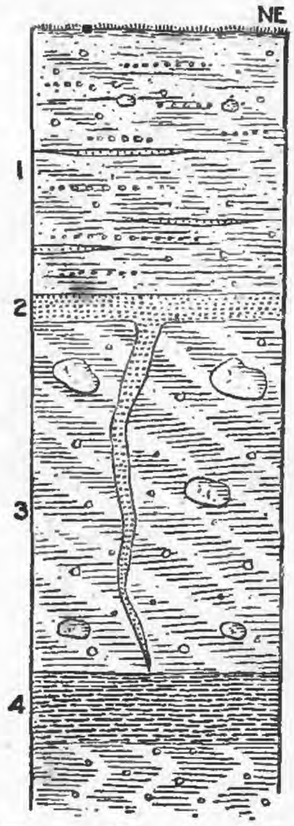

FIG. 76.—Normal position of forest bed, Buchanan County: (1) Sandy and pebbly yellow clay, partially stratified, 4 feet; (2) coarse stratified sand, 6 inches; (3) unstratified yellow clay with striated pebbles and bowlders up to 18 inches in diameter, 6 feet; (4) crumbling loamy black earth with a marshy odor, yielding an inky fluid on compression, with fragments of wood, rootlets, etc., passing into compact blue clay with small striated pebbles, 2 feet.

In Johnson and Muscatine Counties the forest bed is so commonly encountered in well digging as to be well known to residents. Sometimes in whole townships the well water is generally affected by the deposits, perhaps utterly ruined, but again revealing the presence of vegetal matter in the subterranean strata only by characteristic odor or flavor; and the well-diggers aim to so select locations with respect to the topography that the well will lie altogether within the

ceedings of the Davenport Academy, vol. 1, p. 96, Pl. XXXII, and by White in the Geology of Iowa, 1870, vol. 1, p. 119; for it should be observed that the "loess" of these descriptions includes toward its base layers of sand and erratic pebbles.

Elsewhere in Davenport, however, the upper till is better developed, e. g., in the section on the northwest corner of Sixth and Harrison streets, represented by the drawing from a photograph forming Fig. 77. The present surface at this point does not represent the

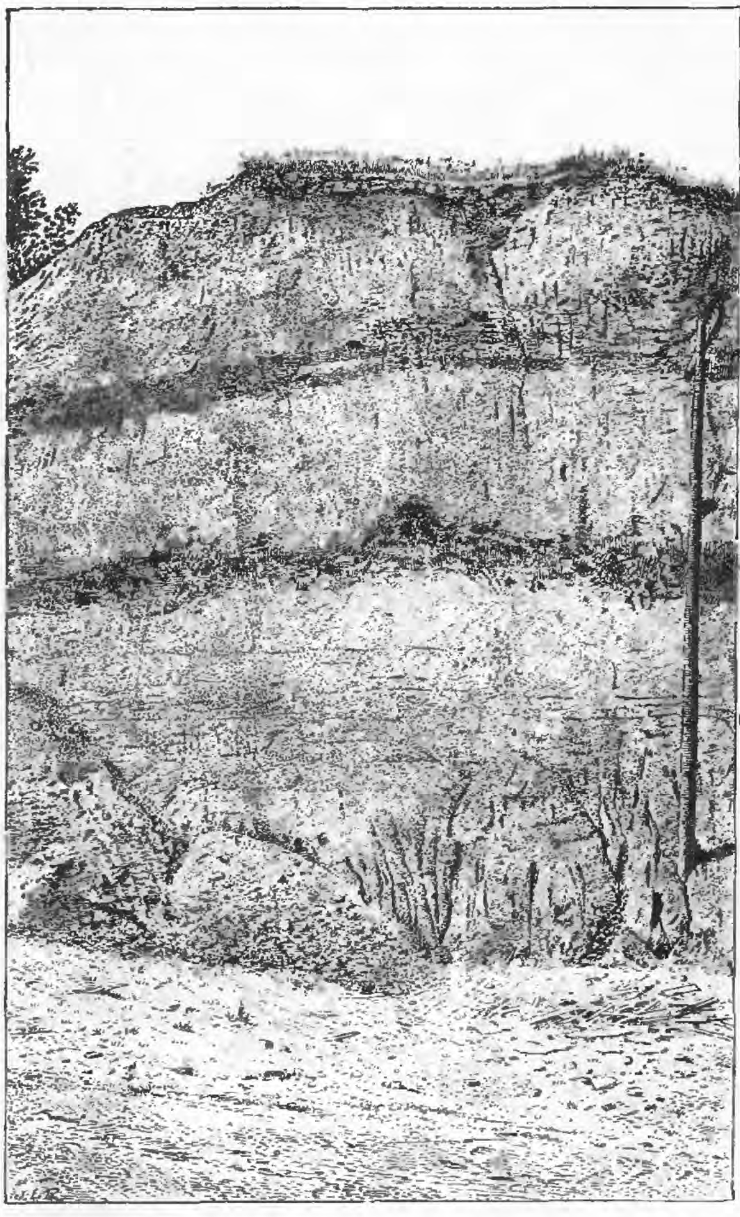

FIG. 77.—Section in Davenport showing relations of forest bed: (1) Loess; (2) pebbly clay (upper till); (3) brown sand, etc.; (4) blue pebbly clay (rearranged lower till); (5) soil, etc. (forest bed); (6) compact pebbly blue clay (undisturbed lower till). Total exposure, about 75 feet.

original loess surface, a considerable thickness of that deposit having been eroded. Thus the loess (which is massive and homogeneous, and abounds locally in loess-kindchen and tubules, contains a few small specimens of *Succinea*, and elsewhere yields a calcareous efflorescence similar to that sometimes observed on the Columbia loam

FOREST BED, NEAR MUSCATINE.

This is the only case in Northeastern Iowa in which the condition of the exposure and the circumstances of observation rendered it at all practicable to photograph the section. It is represented in the photo-mechanical reproduction forming Pl. L.

A specimen of the soil was submitted to the well known paleodendrologist, Knowlton, who reports upon it as follows:

DEPARTMENT OF THE INTERIOR, U. S. GEOLOGICAL SURVEY,
Washington, D. C., February 15, 1890.

DEAR SIR: I have the honor to submit the following brief report upon the interglacial earth from Iowa, which you sent me a few days ago for examination.

At the first glance the material appears to be very largely of vegetable origin, and no one, even the most inexperienced, would hesitate to ascribe its origin at once to this source. It is black in color and contains many fragments of wood of larger or smaller size, and in fact is quite like the humus that may be found in almost any forest at the present day. When a small quantity of this fine black material is viewed under the microscope it is found to be largely composed of more or less completely disintegrated woody tissue, mixed with numerous irregular grains of silica. This woody material is so badly disintegrated that it is quite impossible to determine its exact nature; but from the abundance of fragments of coniferous wood mixed with it, it is more than probable that it is also coniferous.

The best preserved woody material is in the form of small twigs or bits of branches. It is very well preserved, and when suitably prepared for the microscope its internal structure may be almost as well made out as from the living tree. Numerous specimens have been examined and they are *all* coniferous. The wood cells have been but little distorted by the processes of decay and the fine lines and characteristic bordered pits can be clearly made out upon them. In transverse section the annual rings are rather indistinct, yet they can in almost all cases be detected. The wood cells, as seen in this section, are characteristic of young twigs or branches.

As nearly as can be ascertained from the limited study made, this material belongs either to the genus *Juniperus* or *Thuya*, either of which might have occurred in that region during glacial times.

Very respectfully,

F. H. KNOWLTON.

Mr. W J McGEE,
U. S. Geological Survey.

A section related to those of Davenport and Muscatine, in the attenuation of the upper till and in other respects, was observed beyond the limits of the territory in a railway cutting a mile and a

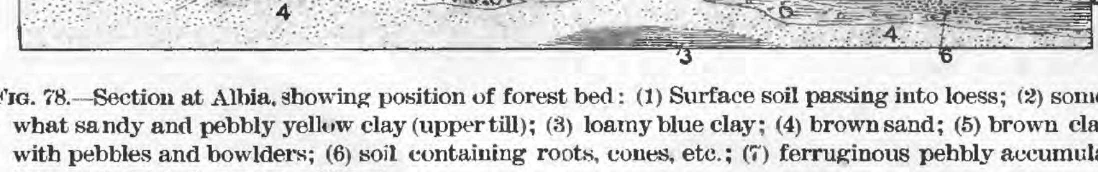

FIG. 78.—Section at Albia, showing position of forest bed: (1) Surface soil passing into loess; (2) somewhat sandy and pebbly yellow clay (upper till); (3) loamy blue clay; (4) brown sand; (5) brown clay with pebbles and bowlders; (6) soil containing roots, cones, etc.; (7) ferruginous pebbly accumulations. Height of exposure 30 feet.

half south of Albia, Monroe County, Iowa. It is illustrated in Fig. 78. Well preserved grasses, endogenous stems, cones, etc., with many rootlets evidently in place, were found in the old soil of this section. But generally in the interior of the drift-covered area the old soil is disrupted, completely removed, or buried beneath deposits evidently derived from the lower till, as in the section observed in the railway excavation at Blue Cut and illustrated in Fig. 79.

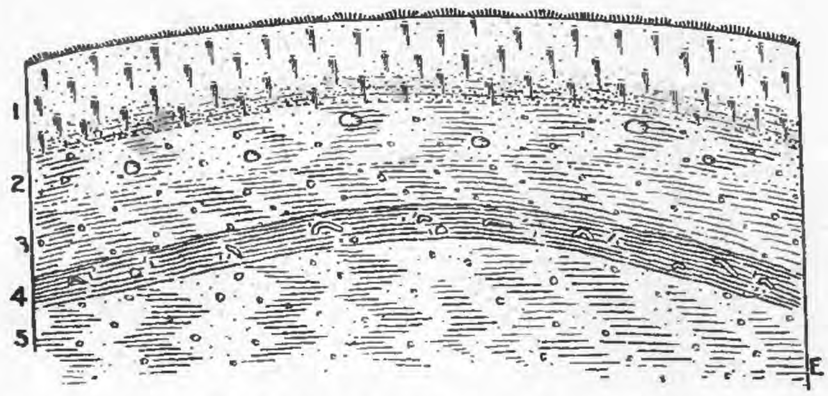

FIG. 79.—Intercalation of forest bed within lower till, Jones County: (1) Loess, sandy and obscurely stratified at base, 8 feet; (2) sandy and gravelly yellow unstratified clay, with local and erratic pebbles, mainly the latter, 4 feet; (3) plastic blue clay, with a few small pebbles and traces of lamination, 3 feet; (4) dark blue and black friable clay, turning brown on exposure, with many ferruginous nodules and a few fragments of much decomposed wood, 18 inches; (5) dense and compact blue clay, with striated pebbles and small bowlders, 8 feet.

A section observed beyond the limits of the territory, and specially notable only in that it was susceptible of reproduction by photography, is illustrated in Pl. LII (p. 517). It is revealed in the "stripping" of Whalen's quarry, a mile north of Durham, Marion County, Iowa. Here the deposit superimposed on the old soil is mainly loess, though it contains toward the base a considerable element of coarse sand with a few pebbles and other materials allying it to the upper till. The photograph, which was obtained through the courtesy of Mr. Charles R. Keyes, of Baltimore, and Mr. F. M. Kinne, of Knoxville, Iowa, is reproduced photomechanically.

In brief, as indicated by the foregoing descriptions and by those relating to the well sections represented in Pl. LI, the forest bed is simply a horizon of ancient soil, normally occurring at the base of the lower till and unconformably overlain by the upper till, though frequently disturbed or profoundly broken up; and in many cases it has apparently been completely removed. Generalizing the various occurrences, it would seem that the soil differs from that of the present, notably in greater thickness and more abundant humus, somewhat less notably in the greater abundance of arboreal vegetation, and still less notably but yet decidedly in the peaty character. There are certain other differences, which may be ascribed to the greater age of the buried soil. Thus, the forest bed soil frequently abounds in ferruginous nodules such as those locally observed now in process of formation in the upper till. In some cases, too, nodules of pyrite, reaching in one instance a diameter of 2½ inches, have been found associated with woody and peaty matter in the

till exceeds that of its newer homologue. It may be roughly estimated at 50 feet. The thickness varies both locally and in a more systematic way. Local variations in thickness are noteworthy in the northwestern part of the territory, where the deposit culminates in thickness in valleys and on the lee (southeasterly) sides of eminences in the indurated rocks, as illustrated in Figs. 61 and 62 (pp. 474, 475); also in the southern-central part of the territory, where there is reason to believe that some of the deep wells of Pl. LI mark lines of preglacial erosion. In its systematic variation the deposit ranges from noteworthy tenuity in the northwestern part of the territory, where the action of the later ice sheet was most energetic, and from feather edges along the margin of the driftless area in Winneshiek, Clayton, Dubuque, and Jackson Counties to a maximum thickness a few dozen miles within the eastern margin of the deposit and the southern line of the territory—the thickness culminating in the tier of counties running from Marshall to Cedar. The law of systematic variation is a compound one: the deposit originally attenuated in a simple way from a central tract toward its periphery; but it was afterward ground down by the later glacier, more deeply toward the central tract than toward the periphery.

It is worthy of specific mention that nowhere does the lower till display a moraine-like peripheral thickening, even to the extent observed in the upper till. Everywhere toward its margin it either attenuates gradually and disappears in a feather edge or suffers horizontal differentiation, the upper part becoming fine, stratified, or laminated and evidently waterlaid, the lower portion retaining the characteristic glacial structure with a concentration of coarse materials, and both the lower and the upper members gradually attenuating and feathering out.

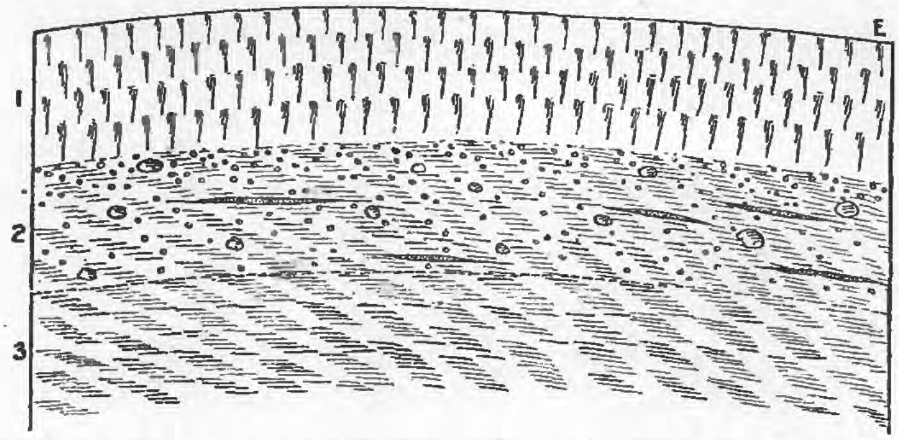

FIG. 80.—Relation of tills near easternmost margin, Dubuque County: (1) Loess, 15 feet: (2) brownish yellow clay with a few erratic pebbles and considerable quantities of chert, especially near summit, 15 feet; (3) clean and plastic blue clay containing a few ferruginous nodules, with some traces of lamination, 12 feet.

In the section illustrated in Fig. 80, the two tills are quite distinct, even to the precise line of junction; for here the older deposit exhibits the clean and plastic peripheral stage. The section is exposed in a railway cutting in the NE. ¼ NW. ¼, Sec. 10, T. 88 N., R. 1. E., Dubuque County, within a mile of the eastern limit of the upper till. Quite similar is the section represented in Fig. 81 (exposed in

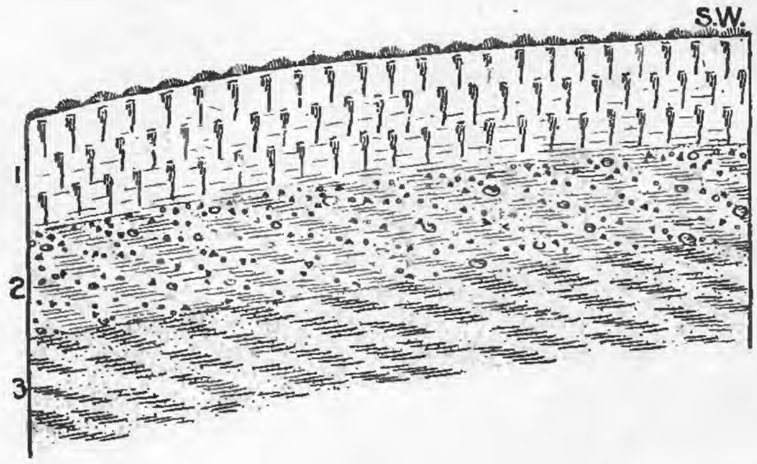

FIG. 81.—Relation of sillt toward easternmost margin, Clayton County: (1) Loess, slightly heterogeneous and obscurely laminated, especially at base, 5 feet; (2) coarse gravel of limestone and chert embedded in yellowish brown calcareous clay and sand, 4 feet; (3) homogeneous blue clay, with fine and uniformly disseminated sand, and with a few small ferruginous nodules, 3 feet.

a wagon-road cutting in the SW. ¼ SE. ¼, Sec. 25, T. 92 N., R. 5 W., Clayton County), save that the superior peripheral phase of the lower till is coarser textured and sandy. This section practically marks the margin of the upper till, and contains a preponderance of local material.

The next section (Fig. 82) is of interest since it represents in normal condition, though attenuated thickness, the various Pleisto-

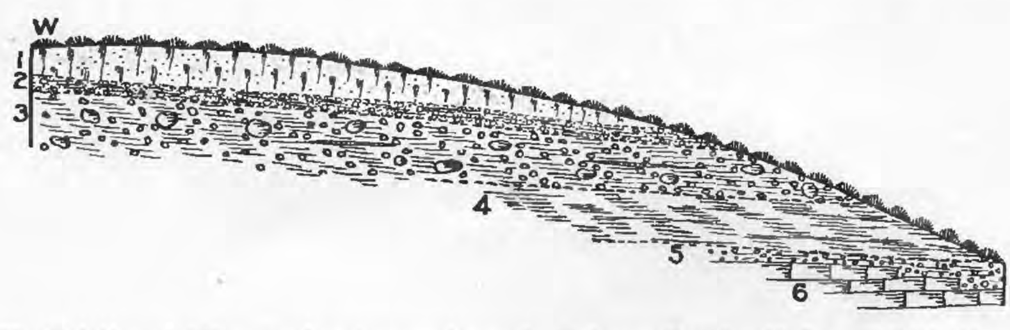

FIG. 82.—Relation of tills toward easternmost margin, Dubuque County: (1) Loess, 5 feet; (2) gravel, sand, and yellowish brown clay, 2 feet; (3) coarse yellow clay, with chert and erratics, 5 feet; (4) clean laminated blue clay, 4 feet; (5) coarse brown gravelly clay with greenstone pebbles, 2 feet; (6) Niagara limestone.

cene deposits found about the margin of the driftless area. It was observed in a wagon-road cutting in the SW. ¼ SE. ¼, Sec. 19, T. 87 N., R. 1 E., Dubuque County.

Although study of the distribution of the two tills and associated deposits indicates that the earlier glacial deposit was frequently removed by erosion before the later was laid down, the effect is seldom indicated by a single section. That illustrated in Fig. 83, however, gives such indication. The lower till is altogether absent from a part of the section and the subjacent limestone is much crushed and broken, and has granite pebbles such as characterize the newer till firmly embedded in its crevices and cavities. The section was ob-

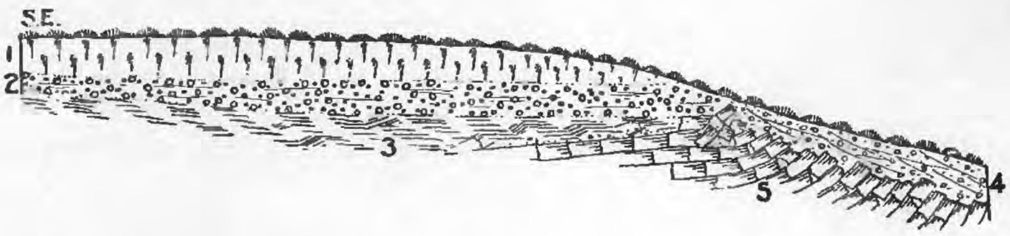

FIG. 83.—Deformation of earlier drift sheet and subjacent rock by later ice invasion, Dubuque County: (1) Loess, 4 feet; (2) gravelly and pebbly yellow unstratified clay, 3 feet; (3) plastic blue clay, clean except at immediate base, 4 feet; (4) talus; (5) Niagara limestone.

served in a roadside gully in the NW. ¼ NW. ¼, Sec. 16, T. 90 N., R. 2 W., Dubuque County. It is possible that the partial absence of the lower till at this point is to be ascribed to the later ice work; but in other examples it is evident that this can not be the case, since the forest bed is preserved in place.

The greater thickness of the lower till, even well toward the margin of the driftless area, is illustrated by the section shown in Fig. 84, constructed from a roadside exposure, a natural gully, and a

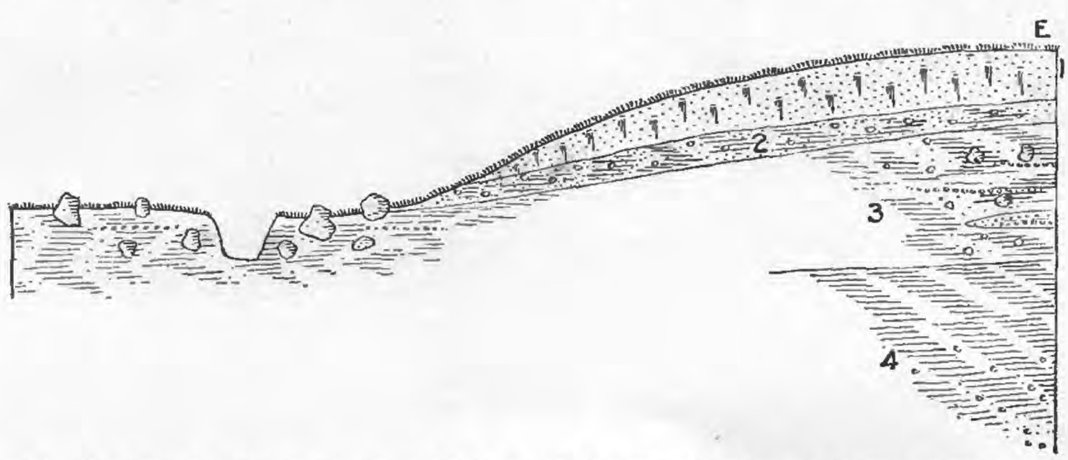

FIG. 84.—Relations of upper and lower drift sheets, Dubuque County: (1) Loess; (2) sand, gravel, rounded pebbles, and brown clay; (3) coarse yellow clay with good sized bowlders and some fragments of chert and limestone; (4) compact blue clay, with traces of lamination.

neighboring well 65 feet deep, in the NE. ¼ NE. ¼, Sec. 21, T. 90 N., R. 2 W., Dubuque County. The upper till here contains abundant rounded bowlders predominantly of granite up to 3 feet in diameter, while the lower till is destitute of erratics in its upper portion, and below contains a few well rounded greenstone pebbles. The lower till was not penetrated.

Sometimes the great compactness and tenacity of the lower till in comparison with the upper is indicated by the configuration of gullies. This is the case illustrated in the section (Fig. 85) exposed in a roadside gully near the northwest corner of Sec. 15, T. 89 N., R. 1 W., Dubuque County. This section displays in miniature the condition displayed on grander scale by the stream-ways of the vicinity.

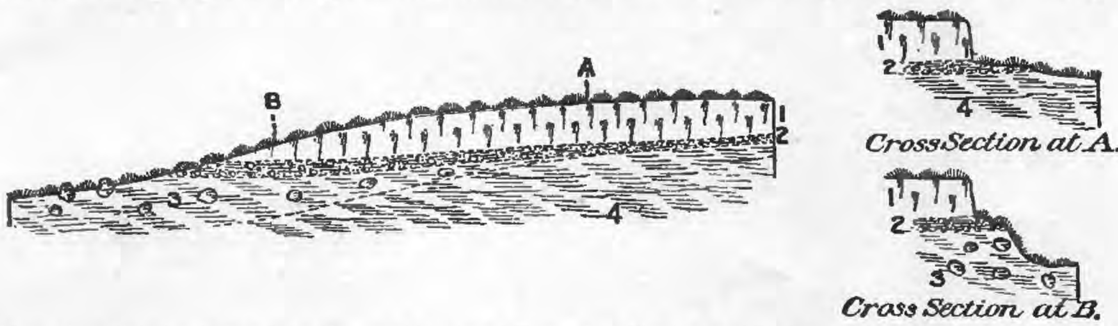

FIG. 85.—Section illustrating the obduracy of lower till. Dubuque County: (1) Loess; (2) sand, gravel, pebbly, and brown clay; (3) coarse yellow clay with large bowlders; (4) clean and plastic blue clay, obscurely laminated. Mean exposure, 8 feet.

The portion of the gully, and of the valley as well, carved in the upper till is deep, large, and irregular; while the parts of gully and valley excavated in lower till are shallow, small, and flat-bottomed.

Despite the general uniformity of the lower till, intercalations of sand and pockets of pebbles are occasional features. A notable example is that illustrated in Fig. 86, representing a section dis-

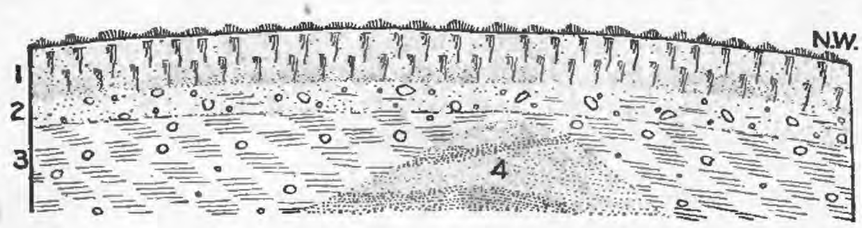

FIG. 86.—Sand pocket in lower drift sheet, Dubuque County: (1) Loess, slightly arenaceous, especially at base, 4 feet; (2) unstratified yellow clay, with worn granite bowlders up to 2½ feet in diameter, 3 feet; (3) compact blue clay with bowlders mainly of greenstone up to 1 foot in diameter in small part striated, 5 feet; (4) coarse and fine cross stratified sand.

played in a railway cutting in the NE. ¼ SE. ¼, Sec. 35, T. 87 N., R. 1 E., Dubuque County. Here the lower till is bowlder-charged throughout, and is intersected by a compact body of stratified and cross laminated brown and yellow sand. This sand bank extends obliquely across the cutting in a direction a little south of east, or nearly that of ice motion.

Within certain limits the color of the lower till may vary with its texture. Thus, the massive, fine-textured portions commonly called clay are usually blue; while intercalated pebble and sand beds and the fairly well defined water bed at the base of the deposit are commonly brown. Moreover, when the whole mass is exceptionally sandy the brown color is sometimes assumed throughout. This is exemplified in two sections exposed in wagon-road cuttings in Clayton County, the first in the NW. ¼ NW. ¼, Sec. 21, T. 94 N., R. 5 W., and the second in the SW. ¼ NE. ¼, Sec. 14, T. 92 N., R. 5 W., which are alike, save that in one the materials of the lower till are fine and clayey, while in the other there is a considerable element of sand, and that the usual blue color is displayed in the first while the other is brown. With the marginal differentiation of the deposit the lower portion sometimes becomes a mass of gravel or bowlders, when the brown color is commonly displayed. This condition is illustrated in a section displayed in the SE. ¼ SW. ¼, Sec. 32, T. 95 N., R. 6. W., in Clayton County, on the Elkader and Clermont road. Here the deposit is represented by a reddish brown sandy gravel and loam largely cross stratified and sometimes imperfectly cemented by infiltration of iron.

It has already been noted that the upper till extends to and terminates at the great Niagara escarpment by which the driftless area is overlooked from the southwest; and the same thing is true in even greater degree of the earlier glacial deposit. Throughout southern Clayton and northern Dubuque Counties the lower till margin is sinuous, creeping out along the salients and retreating along the reentrants of the crenulate escarpment, marking its line almost as closely as would the surface contours of a map. The manner in which the drift runs out to the very verge of the Niagara upland and overlooks the lower driftless area to the northeast is imperfectly illustrated in the general section through Dubuque County, forming Fig. 63. In the northern part of the territory, where the Niagara escarpment is less inconspicuous yet fairly followed by the later drift deposits, the earlier sheet pushed far beyond and well toward the locally more conspicuous escarpment given by the Trenton limestone. It is, indeed, one of the most significant among the glacial phenomena of the territory that the ice sheet advanced to but was unable to push beyond the great crest by which the territory is divided.

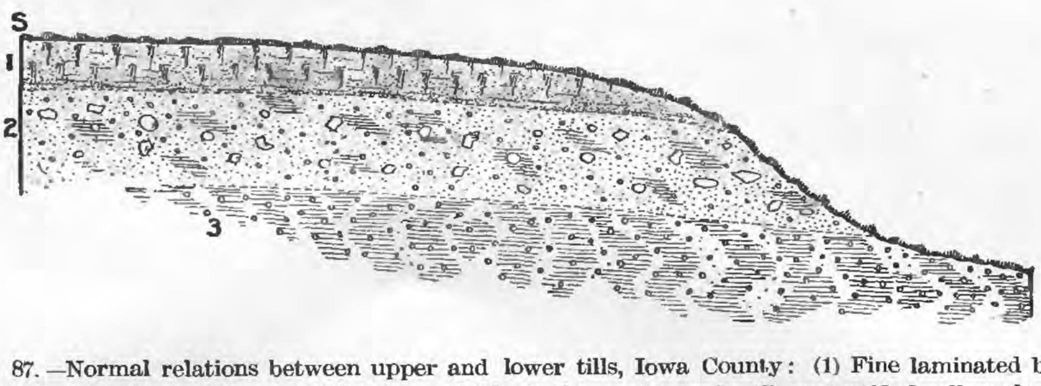

FIG. 87.—Normal relations between upper and lower tills, Iowa County: (1) Fine laminated buff sand forming base of loess, which is seen a little farther southward: (2) unstratified yellow clay intermixed with fine and coarse sand and gravel, and containing a few local and angular, and more erratic and subangular pebbles; (3) compact blue clay with many rounded pebbles, say one-fourth striated, and numerous nodular concretions. Total exposure, about 30 feet.

Although it is usually difficult if not impossible to discriminate the tills unless the forest bed intervenes, they are in some cases fairly distinct. Thus, in the section illustrated in Fig. 87 (displayed in a cutting on the Homestead and Amana wagon road in the SW.

¼, Sec. 25, T. 81 N., R. 9 W., Iowa County), the older formation exhibits several distinctive features: (*a*) Its pebbles are by far the more numerous, smaller in size and better rounded; (*b*) its proportion of striated pebbles is much the greater; (*c*) its proportion of local pebbles is the less—a feature which is locally characteristic, though not characteristic of the territory as a whole; (*d*) the proportion of greenstone among the erratic pebbles is considerably the larger; (*e*) the blue color prevails throughout; and (*f*) there is a vastly larger number of ferruginous nodules. Moreover, here as generally elsewhere the upper till presents a decidedly fresher aspect, due in part to the absence of incipient cementation and ferrugination. The lower till is rectangularly jointed, particularly in its upper portion, and its numerous ferruginous nodules take approximately cubical forms coinciding with the jointing and are of exceptionally large size, often reaching 3 or 4 inches in diameter. Two such nodules at the extreme summit of the formation were found to be distinctly striated on their upper surfaces.

In the section illustrated in Fig. 88, observed in a railway cutting in the eastern part of Brush Creek, in Fayette County, the two glacial deposits may not be discriminated; for, while the upper part of the section displays buff and yellow bowlder clay, with subangular granite bowlders, and the lower part displays much more compact

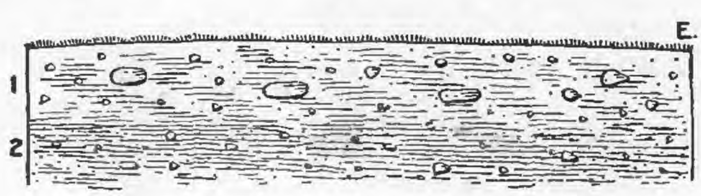

FIG. 88.—Apparent intergradation of drift sheets, Fayette County: (1) Compact and unstratified yellow clay, with erratic bowlders up to 3½ feet in diameter, and with 2½-inch pebbles quite numerous; (2) compact and unstratified blue clay, with bowlders up to 3 feet in diameter, and with numerous pebbles 2 inches in diameter below but not above. Total exposure, say, 13 feet.

blue pebbly clay, with greenstone predominating among its erratics, no line can be drawn between the phases, which appear to intergrade through a stratum of 5 to 8 feet in thickness, in which battered bits of coniferous wood occasionally occur. It is noteworthy that both tills here are auriferous and in very nearly the same degree.

As already noted, there are local variations in thickness of the lower till, some of which are, while others are not, due to erosion by ice or water since deposition. When studied in detail this inequality is found to indicate that in general the drift thickens in depressions and thins over eminences, and the same is indeed true of the upper till. Thus, within certain limits, the tills singly and in combination mantle the surface after the fashion of sediments, softening the ante-Pleistocene contours and bringing the surface approximately to the condition of a plain of construction. One of the sections illustrating this characteristic of the tills is that depicted in Fig. 89. It is based on two wells a thousand feet apart, and several intermediate exposures in the NW. ¼ SE. ¼, Sec. 13, T. 88 N., R. 4 W., Delaware County.

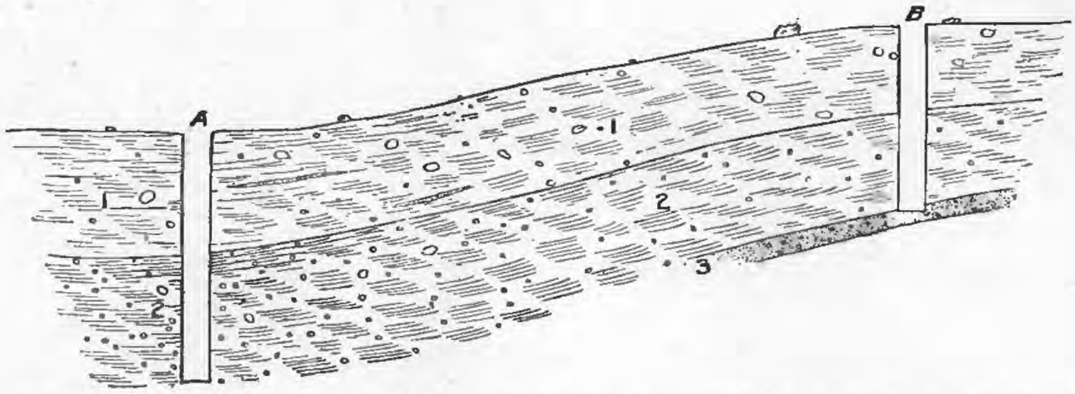

FIG. 89.—Relation of drift sheets to topography, Delaware County: (A1) Yellow clay, with pebbles and bowlders and a trace of stratification, 10 feet; (A2) compact blue clay, with small pebbles, laminated at top, 14 feet. (B1) Unstratified yellow clay, with pebbles and bowlders, 8 feet. (B2) plastic blue clay, with very few pebbles and without lamination, 8 feet; (B3) brown sand and gravel, with water.

In the northwestern part of the territory this mantling is modified, (1) by the rupture and removal of the later sheet over eminences, and (2) by the tenuity and occasional absence of the newer sheet over the higher eminences, as illustrated in Figs. 61 and 62, representing generalized sections in Floyd County. A related case is exhibited in the section illustrated in Fig. 65 (p. 478), found near the margin of the glacial deposits. The upper part of the lower till takes on its usual peripheral aspect of blue (locally tinged greenish), clean,

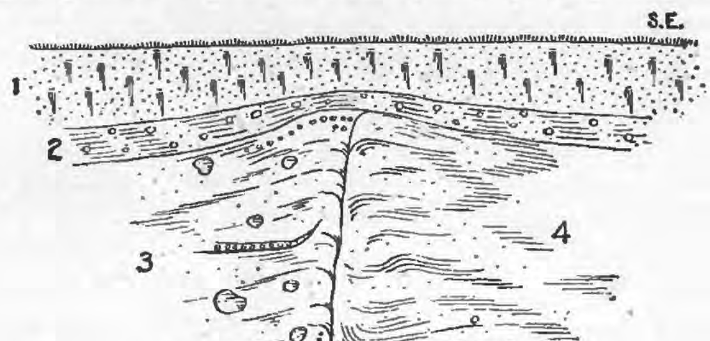

FIG. 90.—Contortion of lower till by later ice invasion, Dubuque County: (1) Loess; (2) sandy, gravelly, and pebbly clay; (3) unstratified yellow clay with rounded and angular erratic bowlders; (4) plastic blue clay, obscurely laminated, and with laminæ contorted; (5) sandy and pebbly brownish yellow clay; (6) Niagara limestone. Total exposure, 23 feet.

plastic, laminated clay, abounding in small ferruginous concretions similar to the "buckshot" of certain Pleistocene deposits of the Lower Mississippi.

Not infrequently the lower till displays crumpling and contortion evidently due to later ice work. An example is illustrated in Fig.

90, observed in a well in the NW. ¼ SW. ¼, Sec. 24, T. 89 N., R. 2 W., Dubuque County. Here the older deposit seems to have been completely removed by the later ice sheet and thrown and compressed into a scarp against which the newer drift sheet abuts. In the section illustrated in Fig. 91 (exposed in a wagon road cutting in the NW.

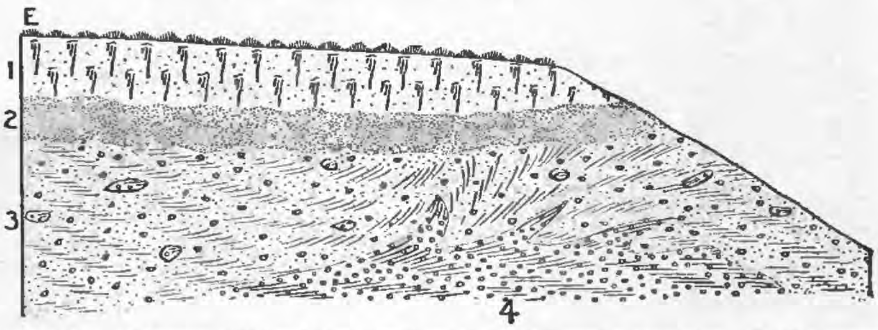

FIG. 91.—Contortion of lower till by later ice invasion, Delaware County: (1) Re-arranged loess; (2) homogeneous fine sand, unconformable to both loess and drift; (3) reddish yellow sandy clay, with northern pebbles and much local chert; (4) dark compact clay with small pebbles. Total exposure 18 feet.

¼ SE. ¼, Sec. 24, T. 88 N., R. 3 W., Delaware County) the lower till was not removed but was so squeezed and compressed as to send tongue-like protuberances into the newer deposit; and the newer deposit contains several completely isolated masses, or clay bowlders, identical in composition and appearance with the lower till. A related and even more striking example of displacement is that illustrated in Fig. 92, which was observed in the bank of the North Maquoketa, in

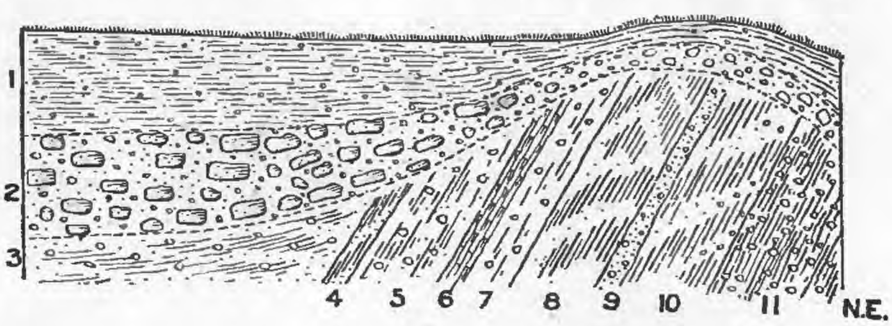

FIG. 92.—Deformation of earlier glacial deposits by later ice work, Dyersville: (1) Yellow and brown sandy and pebbly alluvium; (2) pebbly alluvium of lighter color, containing great numbers of worn bowlders, nearly all local; (3) pebbly yellow clay; (4) sandy blue clay; (5) pebbly red clay; (6) ocherous band, firmly incrusted at both sides; (7) pebbly red clay; (8) plastic blue clay with ferruginous nodules; (9) sandy and pebbly red clay; (10) rather compact blue clay with small pebbles and ferruginous nodules; (11) brown granular clay with white specks, containing worn quartz pebbles. Mean height, about 13 feet.

the northern part of Dyersville. Still more interesting, because of the complete sequence of deposits displayed, is the section illustrated in Fig. 93, observed (in company with President T. C. Chamberlin and Prof. W. H. Norton) in a quarry in the eastern part of Mount Vernon. The uppermost member represents the loess, which thickens in the neighborhood to form the Mount Vernon paha; the second member represents the usual sandy base of this deposit; the third member is the upper till; the fourth and fifth together constitute the lower till, the upper part of which here takes on the peripheral aspect; while the sixth member is largely a residuum formed by decomposition of the subjacent limestone, although as usual in such sections it is somewhat rearranged and intermixed with glacial

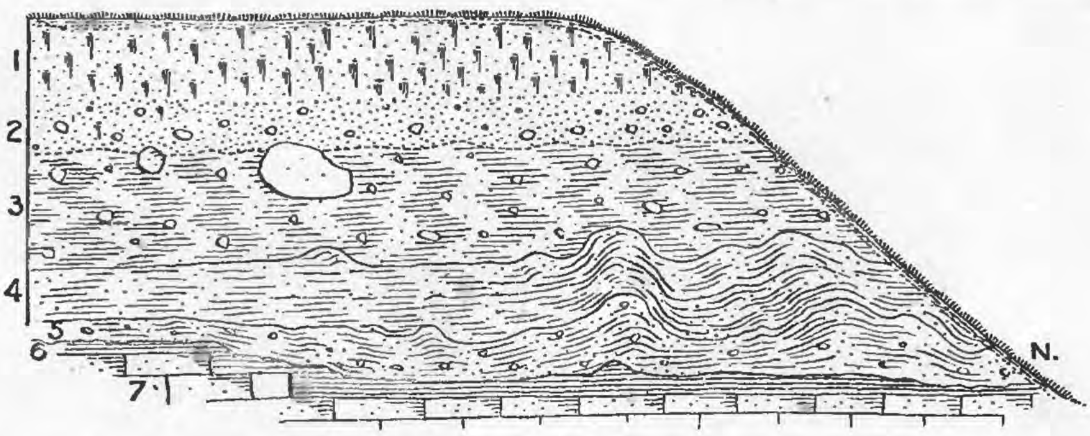

FIG. 93.—Contortion of earlier glacial deposits by the later ice sheet, Mount Vernon: (1) Loess, or loess-like loam, massive, calcareous, firm textured, containing toward base a very few granitic grains up to an eighth of an inch in diameter, 4 feet; (2) stratified sand, containing erratic pebbles, not clearly separable from the loess, 2 feet; (3) massive or obscurely laminated pebbly clay, containing sand pebbles and bowlders up to 8 inches, with one bowlder of 512 cubic feet, well striated and polished on two sides, 5 feet; (4) massive and much more compact clay indistinctly stratified in layers marked by ferruginous staining, without bowlders or large pebbles, 3 feet; (5) massive or obscurely laminated pebbly clay containing small pebbles (predominantly greenstone) frequently striated, 2 feet; (6) black or dark brown plastic clay (geest), 1 foot; (7) Niagara limestone.

débris. Members 4 and 5 are contorted and crumpled in the manner indicated.

An equally interesting example of contortion produced in decomposed limestone by glacial action is illustrated in Fig. 114 (p. 556),

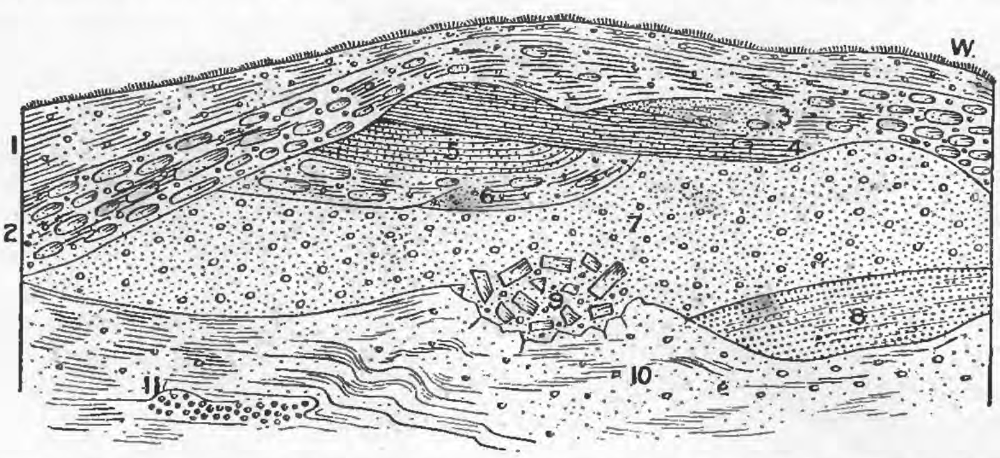

FIG. 94.—Section in St. Paul, exhibiting contortion of lower part of drift by ice action: (1) Gravelly surface soil; (2) ash-colored sand, gravel, and loam, with small erratic pebbles and local subangular bowlders (of Trenton limestone) varying in abundance in different portions as shown, but without other arrangement; (3) a portion of the same becoming extremely sandy; (4) a portion of the same passing into fine laminated loam; (5) coarser loam with sand partings obliquely laminated; (6) the same as 2; (7) coarse sand and gravel, ash-colored and bluish, with a few pebbles up to 5 or 6 inches in diameter, altogether without arrangement, but containing angular fragments of 10, as shown; (8) the same, coarsely laminated; (9) an ular fragments of 10 embedded in 7; (10) fine reddish brown or chocolate loam, containing a few pebbles (in part striated) finely laminated in some portions and these portions sometimes contorted; containing also a pocket of gravel. Maximum exposure, 30 feet.

representing a section observed near Delaware; and examples of contortion observed beyond the limits of the territory are illustrated in

Figs. 94 and 95, representing sections observed in St. Paul, Minnesota, in 1880—the former near the southeast corner of Rosabel and Fifth

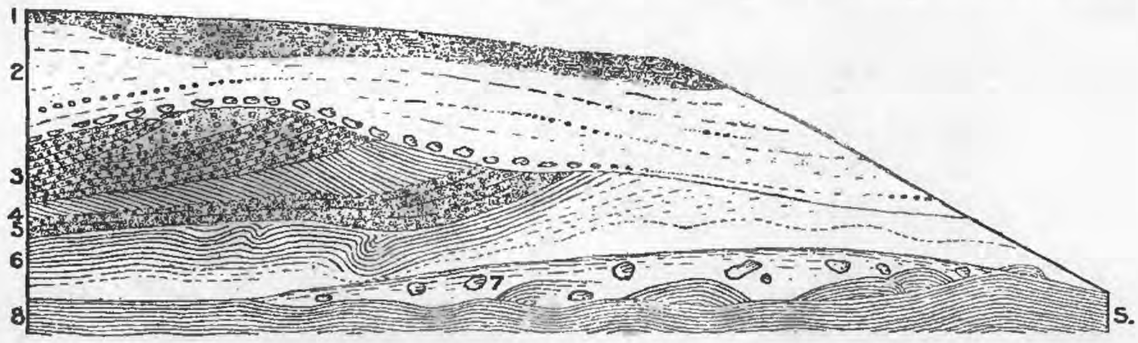

FIG. 95.—Section in St. Paul, Minnesota, exhibiting contortion of lower part of drift by ice action: (1) Reddish sandy and gravelly loam; (2) somewhat sandy and gravelly calcareous loam with a few small erratic pebbles and blocks of sub-angular limestone and with a few obscure lines of stratification, reddish at top then grayish, ash-colored, and finally bluish below; (3) sandy and gravelly reddish brown clay, in part laminated; (4) the same, without gravel; (5) the same, very gravelly; (6) nearly clean, purplish red, loamy clay, partially laminated and with a few erratics as shown; (7) plane of dislocation in same; (8) the same as 6, but distinctly laminated and contorted as shown. Total exposure (from top of embankment to bottom of cellar), 45 feet.

streets, the latter near the southeast corner of Wacouta and Fourth streets.

Only rarely does the lower till form the present surface. In the gumbo area the deposit takes on its usual peripheral differentiation, and it is the plastic clay of its upper member that approaches the surface; and even here the deposit is commonly concealed by a veneer either of loess or of loam of like age and related genesis. Toward the southern limits of the territory generally this attenuation and differentiation of the newer deposits occur. In the southwest the veneer is commonly loess, perhaps passing into pebbly clay as in the section illustrated in Fig. 96 (observed just outside the territory in

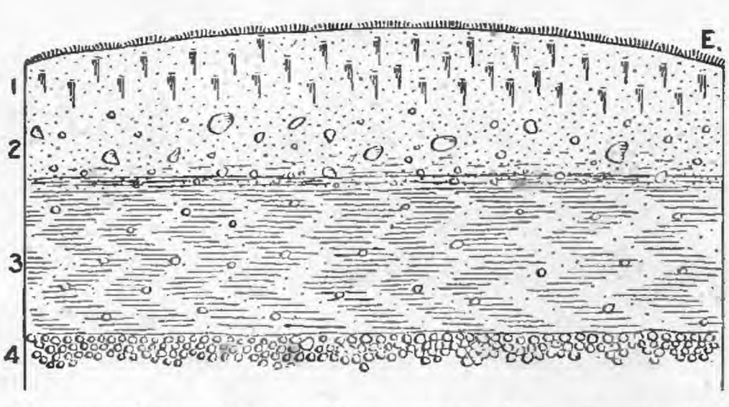

FIG. 96.—Relations of lower till toward its southern margin, Jasper County: (1) Loess, becoming sandy and pebbly at base and passing without distinct line of separation into drift, say 5 feet; (2) upper Till, containing small pebbles medially, and stratified sand and gravel below, say 9 feet; (3) compact blue clay, with many small pebbles and a few bowlders, 13 feet; (4) dark brown and yellow gravel of quartz and greenstone pebbles, partially cemented by iron.

a railway cutting in the NW. ¼, Sec. 33, T. 80 N., R. 17 W., Jasper County); while in the southeast it is either of similar character, as at Davenport (Fig. 77), or—particularly at low levels—a sheet of semi-alluvial sand, perhaps resting on an eroded surface of lower till, as in a section exposed at the eastern margin of the broad late Pleistocene flood plain of the Cedar in the NW. ¼ SW. ¼, Sec. 15, T. 77 N., R. 1 W., Muscatine County (Fig. 97). In some localities, how-

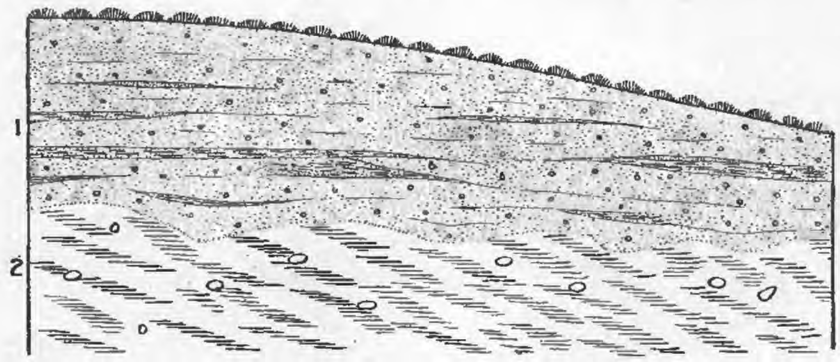

FIG. 97.—Relations of lower till in the southeast, Muscatine County: (1) Stratified brown and yellow sand, both fine and coarse, with a little gravel and several bands of sandy clay; (2) light blue plastic clay with a few small erratics, one striated. Exposure, 28 feet.

ever, the later deposits have either been wholly removed or were never deposited in considerable thickness, and in these, accordingly, the lower till lecomes a superficial deposit. Thus, in the eastern part of Scott County, between Davenport and Princeton, notably about Porter's Corners, the upper till is thin or absent and the loess mantle of limited thickness, and the steep-sided stream-ways and storm runnels radiating toward the Mississippi have generally removed the more friable newer deposits over considerable zones, leaving flat-bottomed intervals of the more obdurate deposit. In the western part of Muscatine County, and in the southeastern townships of Johnson County, too, the altered Pleistocene deposits are thin, and sometimes the lower till (either as a bowlder clay or in its gumbo phase) is denuded over areas reaching some square miles in extent. In southwestern Johnson and southeastern Iowa Counties, also, the lower till, there commonly undifferentiated, frequently approaches the surface and merges into a veneer either of upper till or of loess, and the color and texture of the veneer in a measure reflect the characteristics of the older deposit. Even well within the limits of the upper till that deposit locally fails—e. g., about Martelle, in central Jones County, the tenacious blue clays of the lower till are frequently exposed in shallow roadway excavations, in roadside gullies, in post holes, and are even turned up by the plow. In all of these localities the habit of weathering is alike: Where the clays are exceptionally sandy or gravelly, they weather brown and form a more or less friable and fruitful soil; but where the clay is plastic and sand-free and of the usual blue color, as in the superior peripheral portion generally, it commonly weathers whitish or ashen to a limited depth and forms a tenacious, intractable soil, drowning when wet and baking when dry. This phase is colloquially known as "gumbo," sometimes as "hard pan," and locally as "white clay," or (from its behavior before the plow) "push land." Commonly, when the blue clay weathers white the contained iron segregates in nodules—sometimes the firm, concretionary shells with earthy nuclei such as usually characterize the deposit in the vicinity of the forest bed, again cylindrical concretions accumulated about rootlets, and elsewhere rounded or botryoidal masses ranging from one-eighth to one-half an inch in diameter, colloquially called "buckshot." In a railway cutting 3 miles east of Lone Tree, Muscatine County, concretions of the character last mentioned are found in such abundance as to form nearly one-third of the mass.

SECTION IV.—THE GLACIAL TALUS.

As shown on other pages, the transition from ice-fashioned to water-carved topography along the margin of the driftless area is commonly gradual; and, moreover, the ice forms extend farthest into the driftless area, not in valleys, as in montanic regions, but along ridges and over divides.

There is a coincident distribution of deposits. Glacial drift, more or less closely resembling that of the central part of the area, is pushed out not only to the extremities of the salients in the Niagara escarpment, but on most of the lower divides in Winneshiek and northern Clayton Counties, where the Niagara escarpment is faint,

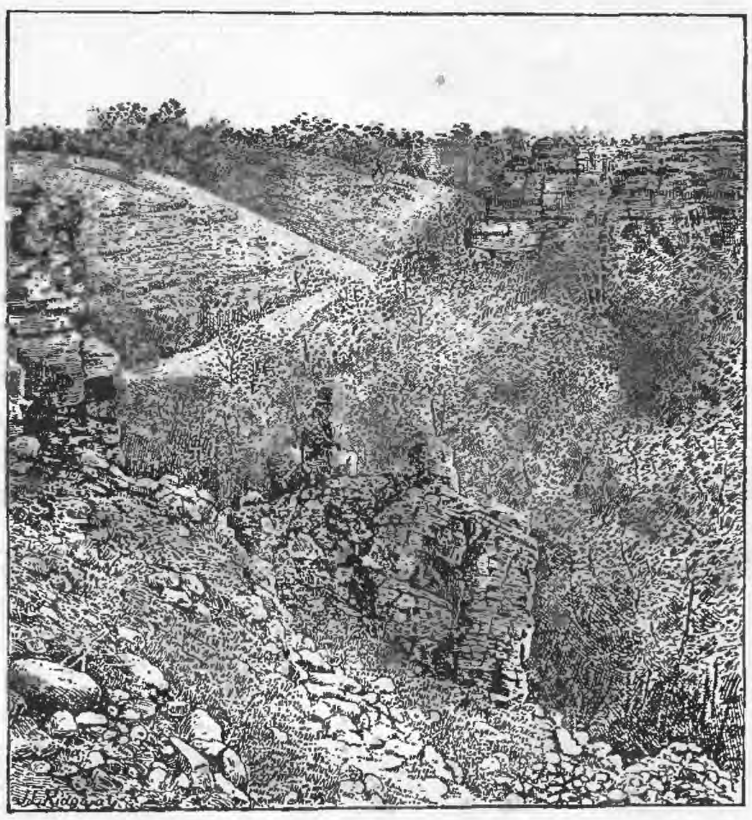

FIG. 98.—Combined water sculpture and ice molding, the former in foreground at lower levels, the latter confined to summits. Near Preston.

and in southern Dubuque and Jackson Counties wherever the ice failed to reach its verge; and moreover, in some cases, sheets of bowlder clay containing beds of erratic pebbles and bowlders have apparently been pushed across transverse valleys and now crown eminences completely isolated from the body of drift. This is well illustrated in northeastern Clinton County, in the neighborhood of Goose Lake, and in contiguous parts of Jackson County; for the abandoned channel of the Mississippi here cutting off the tip of "Cromwell's Nose" was apparently bridged by the ice, and glacial débris

FIG. 99.—Combined water sculpture and ice molding, the former in foreground at lower levels, the latter on summits in distance. Near Preston.

mantles the summits on its eastern side, while its mid-walls display the characteristic features of water carving and are nearly or quite destitute of erratic deposits. But now and then in this transverse valley and in others of like character about the margin of the glacial deposits, as well as sometimes far within the glaciated area, there is a distinctive accumulation more or less closely approaching glacial drift in structure, though made up wholly of local materials. Such a deposit is illustrated in Fig. 100, representing an exposure in the valley of the Wapsipinnicon, 3 miles northwest of Anamosa. The coarse member here is made up of angular blocks and fragments of Niagara limestone, identical with that quarried in the immediate vicinity, embedded in a matrix of worn pebbles, gravel, sand, and finer débris of like material. Fig. 53 represents a neighboring exposure at Stone City, with a coarse member of like character; and Fig. 101 illustrates a section, also exposed in the Wapsipinnicon valley, but at a point several miles below (in a railway cutting in the NE.

¼, Sec. 7, T. 83 N., R. 2 W., Jones County). It is noteworthy that the upper till is unusually thin in this part of the territory (as has already been mentioned, the lower till forms or closely approaches the surface about Martelle, a few miles south of Anamosa). At Stone

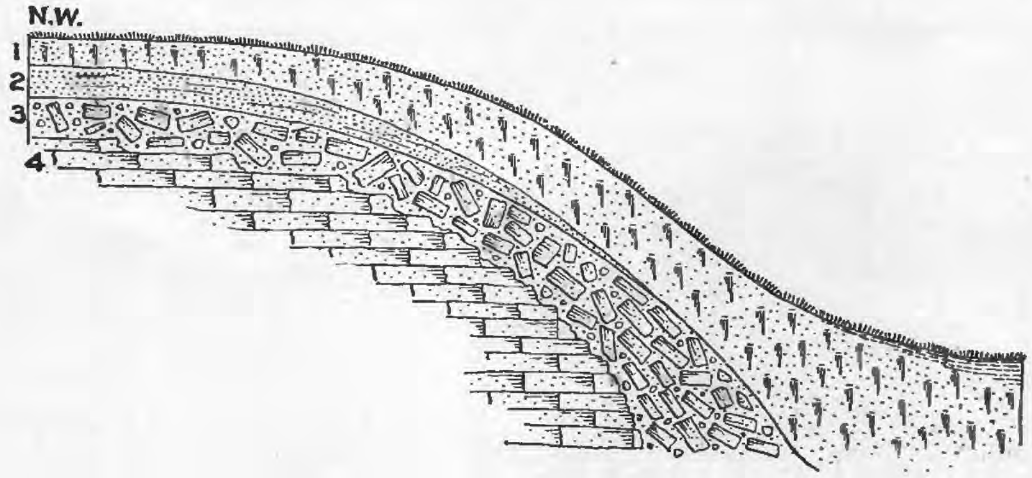

FIG. 100.—Glacial deposit of local materials, near Anamosa: (1) Loess; (2) obscurely laminated sand, generally merging with the loess; (3) light buff calcareous loam containing sand, pebbles, and angular blocks of Niagara limestone; (4) Niagara limestone. Height, 60 feet.

City the loess rests upon the Niagara limestone either directly, as shown in Fig. 54 (reproduced from a photograph), or with a bed of sand intervening, as illustrated in Fig. 53; and it is quite possible

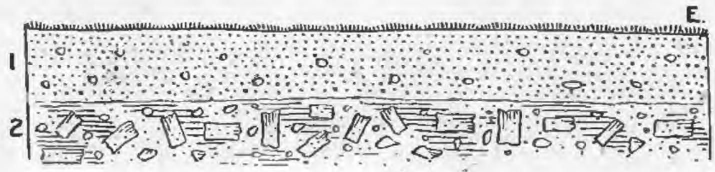

FIG. 101.—Glacial deposit of local materials, Jones County: (1) Fine, clean, obscurely stratified sand with some gravel, largely erratic; (2) reddish yellow clay with gravel and angular blocks of limestone, and a few erratic pebbles. Exposure, 10 feet.

that the later glacial deposits fail completely beneath the loess over a larger area than is represented upon the map of Pleistocene deposits (Pl. XLIII).

The section represented in Fig. 102 was observed in a little valley

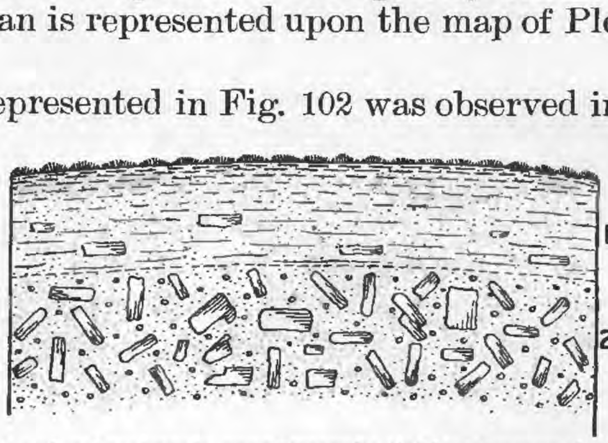

FIG. 102.—Glacial deposit of local materials, near Decorah: (1) Black humus-charged loam with rounded blocks and small fragments of Trenton limesto e; (2) light buff calcareous gravel, sand, and impalpable powder, enclosing great numbers of angular and slightly rounded blocks and fragments of Trenton limestone. Exposure, 7 feet.

opening into the Oneota, near Decorah (SE. ¼ SE. ¼, Sec. 5, T. 98 N., R. 8 W.), just beyond the limits of well characterized ice marking.

The coarse deposit here consists of angular fragments of Trenton limestone, similar to that forming neighboring cliffs, embedded in a matrix of partially oxidized and lixiviated limestone débris. Analogous sections appear near Plymouth Rock in Winneshiek County, near Kidder in Dubuque County, and at several points in western Jackson County, as well as in the vicinity of Goose Lake, Clinton County.

The common situation of such accumulations is in deep, steep-sided, and tortuous valleys, transverse or oblique to the direction of ice flow and about the drift margin; and there are few such valleys so placed that are not at least partially lined with deposits of this character.

These accumulations of angular débris connect themselves definitely with two distinct and well characterized deposits. In some cases the materials sometimes become progressively smaller and better rounded downstream or in the direction of the driftless area, sometimes taking on the character illustrated in Fig. 103 (represent-

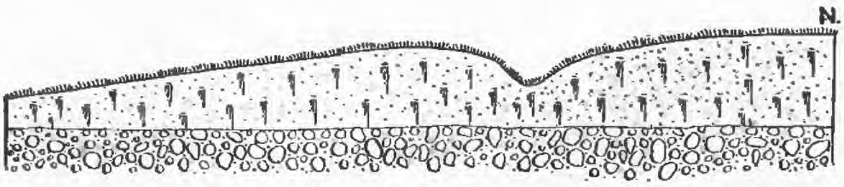

FIG. 103.—Local bowlder deposit beneath loess, Dubuque: (1) Loess; (2) rounded masses of Galena limestone from 8 or 10 inches in diameter downward to fine powder, piled together without arrangement; including also two or three small rounded erratics. Total exposure, 10 feet. The loess is separated from the subjacent bed by a ferruginous band with stains running down to the uppermost bowlders.

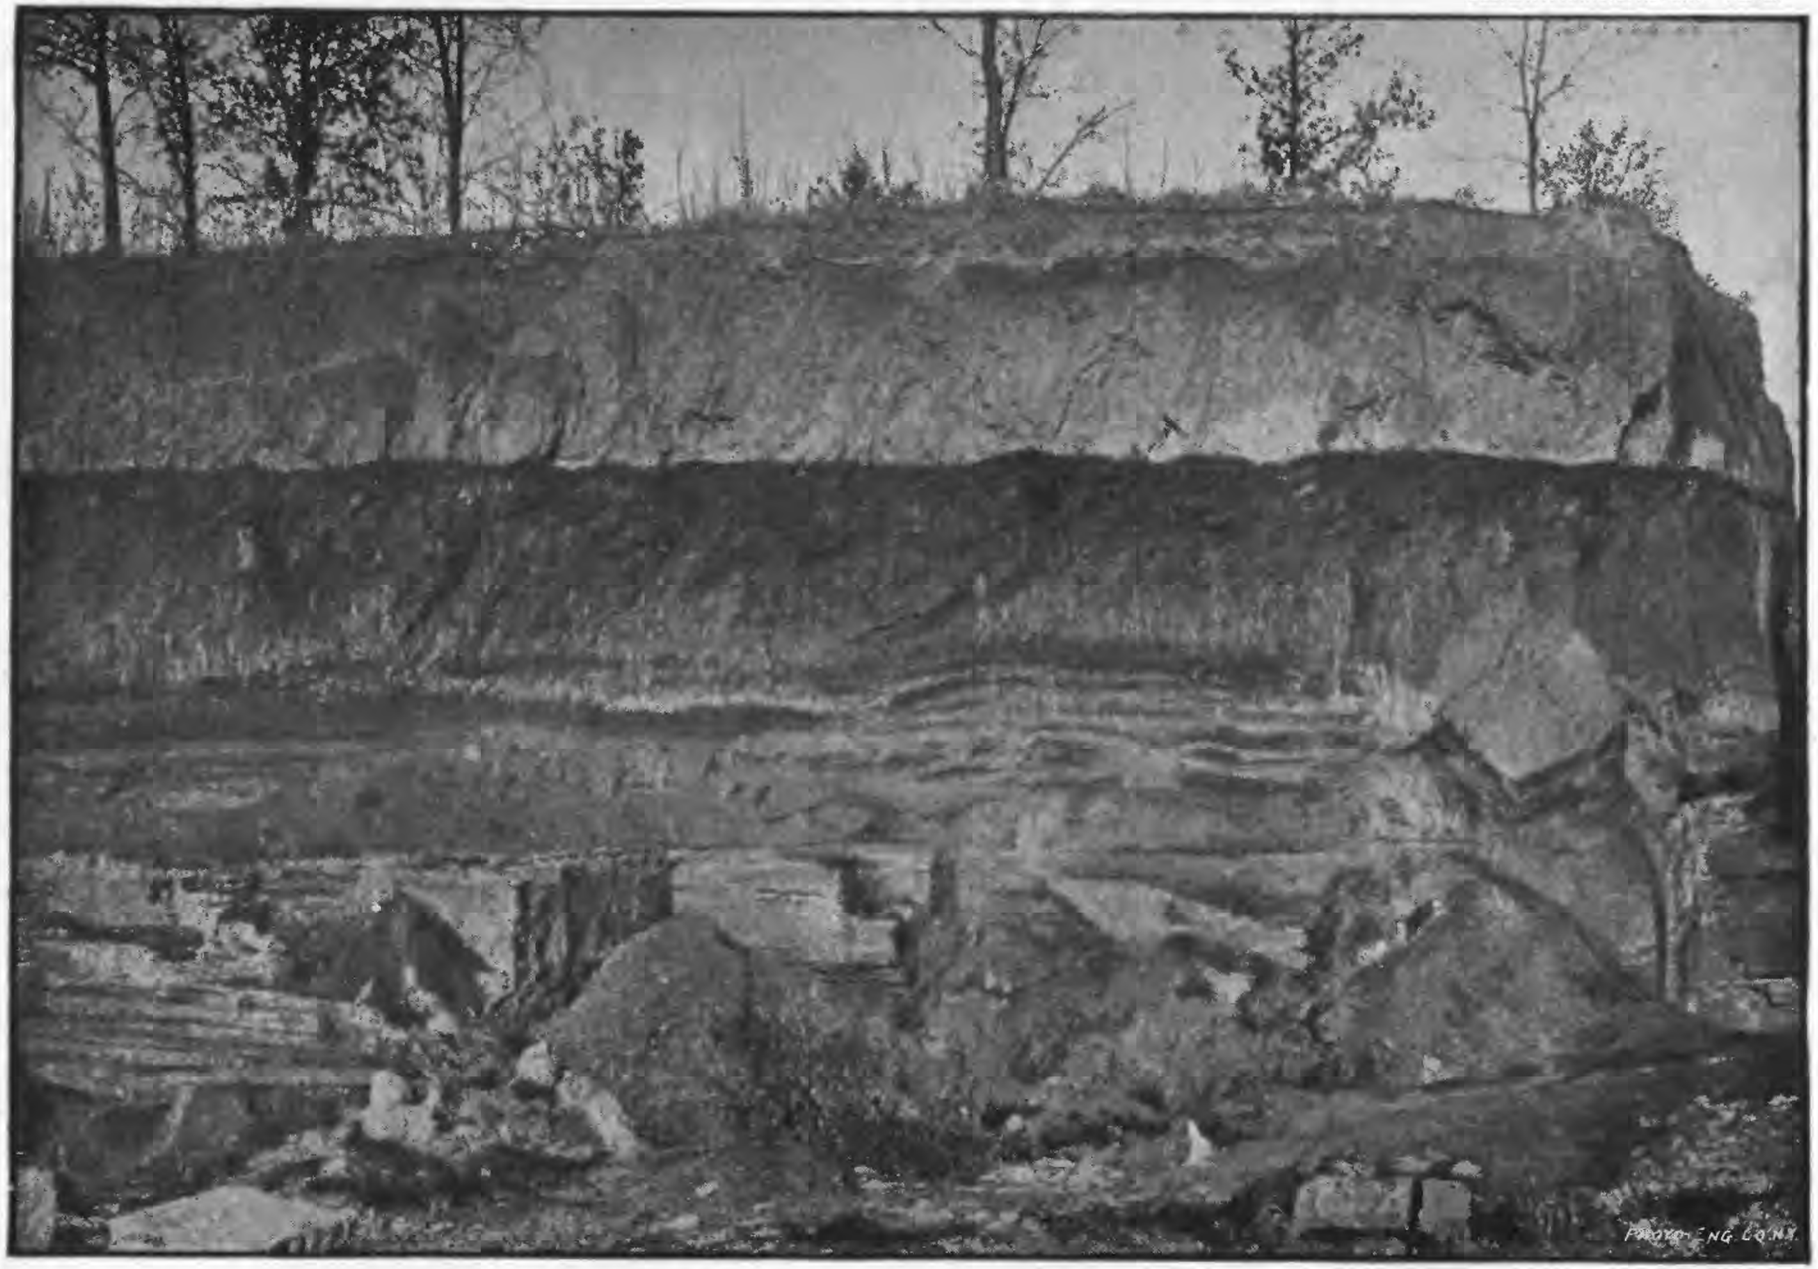
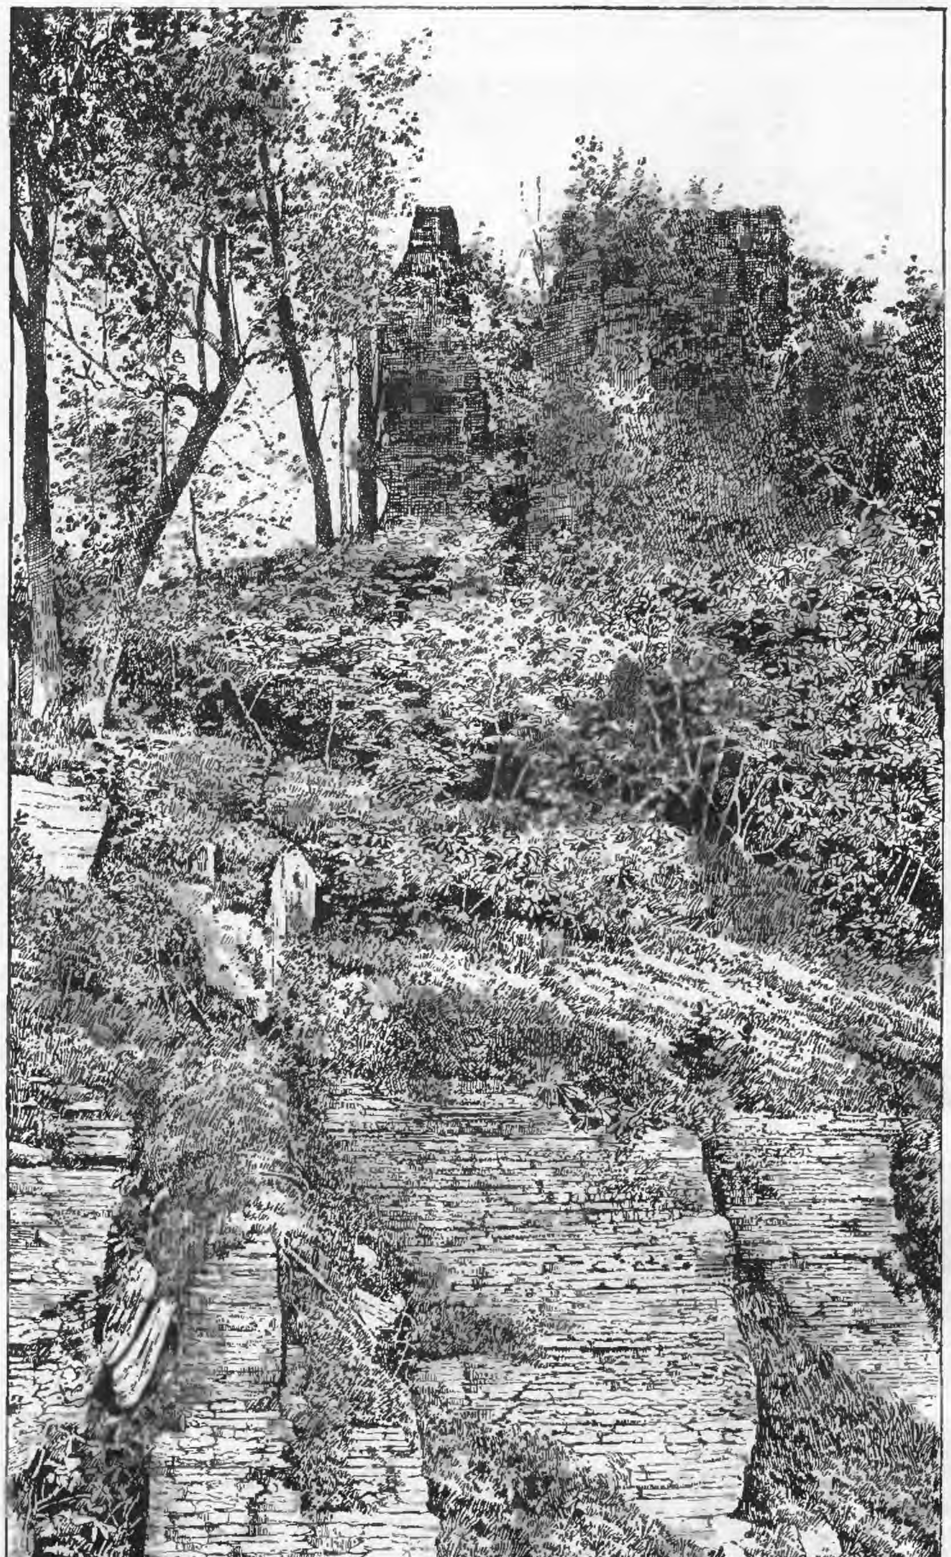
ing a section observed in a street cutting immediately west of Linwood Cemetery, Dubuque), and gradually passing into the pebble bed generally found at the base of the loess in the driftless area. In other cases the deposit passes stratigraphically (upward) and geographically (westward) in the same and contiguous exposures into an accumulation of like massive structure containing progressively larger proportions of rounded rock fragments of local origin and pebbles and bowlders from far to the northward, thus grading into the unmistakable glacial drift of one sheet or the other. Indeed, it is a conspicuous fact that the marginal portions of both tills contain exceptionally large proportions of local débris and that this proportion increases quite to the verge of either sheet, so that the last outcrop of either till on any meridian frequently contains more local than erratic rock fragments. So, too, the proportion of erratic rock fragments in either till, particularly toward the margin, decreases toward the base of the deposit, and the last yard in depth of the drift may thus contain more local than foreign rock fragments, though in the upper part of the same exposure the latter may greatly predomi-



FOREST BED AT DURHAM, MARION COUNTY.



EROSION TOWERS OF TRENTON LIMESTONE, NEAR TURKEY RIVER.

of the residuum left on decomposition. Accordingly, pinnacles and crags rise not only above the surface but even above the tops of the trees by which the surface is clothed, as in Pl. LIII, particularly toward the greater waterways; while smooth rock surfaces may lie within reach of the plow over considerable areas in the interior. The material of the geest over this terrane is commonly a dense, tenacious red clay or lithomarge. This clay appears to be as richly charged with iron as that yielded by the dolomites above and below, yet, probably by reason of the impermeability of the compact mass, the mineral is seldom definitely segregated. The ordinary stratigraphic relation of the clay is exhibited in Fig. 104, representing a road-

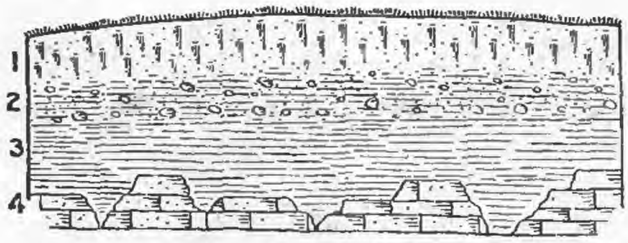


FIG. 104.—Typical exposure of residuary clays of the Trenton terrane, Allamakee County: (1) Dark, loamy loess; (2) pebbly loam, containing both local and erratic pebbles; (3) brown clay, plastic, tenacious, becoming granular on drying; (4) Trenton limestone. Exposure, 6 feet.

cutting in SW. ¼ NW. ¼, Sec. 31, T. 97 N., R. 6 W., Allamakee County.

The common product of the disintegration of the Trenton and Maquoketa shales is a tenacious clay, blue, buff, white, drab, orange, or brown in color; but the residua are sometimes discriminated only with difficulty from the clays of which these formations locally consist. The fully decomposed residuum may generally be recognized, however, by a peculiar granular texture exhibited on drying, and in good exposures by a dark line marking its base. The Trenton and Maquoketa terranes are generally overlain by loess, and the loess and the residuary clays sometimes intergrade in such manner as to indicate that the former is in part made up of materials derived from the latter; but in the section represented in Fig. 105 the pebbly

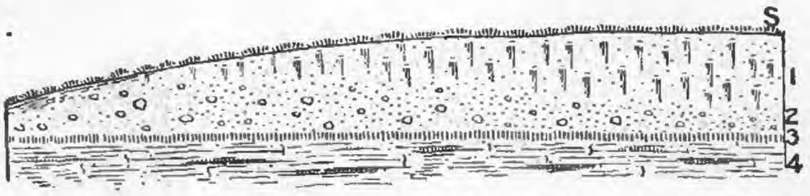

FIG. 105.—Unconformity between loess and residuary clays, Clayton County: (1) Loess; (2) reddish brown sand and gravel containing local and erratic pebbles up to 3 inches in diameter; (3) an ocherous line weathering into earthy limonite; (4) light buff jointed clay, containing ferruginous nodules, with jointage planes stained brown. Exposure, 6 feet.

basal stratum of the loess is clearly separated from the clays by an ocherous band doubtless representing an ancient surface; and the subjacent clays are mottled with brown stains running down from this band to the base of the exposure, and spreading laterally along certain lines probably representing original bedding. This section is exposed in a road-cutting in the SE. ¼ NW. ¼, Sec. 34, T. 94 N., R. 5 W., Clayton County. In an otherwise similar exposure in the NW. ¼ SE. ¼, Sec. 15, T. 92 N., R. 3 W., in the same county, the sand and gravel stratum is quite absent, the ocherous band less distinct, and the loess reposes directly upon a mass of bluish white clay which, 4 or 5 feet beneath its summit, yielded numberless small spherical or flattened concretions formed around the calcareous shells of Maquoketa brachiopods and cephalopods.

Throughout the Galena terrane the dolomites are everywhere concealed beneath a heavy bed of tenacious red clay, except in the ravines and gorges of the waterways and in the precipitous cliffs by which they are overlooked. This clay is commonly sand-free and homogeneous, and on partial drying exhibits finely jointed or granular structure, the jointed surfaces being sometimes lustrous or glossy. On complete drying, the clay crumbles readily into a mass of cubical or irregularly angular grains, themselves not readily pulverulent. When the granular texture is destroyed by freezing and thawing or by other means, the clay becomes plastic and extremely tenacious when wet, and firm and compact when dry, like the "gumbo, of Muscatine County and the southwest. This clay is identical in appearance and texture with that found beneath the stalagmitic floor in the limestone caverns and in the deeper fissures of the lead region in Iowa, Wisconsin, and Illinois. Sometimes it contains nodules of chert and crystals of galenite, as well as bands, plates, pipes, and irregular nodules of earthy limonite and pockets of red ocher. In some localities the galenite is so abundantly distributed that the "clay diggings" of eastern Dubuque County were at one time famous. The relation of the clay to the magnesian limestone from which it was derived is illustrated in the accompanying Fig. 106, exposed in a quarry on Eagle Point in the northern part of

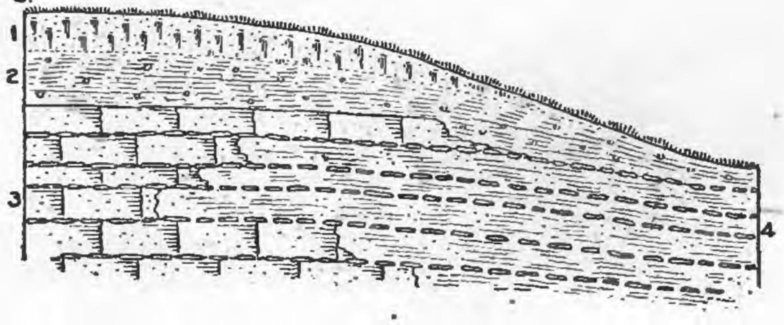

FIG. 106.—Residuary clays of the galena limestone, Dubuque: (1) Somewhat sandy and clayey loess; (2) obscurely stratified red loam containing chert, rounded fragments of limestone, and a few erratic pebbles; (3) Galena limestone with elongated nodules and plates of chert at partings; (4) red clay, finely jointed, with nodules and plates of chert in lines corresponding to those of the rock. Exposure, 9 feet.

Dubuque. This section is of interest in that it indicates the relative thickness of the residua and of the original strata. The thicknesses of the second, third, and fourth ledges (from bottom) of limestone and of the corresponding layers of clay are respectively as follows·

Limestone.	Clay.
Inches.	*Inches.*
16	14
13	10
12	9
41	33

Thus the limestone (here somewhat sandy and so less pure than the average) appears to have lost only 20 per cent of its volume on decomposition; and the total loss in volume of the entire mass of dolomite and chert is still less, since the latter element remains intact.

In general, the surface of the Galena geest, like that derived from other formations, is more or less disturbed and its materials are intermingled with superjacent deposits, as illustrated in Fig. 107, ob-

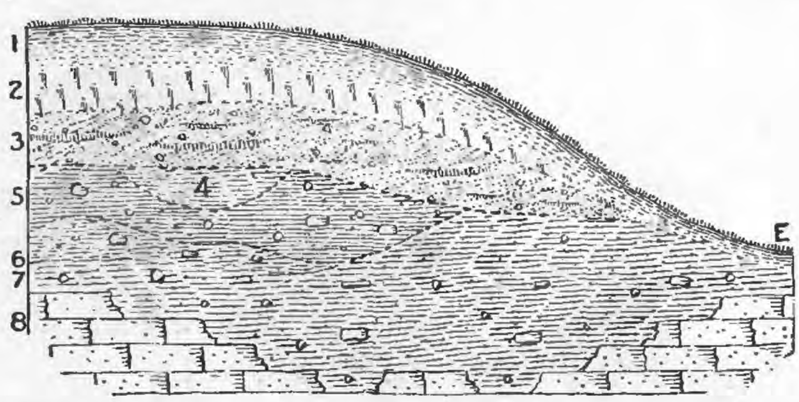

FIG. 107.—Residuary clays of the Galena limestone, Dubuque: (1) Surface soil; (2) slate-colored loess; (3) stratified and cross laminated sand; (4) hard calcareous white clay; (5) tenacious red clay containing fragments of chert and small blocks of limestone; (6) similar clay, brown and even black, flecked and streaked with white; (7) red clay, similar to 5, containing fragments of chert and somewhat worn bits of limestone; (8) Galena limestone. Exposure, 18 feet.

served on the east side of the ravine running south from Linnwood Cemetery, Dubuque. Here the loess is sandy and passes down into stratified and cross-laminated sand containing a few local pebbles and in part cemented by iron oxide; this sand rests in part upon undisturbed residuary clays, in part upon a mass of similar but evidently redeposited clays containing a few erratic pebbles, and in part upon an irregular pocket of residuary clay unlike that beneath, and evidently transported some yards or rods. Fig. 108, illustrating a section observed half a mile north of Elkader, is representative of the sections exposed in roadside gullies. Here the upper portion of the residuary clay is deeply ferruginated and irregularly eroded, and the nearly pure lithomarge of which it in part consists disappears on weathering, leaving thin but firm crusts of dark brown limonite either in the form of irregular nodules or coating the subjacent

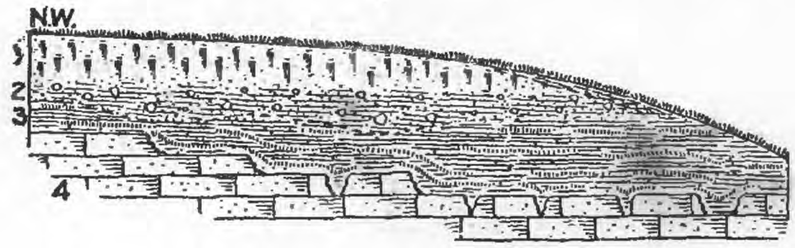

FIG. 108.—Typical exposure of residuary clays of the Galena, Elkader; (1) Brownish loamy loess; (2) reddish sandy clay containing nodules and spalls of chert and rounded and subangular fragments of both local and erratic rocks; (3) unctuous red clay marked by brown and white streaks conforming roughly to underlying rock surface; (4) Galena limestone. Exposure, 6 feet.

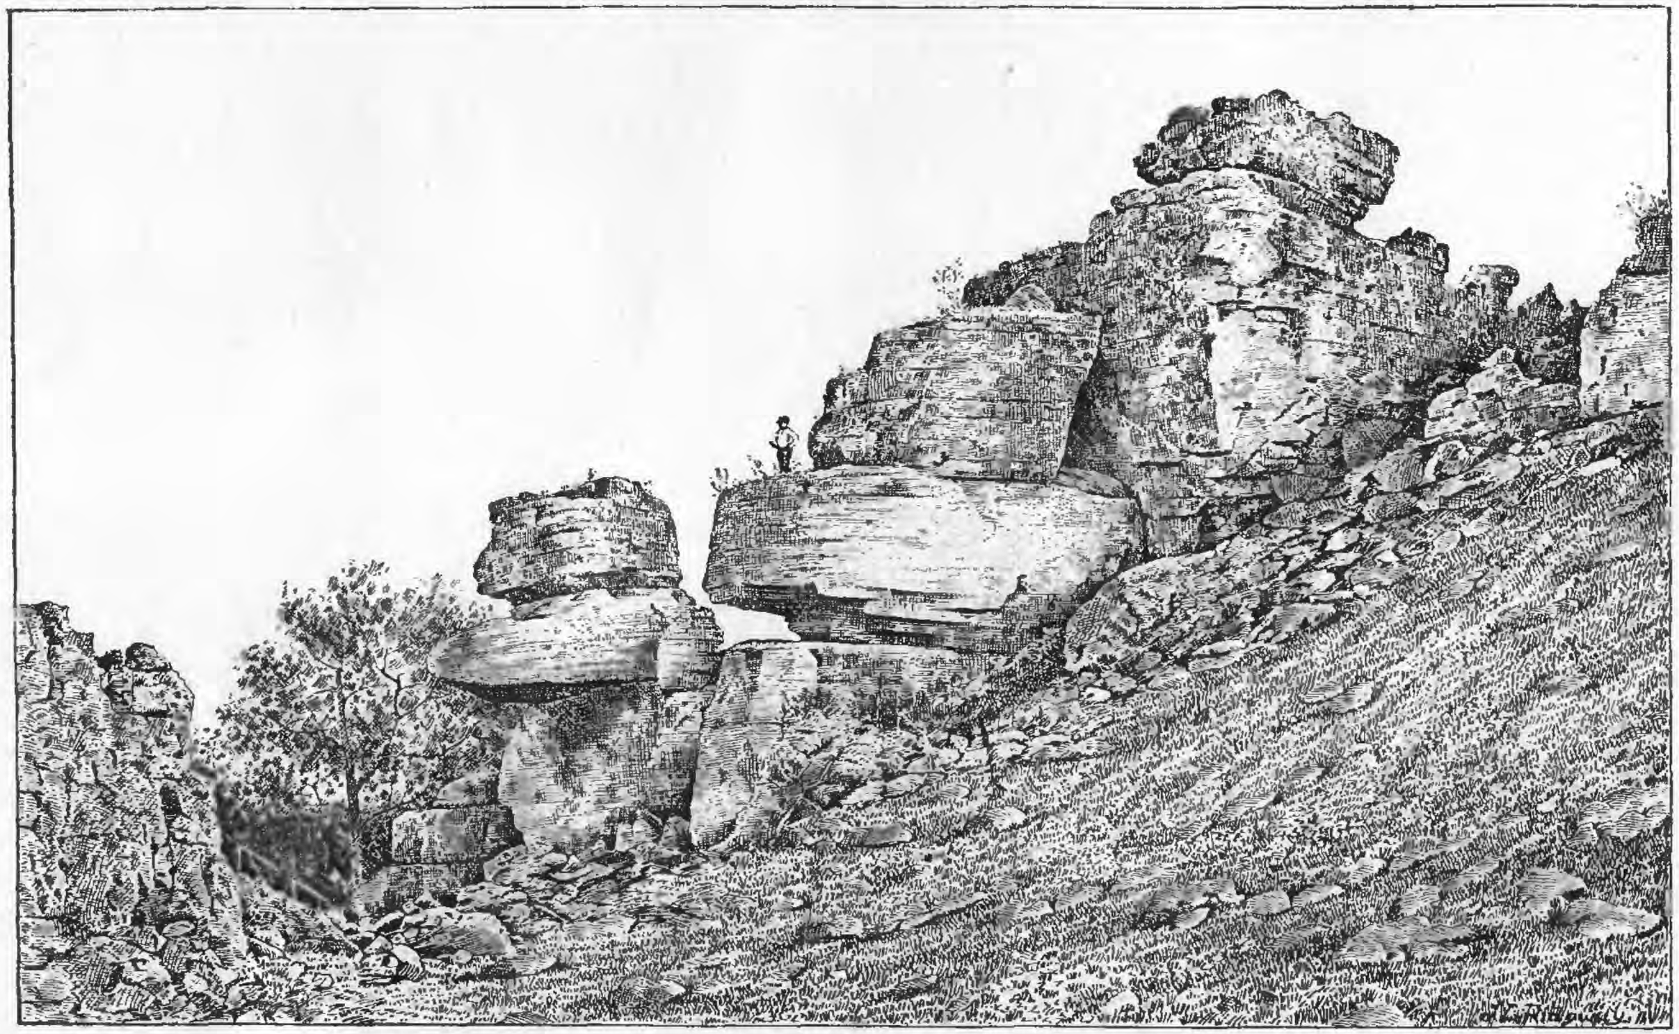
rock surfaces. Along the larger waterways the Galena dolomites have been bared by erosion and crop out through the mantle of geest in great crags and cliffs. Types of these are illustrated in Pl. LIV and Fig. 109.

FIG. 109.—Cliff of Galena limestone, near Dubuque.

Although the Niagara terrane is sheeted with glacial drift throughout nearly the whole of its extent in the territory, there is ample



CRAGS OF GALENA LIMESTONE, MINERAL STREET, DUBUQUE.

evidence that its surface was deeply decayed before the ice invasion. The relation of the residua formed by this decay of the loess was clearly exhibited in a well in the NE. $\frac{1}{4}$ SW. $\frac{1}{4}$, Sec. 32, T. 89 N., R. 1 W., Dubuque County, illustrated in Fig. 110. Here the loess forming the upper part of the section exhibits the features normal to the driftless area. It passes below into stratified and cross-laminated sand. This sand rests upon an irregular ferruginous band, evidently representing an ancient surface. Below this line there is found dense, homogeneous, plastic red or brown clay, with a few disseminated nodules of chert; toward its base regular bands of cherty nodules divide the clay into layers corresponding to the ledges of limestone exposed still lower, the considerable inclination of the strata being quite local, and of no special significance. Like relations are exhibited in a railway cutting in the NW. $\frac{1}{4}$ SW. $\frac{1}{4}$, Sec. 18, T. 84 N., R. 1 E., Jackson County, as illustrated in Fig. 111. Here again there is a well-marked plane of division between the sandy loess above and the geest below; and here, too, coarser drift deposits are lacking.

In this part of the terrane (i.e., toward the Niagara escarpment in Jackson and Dubuque Counties) the basal portion of the clay may be a nearly pure ocher or lithomarge; within it considerable quantities of limonite are occasionally accumulated in bands or nodules. In pioneer days this limonite was sometimes wrought in a small way, and is even now occasionally reduced in ordinary blacksmith's forges; but the quantity is insufficient for systematic exploitation, although it is sometimes found filling rock cavities or even lying loosely upon the surface where the rocks have been laid bare by erosion in such amount as to excite prospectors. The limo-

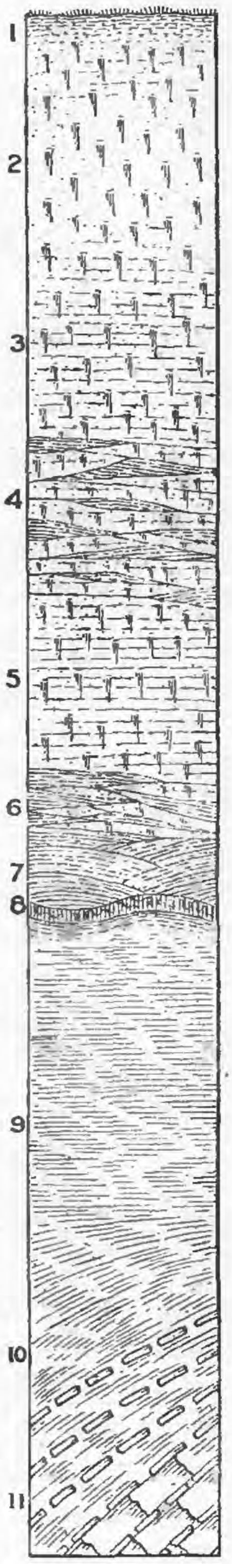


FIG. 110.—Well section exhibiting relation between loess, residuary clay, and Niagara limestone, Dubuque County: (1) Surface soil passing into loess, 2 feet; (2) fine clean homogeneous, and perfectly unstratified buff-colored loess, 4 feet; (3) the same faintly laminated, 3½ feet; (4) the same interlaminated with bluish lines, the buff predominating, 3 feet; (5) the same as in 3, but more distinctly laminated, 2 feet; (6) the same as 4, but with the blue predominating, 2 feet; (7) the same, slightly coarser in texture, especially at base, more distinctly laminated, and wholly blue, 2½ feet (6 and 7 contain cylindrical ferruginous concretions); (8) a thin band of iron oxide, pretty firm above, incoherent and ocherous medially and less firm below than above, with brown stains passing downward several inches; (9) clean, red granular clay, dark and structureless for 2 feet at top, horizontally laminated below (generally obscurely, but toward the base more distinctly), 9 feet; (10) red granular clay in oblique layers separated by cherty or ferruginous partings above, and by heavy lines of chert below, 5 feet; (11) Niagara limestone, with heavy partings of chert.

nites of this character were first examined by Whitney in 1858; and it was by him supposed that the iron was originally distributed irregularly throughout the dolomites in the form of nodules of pyrites. It is true that the ore masses sometimes contain nuclei of sulphide of iron or are even pseudomorphs after that mineral; but it is evident that portions of the iron were originally disseminated

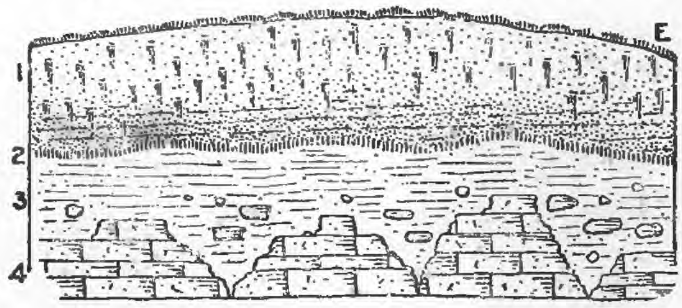

FIG. 111.—Unconformity between loess and residuary clays. Jackson County: (1) Loess, stratified and sandy at base; (2) an ocherous band, forming a firm crust above but passing into the clay below, indurating on exposure so as to form a projecting crust or ledge which eventually breaks off and becomes imbedded in the talus; (3) red granular clay, flecked and streaked with brown, passing into lithomarge in cavities, containing a few nodules of chert and fragments of limestone; (4) Niagara limestone. Exposure, 16 feet.

throughout the rock and underwent segregation after the decomposition of the rock; for an indefinite number of gradations between the slightly ferruginous undecomposed rock, the residuary clays in chert-divided layers corresponding to the original ledges, the same clays more deeply ferruginated, ocher and lithomarge, hollow nodules of impure limonite, and solid masses of ore, may readily be observed.

When glacial drift is superimposed upon geest about the margin of the driftless area, the two deposits may or may not be distinct. In the section shown in Fig. 112 (exposed in a railway cutting half

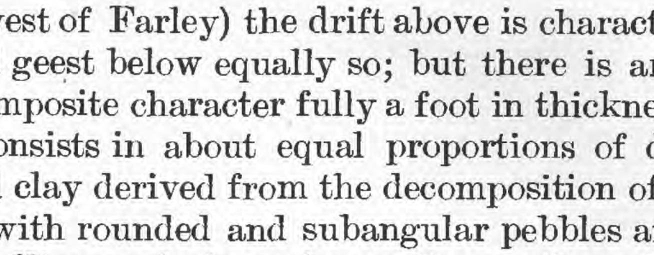

FIG. 112.—Apparent transition between drift and residuary clays, Farley: (1) Unmodified glacial drift; (2) compact red clay charged with nodules and spalls of chert. Exposure, 9 feet.

a mile southwest of Farley) the drift above is characteristic and the chert-charged geest below equally so; but there is an intermediate stratum of composite character fully a foot in thickness. This composite band consists in about equal proportions of drift materials and of the red clay derived from the decomposition of the dolomite; it is charged with rounded and subangular pebbles and small bowlders of crystalline rock from far to the northward from base to summit, but nodules and spalls of chert from the subjacent strata are still more abundant; and the sandy drift clays and the rounded erratics decrease and the sand-free residuary clay and cherty débris increase downward so gradually that it is impossible to demark the deposit save by a purely arbitrary line. And this is by no means an isolated case. In northeastern Delaware County and in western Dubuque County, in southern Jackson and northern Clinton Counties, the Niagara formation is frequently made up largely of chert either segregated in abundant nodules or accumulated in definite ledges alternating with dolomite; and on complete decay of the dolomitic matter the nodules and layers of chert break up into sharply angular chips and spalls, and thus become imbedded in a matrix of tenacious red clay sometimes so meager as barely to fill the interstices. These masses of chert or cherty clay are exceedingly obdurate; they are much more difficult of removal in making roadways or excavating wells than solid rock; they sometimes form natural roadbeds which have borne the traffic of the country ever since its first settlement without yielding perceptibly to the beating of hoofs or the grinding of wheels; yet into these obdurate masses the ice-sheet by some means insinuated itself and pushed its bowlders and pebbles to such an extent that it is impossible to say where the disturbed residuum ends and the undisturbed mass begins. Two miles north of Farley, just at the north line of T. 88 N., R. 1 W., shallow road-cuttings excavated at great cost in such a chert mass exhibit pebbles and bowlders up to 1½ feet in diameter partially or wholly imbedded within, and sometimes buried as much as 2 feet below the surface of, the intractable terrane. Half a mile farther north, where the matrix of clay is more abundant, bowlders were found in wells 3 or 4 feet below the summit of a cherty mass which would have otherwise been regarded as undisturbed. Here the geest is 10 to 20 feet in thickness, and the clays are charged not only with chert but with silicified fossils characteristic of the Niagara formation; and it is noteworthy that the fossils were found in nearly as great perfection above as below the deepest bowlder in one of the wells. Elsewhere, however, the ice-plow appears to have slipped over the clays, even where they are not stiffened by chert but remain plastic, without materially affecting their composition and structure. Thus, in

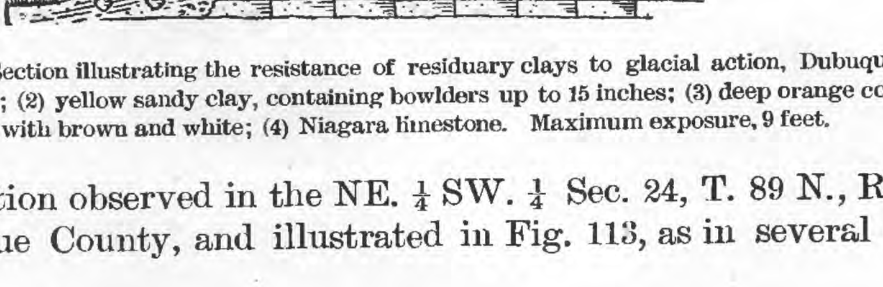

FIG. 113.—Section illustrating the resistance of residuary clays to glacial action, Dubuque County: (1) Loess; (2) yellow sandy clay, containing bowlders up to 15 inches; (3) deep orange colored clay streaked with brown and white; (4) Niagara limestone. Maximum exposure, 9 feet.

the section observed in the NE. ¼ SW. ¼ Sec. 24, T. 89 N., R. 2 W., Dubuque County, and illustrated in Fig. 113, as in several others, the clay is sand-free, granular but easily made plastic by kneading when wet, and spotted and streaked with iron stains, perhaps indicating either original structure lines or lines of progressive decay; but although the mass has undoubtedly been partly removed, the remnant is quite undisturbed, distinctly parted from the superjacent drift, and its surface quite unmarked.

In some cases the work of the ice-plow is definitely recorded in the crumpling and distortion of the partially or wholly disintegrated strata over which it pushed. Fig. 114 represents a section exposed

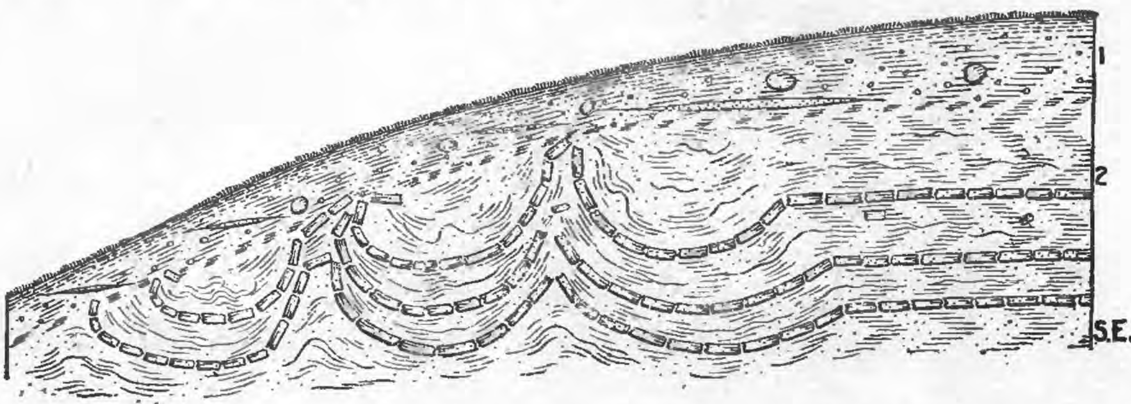

FIG. 114.—Deformation of residuary clays by glacial action, Delaware: (1) Soil, passing into sandy brownish yellow clay containing erratic pebbles and bowlders with a few bits of local chert; (2) compact red clay with nodules and spalls of chert and three definite beds of the same material, contorted. Exposure, 12 feet.

in a railway cutting a mile north of Delaware, in which the plane of contact between drift above and geest below is indistinct, yet in which the whole subjacent mass was thrust upon itself, compressed longitudinally and at the same time crumpled and contorted as indicated by the disturbed siliceous ledges representing original stratification. It is noteworthy that such witnesses to the energy of ice-work increase in number and in the eloquence of their testimony northwestward; and one such, observed far beyond the limits of Northeastern Iowa, is introduced for comparison (Fig. 115). It is

FIG. 115.—Section in St. Paul exhibiting deformation of Paleozoic clays by glacial action: (1) Surface soil and débris from slope; (2) gray or ash colored loamy clay with a few small erratics and numerous angular and subangular fragments of Trenton limestone varying in abundance in different parts as shown; (3) compact orange and chocolate-colored clay, with much-worn erratic pebbles; (4) jointed blue or bluish buff clay containing Trenton fossils. Maximum height of exposure, 15 feet; length. 60 feet.

revealed on the east side of Huffman avenue, between Second and Third streets, St. Paul, Minnesota. The materials beneath the drift are not, indeed, strictly residuary, in that they represent a non-indurated bed of clay within the lower part of the Trenton limestone, and have suffered little if any weathering. A few yards distant the same clay bed yielded abundant characteristic Trenton fossils (*Orthis testudinaria*, *Rhynchonella capax*, *Murchisonia milleri*, and numerous specimens of *Chætetes* representing two or three species). The divisions numbered 2 and 3, respectively, are both of glacial origin, yet quite distinct.

Although nearly the entire Niagara terrane is drift-sheeted, a few slender salients and isolated knobs lie beyond the drift margin; and in such outliers the dolomite, like that of the Galena, is often weathered into castellated crags and pinnacles along the water-ways, as illustrated in Fig. 116.

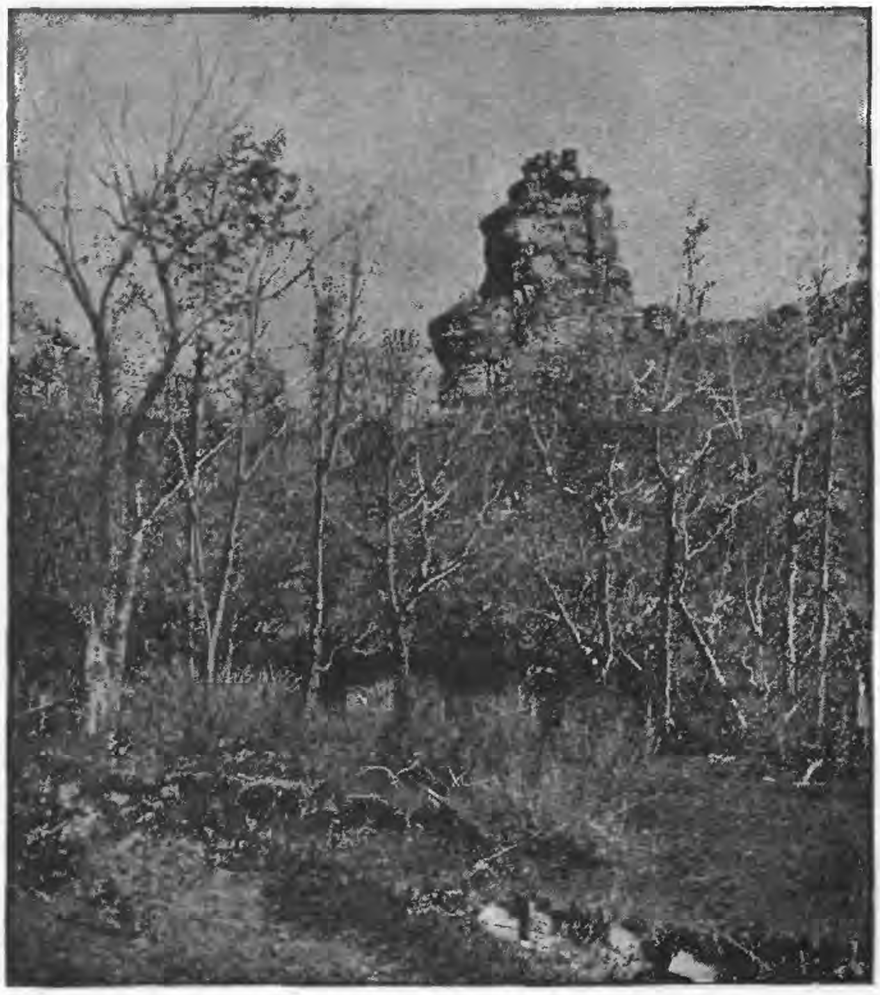

FIG. 116.—Castellated crag on Little Maquoketa River, Dubuque County.

The Cedar Valley limestones have everywhere suffered glaciation and are generally overlain by drift, and seldom exhibit the products of secular decay. So far as seen the prevailing product is a tenacious clay, generally deep red or dark brown; but sometimes the iron is segregated in ocherous nodules or pockets, when the surrounding clay may be lighter or even whitish in color. In the section illustrated in Fig. 117, representing the "stripping" of a quarry near Osage (NW. ¼ NW. ¼, Sec. 35, T. 98 N., R. 17 W.) the clay is not decidedly ferruginous, and contains a small amount of disseminated siliceous matter derived from the parent rock, and so is less dense

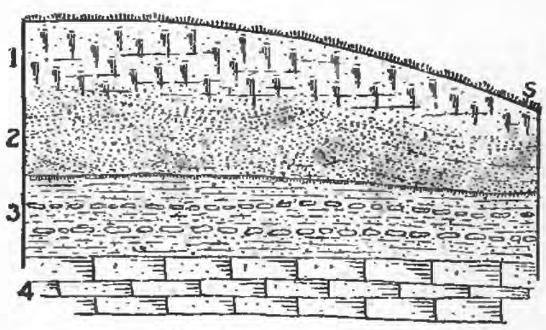

FIG. 117.—Residuary clays of the Cedar Valley terrane, near Osage: (1) Loess, obscurely laminated below; (2) fine sand, buff, gray, golden yellow, and yellowish brown in color, faintly cross-stratified; (3) light orange-colored clay, with discontinuous siliceous bands marking original bedding planes; (4) Cedar Valley limestone. Exposure, 17 feet.

and compact than the prevailing residua of the Galena and Trenton formations. It exhibits a ferruginous line at its summit, apparently representing an ancient surface, and so would appear to have been undisturbed by the later ice sheet. Measurements made in two contiguous sections here indicate that the volume of the layers of clay between the lines of siliceous nodules is but 60 per cent of that of the ledges they represent.

Well differentiated residua have not been observed over the terranes newer than the Cedar Valley limestone.

The products of secular decay in the terranes of the territory were evidently accumulated in considerable volume before the Pleistocene ice invasion, and contributed materially to the volume of the glacial deposits. The wealth of this contribution can seldom be determined even approximately, because the finer materials of local and erratic origin either are alike or can not be discriminated by reason of the fineness of comminution; but upon the Niagara terrane some idea of the relative volume of local erratic materials may be formed from the abundance of the indestructible chert; and in some other cases the glacier only partially kneaded the residua over which it ran without destroying all of their characters, so that the local clays may be recognized either in bowlders or as beds within the glacial deposits. Such a case is illustrated in Fig. 118, representing a section on the west side of the Iowa River below the upper bridge at Iowa City. Here the great mass of clay overlying the rock is jointed and exhibits a peculiar granular texture characteristic of the residuary clays in general; yet lenticular sheets of sand and erratic gravel and striated pebbles and bowlders are distributed through it in diminishing abundance from the summit to within a few inches of the subjacent limestone. Practically the whole of the mass is unquestionably glacial drift; yet its principal element is geest, perhaps not far removed from its original situation. This section is intermediate

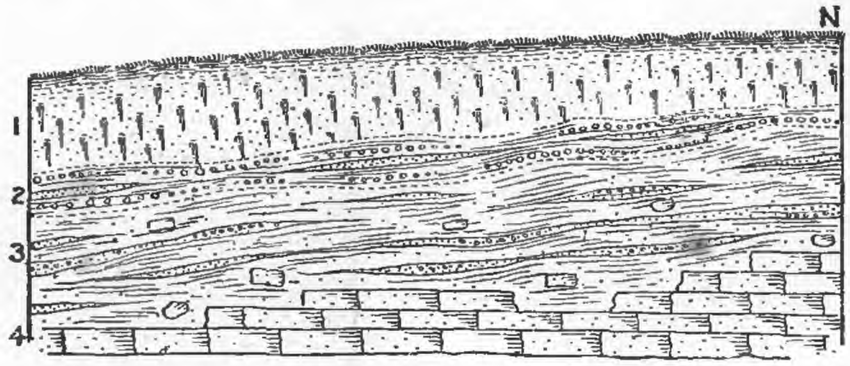

FIG. 118.—Section at Iowa City illustrating partial incorporation of residuary clays in glacial drift: (1) Brown surface soil passing into loess; (2) coarse sand, gravel, and pebbles, irregularly stratified; (3) jointed clay containing a few scattered pebbles, interstratified with fine sand; (4) Devonian limestone. Exposure, 18 feet.

between one in the neighborbood in which the surface was first washed into pot holes and subsequently striated by the ice sheet, as noted elsewhere,[1] and that illustrated in Fig. 119, observed in the same

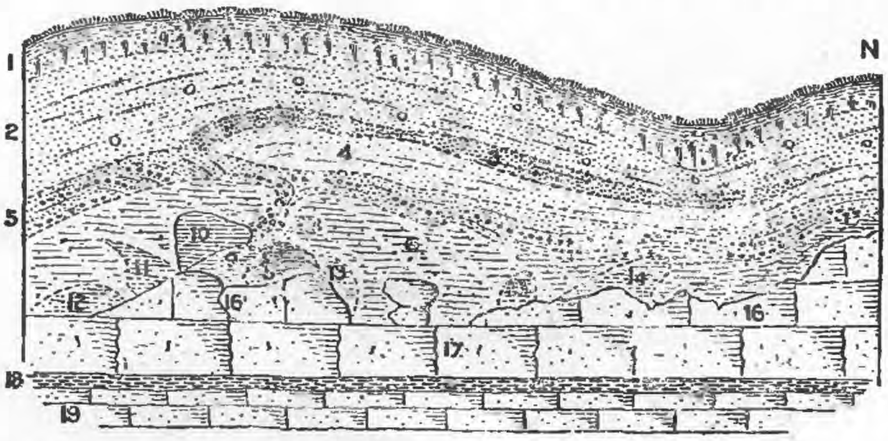

FIG. 119.—Section at Iowa City illustrating relation between residuary clays and glacial drift: (1) Loess-like soil, increasing to 8 feet in thickness farther north in the same quarry; (2) partially cemented reddish brown sand, obscurely laminated, of medium fineness, with an occasional local pebble, weathering first to brownish red and becoming more firmly cemented, then to dark brown and becoming incoherent; (3) the same, coarser and darker; (4) the same, finer than either of the last; (5) coarse red sand gravel of both local and erratic constituents, distinctly laminated, with a prolongation downward; (6) irregularly jointed clay with a little fine sand disseminated throughout, generally brownish buff in color, and with faint traces of lamination in the northern part of the exposure; (7) clean granular black clay, apparently highly corbonaceous; (8) red sand, much like 2; (9) fine white jointed clay; (10) fine and clean horizontally laminated yellow clay; (11, 12, 13, and 14) clean and plastic or granular clay or lithomarge, dark brown or reddish brown; (15) orange-red sand, like 8 and 2; (16) irregular masses of Cedar Valley limestone; (17) a smooth heavy ledge of the same, (18) black bituminous shale, forming a thin parting; (19) medium ledges of the same. Height of exposure, 20 feet; length, 60 feet.

bluff face but below the lower bridge. In the last section the mass of the jointed clay is commonly homogeneous and uniform and without conspicuous horizontal structure; but in its upper portion erratic pebbles occasionally appear. The lower portion of the bed is, how-

[1] Cf. Webster, Am. Nat., 1888, vol. 22, pp. 408–419, pl. v.

ever, made up largely of immediate products of rock decay, little if at all disturbed by glacial action, as indicated by the presence of the pockets of distinctive materials indicated in the figure; yet here, as in other cases, it is impossible definitely to demark the disturbed and undisturbed portions of the geest.

Toward the drift margin in the northern part of the territory, certain puzzling accumulations occasionally lie beneath the well-characterized glacial deposits, commonly as isolated remnants of a rock mantle wrapped around the bases of knobs, lining depressions and filling crevices of the subjacent Niagara limestone; the structural relations being those of the ordinary residua, while the composition differs in the essential particular that pebbles of quartz, jasper, etc., are more or less abundantly disseminated through the mass, which is sometimes cemented by iron. A representative section, observed in the northeastern part of Dyersville, is introduced in Fig. 120. Here the materials are semi-indurated, and rounded fragments are incorporated in the overlying lower till as pebbles and bowlders. Analogous exposures have been observed in Delaware, Fayette, Chickasaw, and Howard Counties. The presence of northern rocks in the form of much worn pebbles suggests glacial origin,[1] but anterior to the first ice invasion of the Pleistocene. Since the erratic material is similar to that found in the Rockville conglomerate, it would seem more probable that the accumulation is a slightly rearranged re-

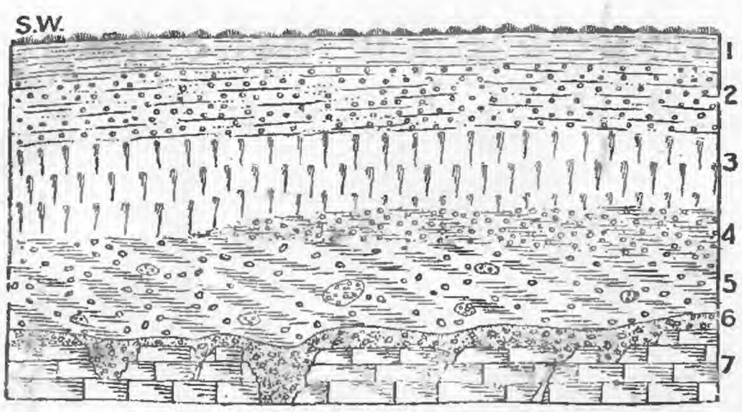

FIG. 120.—Pebbly residuary accumulation, Dyersville: (1) Yellowish sandy and pebbly alluvium, probably formed since the erection of a neighboring dam, 15 inches; (2) brown and black sandy and pebbly alluvium, partially stratified, 5 feet; (3) light buff loess, possibly redeposited, 5 feet; (4) yellow sandy gravelly and pebbly clay, 2 feet; (5) compact blue clay with a few hornblendic pebbles and small masses of puddingstone irregularly scattered through it (lower till), 5 feet; (6) imperfectly cemented brown puddingstone of quartz, chert, and jasper pebbles and coarse quartz sand in a matrix of earthy limonite, becoming nearly clean and passing into brown granular clay in places, 1 to 3 feet; (7) Niagara limestone.

siduum of both the Cretaceous conglomerate and the Silurian limestone, the pebbles being derived from the former and the matrix mainly from the latter.
