FIG. 1.—GEOLOGICAL HORIZONS OF VERTEBRATE FOSSILS IN NORTH AMERICA.

PART I.

TRIASSIC DINOSAURS.

THEROPODA.

The remains of dinosaurs first discovered in this country were found in the Triassic sandstone of the Connecticut Valley, so famous for its fossil footprints, many of which were long supposed to have been made by birds. It is a remarkable fact that the first discovery in this sandstone was that of the skeleton of a true dinosaur, found in East Windsor, Conn., in 1818, many years before the first footprints were recorded. This discovery was announced in the American Journal of Science for November, 1820, and later numbers contain descriptions of the remains, some of which are now preserved in the museum of Yale University.

FIG. 2.—Slab of Connecticut River sandstone; showing footprints of two dinosaurs on a surface marked by raindrop impressions. One-tenth natural size. Triassic, Massachusetts.

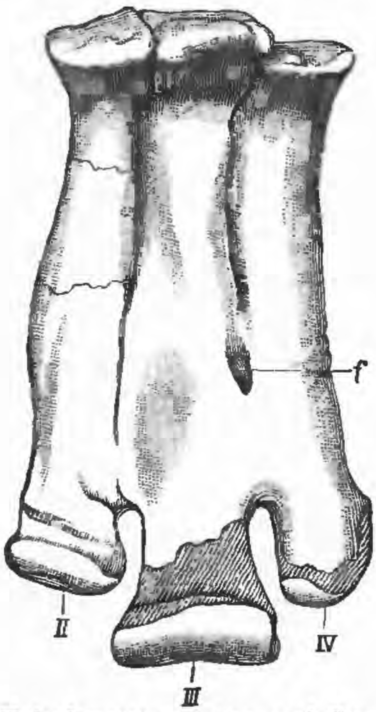
When the footprints in the Connecticut sandstone first attracted attention, in 1835, many of these impressions resembled so closely those made by birds that they were from the first attributed to that class, and for many years it was not seriously questioned that all the three-toed impressions, even the most gigantic, were really the footprints of birds. The literature on this subject is very extensive, but its value to science has been seriously impaired by the discovery of dinosaurian remains in various parts of the world, which prove that many of these reptiles were remarkably bird-like and that their tracks could not be distinguished from those of birds.

end fitting into the calcaneum. The tarsals of the second row are very thin, and united to the metatarsals below them.

THE METATARSALS.

One of the most interesting features in the extremities of Ceratosaurus is seen in the metatarsal bones, which are completely anchylosed, as were the bones of the pelvis. There are only three metatarsal elements in the foot, the first and fifth having apparently disappeared entirely. The three metatarsals remaining, which are the second, third, and fourth, are proportionately shorter and more robust than in the other known members of the order Theropoda, and, being firmly united to each other, they furnish the basis for a very strong hind foot.

4



5

FIG. 4.—United metatarsal bones of *Ceratosaurus nasicornis* Marsh; left foot; front view. One-fourth natural size.

FIG. 5.—United metatarsal bones of great Penguin (*Aptenodytes Pennantii* G. R. Gr.); left foot; front view. Natural size.

f, foramen: *II*, *III*, *IV*, second, third, and fourth metatarsals.

In fig. 4, above, these coosified metatarsals of Ceratosaurus are represented, and in fig. 5 the corresponding bone of a penguin is given for comparison.

In comparing these two figures, it will be seen that the three metatarsal elements of the dinosaur are quite as closely united as those of the bird. To the anatomist familiar with the tarsometatarsal bones of existing birds the specimen represented in fig. 4 will appear even more like this part in the typical birds than the one shown in fig. 5.

The position of the foramen, as seen in fig. 4, *f*, is especially characteristic of recent birds, and, as a whole, the hind foot of this Jurassic dinosaur was evidently similar to that of a typical bird.

All known adult birds, living and extinct, with possibly the single exception of Archæopteryx, have the metatarsal bones firmly united,

SAUROPODA.

The herbivorous dinosaurs of the American Jurassic are of special interest. To begin with the order Sauropoda, which includes the most primitive and gigantic forms, it is an interesting fact that the first specimen found in this country was one of the rarest of the group, and one of the most diminutive. A few teeth and bones only were obtained by Prof. P. T. Tyson, about 1858, near Bladensburg, Md. The teeth were named Astrodon by Dr. Christopher Johnston, in 1859, and in 1865 were described and figured by Dr. Leidy. The type specimens are now in the Yale museum, and one tooth is represented below in fig. 6. The strata containing these remains are known as the Potomac beds, but their exact age is a matter of doubt. They have been referred by some geologists to the Jurassic, and by others to the Cretaceous.

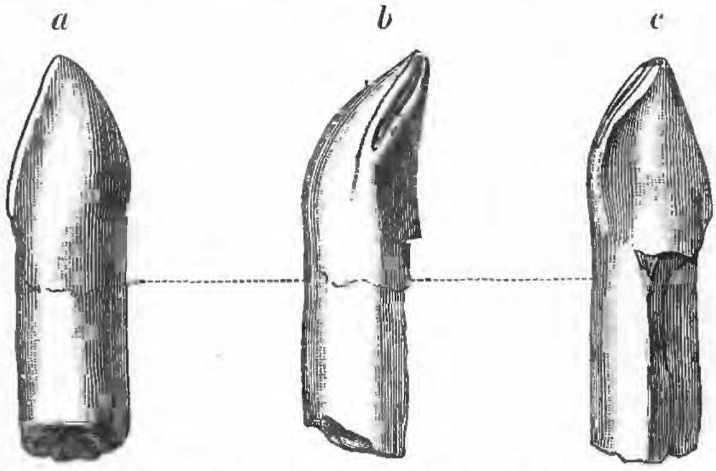


FIG. 6.—Tooth of *Astrodon Johnstoni* Leidy. Natural size. Potomac, Maryland. *a*, outer view; *b*, end view; *c*, inner view.

ATLANTOSAURUS BEDS.

The first known specimen of Sauropoda from the West was secured by the writer in August, 1868, near Lake Como, in Wyoming Territory. This fossil, an imperfect vertebra belonging to the genus since named Morosaurus, was found in the upper Jurassic clays, in the horizon now known as the Atlantosaurus beds. The section on page 145 will show the position of these beds in the geological scale, and their relation to other deposits in which Dinosauria have been found. This locality has since become one of the most famous in the entire Rocky Mountain region, and the writer has secured from it remains of several hundred dinosaurs, among which are many of the type specimens here described.

Remains of an enormous dinosaurian were found in 1877, near Morrison, Colo., by Prof. Arthur Lakes and Capt. H. C. Beckwith, U. S. N., and this was the beginning of a series of similar discoveries. These remains, described by the writer in the American Journal of Science for July of that year, proved to be those of a dinosaur far surpassing in size any previously known, and having characters that indicated a new order of these reptiles.

This enlargement of the neural cord in the sacral region exists to some degree in reptiles and birds now living, but does not approach that found in the Sauropoda, or especially that in the Stegosauria, where, as will be shown later in the present article, this expansion reaches its maximum, and its functional importance must make it a dominant factor in the movements of the reptiles in which it is so highly developed. This great development has been found only in extinct reptiles in which the brain was especially diminutive, and the relation of the two nervous centers to each other offers a most interesting problem to physiologists.

THE VERTEBRÆ.

In Pl. XVIII, fig. 1, is shown a posterior cervical vertebra of Apatosaurus, and in fig. 2 of the same plate a dorsal vertebra is also represented, both being typical of the family Atlantosauridæ. The cervical

7 8

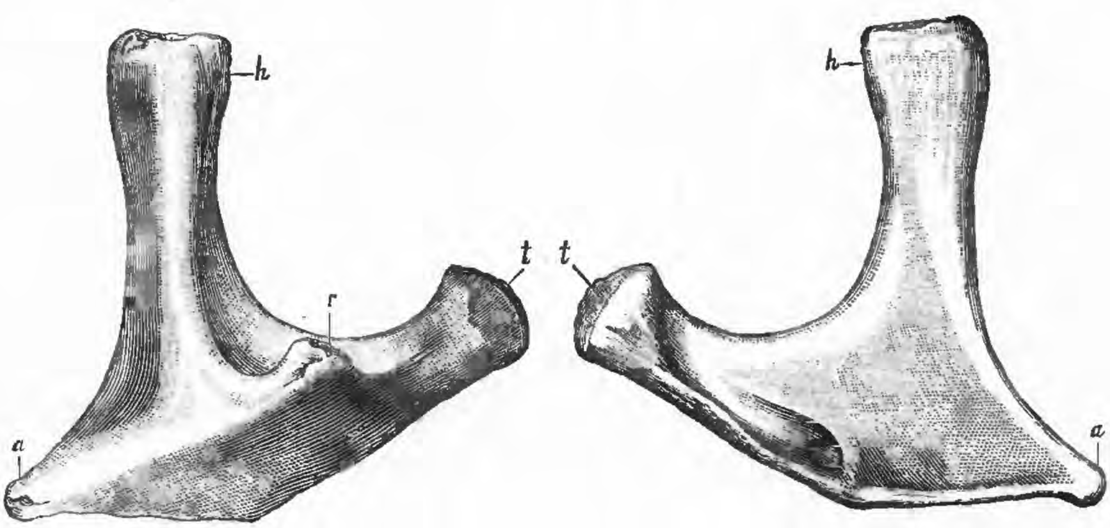

FIG. 7.—Cervical rib of *Apatosaurus ajax* Marsh; outer view.
FIG. 8.—The same rib; inner view.
Both figures are one-eighth natural size. *a*, anterior extremity; *h*, head; *r*, posterior process; *t*, tubercle.

vertebra, seen from behind, shows the deep, transverse cup of the posterior articular end of the centrum, as well as the coossified cervical ribs, both typical of the Sauropoda. A cervical rib of one species is shown in figs. 7 and 8.

The dorsal vertebra, seen from in front, presents the convex anterior ball of the centrum, and also the massive neural arch of the vertebra, with its elevated metapophyses, constituting a neural spine. The expanded diapophyses, or transverse processes, are especially noteworthy, as they aid in supporting the massive ribs, their extremities articulating with the tubercle of the rib, while the head is supported at the base of the arch by a sessile facet representing the parapophysis of the cervicals. The small neural canal in each vertebra is also an interesting feature, especially when contrasted with the expanded cavity in the sacrum shown in fig. 3 of the same plate.

articulation. This is shown in fig. 3. In the vertebra figured, at the base of the neural spine, there is a strong anterior projection, which was inserted into the cavity between and above the posterior zygapophyses of the vertebra in front. There appear to be no true lumbar vertebræ, as those near the sacrum supported free ribs of moderate size. The vertebræ in this region have both faces of the centrum nearly flat or biconcave. An anterior dorsal rib is shown below.

THE SACRUM.

The sacrum in the present species consists of five well-coossified vertebræ, and in the type specimen the centrum of the last lumbar is firmly united with it, as shown in Pl. XXIII. The striking feature

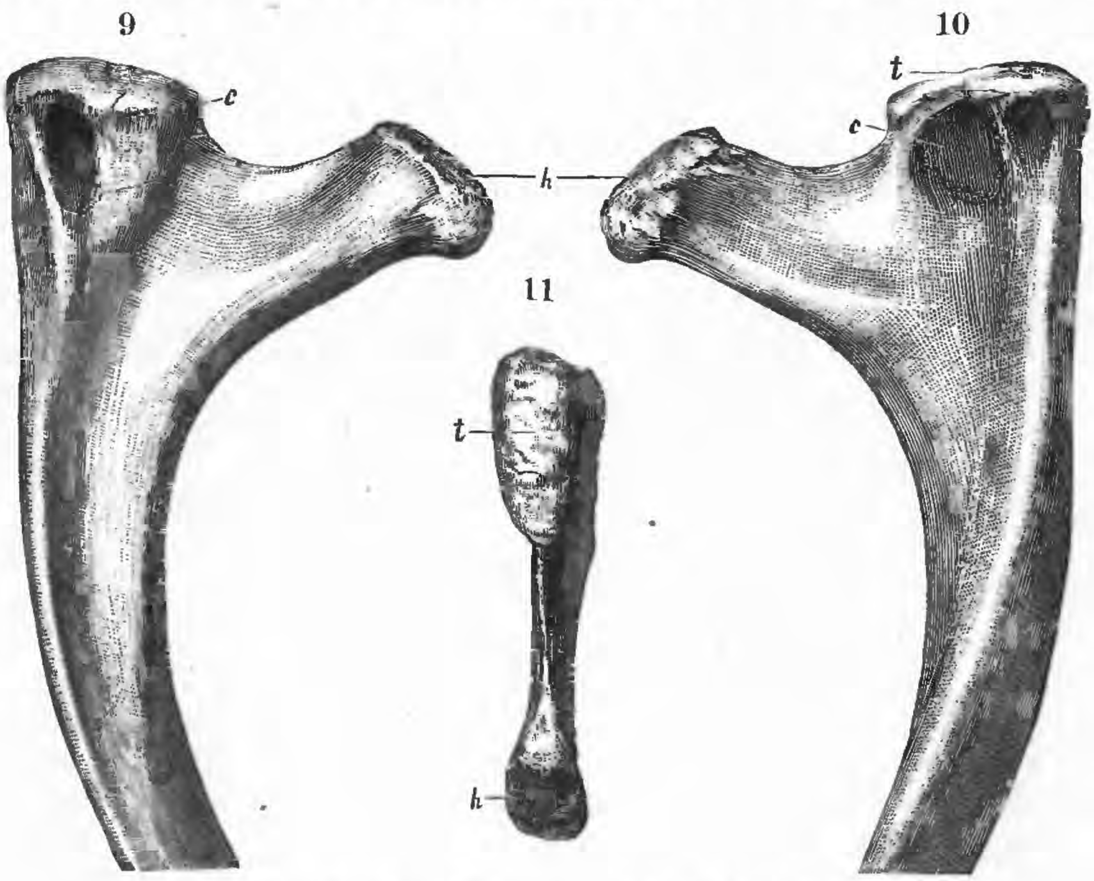

FIG. 9.—Proximal end of rib of *Brontosaurus excelsus* Marsh; front view.
FIG. 10.—The same bone; back view.
FIG. 11.—The same; superior view.
All the figures are one-eighth natural size. *c*, cavity; *h*, head; *t*, tubercle.

about this sacrum is the large general cavity it contained. This was divided in part by a median longitudinal partition, as shown in Pl. XXIII, fig. 2. The septum, however, was not continuous the whole length of the sacrum, so that the two lateral cavities were virtually one. This extended even into the lateral processes. The transverse partitions formed by the ends of the respective centra were also perforate, so that the sacrum proper was essentially a hollow cylinder. The cavernous character of the sacrum is one of the peculiar features of the suborder Sauropoda, and was described by the writer when the first species of this group was discovered in this country. The statement that any of the species has the sacrum solid is evidently based on erroneous observation.

Another peculiar character of the sacrum in the present genus is its lofty neural spine. This is a thin, vertical plate of bone with a thick massive summit, evidently formed by the union of the spines of several vertebræ. In front it shows rugosities for the ligament uniting it to the adjoining vertebra, and its posterior margin likewise indicates a similar union with the first caudal. In this genus, as in all the Sauropoda, each vertebra of the sacrum supports its own transverse processes. As shown in Pl. XXIII, the articulation for the ilium is formed by the coossification of the distal ends of the transverse processes. The neural canal is much enlarged in the sacrum, but less proportionally than in Stegosaurus.

14 12 13 15

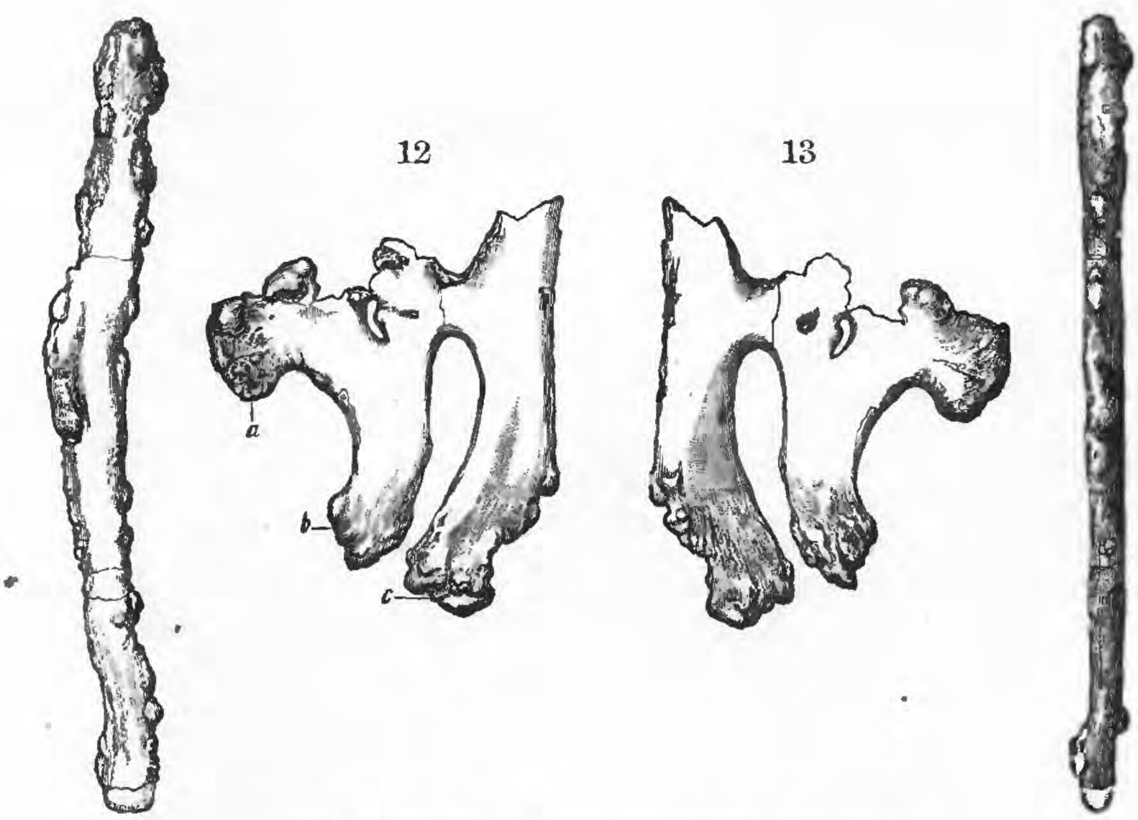

FIG. 12.—Sternal ribs of *Brontosaurus excelsus*; outer view.
FIG. 13.—The same specimen; inner view.
FIG. 14.—Sternal rib of same individual; outer view.
FIG. 15.—The same rib; inner view.
All the figures are one-eighth natural size.

THE CAUDAL VERTEBRÆ.

In the present species the three vertebræ next behind the sacrum have moderate-sized cavities between the base of the neural arch and the transverse processes. These shallow pockets extend into the base of the processes, but the centra proper are solid. All the other caudals have the centra, processes, and spines composed of dense bone. The fourth caudal vertebra, represented in Pl. XXIV, figs. 2 and 3, is solid throughout, and the same is true of the chevron, figs. 4 and 5. The neural spines of the anterior caudal vertebræ are elevated and massive. The summit is cruciform in outline, due to the four strong buttresses which unite to form it.

The median caudals all have low, weak spines, and no transverse processes. The posterior caudals are elongate and without spines or zygapophyses.

THE PELVIC ARCH.

The pelvic bones in the present species are shown in fig. 16. The ilium represented is not quite perfect on its upper margin. Its anterior process for the support of the pubis is much larger than the poste-

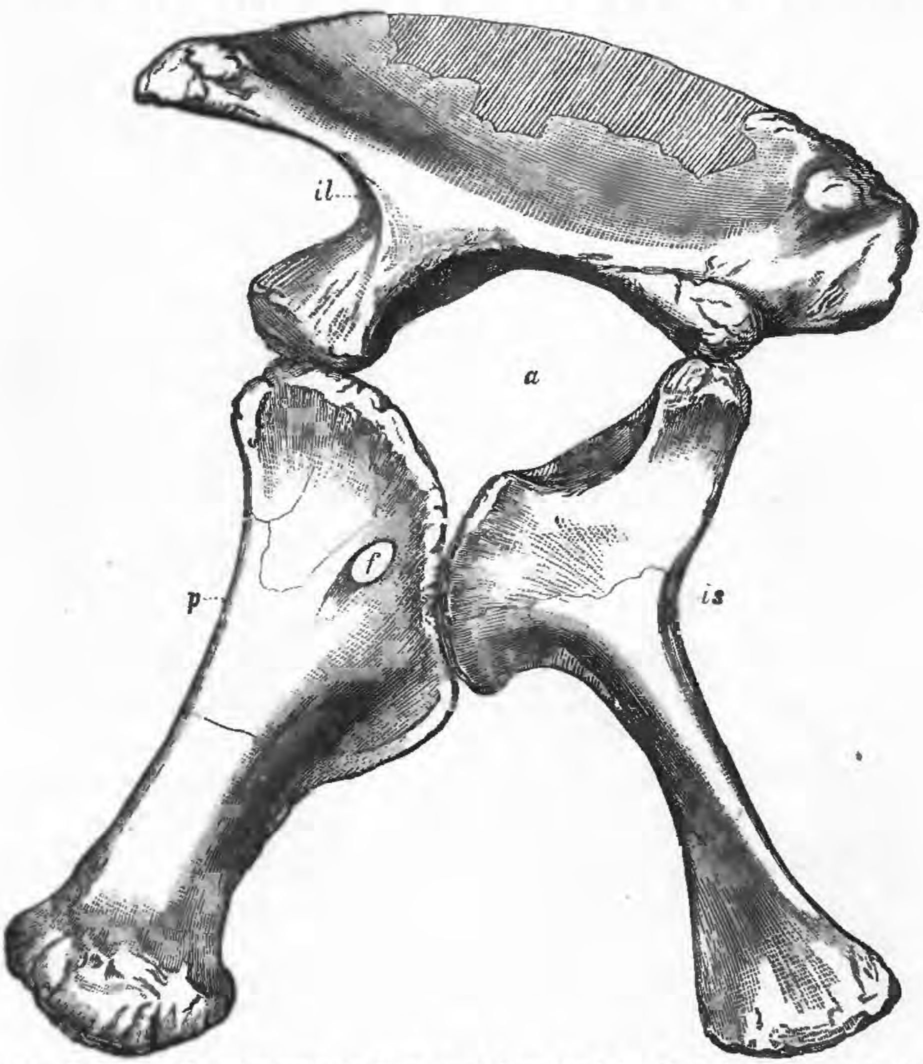

FIG. 16.—Pelvis of *Brontosaurus excelsus;* seen from the left. One-sixteenth natural size. *a*, acetabulum; *f*, foramen in pubis; *il*, ilium; *is*, ischium; *p*, pubis.

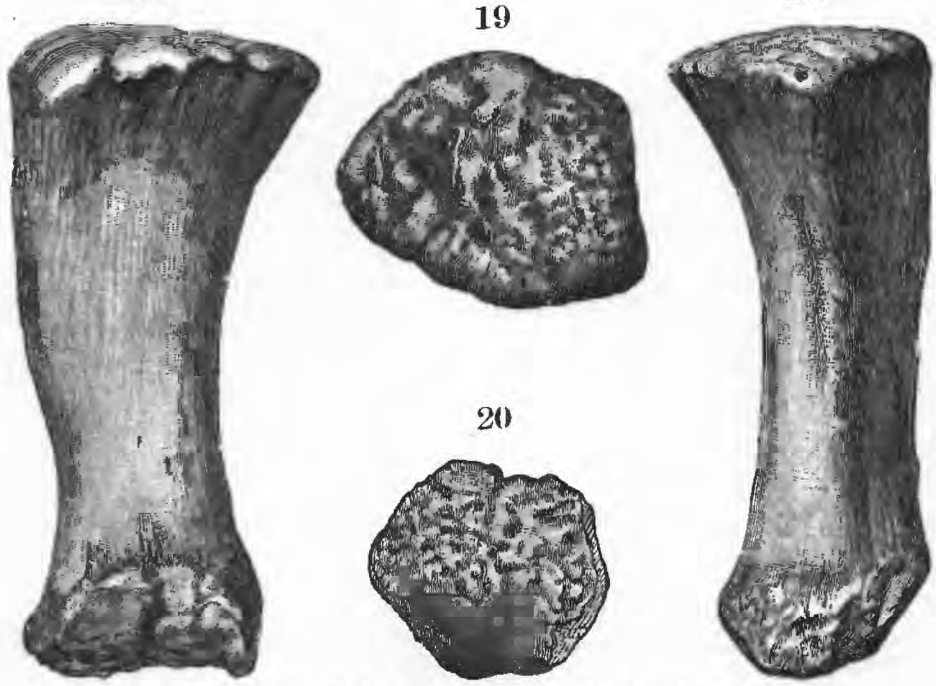
rior one which meets the ischium. The pubis is elongate and massive. It sends down a strong wing for union with the ischium, and has in front of this the usual foramen. The distal end is expanded, and has on the inner surface a rugose facet for union with its fellow by cartilage. The ischium is more slender than the pubis, and has its lower end expanded for symphysial union with the one on the other side (Pl. XXIV, figs. 1 and 1*a*). This pelvis is more like that of Atlantosaurus than any other of the known genera of the Sauropoda. The three bones shown in fig. 16 were found nearly in the position represented.

THE FORE LIMBS.

The fore limbs of Brontosaurus, as in most of the Sauropoda, were of large size and of massive proportions. The limb bones are all solid, and those of the feet are quite robust. There were five well-developed digits in the manus, and the metacarpals were all moderately elongate. A characteristic example is shown in figs. 17–20, below.

17 19 18



20

FIG. 17.—First metacarpal of *Brontosaurus amplus* Marsh; front view.
FIG. 18.—The same bone; side view.
FIG. 19.—Proximal end of same.
FIG. 20.—Distal end of same.
All the figures are one-fourth natural size.

THE HIND LIMBS.

The hind limbs of Brontosaurus were larger than those in front, and the bones were all solid, thus being in remarkable contrast to the elements of the vertebral column. The hind feet were plantigrade, and had five powerful digits. The first was very stout, and its terminal phalanx, shown in figs. 21–23, supported a powerful claw.

RESTORATION OF BRONTOSAURUS.

PLATE XLII.

Nearly all the bones represented in this restoration belonged to a single individual, which when alive was nearly or quite 60 feet in length. The position here given was mainly determined by a careful adjustment of these remains. That the animal at times assumed a position more erect than here represented is probable, but locomotion on the posterior limbs alone was hardly possible.

The head was remarkably small. The neck was long and flexible, and, considering its proportions, was the lightest portion of the vertebral column. The body was short, and the abdominal cavity of moderate size. The legs and feet were massive and the bones all solid. The feet were plantigrade, and each footprint must have been about a square yard in extent. The tail was large and nearly all the bones are solid.

The diminutive head will first attract attention, as it is smaller in proportion to the body than in any vertebrate hitherto known. The entire skull is less in diameter or actual weight than the fourth or fifth cervical vertebra.

A careful estimate of the size of Brontosanrus, as here restored, shows that when living the animal must have weighed more than 20 tons. The very small head and brain, and the slender neural cord, indicate a stupid, slow-moving reptile. The beast was wholly without offensive or defensive weapons or dermal armatnre.

21 22 23

FIG. 21.—Terminal phalanx of *Brontosaurus excelsus;* outer view.
FIG. 22.—The same bone; front view.
FIG. 23.—The same; inner view.
All the figures are one-fourth natural size.

In habits Brontosaurus was more or less amphibious, and its food was probably aquatic plants or other succulent vegetation. The remains are usually found in localities where the animals seem to have been mired. The type specimen was discovered by W. H. Reed, near Lake Como, Wyoming.

BAROSAURUS.

Another genus of the Sauropoda is indicated by various remains of a gigantic reptile described in 1890 by the writer. The most characteristic portions examined are the caudal vertebræ, which in general form resemble those of Diplodocus. They are concave below, as in the caudals of that genus, but the sides of the centra are also deeply excavated.

In the anterior caudals this excavation extends nearly or quite through the centra, a thin septum usually remaining. In the median caudals a deep cavity on each side exists, as shown in figs. 24–26, below.

On the distal caudals the lateral cavity has nearly or quite disappeared. All the caudal vertebræ are proportionally shorter than in Diplodocus, and their chevrons have no anterior projection, as in that genus.

The remains on which the present description is based are from the Atlantosaurus beds of South Dakota, about 200 miles farther north than this well-marked horizon has hitherto been recognized.[1]

DIPLODOCIDÆ.

DIPLODOCUS.[2]

THE SKULL.

The skull of Diplodocus is of moderate size. The posterior region is elevated and narrow. The facial portion is elongate and the anterior part expanded transversely. The nasal opening is at the apex of the cranium, which from this point slopes backward to the occiput. In front of this aperture the elongated face slopes gradually downward to the end of the muzzle, as represented in Pl. XXV, fig. 1.

Seen from the side the skull of Diplodocus shows five openings: a small oval aperture in front, a large antorbital vacuity, the nasal aperture, the orbit, and the lower temporal opening. The first of these has not been seen in any other Sauropoda; the large antorbital vacuity is characteristic of the Theropoda also; while the other three openings are present in all the known Dinosauria.

On the median line, directly over the cerebral cavity of the brain, the type specimen of Diplodocus has also a fontanelle in the parietals. This, however, may be merely an individual peculiarity.

The plane of the occiput is of moderate size, and forms an obtuse angle with the frontoparietal surface.

The occipital condyle is hemispherical in form, and seen from behind is slightly subtrilobate in outline. It is placed nearly at right angles

[1]Strata that may represent this horizon have been observed still farther north, especially in Montana, but have not yet been identified by characteristic fossils.

[2]American Journal of Science, 1878–1884.

indications of sclerotic plates have been found either in Diplodocus or in the other genera of Sauropoda.

The supratemporal fossa is small, oval in outline, and directed upward and outward. The lateral temporal fossa is elongated, and oblique in position, bounded, both above and below, by rather slender temporal bars.

The prefrontal and lachrymal bones are both small; the suture connecting them, and also that uniting the latter with the jugal, can not be determined with certainty.

The postfrontals are triradiate bones. The longest and most slender branch is that descending downward and forward for connection with the jugal; the shortest is the triangular projection directed backward and fitting into a groove of the squamosal; the anterior branch, which is thickened and rugose, forms part of the orbital border above.

The squamosal lies upon the upper border of the paroccipital process. The lower portion is thin and closely fitted over the head of the quadrate bone.

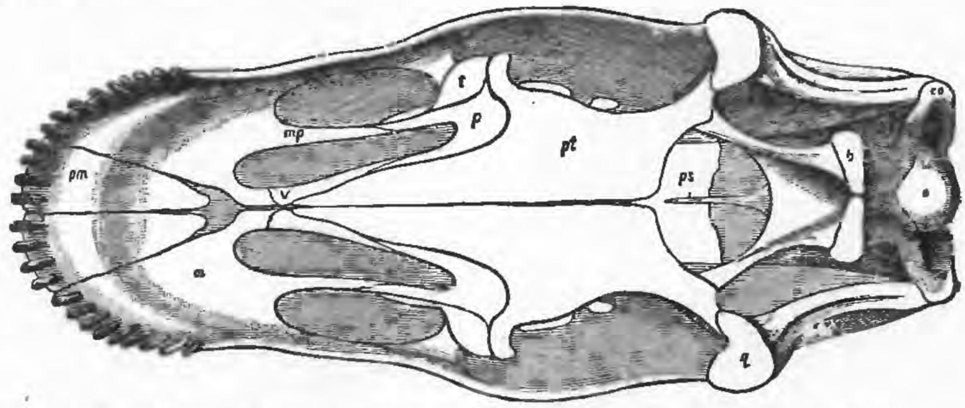

FIG. 27.—Skull of *Diplodocus longus* Marsh; seen from below. One-sixth natural size.
b, basioccipital process; *eo*, exoccipital; *m*, maxillary; *mp*, maxillary plate; *o*, occipital condyle; *p*, palatine; *pm*, premaxillary; *pt*, pterygoid; *ps*, parasphenoid; *q*, quadrate; *t*, transverse bone; *v*, vomer.

The quadrate is elongated and slender, with its lower end projecting very much forward. In front it has a thin plate extending inward and overlapping the posterior end of the pterygoid.

The quadratojugal is an elongate bone, firmly attached posteriorly to the quadrate by its expanded portion. In front of the quadrate it forms for a short distance a slender bar, which is the lower temporal arcade.

The palate is very high and roof-like, and composed chiefly of the pterygoids, as shown above in fig. 27. The basipterygoid processes are elongate, much more so than in the other genera of Sauropoda.

The pterygoids have a shallow cavity for the reception of these processes, but no distinct impression for a columella. Immediately in front of this cavity the pterygoids begin to expand, and soon form a broad, flat plate, which stands nearly vertical. Its upper border is thin, nearly straight, and extends far forward. The anterior end is acute and unites along its inferior border with the vomer. A little in front of the middle a process extends downward and outward, for union with the transverse bone. In front of this process, uniting with it and with the transverse bone, is the palatine.

The palatine is a small semioval bone fitting into the concave anterior border of the pterygoid, and sending forward a slender process for union with the small palatine process of the maxillary.

The vomer is a slender, triangular bone, united in front by its base to a stout process of the maxillary, which underlaps the ascending process of the premaxillary. Along its upper and inner border it unites with the pterygoid, except at the end, where for a short distance it joins a slender process from the palatine. Its lower border is wholly free.

THE BRAIN.

The brain of Diplodocus was very small, as in all dinosaurs from the Jurassic. It differed from the brain of the other members of the Sauropoda, and from that of all other known reptiles, in its position, which was not parallel with the longer axis of the skull, as is usually the case, but inclined to it, the front being much elevated, as in the ruminant mammals (Pl. LXXVI, fig. 4). Another peculiar feature of

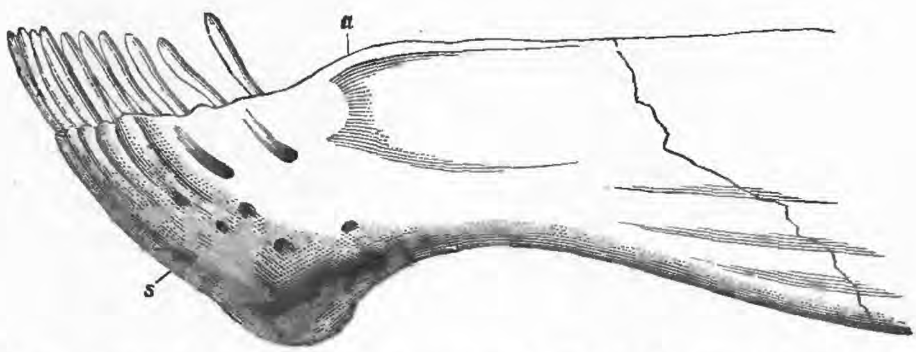

FIG. 28.—Dentary bone of *Diplodocus longus;* seen from the left. One-third natural size. *a*, edentulous border; *s*, symphysis.

the brain of Diplodocus was its very large pituitary body, inclosed in a capacious fossa below the main brain case. This character separates Diplodocus at once from the Atlantosauridæ, which have a wide pituitary canal connecting the brain cavity with the throat. In the Morosauridæ the pituitary fossa is quite small.

The posterior portion of the brain of Diplodocus was diminutive. The hemispheres were short and wide and more elevated than the optic region. The olfactory lobes were well developed, and separated in front by a vertical osseous septum. The very close proximity of the external nasal opening is a new feature in dinosaurs, and appears to be peculiar to the Sauropoda.

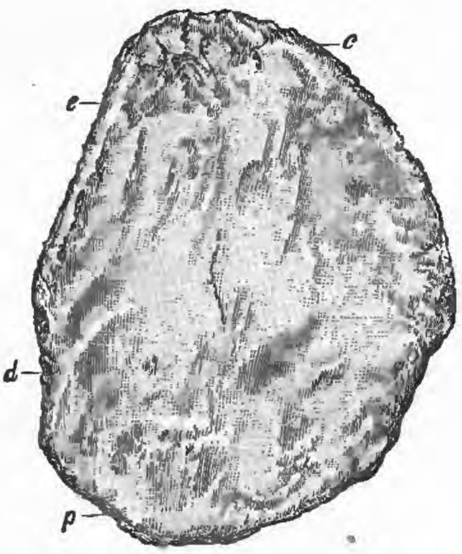
THE LOWER JAWS.

The lower jaws of Diplodocus are more slender than in any of the other Sauropoda. The dentary especially lacks the massive character seen in Morosaurus, and is much less robust than the corresponding bone in Brontosaurus. The short dentigerous portion in front is decurved (Pl. XXV, fig. 1), and its greatest depth is at the symphysis, as shown in fig. 28 above. The articular, angular, and surangular bones are well developed, but the coronary and splenial appear to be small.

THE TEETH.

The dentition of Diplodocus is the weakest seen in any of the known Dinosauria, and strongly suggests the probability that some of the more specialized members of this great group were edentulous. The teeth are entirely confined to the front of the jaws (Pl. XXV, fig. 1), and those in use were inserted in such shallow sockets that they were readily detached. Specimens in the Yale museum show that entire series of upper or lower teeth could be separated from the bones supporting them without losing their relative position. In Pl. XXVI, fig. 1, a number of these detached teeth are shown.

29



30

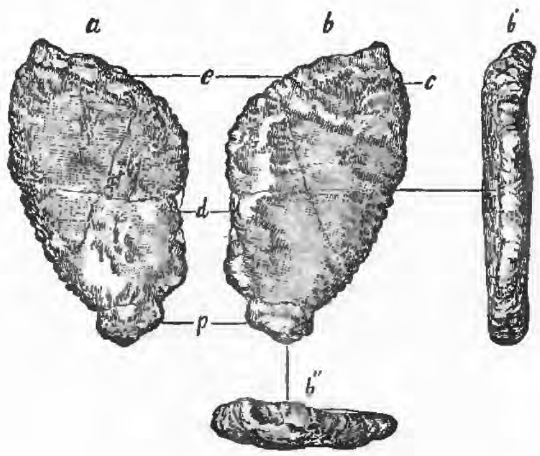


FIG. 29.—Sternal plate of *Brontosaurus amplus*; top view.
FIG. 30.—Sternal plate of *Morosaurus grandis* Marsh.
Both figures are one-eighth natural size. *a*, bottom view; *b*, top view; *b′*, side view; b″, end view; *c*, face for coracoid; *d*, margin next to median line; *e*, inner front margin; *p*, posterior end.

The teeth of Diplodocus are cylindrical in form and quite slender. The crowns are more or less compressed transversely and are covered with thin enamel, irregularly striated. The roots are long and slender and the pulp cavity is continued nearly or quite to the crown. In the type specimen of Diplodocus there are four teeth, the largest of the series, in each premaxillary; nine in each maxillary, and ten in each dentary of the lower jaws. There are no palatine teeth.

The jaws contain only a single row of teeth in actual use. These are rapidly replaced, as they wear out or are lost, by a series of successional teeth, more numerous than is usual in these reptiles. Pl. XXVI, fig. 2, represents a transverse section through the maxillary, just behind the fourth tooth. The latter is shown in place, and below it is a series

MOROSAURIDÆ.

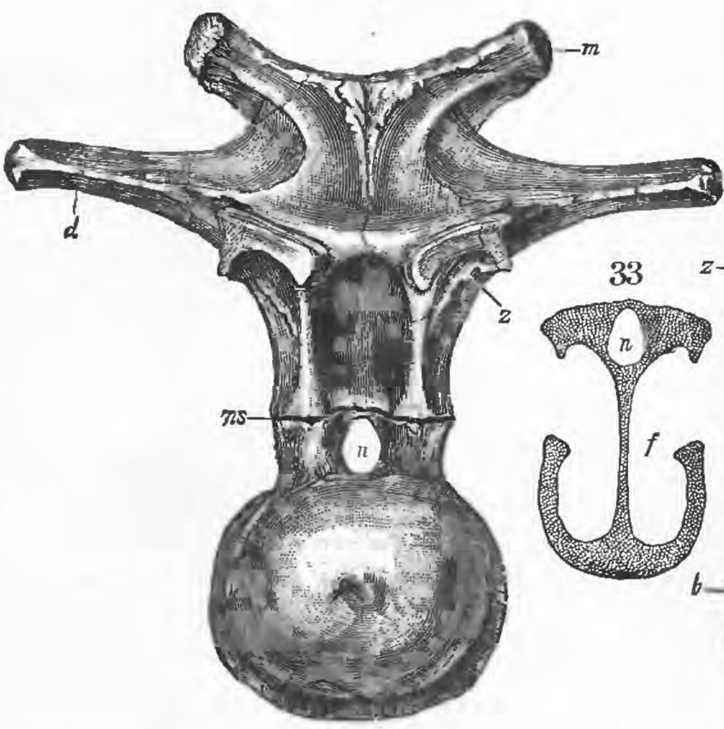
MOROSAURUS.

The genus Morosaurus, the type of the family, was described by the writer in 1878, in the American Journal of Science, which contains most of the original descriptions of Sauropoda found in this country.

THE SKULL.

The head in this genus was very small. The posterior part of the skull resembled that in Diplodocus, but the front was much more massive. The lower jaw was especially powerful, as shown by the dentary bone figured in Pl. XXX, fig. 3. This figure also shows the size and position of the teeth, one of which is figured in Pl. XXXI, figs. 1 and 2.

31



33

32

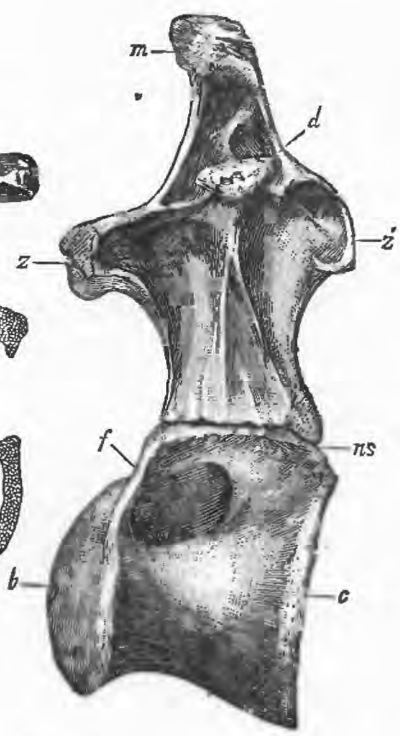


FIG. 31.—Anterior dorsal vertebra of *Morosaurus grandis;* front view.
FIG. 32.—The same vertebra; side view.
FIG. 33.—Transverse section through centrum of same.
All the figures are one-eighth natural size. *b*, ball ; *c*, cup ; *d*, diapophysis ; *f*, cavity in centrum; *m*, metapophysis ; *n*, neural canal ; *ns*, neural suture ; *z*, anterior zygapophysis ; *z'*, posterior zygapophysis.

The brain was very small. Its form and position in the skull are shown in fig. 2 of Pl. XXX. At the back of the skull there are two peculiar bones, called by the writer the postoccipital bones, which are shown in Pl. XXX, fig. 1.

THE VERTEBRÆ.

The neck was elongated, and except the atlas all the cervical vertebræ have deep cavities in the sides of the centra, similar to those in birds of flight. They are also strongly opisthocœlous. The atlas and axis are not anchylosed together, and the elements of the atlas are separate (Pl. XXXI).

The dorsal vertebræ are distinctly opisthocœlous. The posterior dorsals have elongated transverse neural spines, and have deep cavities in the sides. An anterior dorsal is shown in figs. 31–33, p. 181. There are four vertebræ in the sacrum, all with cavities in the centra. Their transverse processes, or sacral ribs, are vertical plates with expanded ends. The anterior caudal vertebræ are plano-concave, and nearly or quite solid. The tail was elongated, and the chevrons are similar to those in crocodiles (Pl. XXXIX). The vertebræ of Morosaurus are represented on Pls. XXXI–XXXIV.

THE FORE LIMBS.

The scapula is elongated and very large, and the shaft has a prominent anterior projection. The coracoid is small, suboval in outline, and has the usual foramen near its upper border. These two bones are well represented in Pl. XIX, nearly in the relative position in which they were found. The humerus is very large and massive, and its radial crest prominent. This bone is nearly solid, and its ends were rough and well covered with cartilage. This is true, also, of all

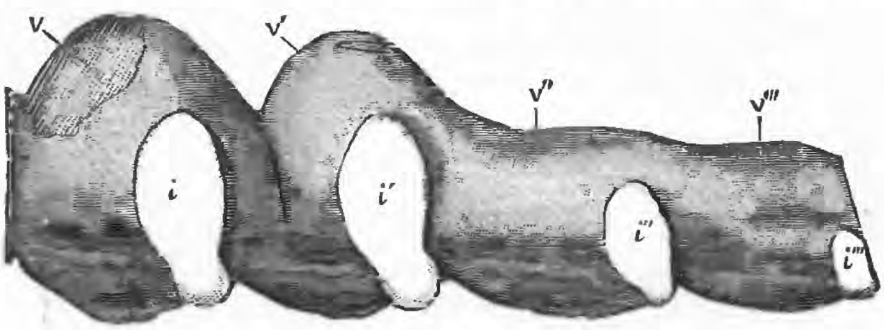

FIG. 34.—Cast of neural cavity in sacrum of *Morosaurus lentus* Marsh; side view. One-fourth natural size.
i, *i'*, *i''*, *i'''*, intervertebral foramina; *v*, *v'*, *v''*, *v'''*, cavities in first, second, third, and fourth sacral vertebræ.

the large limb bones in this genus. The radius and ulna are nearly equal in size. The carpal bones are separate and quite short. The five metacarpals are elongated, and the first is the stoutest. The toes were thick, and the ungual phalanges were evidently covered with hoofs. In Pl. XXXVIII, fig. 1, the restoration of the scapular arch and entire fore limb of one species of Morosaurus well illustrates this part of the skeleton.

THE PELVIS.

The pelvic bones are distinct from each other and from the sacrum. The ilium is short and massive, and shows on its inner side only slight indications of its attachment to the sacrum. More than half the acetabulum is formed by the ilium, which sends down in front a strong process for union with the pubis, and a smaller one behind to join the ischium (Pl. XXXV, fig. 1, *a* and *b*). The acetabulum is completed below by the pubis and ischium. The pubis is large and stout, and

vertebræ are much longer than the corresponding vertebræ of Morosaurus, and have a very long, deep cavity in each side of the centrum, to which the generic name refers. All the trunk vertebræ hitherto found are proportionately nearly double the length of the corresponding centra of Morosaurus, and the lateral cavity is still more elongate. These points are shown in the posterior dorsal vertebra represented in figs. 4 and 5 of Pl. XL. The neural arch in this region is lightened by cavities, and is connected with that of the adjoining vertebræ by the diplosphenal articulation. A dorsal centrum of another species is shown below in figs. 35–37.

The sacral vertebræ in Pleurocœlus are more solid than in Morosaurus, but more elongate. The surface for the rib, or process which abuts against the ilium, is well in front, more so than in any of the known

FIG. 39.—The same vertebra; side view.
FIG. 40.—The same; back view.
FIG. 41.—The same; top view.
All the figures are one-half natural size. *a*, anterior end; *f*, cavity in centrum; *n*, neural canal; *p*, posterior end.

Sauropoda. Behind this articular surface is a deep pit, which somewhat lightens the centrum. These characters are seen in the sacral vertebra represented in figs. 6 and 7 of Pl. XL.

The first caudal vertebra has the centrum very short, and its two articular faces nearly flat, instead of having the anterior surface deeply concave, as in the other known Sauropoda. An anterior caudal is shown in figs. 38–41, above. The neural spines in this region are compressed transversely. The middle and distal caudals are comparatively short and the former have the neural arch on the front half of the centrum, as shown in figs. 8 to 11 of Pl. XL.

The bones of the limbs and feet preserved agree in general with those

the main characters of the animal can be determined with considerable certainty.

A study of these remains shows that the reptile they represent was one of the typical Ornithopoda, and one of the most bird-like yet discovered. A dentary bone in fair preservation (fig. 42) indicates that the animal was herbivorous, and the single row of pointed and compressed teeth, thirteen in number and small in size, forms a more regular and uniform series than in any other member of the group. The ilium, also, shown in fig. 43, is characteristic of the Ornithopoda, having a slender, pointed process in front, but one much shorter than in any of

FIG. 48.—Distal end of same.
All five figures are one-half natural size.

the larger forms. The posterior end is also of moderate size. All the bones of the limbs and feet are extremely hollow, strongly resembling in this respect those of birds. The femur was shorter than the tibia. The metatarsals are greatly elongated and very slender, and there were probably but three functional toes in the hind foot.

A second form referred by the writer to this genus, under the name *Nanosaurus rex*, may perhaps belong to the genus Laosaurus. The femur is shown in figs. 44 to 48, above. The animal thus represented

In fig. 3 of the plate the three phalanges represented belong with the second metatarsal, and were found together in place.

The three metacarpals represented in fig. 4 were found together in position, near the remains of the hind limb here described. Their very small size is remarkable, and they may possibly belong to a smaller individual, but with this exception there is no reason why they do not pertain to the same specimen as the hind foot. The remains of this species were found by George L. Cannon, jr., in the Ceratops beds of Colorado.

THE PELVIC ARCH.

A larger species from the same horizon, *Ornithomimus sedens*, more recently described by the writer, is based upon the nearly complete

49 50 51

52

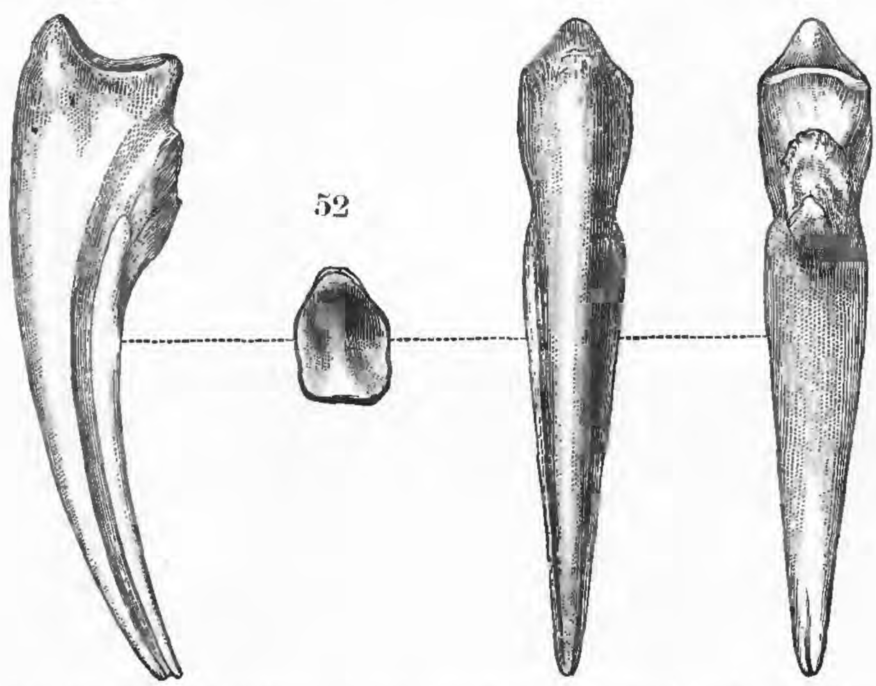

FIG. 49.—Terminal phalanx, manus of *Ornithomimus sedens* Marsh; side view.

FIG. 52.—Proximal end of same.
All the figures are one-half natural size.

pelvis, with various vertebræ, and some other parts of the skeleton. The most striking feature of the pelvis is the fact that the ilium, ischium, and pubis are firmly coossified with one another, as in recent birds. This character has been observed hitherto among dinosaurs only in the genus Ceratosaurus, described by the writer from the Jurassic of Wyoming. The present pelvis resembles that of Ceratosaurus in its general features, but there is no foramen in the pubis.

There are five vertebræ in the sacrum, firmly coossified with one another, as are also the sacral spines. The sacral vertebræ are grooved below, with the sides of the centra excavated. The caudals have the diplosphenal articulation, and the first caudal bears a chevron. All the bones preserved are very delicate, and some of them, at least, are

This geological horizon is a distinct one in the upper Cretaceous, and is indicated for more than 800 miles along the eastern flank of the Rocky Mountains. It is marked at nearly every outcrop by remains of these reptiles, and hence the strata containing them have been called the Ceratops beds. They are fresh-water or brackish deposits which form a part of the so-called Laramie, but are below the uppermost beds referred to that group. In some places, at least, they rest upon marine beds, which contain invertebrate fossils characteristic of the Fox Hills deposits. The most important localities in the Ceratops beds are in Wyoming, especially in Converse County.

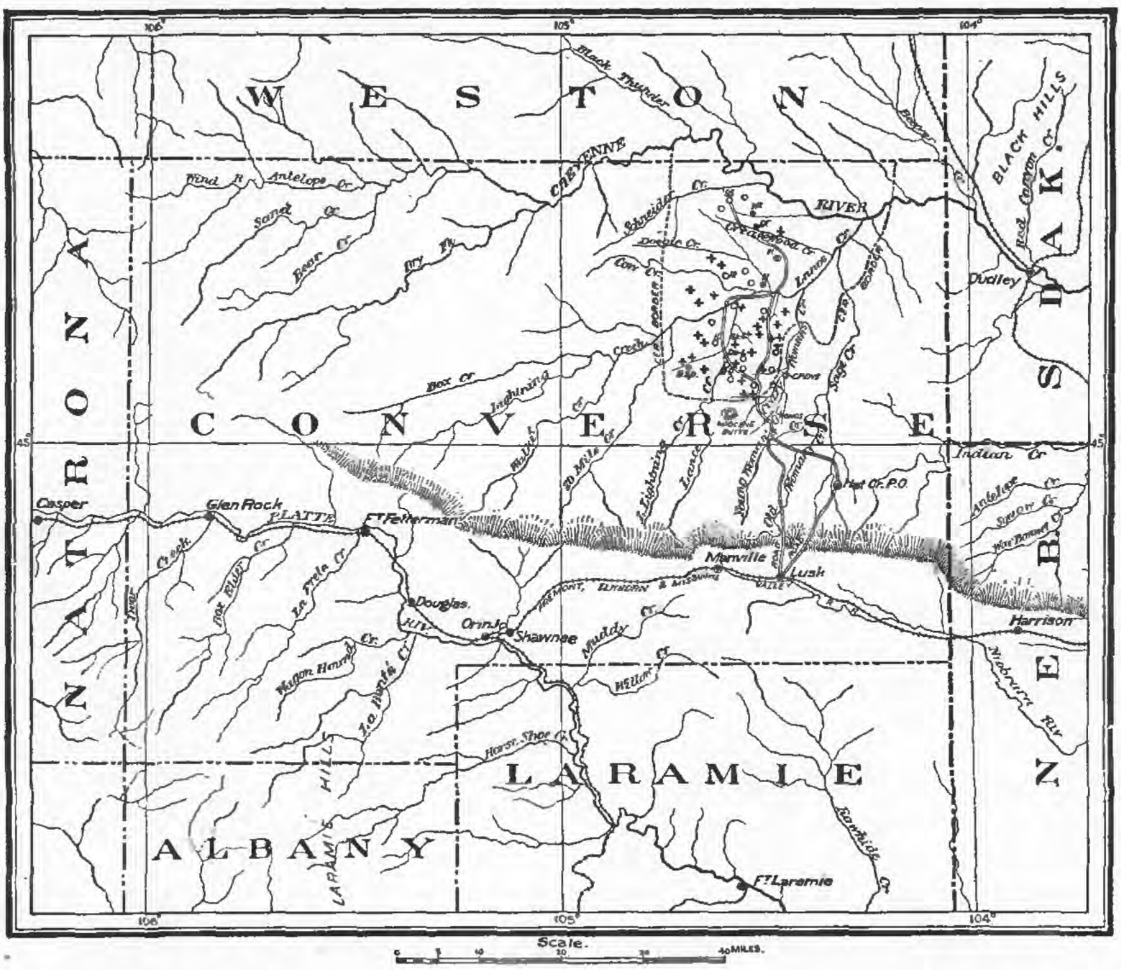

FIG. 53.—Map of Converse County, Wyoming; showing localities where skulls of the Ceratopsidæ have been discovered.

The position of each skull is indicated by a cross (+), and more than thirty of these specimens were found within the area bounded by the Cheyenne River and the dotted line. The localities given are based upon field notes made by Mr. J. B. Hatcher.

The fossils associated with the Ceratopsidæ are mainly dinosaurs, representing one or two orders and several families. Plesiosaurs, crocodiles, and turtles, of Cretaceous types, and many smaller reptiles, have left their remains in the same deposits. Numerous small mammals, also of ancient types, a few birds, and many fishes, are likewise entombed in this formation. Invertebrate fossils and plants are not uncommon in the same horizon.

nasal horn core is compressed, with a sharp apex directed forward. The frontal horn cores are large and strongly inclined to the front, extending apparently in advance of the nasal protuberance. The long, slender squamosals diverge rapidly as they extend backward, their outer margins being nearly on a line with the facial borders in the maxillary region.

The parietal forms more than half of the upper surface of the skull, and is the most characteristic element in its structure. In the posterior part are two very large apertures, oval in outline, with their outer margin at one point formed by the squamosal. The rest of the border is thin and somewhat irregular, showing that the openings are true

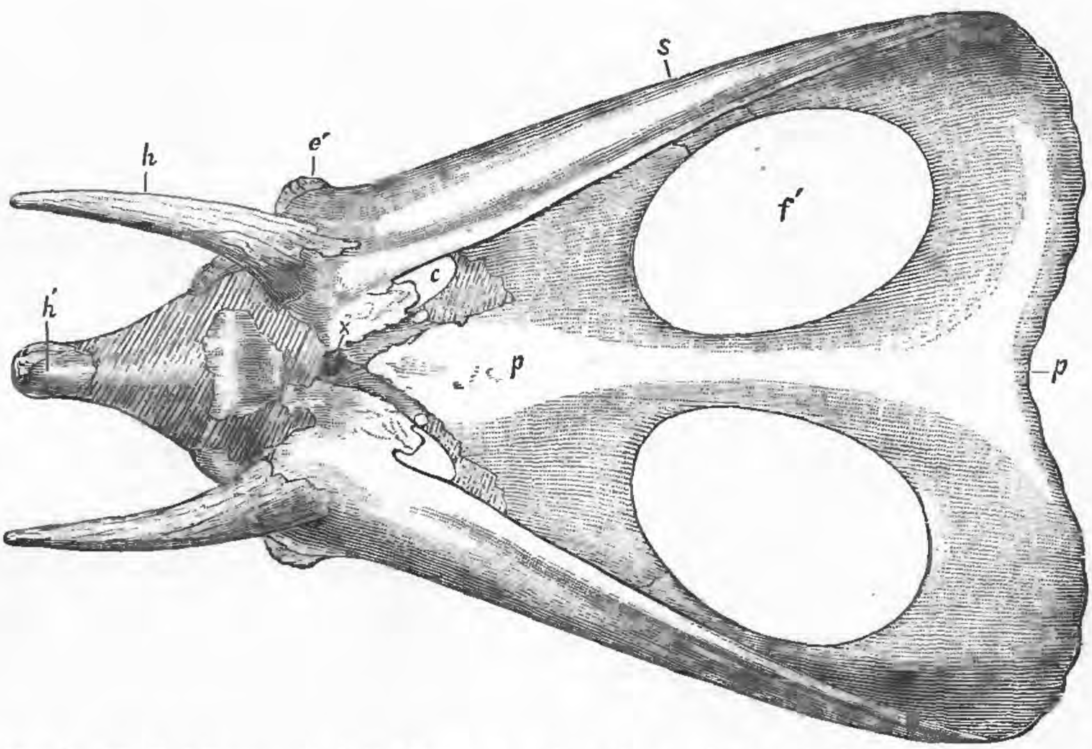

FIG. 54.—Skull of *Torosaurus gladius* Marsh; seen from above. One-twentieth natural size. *c*, supratemporal fossa; *e'*, epijugal bone; *f'*, parietal fontanelle; *h*, horn core; *h'*, nasal horn core; *p*, parietal; *s*, squamosal; *x*, pineal foramen (?).

fontanelles. This is still better seen in the second species represented in the same plate, fig. 2, and in fig. 54, above. In the latter specimen, however, these vacuities are entirely in the parietal, a thin strip of bone separating them on either side from the squamosal. A second pair of openings, much smaller, apparently the true supratemporal fossæ, are shown in the type specimen. These are situated mainly between the parietal and squamosal, directly behind the bases of the large horn cores (Pl. LXII, fig. 1, *c*). The same apertures are represented in the genus Triceratops by oblique openings, as in the skull shown on Pl. LX, fig. 3, *c*, where the front border of each is formed by the postfrontal.

Between these openings, in the type of Torosaurus, is a third pair of apertures (Pl. LXII, fig. 1, *c'*). These are quite small, nearly circular in outline, and entirely in the parietal, although probably connected

margin, above the articulation for the coracoid, is a strong protuberance, with a well-defined facet, adapted to the support of the clavicle, if such a bone were present. The coracoid is very small, and is perforated by a large foramen. The two peculiar bones now generally regarded as belonging to the sternum were separate, as shown in Pl. LXXV, fig. 4.

The humerus is comparatively short, and has a prominent radial crest. The radius and ulna are much elongated, the latter being longer than the humerus, and the radius about the same length. The ulna has a prominent olecranon process, and is a stouter bone than the radius. The carpal bones were quite short, and appear to have been only imperfectly ossified. The fore foot, or manus, was very long, and contained three functional digits only. The first digit was rudimentary, the second and third were nearly equal in length, the fourth was shorter and less developed, and the fifth entirely wanting, as shown in Pl. LXXIII, fig. 1.

In the functional digits (II, III, IV) the phalanges are elongate, thus materially lengthening the fore foot. The terminal phalanges of these digits are broad and flat, showing that they were covered with hoofs, and not with claws. The limb as a whole was thus adapted to locomotion or support, and not at all for prehension, although this might have been expected from its small size and position.

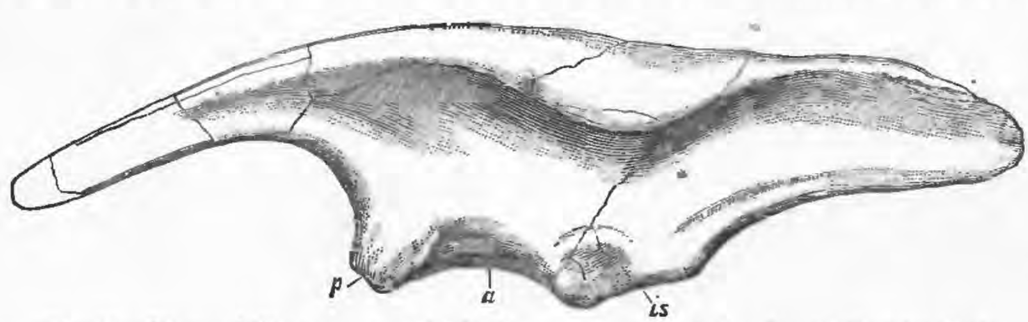

FIG. 55.—Ilium of *Claosaurus agilis* Marsh; seen from the left. One-sixth natural size *a*, acetabular border; *is*, face for ischium; *p*, face for pubis.

The elongation of the forearm and manus is a peculiar feature, especially when taken in connection with the ungulate phalanges. It may, perhaps, be explained by supposing that the animal gradually assumed a more erect position until it became essentially a biped, while the fore limbs retained in a measure their primitive function, and did not become prehensile as in some allied forms.

The pelvis is shown in Pl. LXXIII, figs. 2 and 3, and has been fully described by the writer. Its most notable features are seen in the pubis and ischium, the former having a very large expanded prepubis, with the postpubis rudimentary, while the shaft of the ischium is greatly elongated. The ilium of the type species is shown in fig. 55.

The femur is long, and the shaft nearly straight. The great trochanter is well developed, while the third trochanter is large and near the middle of the shaft, as shown in Pl. LXXIII, fig. 2. The external condyle of

the accompanying plate, based mainly upon a study of the original specimens.

Besides the four genera here represented, no other European dinosaurs at present known are sufficiently well preserved to admit of accurate restorations of the skeleton. This is true, moreover, of the dinosaurian remains from other parts of the world outside of North America.

AFFINITIES OF DINOSAURS.

The extinct reptiles known as dinosaurs were for a long time regarded as a peculiar order, having, indeed, certain relations to birds, but without being closely allied to any of the groups of known reptiles. Megalosaurus and Iguanodon, the first dinosaurian genera described, were justly considered as representing two distinct families, one including the carnivores, and the other the herbivorous forms.

With the discovery and investigation of Cardiodon (Cetiosaurus) and its allies in Europe, and especially of the gigantic forms with similar characters in America, it became evident that these reptiles could not be placed in the same families with Megalosaurus or Iguanodon, but constituted a well-marked group by themselves. It was this new order, the Sauropoda, as the writer has named them, that first showed definite

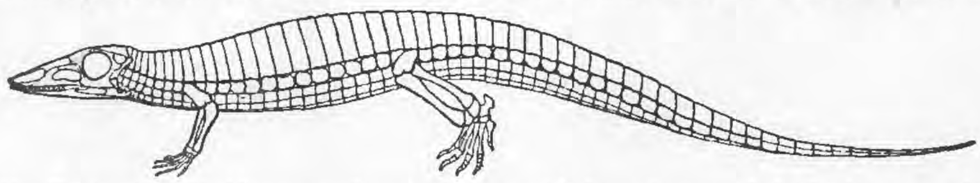

FIG. 56.—Restoration of *Aëtosaurus ferratus* Fraas; with dermal armor of the limbs removed. One-eighth natural size.

characters allying them with other known groups of reptiles. In 1878 he pointed out that the Sauropoda were the least specialized of the dinosaurs, and gave a list of characters in which they showed such an approach to the Mesozoic crocodiles as to suggest a common ancestry at no very remote period.[1]

AFFINITIES WITH AËTOSAURIA.

Again, in 1884, the writer called attention to the same point, and also to the relationship of dinosaurs with the Aëtosauria, as he has named them, a group of small reptiles from the Triassic of Germany showing strong affinities with crocodilians.[2] A restoration of one of these small animals is shown in fig. 56. In the same communication he compared with dinosaurs another allied group, the Hallopoda, which he described from the lower Jurassic of America, but had not then fully investigated. Subsequent researches proved the latter group to be of the first importance in estimating the affinities of dinosaurs, and in figs. 59 and 60 are restorations of the fore and hind limbs of the type species (*Hallopus victor*).

[1] American Journal of Science, Vol. XVI, p. 412, November, 1878.
[2] Report British Association, Montreal Meeting, 1884, p. 765.

AFFINITIES WITH BELODONTIA.

Another group of extinct reptiles, which may be termed the Belodontia, were considered in the same paper as allies of the Dinosauria. They are known from the Trias of Europe and America, and the type genus, Belodon, has been investigated by many anatomists, who all appear to have regarded it as a crocodilian, an opinion that in the light of our present knowledge may fairly be questioned.

58

57

FIG. 58.—Diagram of left hind limb of *Aëtosaurus ferratus;* in same position. One-half natural size.

AFFINITIES WITH CROCODILIA.

The relations of these various groups to the true crocodiles on the one hand and to dinosaurs on the other is much too broad a subject to be introduced here, but attention may at least be called to some points of resemblance between the dinosaurs and these supposed crocodilian forms that seem to indicate genetic affinities.

If some of the characteristic parts of the skeletons of these groups are compared, e. g., of the true Crocodilia as existing to-day, the Belodontia, the Aëtosauria, and the Hallopoda, and all with the corresponding portions of the more typical dinosaurs, the result may indicate in some measure the relationship between them. Taking first the pelvis and hind limb, as being especially characteristic. it will be seen in

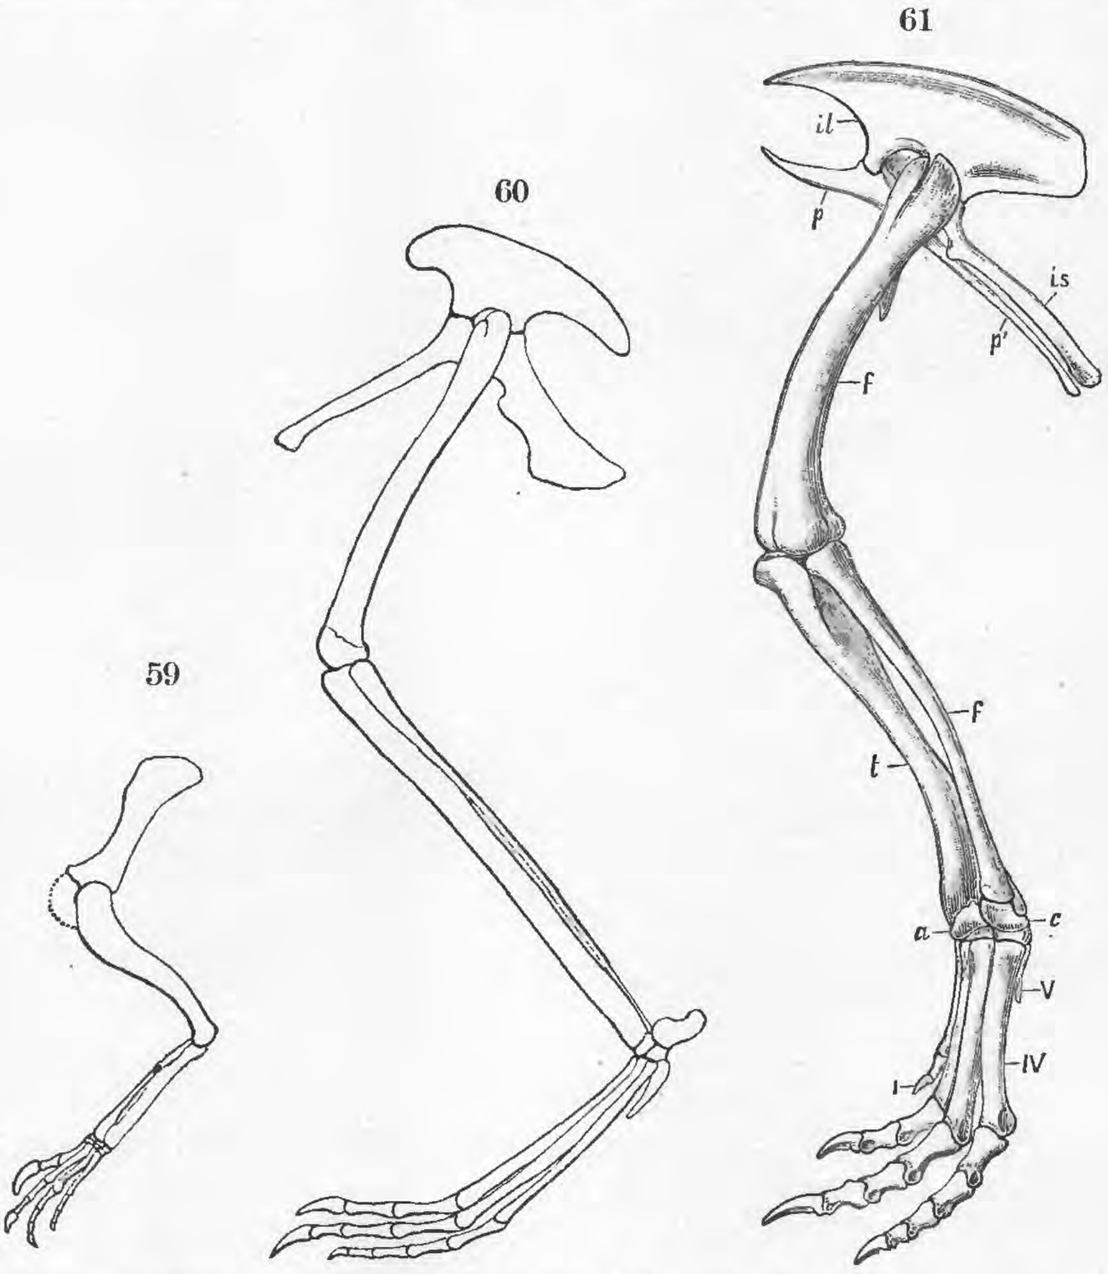

FIG. 59.—Diagram of left fore limb of *Hallopus victor* Marsh; seen from the left.
FIG. 60.—Diagram of left hind limb of same individual. Both figures are one-half natural size.
FIG. 61.—Left hind leg of *Laosaurus consors* Marsh; outside view. One-sixth natural size.

the existing alligator, as represented in fig. 57, that the pubic bone is excluded from the acetabulum, articulating with the ischium only, and not at all with the ilium. The calcaneum, moreover, has a posterior extension. In Aëtosaurus, as shown in fig. 58, the pubic bone forms part of the acetabulum, as in dinosaurs and birds, and this is a noteworthy difference from all the existing crocodiles. The hind foot, however, is of the crocodilian type, with the calcaneum showing a posterior projection.

In Belodon, only the pelvis of which is here represented (fig. 62), the pubis contributes a very important part to the formation of the acetabulum, and to the entire pelvic arch. The latter differs from the pelvis of a typical dinosaur mainly in the absence of an open acetabulum, but a moderate enlargement of the fontanelle at the junction of the three pelvic elements would practically remove this difference. A more erect position of the limb, leading to a more distinct head on the femur, might possibly bring about such a result. The feet and limbs of Belodon are crocodilian in type.

Bearing these facts in mind, the diagram representing the restored fore and hind limbs of the diminutive Hallopus (figs. 59–60) shows first

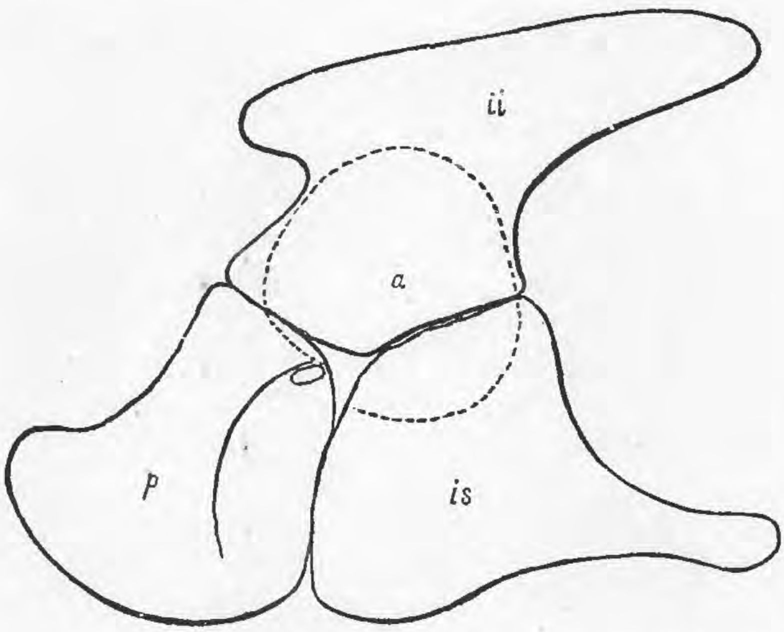

FIG. 62.—Diagram of pelvis of *Belodon Kapffi* von Meyer; seen from the left. One-fourth natural size.

a, acetabular surface within dotted line; *il*, ilium; *is*, ischium; *p*, pubis.

of all the true dinosaurian pelvis, with the pubic bone taking part in the open acetabulum, and forming an important and distinctive element of the pelvic arch. The delicate posterior limb and foot, evidently adapted mainly for leaping, as the generic name suggests, are quite unique among the Reptilia, but the tarsus, especially the calcaneum, recalls strongly the same region in the orders already passed in review.

Just what this posterior extension of the calcaneum signifies in this case it is difficult to decide from the evidence now known. It may be merely an adaptive character, as Hallopus appears in nearly every other respect to be a true carnivorous dinosaur. It may, however, be an inheritance from a crocodilian ancestry, preserved by a peculiar mode of life. Whatever its origin may have been, it was certainly, during the life of the animal, an essential part of the remarkable leaping foot to which it belonged, and in which it has since kept its position undisturbed. The presence of such an element in the foot of this diminutive dinosaur certainly suggests that the group Hallopoda, which the writer has here considered a suborder, stands somewhat apart from the typical Theropoda, but not far enough away to be excluded from the subclass Dinosauria, as defined in the present paper.

The genus Plateosaurus (Zanclodon), which is from essentially the

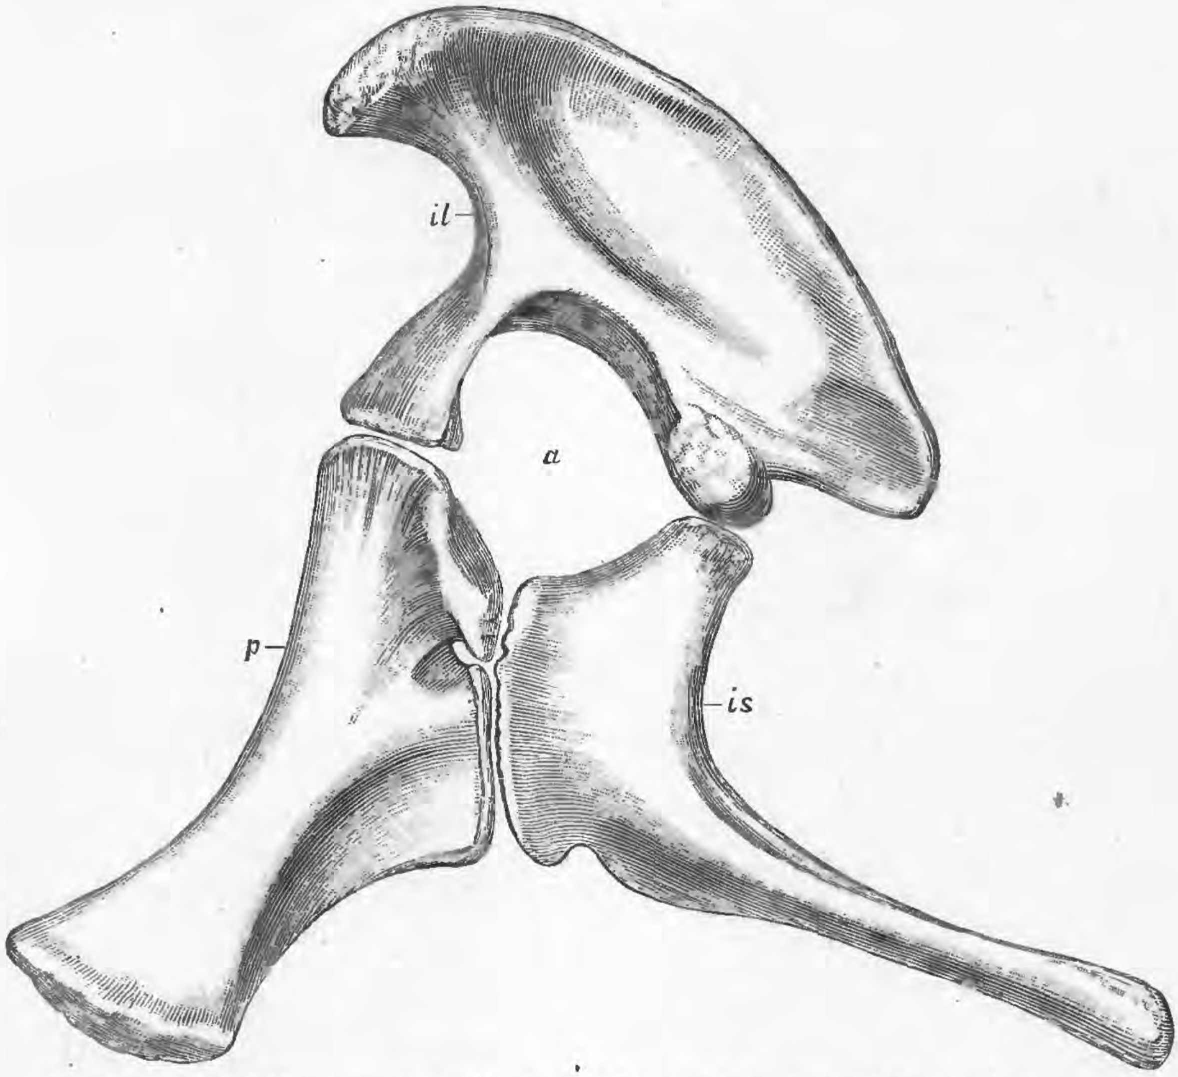

FIG. 63.—Pelvis of *Morosaurus lentus* Marsh; seen from the left. One-eighth natural size. *a*, acetabular opening; other letters as in fig. 62.

same geological horizon in Germany as Aëtosaurus and Belodon, is one of the oldest true dinosaurs known, and a typical member of the order Theropoda. In the pelvic arch of this reptile the ilium and ischium are in type quite characteristic of the group to which it belongs, but the pubic elements are unique. They consist of a pair of broad, thin plates united together so as to form an apron-like shield in front, quite unlike anything known in other dinosaurs. The wide pubic bones of Belodon, and the corresponding plates in some of the Sauropoda (Morosaurus, fig. 63), indicate that this feature of the reptilian pelvis may have been derived from some common ancestor of a generalized primitive type. The known transformations of this same pelvic element in one other order of dinosaurs (the Predentata) show that the modifications here suggested are well within the limits of probability. The hind limb of one genus of this order is shown in fig. 61 (p. 233).

GROUP OF CYCADEAN TRUNKS FROM THE BLACK HILLS OF SOUTH DAKOTA; LOWER CRETACEOUS.

phere. There were no vestiges of the bark in a carbonized state, nor of the natural external surface of the stems, as in the prostrate trees at Brook Point in the Isle of Wight.

The cycadaceous plants occur in the intervals between the trees, and the dirt-bed is so little consolidated that I dug up with a spade several specimens that were standing erect, in the position in which they originally grew. . . . The specimens are called *"crow's-nest"* by the workmen, who believe these plants to be bird's nests, originally built by crows in the fossil trees, which have become petrified. The largest specimens are about 2 feet high and 3 feet in circumference.[1]

The trees stand in the part of the series immediately above the upper "dirt-bed," locally termed the "soft burr," and project up through the several overlying deposits; but the erect portion is always comparatively short, not often exceeding 3 or 4 feet. They have their roots in the dirt bed itself. I have reproduced (Fig. 68) the excellent section

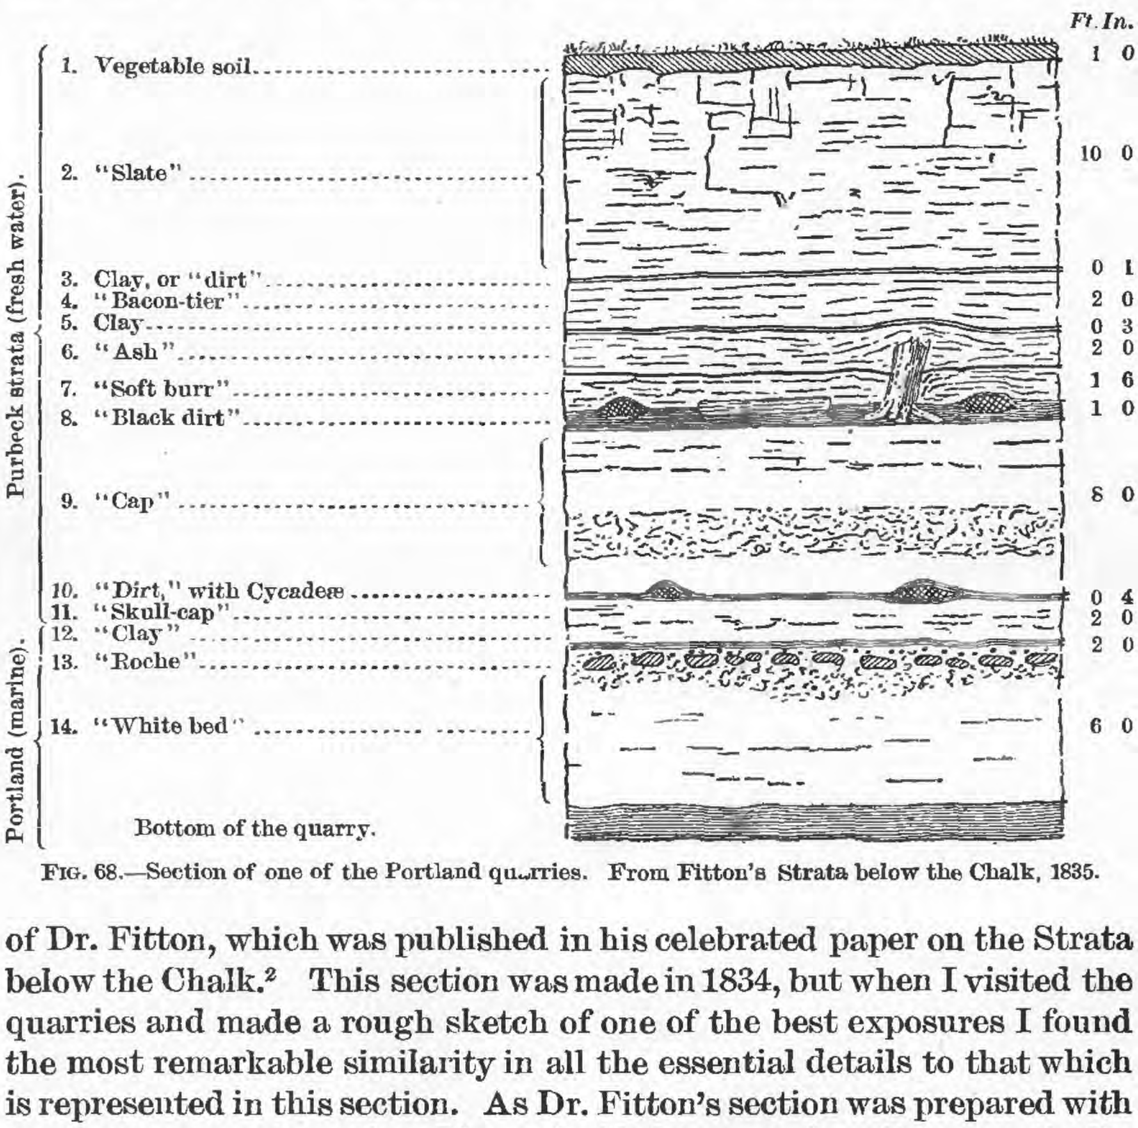

FIG. 68.—Section of one of the Portland quarries. From Fitton's Strata below the Chalk, 1835.

of Dr. Fitton, which was published in his celebrated paper on the Strata below the Chalk.[2] This section was made in 1834, but when I visited the quarries and made a rough sketch of one of the best exposures I found the most remarkable similarity in all the essential details to that which is represented in this section. As Dr. Fitton's section was prepared with much more care than mine, I have decided to reproduce it as practically representing the exact present state of things. He has introduced cycadean trunks at both the lower and upper dirt beds, where they are known to occur, and he also shows one of the erect trunks with its roots in the

COLUMNAR AND PROFILE SECTIONS OF THE CRETACEOUS OF PORTUGAL.

matrix in which the Portuguese fossil plants occur. It evidently corresponds very closely with that of the great majority of the Potomac deposits. The plants occur in the clays, which are more or less soft and even plastic when first exposed, but harden on drying. In some of the Potomac beds the vegetable matter of the leaves remains as a thin, black film covering the clay, which, being damp when first exposed to the light, almost immediately cracks and crumples on drying, and is thus more or less completely lost. But in most cases the vegetable matter is reduced by compression and other influences almost to a mere stain, often of a brownish color, upon which the fine nerves are distinctly visible. This last seems to be the character of the preservation of these impressions in the Portuguese beds, and the similarity in the nature of the matrix is very marked.

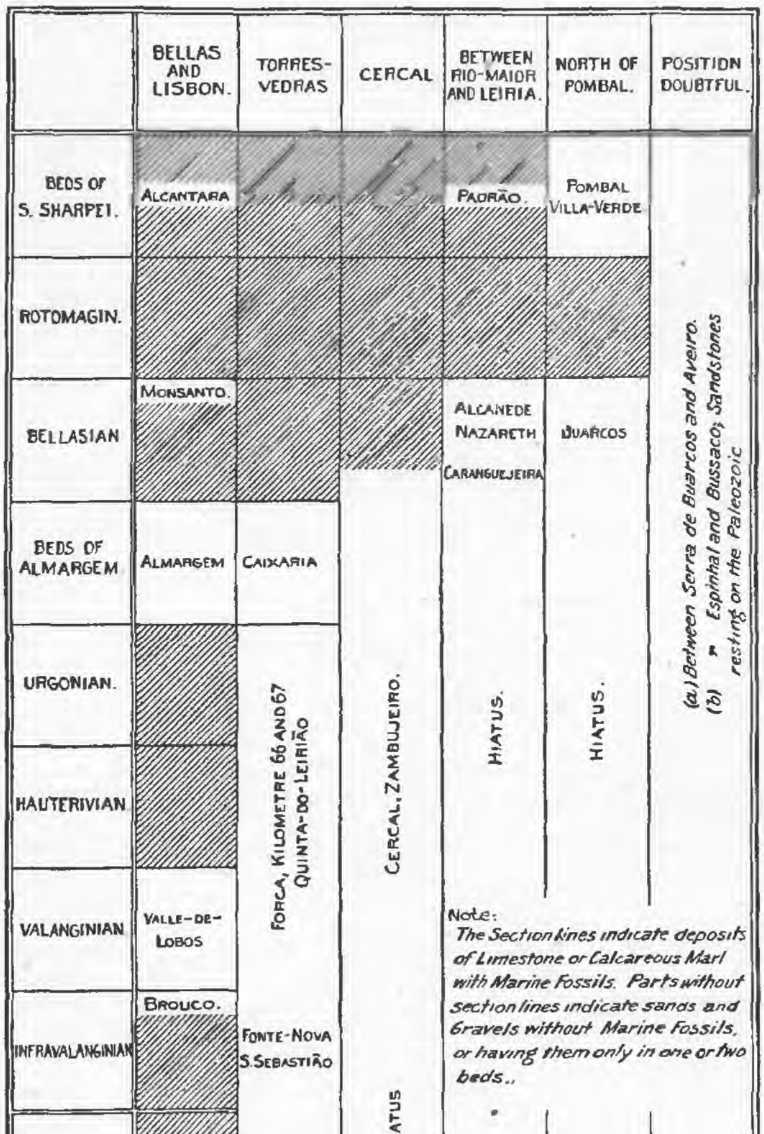

FIG. 69.—Correlation table of the Mesozoic deposits of Portugal. From Paul Choffat, 1894.

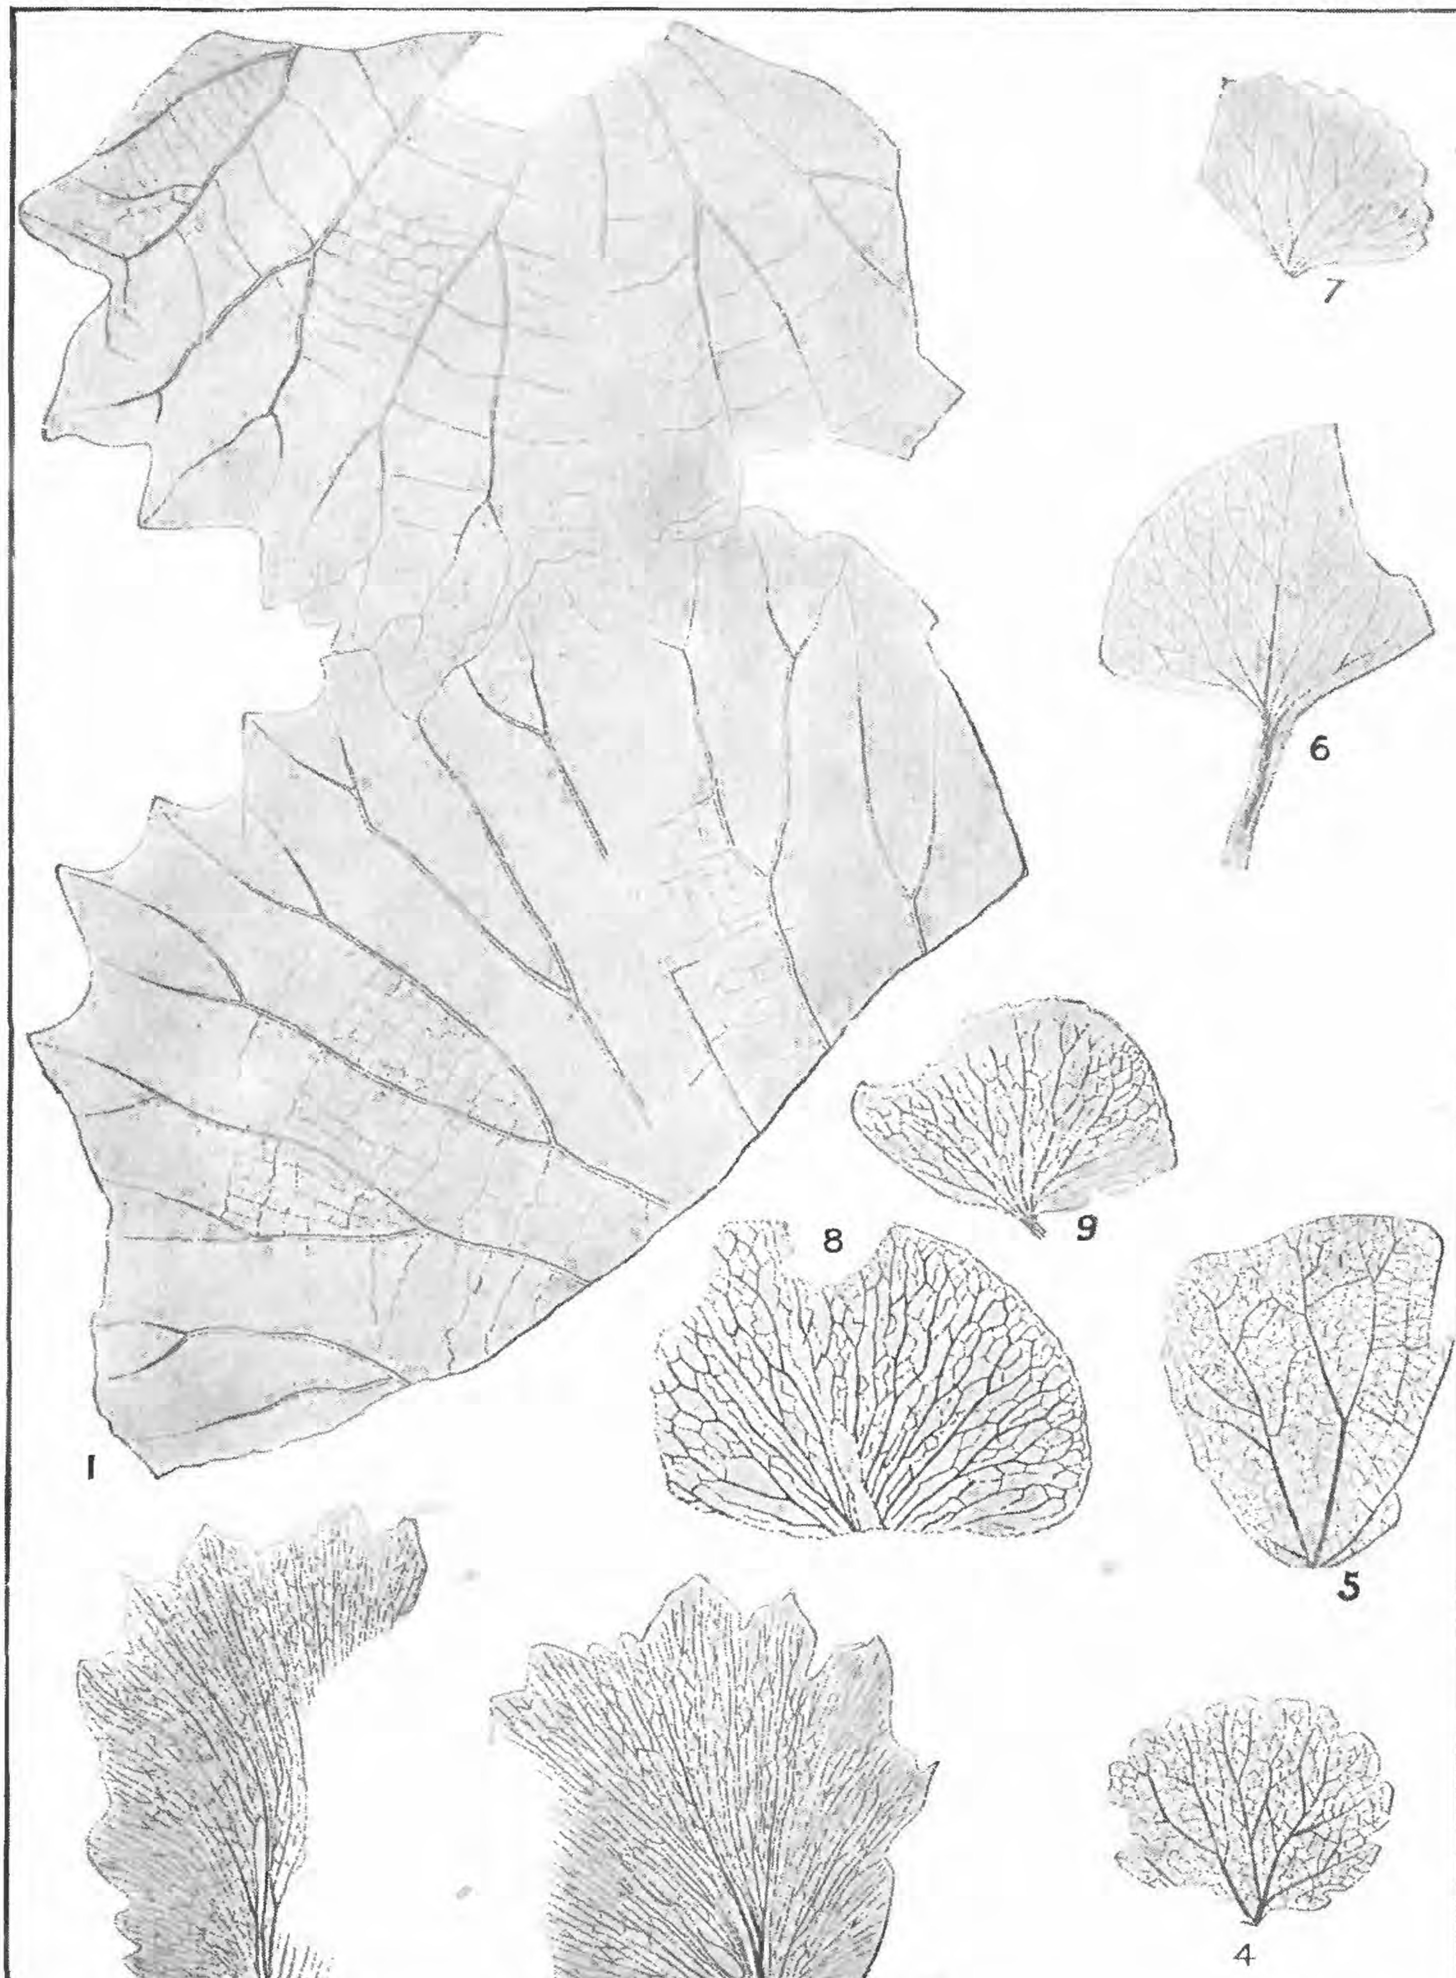
I give herewith (Pl. CV) the diagram of the Cretaceous plant-bearing beds of Portugal prepared by M. Choffat and published in the joint memoir of Saporta and himself. It embraces a small sketch map of the locality and profiles. I also give (Fig. 69) his diagram showing the correlation of these several beds.

Properly to illustrate the character of the Lower Cretaceous flora of Portugal I have prepared three tables of distribution.

The first embraces the entire flora of 204 species and shows their distribution in Portugal alone, but throughout not only all the Lower Cretaceous beds, but also the Jurassic below and the Cenomanian above.



ARCHETYPAL ANGIOSPERMS FROM THE MESOZOIC OF EUROPE AND AMERICA.

beds along the apex of the fold is well shown. In one of the upper beds (fig. 70) a slight faulting has resulted. The southern face (fig. 71) has suffered more weathering, and shows a very low easterly cleavage crossing all the beds and evidently subsequent to the folding. In limestone, weathering often brings out structural features which could otherwise hardly be detected. Overturned folds, i. e., with axial planes

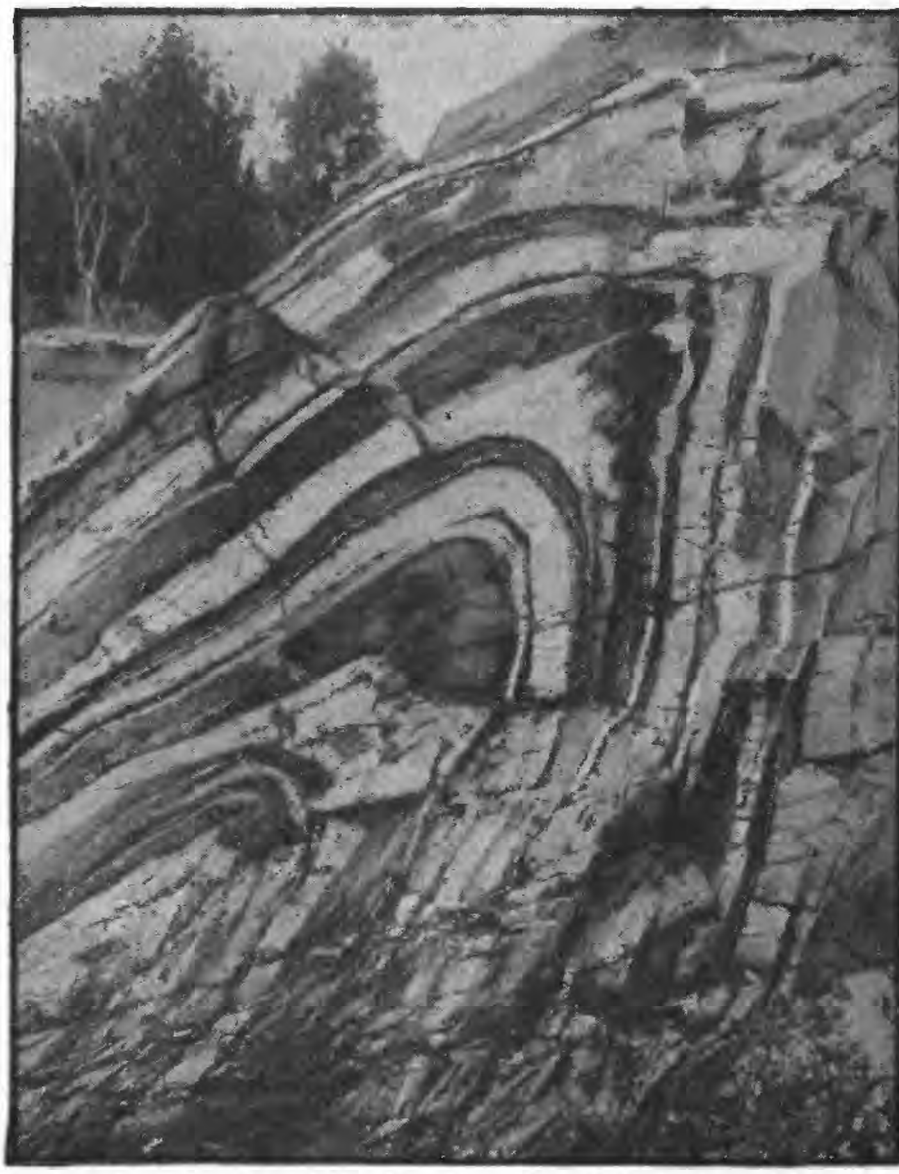


FIG. 70.—Overturned anticline of crystalline limestone with easterly dipping axial plane, Lenox, Mass. Photograph taken looking south. Height, 15 feet. The dark layers are due to yellowish weathering. The folds are thickened at the top and drawn out. Some faulting has occurred here in the upper layers.

dipping east or west—more frequently, however, to the east—are well known as typical of the western part of the northern Appalachian region.

Within a few hundred feet of this is another limestone fold (fig. 72), in which the overturn has proceeded a step farther. We have either the eastern or the western limb of a syncline folded over onto itself so as to form a minor anticline and syncline.

A cliff of Silurian shale along the gorge of the Hoosick at Schaghticoke, Rensselaer County, N. Y., 5 miles west of the Hudson (fig. 73), shows how misleading a series of such similarly overturned folds may be to one making estimates of thickness, even when cleavage phenomena are absent. In crossing the upper edges of such a series the observed dips would all be easterly at various angles. This series of small, acute folds

FIG. 71.—Same anticline as in fig. 70, but 10 feet farther north. Photograph taken looking north. The face has suffered erosion, bringing out a very low easterly dipping cleavage.

with easterly dipping axial planes probably forms part of the side of a broad fold, and the dip to be entered in the geologist's note-book in such a locality ought to be "low west, in small folds."

On the Lebanon Springs Railroad a little south of Stephentown, Rensselaer County, N. Y., the Silurian slates contain a small, extremely compressed anticline so overturned that its axial plane dips only 10° (fig. 74). It is traversed by a slaty cleavage parallel to its axial plane.

Slightly overturned folds may be confined to certain zones of strata and also have pitching axes. Thus at Ashley Hill, near Rayville, in the northern part of Columbia County, N. Y., there are beds of red shale 5 to 6 inches thick alternating with beds of very quartzose limestone 1 to 3 inches thick (fig. 75). The axes of the folds pitch 60° south. This folding seems to be confined to some 10 feet or so of strata, for a few feet east and west the beds resume their usual northerly strike and easterly dip, and the folding disappears. The shale beds have a cleavage which strikes and dips conformably to the unfolded beds on both sides of the folded zone (see fig. 76).

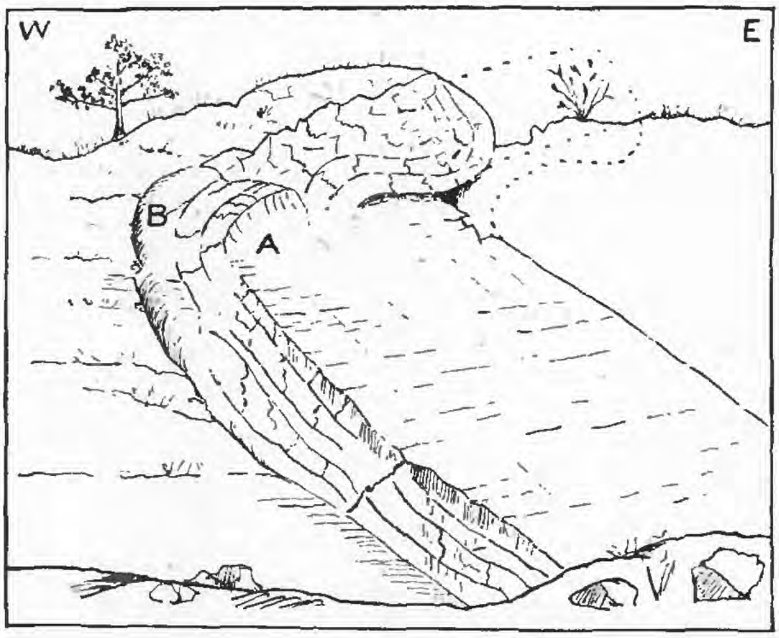

FIG. 72.—A fold within the limb of a syncline of crystalline limestone, Lenox, Mass. Sketch taken looking north; area 15 by 15 feet. At A the upper side of the bed; at B the lower side reflexed.

Such small belts of strata plicated along the strike within a mass of strata which is broadly folded in a direction across the strike are not of very frequent occurrence. They may, perhaps, be accounted for by the unequal plasticity of different beds, the softer ones thinning out under pressure more than the harder ones, that is, becoming longer. The plication of such beds along the strike would then be the result of the taking up of their surplusage in that direc-

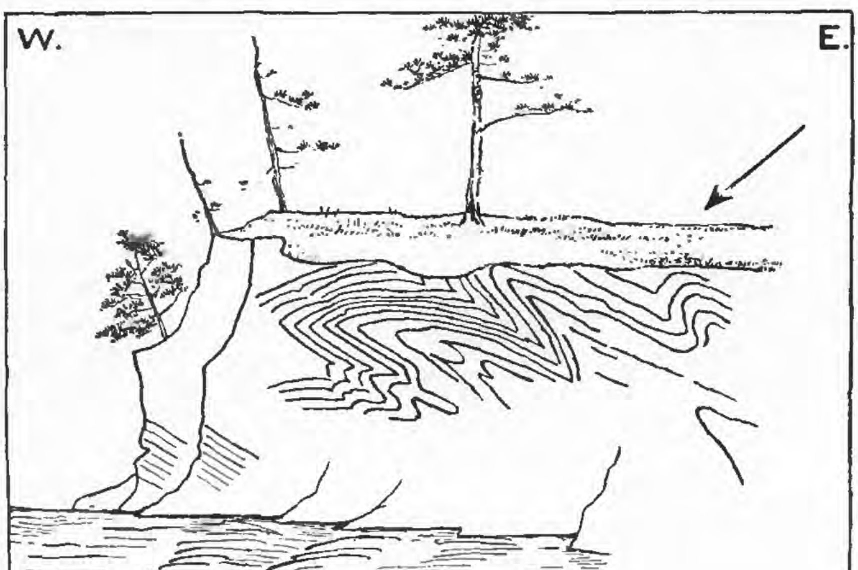

FIG. 73.—Sketch of a series of overturned folds of shale, with easterly dipping axial planes, on the right bank of the Hoosick, at Schaghticoke, N. Y.

tion.[1] In this instance this plication, instead of acting directly along the strike, seems to have acted in a direction between it and that of the general dip of the entire series, thus giving a southerly pitch to the subordinate folds.

FIG. 74.—Overturned compressed anticline of slate with axial plane dipping 10°, and with slaty cleavage parallel to it. Length, 6 feet. Stephentown, Rensselaer County, N. Y. Photograph.

TRANSVERSE FOLDS.

In Dr. J. E. Wolff's section of Hoosac Mountain[2] the folding of a great mass of beds in two directions at right angles to each other, i. e., with and across the strike, is finely shown.

The anticline is 1½ miles broad at the surface from east to west, and the transverse anticline, i. e., the one in the axis of the fold, is about 4½ miles long at the surface from north to south.

At the foot of the Taconic Range, near the west end of the village of Williamstown, about 8½ miles northwest of the great complex Hoosac anticline, is a hillock of quartzite and limestone of Cambrian and Silurian age[3] in which the Hoosac structure is repeated in miniature, the whole structure being exposed within about one-third of a mile square. Further study may show that this structure is characteristic of the Green Mountain region.

On the north, the east, and the southwest sides of the hillock the limestone crops out, overlying, as it should, the quartzite of the Vermont formation, which constitutes its center and top. Similar relations, if one may judge from the outcrops along the strike to the south, probably

[1] See Archibald Geikie's report on recent work of the Geological Survey in the Northwest Highlands of Scotland, etc.: Quart. Jour. Geol. Soc., London, Vol. XLIV, p. 397, where he describes a similar overfolding of small micaceous layers. This structure also occurs in Cambrian schists and quartzites at Clarendon in Vermont.

[2] Mon. U. S. Geol. Survey, Vol. XXIII, Pl. VI, Secs. V, X, XII.

[3] See Ibid., Pl. I (map).

recur on the west side, which, however, is covered with drift. The dips on the east are about 30° east, on the north about 30° northeast, and on the southwest about 45° southwest. Fig. 77 represents a section crossing the hill nearly in the direction of the axes of the folds of the region; fig. 78, one crossing it at right angles to them. In fig. 77 the parallelism between the faulting and the cleavage is noticeable, also the partial protection afforded to the limestone synclinal cores by the quartzite anticlines.[1] Such longitudinally folded anticlines show that the compression which was concerned in the formation of the Green Mountains operated both in a northwest-southeast and in a northeast-southwest direction. On the theory of the contraction of the earth's interior as the cause of mountain systems, and even on that of the expansion of the crust, it seems more rational that the corrugation of the sedimentary beds should have occurred simultaneously in two directions at right angles to each other than that it should have been confined to one. It must be admitted, however, that the Hoosac structure is probably uncommon in the Green Mountain region. That the northeast-southwest folding was the result of a secondary movement seems difficult to believe, on account of the great rigidity which the first folding and its accompanying metamorphism must have imparted to the masses.

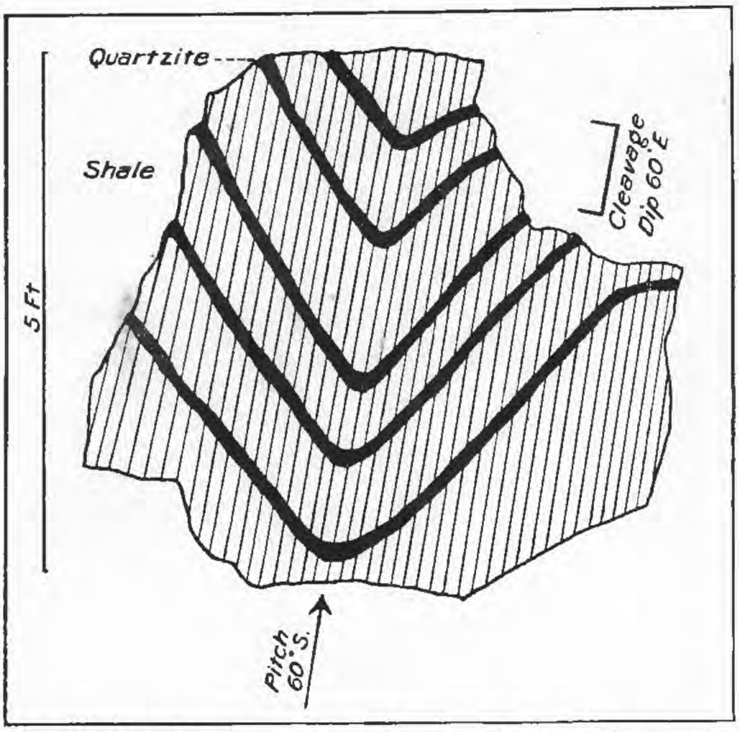

FIG. 75.—Belt of folded and pitching strata of shale and quartzose limestone, with a slaty cleavage confined to the shale. Sketch taken looking down along the pitch. Ashley Hill, Columbia County, N. Y.

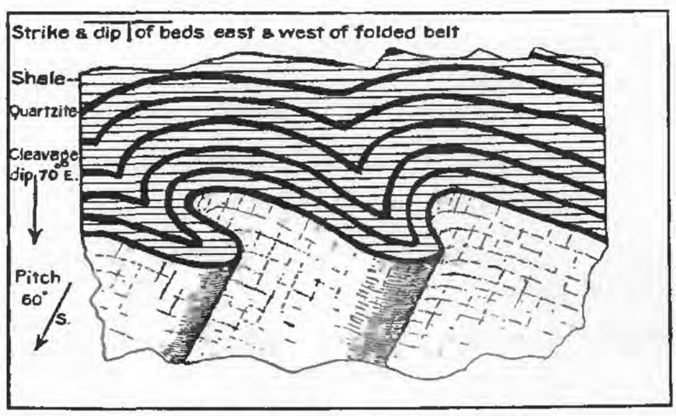

FIG. 76.—Diagram of above, looking across the strike. The cleavage in the shale is parallel to bedding east and west of folded belt.

[1] In gathering material for this section the author has availed himself to some extent of the labor of a former student of his, Mr. Alexander Sloan.

VERTICAL DISAPPEARANCE OF FOLDS.

A specimen, fig. 79, from the Taconic Range, about 6 miles west of Pittsfield and a mile north of Perry Peak, illustrates a familiar fact in stratigraphical and experimental geology, namely, that crumpling in a

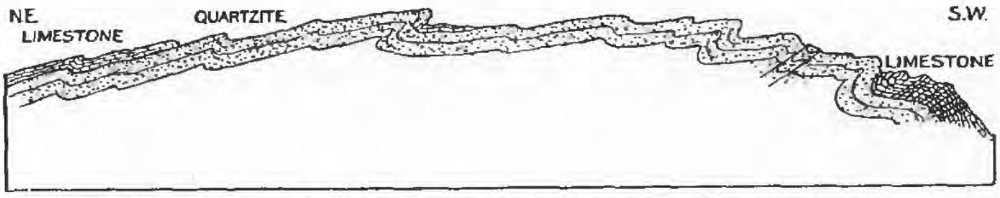

FIG. 77.—Longitudinal section of hillock ("Bullock's cobble") at west end of Williamstown village, Mass., showing longitudinal folding, faulting, and cleavage. Looking southeast.

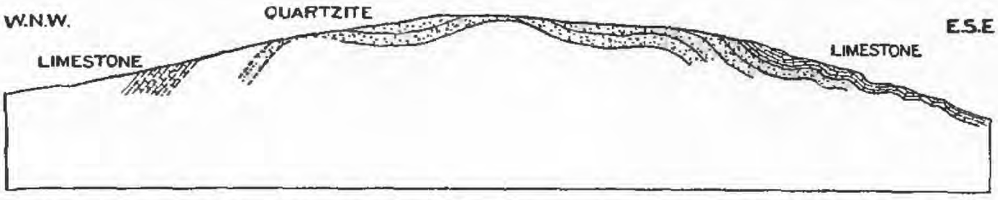

FIG. 78.—Cross-section of same hillock (fig. 77), looking north-northeast along the strike; the portion at the left taken from supposed relations south along the strike. The limestone may be overturned and, for a space, dip easterly under the quartzite.

series of superposed strata can not be uniform for any great vertical distance, even where there is no change in the material of the strata.

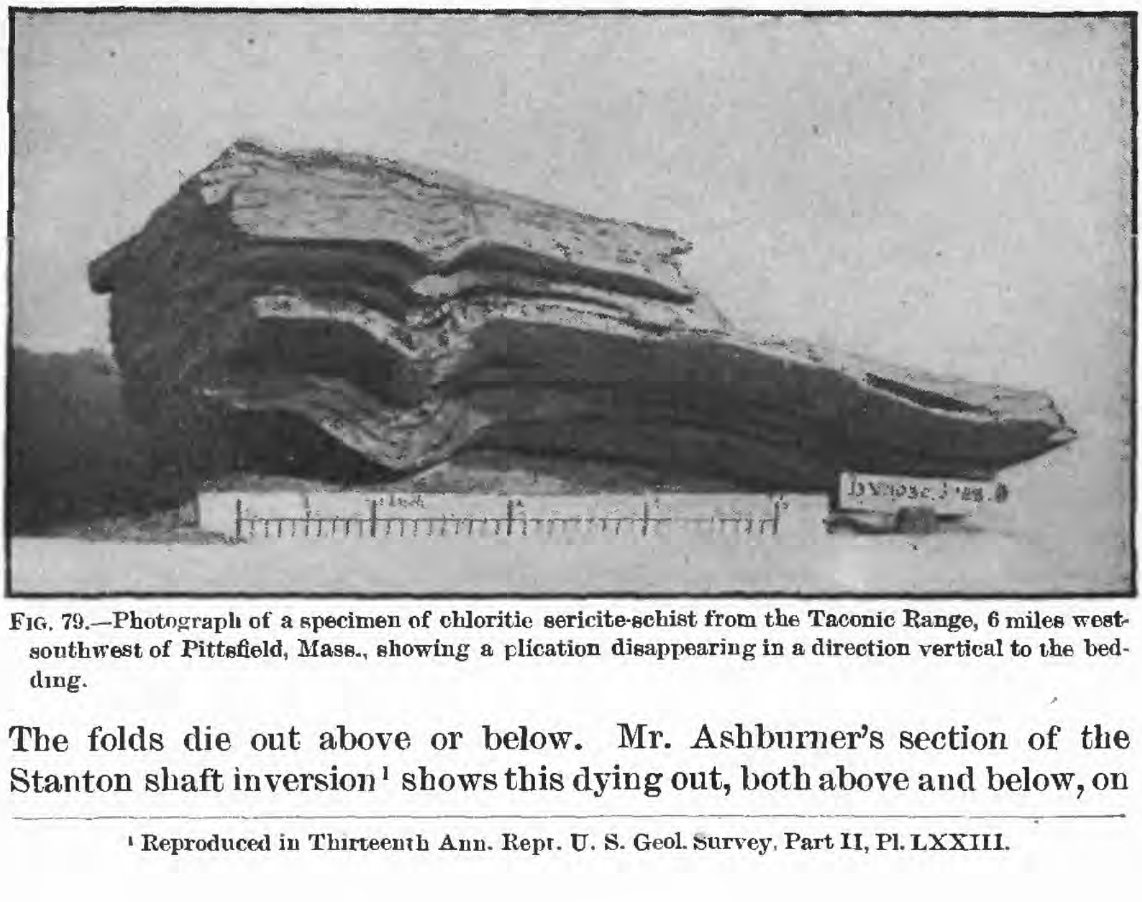

FIG. 79.—Photograph of a specimen of chloritic sericite-schist from the Taconic Range, 6 miles west-southwest of Pittsfield, Mass., showing a plication disappearing in a direction vertical to the bedding.

The folds die out above or below. Mr. Ashburner's section of the Stanton shaft inversion[1] shows this dying out, both above and below, on

[1] Reproduced in Thirteenth Ann. Rept. U. S. Geol. Survey, Part II, Pl. LXXIII.

a large scale. The same occurs on a small scale in fig. 80. In such cases the cause may lie in the different tenacity of the material, as was supposed in explaining fig. 76. These possibilities should be taken account of in the construction of sections.

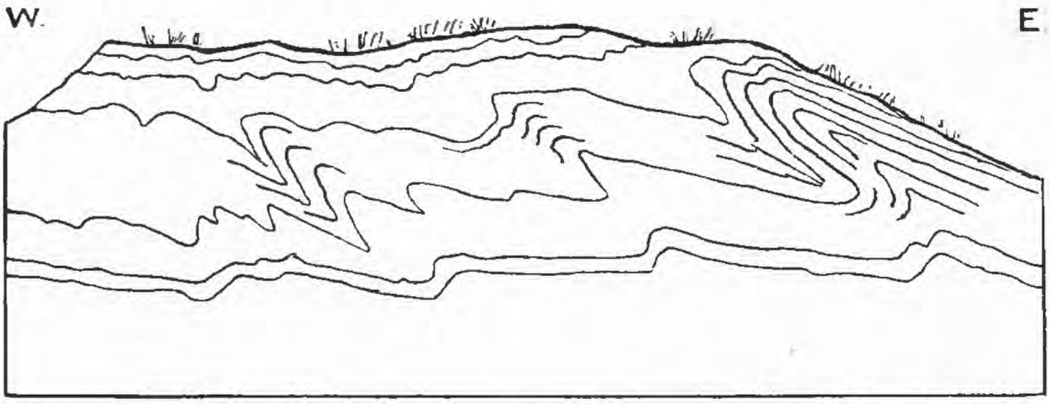

FIG. 80.—Sketch of a ledge of micaceous quartzite on the west side of Rattlesnake Hill, Stockbridge, Mass., 25 by 8 feet, showing the folds diminishing both above and below.

ORIGIN OF QUARTZ LENSES IN THE BEDDING-PLANES OF SERICITE-SCHIST.

Quartz veins and lenses occur almost everywhere in the sericite-schist of the Taconic Range in Vermont and Massachusetts, and also characterize the Cambrian-Silurian schist mass of Hoosac Mountain.[1]

FIG. 81.—Photograph of a ledge of plicated sericite, chlorite, quartz-schist in the Taconic-Greylock mass, New Ashford, Mass., showing quartz lenses and laminæ in the bedding; in lower part, quartz in cleavage. Size of ledge, 14 by 10 feet.

Some of them are evidently in bedding planes; others, however, lie in cleavage planes crossing the former, and others again occur in joints (see fig. 81).

[1] See Mon. U. S. Geol. Survey, Vol. XXIII, figs. 7, 31, 41, 46, 47, 50, 51, 58, 70.

The question arises whether those which lie in the bedding planes are silica which has filtered into partings between the strata formed during their plication and metamorphism, or whether they are replacements of sedimentary material.

In traveling westward from Shaftsbury and Arlington, in Vermont, across the Taconic Range into Washington County, N. Y., one crosses a great schist mass, part of which is of Silurian and part of Lower Cambrian age; as a whole, therefore, it seems to correspond to the Hoosac schist of western Massachusetts. In the western portion the typical quartz veins and lenses give place to small beds, $\frac{1}{2}$ to 3 inches thick, of quartzite, which in places is more or less calcareous, and instead of the schist we have a fine-grained slate.

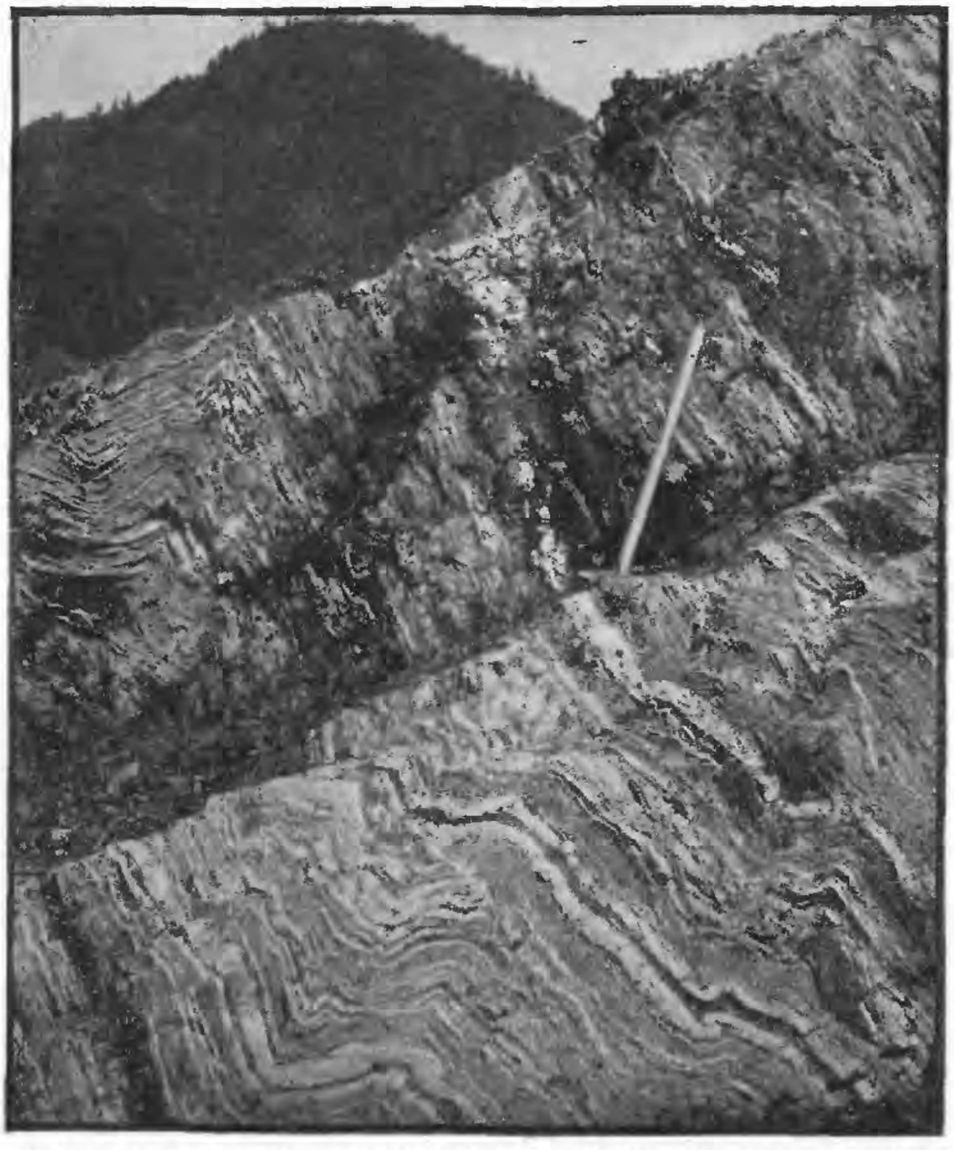

FIG. 82.—Photograph of the southern side of a ledge of small alternating beds of plicated slate and quartzite, the latter weathering white. Two miles west of the Vermont line, in White Creek, Washington County, N. Y. A mile off, along the strike of the folds, is seen the top of Goose-egg Hill, which consists of similar rocks. Hammer handle, 30 inches long.

Fig. 82 shows a plicated mass of such alternating beds of slate and quartzite. Under the microscope the quartzite consists of interlocking quartz areas, with here and there a grain of plagioclase or a plate of muscovite or a fiber of sericite.

About a quarter of a mile west of this locality the slate is finely and sharply plicated, and contains small beds of quartzose material. Under the microscope these are found to consist of quartzite similar to that just described, but with cavities lined with limonitic staining from the decomposition of some ferruginous mineral. These beds, even when only one-fourth of an inch thick, are traversed by vein quartz, and particularly at the sharp turns where fractures would be likely to occur, so that it is difficult in the field to determine where the quartzite ends and the quartz begins. On the whole it seems probable that the quartz lenses of the bedding originated in either of the following three ways:

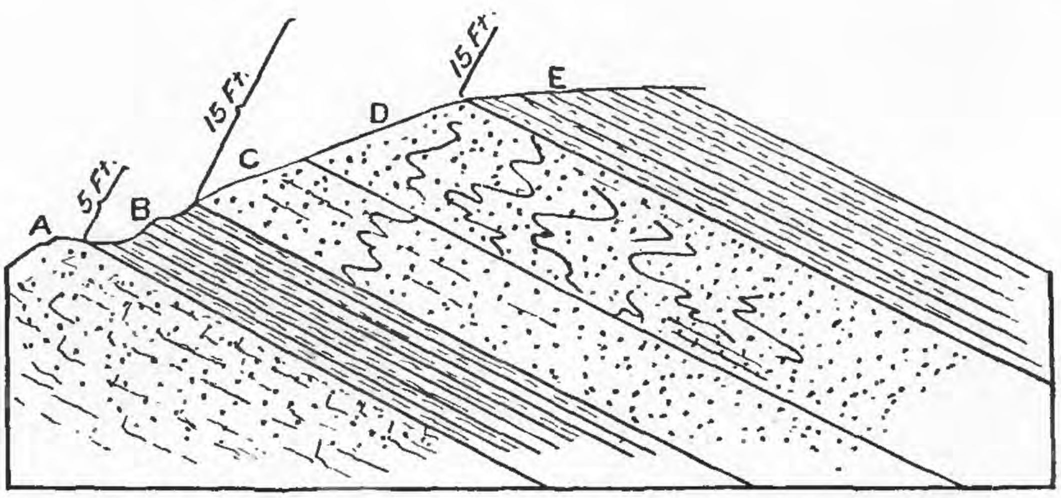

FIG. 83.—Section of crystalline limestone, mica-schist, and quartzite, 1½ miles south of Jamaica village, Windham County, Vt., showing false bedding. A, white and pink marble; B, feldspathic biotite-schist, 6 feet; C, quartzose limestone; D, micaceous quartzite; (C and D together, 15 feet); E, feldspathic biotite-schist, 15 feet.

1. As infiltrations in partings parallel to the bedding during plication and metamorphism.[1]

2. As infiltrations in small, plicated, stretched, and fractured beds of quartz sandstone or quartzite.

3. As replacements of calcareous beds after their plication and stretching.

A case like that figured on page 147 of Monograph XXIII, where the quartz of the bedding has suffered cleavage, points to movement subsequent to the cleavage and the metamorphism which attended the formation of the lenses. A large quartz vein in the pre-Cambrian granitoid gneiss of Stamford, Vt., is thus minutely cleaved. Careful observation and coordination of such instances in veins of segregation may lead to interesting inferences.

[1] Mr. C. L. Whittle, in a paper on "The occurrence of Algonkian rocks in Vermont and the evidence for their subdivision," Jour. of Geol., May–June, 1894, considers the secondary quartz in the bedding and cleavage planes of mica-schist to have originated in "the excess of silica resulting in great part from the decomposition of silicates originally in the rock, the alumina and potassium going to form the muscovite."

FALSE BEDDING.

Besides all the structural difficulties arising from complex folding and metamorphism, there occurs now and then false bedding, or "contorted false bedding."

On the east side of the Green Mountain range, about 1½ miles southeast of Jamaica village, the Brattleboro and Whitehall Railroad cuts a series of alternating beds of feldspathic, quartzose biotite-schist and of crystalline limestone, here and there of a delicate pink.

Two of the beds of limestone, more quartzose than the rest, and about 15 feet thick, with the mica-schist both above and below them in conformable contact, have the structure shown in fig. 83. The plicated structure can hardly be ordinary stratification. It may be a cleavage foliation originally diagonal to the bedding, but plicated in a secondary movement, or we may have to do here with such minor unconformities as are caused by the deposition of the limestone along a sloping bottom with currents occasionally eroding portions of the small beds, creating a plunge-and-flow structure, and this may have been plicated in the general compression of the mass. Someone may suggest a thrust plane between B and C, and another between D and E.

CLUES TO BEDDING.

Wherever bedding is obscured by cleavage one of the first things to be done is to distinguish, if possible, the bedding by tracing out the continuity of some minute line of sedimentary grains.[1] When the sediment is homogeneous this becomes impossible. In the Cambrian-Silurian shales and slates of Washington County, N. Y., lines of holes occur now and then on transverse joint faces (see fig. 84, A, B, C). Upon a closer inspection these are found to be due to a very slight calcareousness of the shale along certain bedding planes. Weathering attacks these planes more readily, but at irregular intervals, and the effect is as though small limestone pebbles had been dissolved out. Again, sometimes, in weathering, a slight parting in the stratification is sufficient to arrest vertical erosion for a time and expose the actual

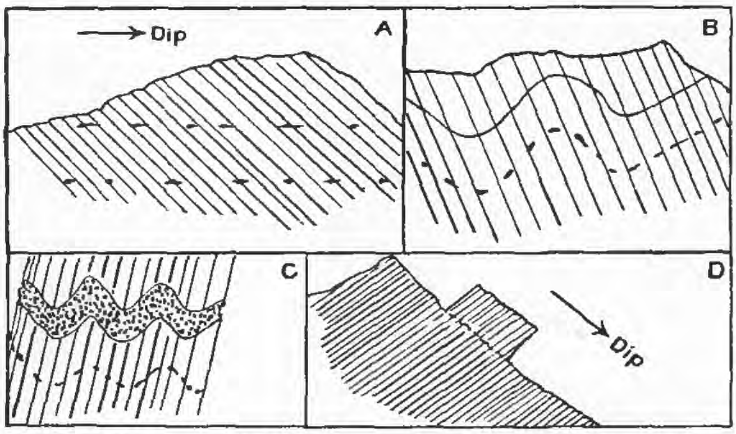

FIG. 84.—Diagrams of shale ledges showing obscure traces of bedding, Washington County, N. Y. A, bedding shown by lines of holes (due to dissolution of calcareous matter) crossing the cleavage; B, C, proof of interpretation of A; lines of holes parallel to small calcareous bed; D, bedding shown by uneven surface continuous with a delicate parting in the stratification.

[1] See Thirteenth Ann. Rept. U. S. Geol. Survey, Part II, pp. 322-323, figs. 28, 29, 31.

surface of a stratum, even where the cleavage foliation is the dominant one. (See fig. 84, D.)[1]

In fig. 85 is shown a plicated bed of limestone in a mass of shale. In determining the dip of such a mass neither the dip of the cleavage nor that of the separate limbs of the step-like folds of the limestone should be taken, but the general course of the limestone bed.

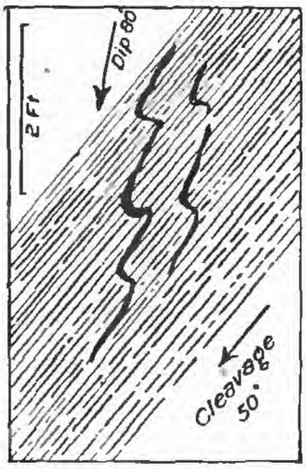

FIG. 85.—Diagram of ledge of cleaved shale inclosing small bed of limestone in step-like folds. Height, 10 feet. Locality, 1½ miles southeast of North Greenwich, Washington County, N. Y.

DIFFERENTIAL CLEAVAGE.

Where a bed of shale or other fine-grained rock is inclosed in a coarser-grained one cleavage foliation is apt to be confined to the former (fig. 86). Where the adjoining strata are not plicated such localities may afford a clue to the relation between the dip of the cleavage and the direction of the pressure which produced it. If we suppose the cleavage in fig. 86 to have originated at the time of the folding, the force which produced the fold would seem to have operated in a direction nearly at right angles to the cleavage; but if the cleavage was produced while the beds were still horizontal, the direction of the pressure would be about 45° to the dip of the cleavage.

How slaty cleavage may be confined to particular beds is also well shown in figs. 75, 76, 85. J. Gosselet gives a fine illustration of this in a section of certain slate quarries in northeastern France.[2] That the angle of the dip of the cleavage is determined in part by the physical character (tenacity) of the rock materials is shown at the locality represented in fig. 87. Different materials diffract, as it were, the cleavage differently. Here the cleavage, in crossing alternating beds of shale and limestone, changes its dip, being almost vertical in the limestone and only 40° in the shale,

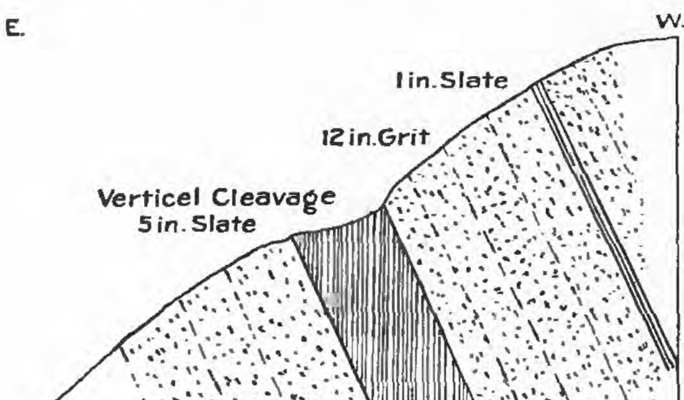

FIG. 86.—Diagram of ledge of grit and red slate in Grafton, Rensselaer County, N. Y. One of the beds of slate has a vertical cleavage which does not extend into the grit.

[1] Compare William W. Mather, Geology of New York, Part I, Pl. X, fig. 6, 1843.

[2] J. Gosselet, L'Ardenne, Mémoires pour servir à l'explication de la carte géologique détaillée de la France, p. 41, fig. 7, Paris, 1888. See, also, Mather, op. cit., Pl. X, figs. 7 and 8.

a difference of over 50° within a mass which must have been subjected to a uniform pressure. This is what Sir Archibald Geikie has termed "differential cleavage," and about which he says: "In fact, there seems to be a constant relation between the inclination of the cleavage planes and the texture of the strata; the fine flags and shale behave, so to speak, like lines of weakness, their constituent particles having been drawn out or dragged much farther than those of the grits."[1] But in the locality which he figures the cleavage planes, instead of merely altering their dip angle in passing from one material to another, as in fig. 87, form in the coarser beds "sigmoidal curves," which seem to be the result of a continuance of the motion after the formation of the cleavage. Fig. 87 represents simple differential cleavage, but Sir Archibald Geikie's, a more complex thing, a flexed or slightly plicated differential cleavage.

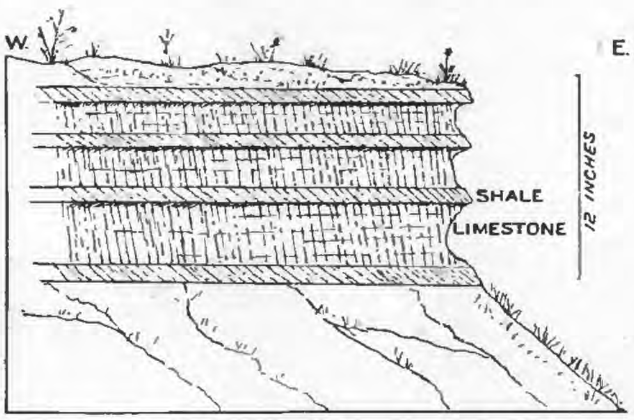

FIG. 87.—Sketch of ledge of alternating beds of limestone and shale, showing the different effect of these materials upon cleavage ("differential cleavage"). Erosion has in turn also affected these materials differently. Jackson, Washington County, N. Y.

In fig. 87 the effect of the more tenacious or brittle material, limestone, upon the cleavage has been similar to that of a denser medium upon a ray of light—the cleavage has been, as it were, refracted toward the perpendicular.

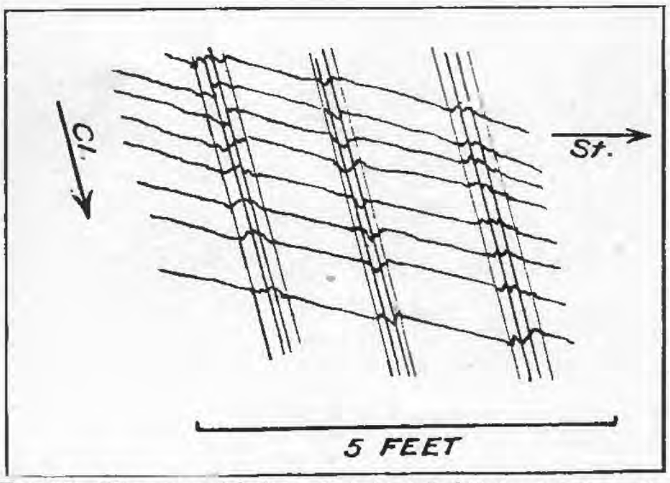

FIG. 88.—Diagram of ledge of slate (phyllite), showing slip cleavage confined to the tops and shorter limbs of the plications, giving the rock a banded structure across the bedding planes. On the Battenkill, 1½ miles west of Vermont line, in Salem, Washington County, N. Y.

CLEAVAGE BANDING.

One of the more interesting developments of slip cleavage is shown in figs. 88 and 89, from the schist and slate region of Salem and White Creek, in Washington County, N. Y. In fig. 89 the weathered bed of coarsely plicated quartzose limestone indicates plainly the direction of

[1] Archibald Geikie, Report on the recent work of the Geological Survey in the northwest Highlands of Scotland, etc.: Quart. Jour. Geol. Soc., London, 1888, Vol. XLIV, p. 432, fig. 23. See, also, his Text-Book of Geology, 3d ed., 1893, p. 706, fig. 335.

the bedding. The slippage due to cleavage seems to have been mostly confined to certain narrow belts or bands, which recur at intervals of a foot or so. This appears to be the result, in some cases, of the inequality of the limbs of the plications and of the slippage occurring at the apex of the fold and within the shorter limb (see fig. 88). The effect is to give the rock a somewhat stratified appearance in the cleavage direction, i. e., across the stratification. My assistant, Mr. Louis M. Prindle, recently found in Bennington County, Vt., 1½ miles west of Rupert and one-fourth of a mile east of the Hebron (N. Y.)

FIG. 89.—Photograph of slate ledge (phyllite) on the southeastern foot of Goose-egg Hill, in White Creek, Washington County, N. Y., looking north along the strike, showing, in upper part, a coarsely plicated easterly dipping bed of quartzose limestone eroded so as to leave a series of small caves in which ferns are growing. Above and below and parallel to this bed are the coarse plications of the noncalcareous slate, with a coarse slip cleavage, forming here and there cleavage bands. One of these traverses the calcareous bed, having withstood erosion. Hammer handle, 30 inches long.

line, some shales in which this structure is still more highly developed (see fig. 90).

The rock is plicated in roundish folds measuring in places about an inch in diameter. Each fold is gently arched for a space of one-half inch to 2 inches, and this portion of the rock appears massive; but under the microscope it shows about 360 imperfectly developed slip cleavage planes to the inch, which are vertical to the tops of the arches. The shanks of the folds are very long (measuring at least 1½ inches in about one-fourth of an inch thickness of rock), and make an angle of only about 20° to 40° with the cleavage. The cleavage within that part of the rock traversed by the shank of the folds, although not any more minute than in the arches, is much more continuous, and there breaks up the rock into slaty laminæ. Along these shanks, therefore, most of the motion has taken place. The general appearance of the rock is that of a series of alternating beds measuring about one-fourth of an inch and three-fourths of an inch, respectively, or even more, but running transversely to the actual bedding. The change in the course of the cleavage is here not due to a change of material, but to a change of motion in the same material.[1]

Furthermore, there appears under the microscope a ferruginous staining along the cleavage of the more slaty bands (see fig. 91). Under higher magnifying powers the muscovite scales, which, together with quartz fragments, largely make up the rock, lie nearly all with their axial planes in the bedding planes of the rock instead of in that of the cleavage.[2]

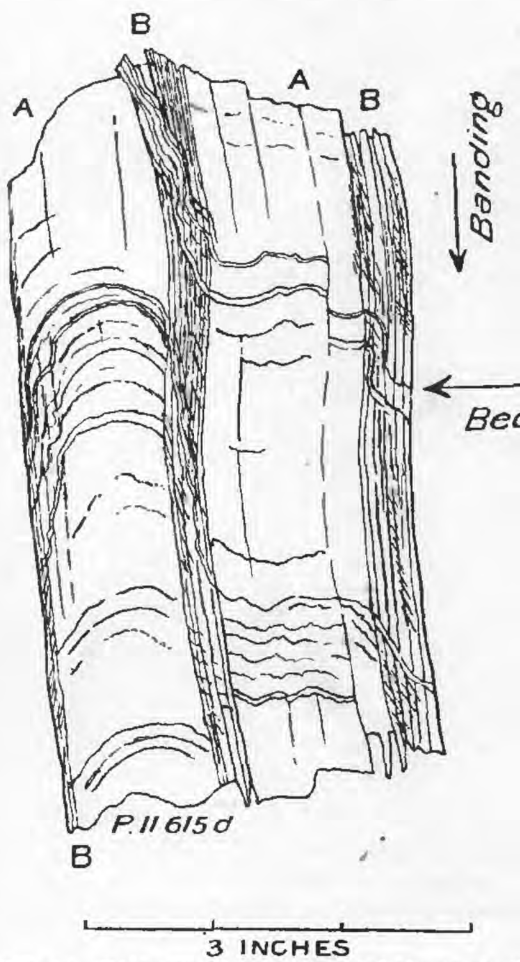

FIG. 90.—Diagram of specimen of shale, or phyllite, from near Rupert, Bennington County, Vt., showing the development of cleavage banding along the shanks of the plications, giving the rock the appearance of being stratified across the real bedding.

This cleavage banding may explain some perplexing localities where there appears to be a distribution of different coloring materials in parallel belts across the bedding. Such color bands seem to be due to the unequal development of cleavage. The more highly cleaved belts more readily admit percolating waters holding various iron compounds in solution, which they deposit within the cleavage foliation, while the less highly cleaved belts, being less permeable, show less staining or preserve the original color of the rock. The result is a rock striped in two colors or in several

[1] Since the preparation of this paper this locality has been revisited and photographed, for future publication. Cleavage banding is not infrequent in Washington County and the adjacent parts of Vermont.

[2] This rock possesses the character of a shale (mica scales and numerous quartz fragments), and in places that of a phyllite or slate (sericite fibers).

shades across the bedding. Such alternations of color or shade are naturally taken as indications of bedding, and the stratigraphy is confused. See fig. 92.

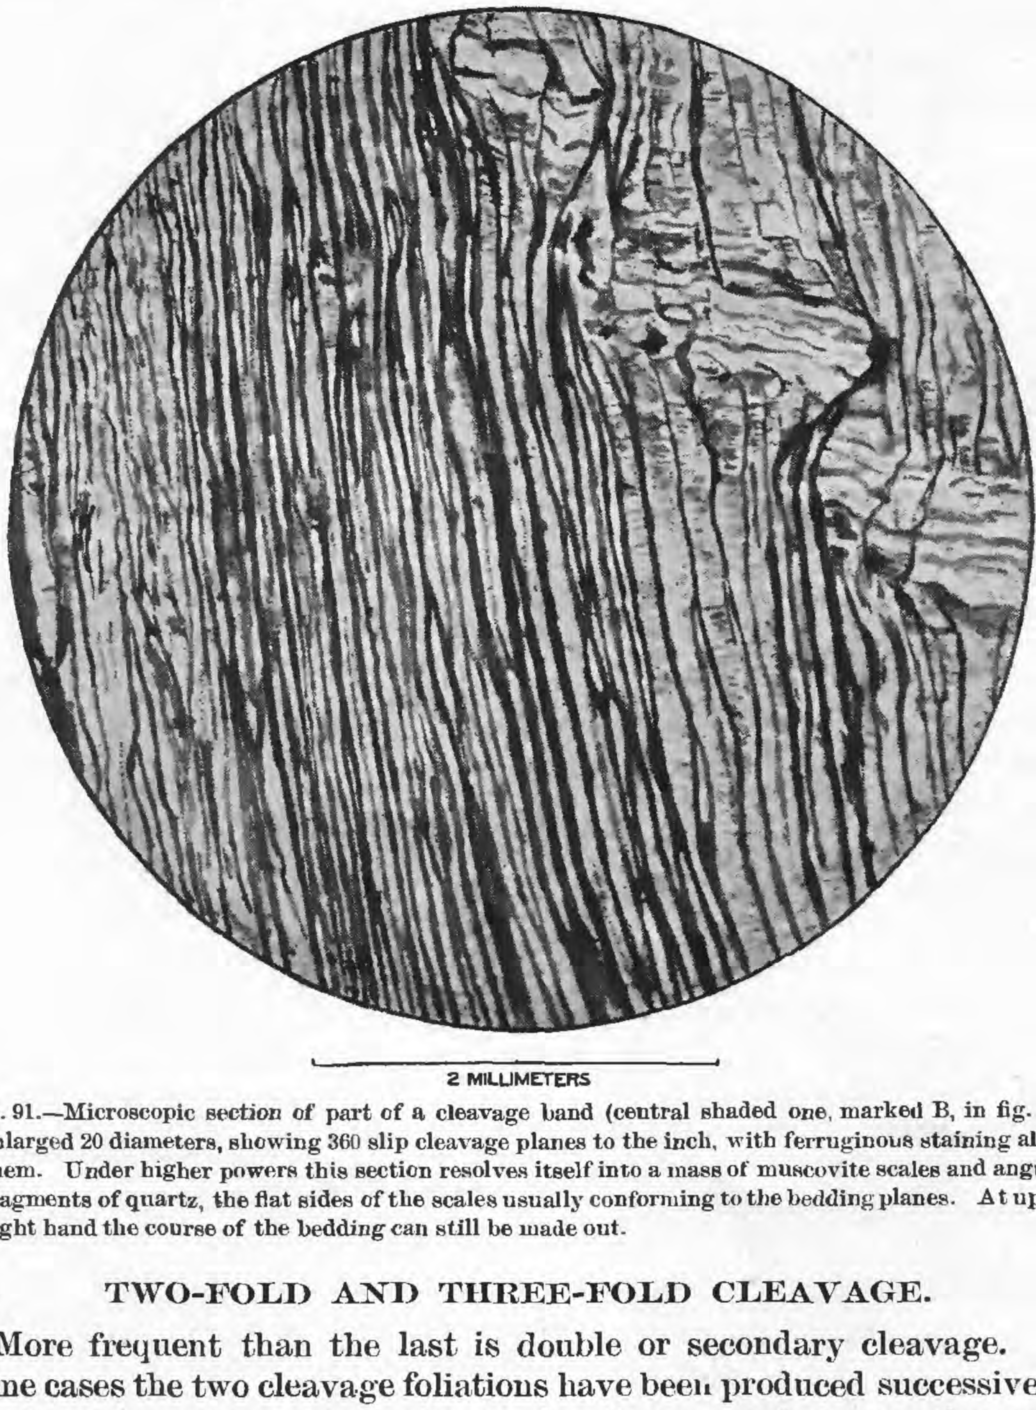

FIG. 91.—Microscopic section of part of a cleavage band (central shaded one, marked B, in fig. 90), enlarged 20 diameters, showing 360 slip cleavage planes to the inch, with ferruginous staining along them. Under higher powers this section resolves itself into a mass of muscovite scales and angular fragments of quartz, the flat sides of the scales usually conforming to the bedding planes. At upper right hand the course of the bedding can still be made out.

TWO-FOLD AND THREE-FOLD CLEAVAGE.

More frequent than the last is double or secondary cleavage. In some cases the two cleavage foliations have been produced successively, as shown by microscopic sections. In other cases, however, they may have arisen simultaneously by complex pressure. In fig. 93 both cleavages are distinct. The bedding is shown by the course of the quartz veins. The difference in the size and number of the plications in the same vertical series is noticeable here, the broad fold of the thicker material corresponding to several smaller folds of the thinner material. This accords with numerous observations that the less tenacious the material the smaller the folds.

In fig. 94 a hand specimen of slate from Petersburg, Rensselaer County, N. Y., shows three cleavage foliations crossing the bedding, which is distinctly marked by changes in sediment. Of these, Cleavage I is the usual slip cleavage, striking with the bedding. Cleavage II, striking at right angles to the bedding, is what the French call "longrain,"[1] and is analagous to much of the coarse jointing observed in our slate regions, and probably to the "grain" of our Welsh quarrymen. Cleavage III is diagonal to the other two. There need be no limit to the number of foliations which may be set up in such a fine-grained rock by pressure from varying directions and the resultant motions of the particles. At Cavendish, Vt., a mass of limestone at its contact (a fault plane) with a gneiss has five foliations crossing the bedding plane. English geologists have long ago described similar instances.

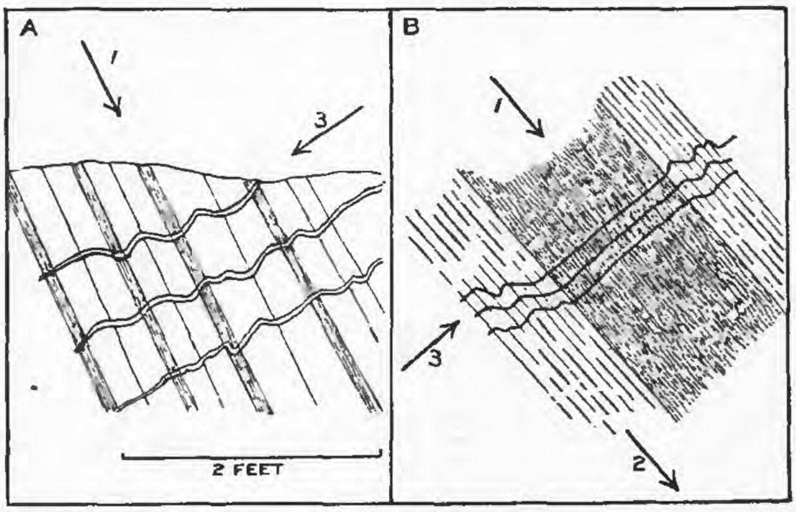

FIG. 92.—A. Diagram of ledge of micaceous slate near Ash Grove in White Creek, Washington County, N. Y., showing plicated quartz veins (3), dipping west across light and dark bands of shale (1 and 2). If the quartz is in a plicated cleavage then the bands represent bedding; otherwise the bands are cleavage bands. B. Microscopic section of slate from Conanicut, R. I., showing plications crossing greenish (2) and reddish (1) bands. Unless the plications represent cleavage the banding originated as in fig. 90. Compare A. Geikie, Text-Book of Geology, p. 546, fig. 258, which shows a plication of the cleavage at contact of two dissimilar rocks.

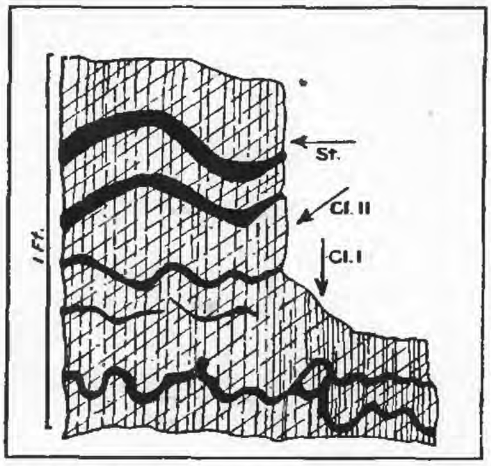

FIG. 93.—Diagram of part of a ledge of chloritic sericite-schist in the southwestern part of Salem, Washington County, N. Y., showing quartz laminæ in the stratification and two cleavage foliations across it. The two upper laminæ may be quartzite.

CLEAVAGE ALONG FAULT LINES.

The beds near a fault have usually been exposed to great compression, and in them, if the material be favorable, cleavage may be expected. Where the cleavage has originated with the faulting, it will usually be found to be parallel with the fault plane. When the actual fault plane

[1] Ed. Jaunetaz, Mémoire sur les clivages des roches (schistosité, longrain) et sur leur reproduction: Bull. Soc. Géol. France, ser. 3, Vol. XII, p. 211, 1884.

has not been exposed the strike and dip of the cleavage adjacent to it afford indications of its probable direction. This parallelism is shown in fig. 95.

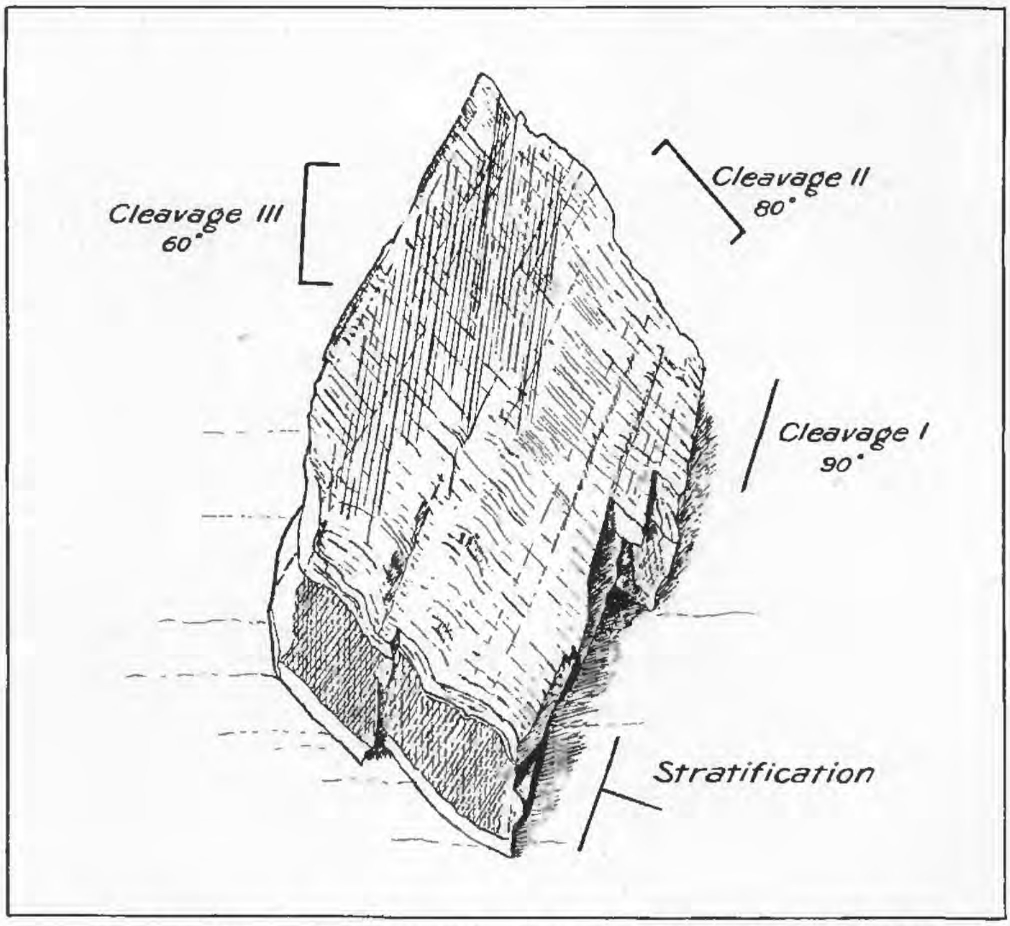

FIG. 94.—Sketch of specimen of phyllite (slate) from Petersburg, Rensselaer County, N. Y. Size, 4 by 3½ inches. The bedding, indicated by small calcareous beds, is crossed by three cleavage foliations. The dips of Cleavages I and III are seen crossing each other on the front end.

THE BEGINNING OF A CLEAVAGE PLANE.

As the microscopic study of massive crystalline rocks impresses one with the chemical changes which their constituent minerals have undergone, so the microscopic study of sedimentary rocks in such a folded region as that of the Green Mountains impresses one with the movements which have affected their particles. Indeed, the evidences of motion are so clear that it requires but little imagination to conceive of the particles as moving into their present relations on the stage of the microscope. Figs. 96 and 97 show how the undulatory motion imparted

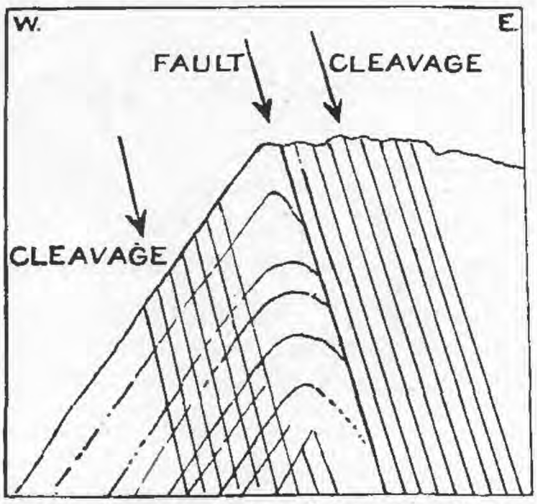

FIG. 95.—Diagram of ledge of shale, 3 by 4 feet, in Brunswick, Rensselaer County, N. Y., showing relation of cleavage to faulting.

to the stratification laminæ and sericitic fibers became so sharp as to fracture them and start a plane of slip cleavage.

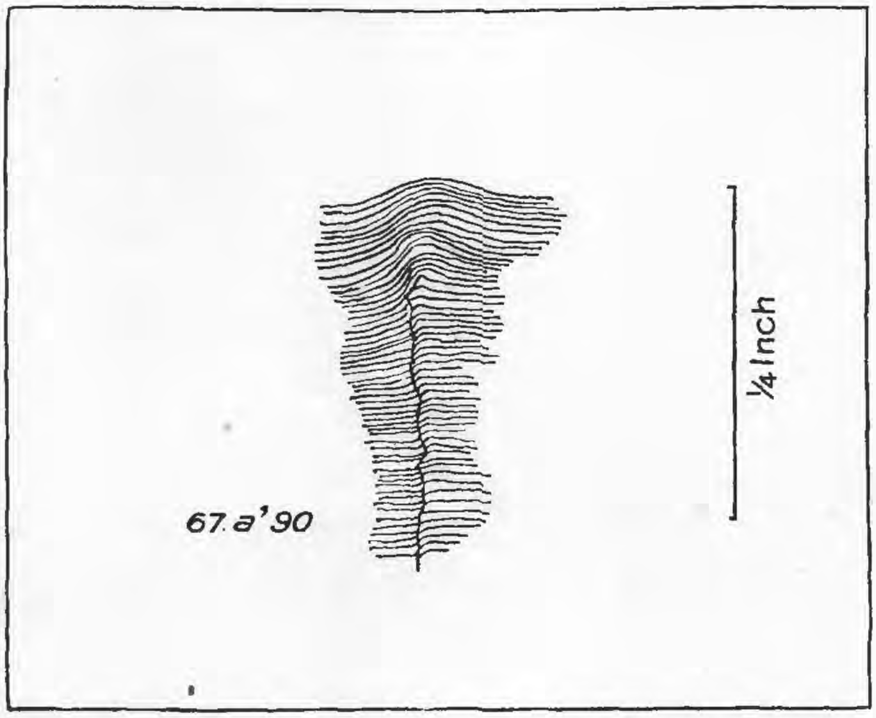

FIG. 96.—Microscopic section of phyllite (slate) made across the bedding from near North Stephentown, Rensselaer County, N. Y., showing a fold giving rise to a plane of slip cleavage.

EVIDENCES OF STRETCHING.

Every geologist is familiar with the fact that in the great mountain-making movements rocks have not only been powerfully compressed, but stretched. Indeed, stretching is one of the results of compression. The elongation of pebbles in conglomerate, the separation within the rock of the fragments of a crystal, or of the fragments of an elongated fossil, are all evidences of stretching. Fig. 98 represents a horizontal surface of grit in which appear bedding, cleavage, and joint planes intersecting one another at various angles. In the direction of the cleavage a series of more or less parallel openings has been formed and filled with quartz. While these openings may have been produced

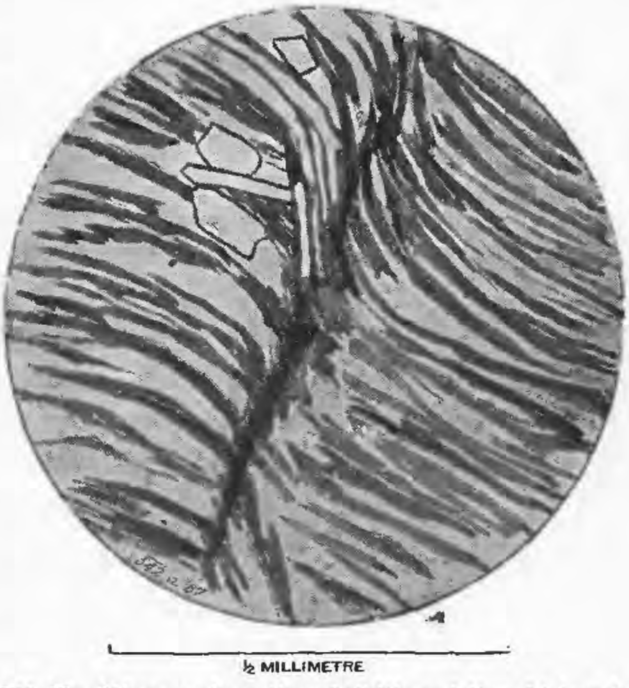

FIG. 97.—Microscopic section of albitic sericite-schist made across the bedding from Mount Greylock, Mass., showing a fold giving rise to a plane of slip cleavage. Enlarged 80 diameters.

by a shearing pressure, the result, in any case, has been to open the rock in the direction of the double arrow and permit the infiltration of quartz. The rough parallelism of the quartz lenses and their shapes convey a notion of the strain to which the rock must have been subjected.

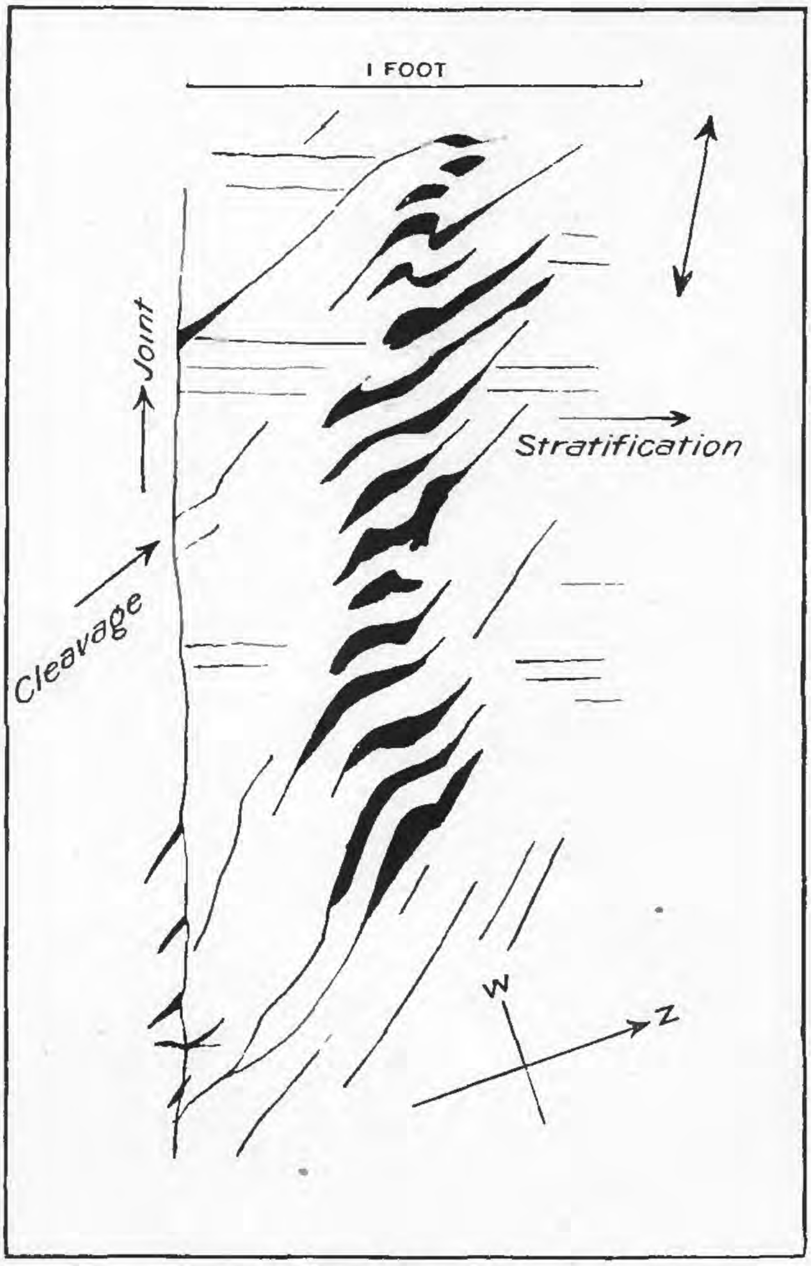

FIG. 98.—Sketch of horizontal surface of ledge of grit in Grafton, Rensselaer County, N. Y., showing bedding, jointing, and cleavage. A series of parallel gaps has been formed in the cleavage foliation and filled with quartz, showing the direction in which the rock has been stretched.

BRECCIATION AND BRECCIATION-PEBBLES.

In the Cambrian-Silurian belt, between the Hudson and the States of Massachusetts and Vermont, conglomerates and breccias are of frequent occurrence. Fig. 99 represents a Cambrian calcareous sandstone in which the grains of quartz sand are mostly spherical. The sandstone was evidently once interbedded with small layers of limestone. The relations of the fragments, however interpreted, show a horizontal, if not also a vertical, compression. Some of the fragments may have suffered from solution within the rock mass since the brecciation.

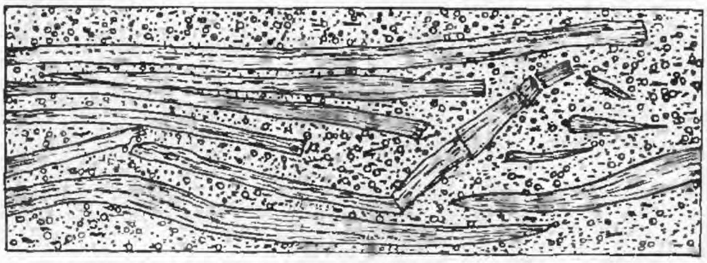

Fig. 99.—Sketch of specimen of calcareous sandstone, about one-third natural size, from south of Lake Aries, in North Greenbush, Rensselaer County, N. Y., showing several small beds of limestone broken up and pushed across one another.

Mr. Aug. F. Foerste, in a manuscript report on the geology of the vicinity of Troy, N. Y., made in 1892, gives a diagram, reproduced in fig. 100, illustrating his observations there. This shows the conversion of a small bed of limestone within a mass of shale into roundish pebbles by means of pressure. It is really the process of slip cleavage isolating the longer limb of each fold.[1] The rounding of the fragments thus formed may have been completed by the dissolving action of acid waters under pressure. Beds of such "pebbles" inclosed in shale form extensive deposits in Columbia, Rensselaer, and Washington counties, N. Y. These brecciation-pebbles might be taken for concretions or beach pebbles. True conglomerates, however, also occur in the region

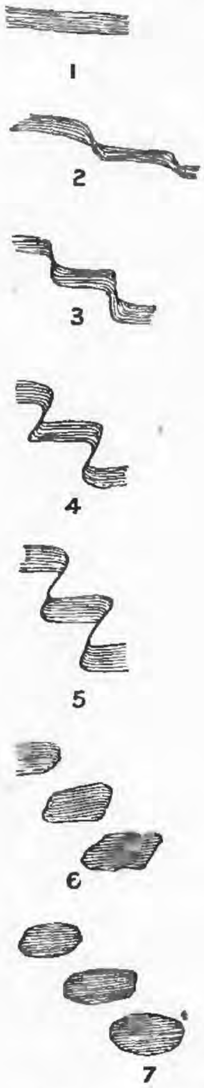

FIG. 100.—Diagram showing the development of nodules (brecciation-pebbles) of limestone by the plication and cleavage (slip cleavage) of a small bed of limestone within a mass of shale, as observed near Troy, N. Y., by A. F. Foerste.

CONCLUSION.

All the phenomena described—inclined, overturned, and transverse folding, unequal folding, false bedding, obscuration of bedding by cleavage, differential cleavage, cleavage banding, two-fold and three-fold cleavage, cleavage along fault lines, stretching, brecciation and the formation of brecciation-pebbles by slip cleavage, and various siliceous replacements or infiltrations—these may characterize any region of crumpled, more or less metamorphic, argillaceous, calcareous, and quartzose sediments. Although the modes of stratigraphic deformation are many, and

[1] Compare J. E. Marr, On some effects of pressure on the Devonian sedimentary rocks of North Devon, Geol. Mag., Dec. III, Vol. V, p. 219, London, 1888.

rarily, it is probable that the material flowed to its new position quietly, without shock, under the enormous stress to which it was subjected.

Even if in the zone of flowage, the relative thickness and strength of the members folded will play their part. If the mass were exactly homogeneous it would flow in the direction of least resistance, like a mass of tallow. But the rock masses are heterogeneous, and the alternating layers of different plasticity may retain their individuality, there being no considerable commingling of the materials of one layer with others (Pl. CXI). The strong, thick beds will greatly vary the direction of movement of the material at a given place, and thus, as explained by Willis, develop folds of great length and amplitude.

FIG. 101.—Thin section of a mashed quartz-porphyry.

On account of their relatively resistant character when bent into anticlines and synclines, the anticlines will be able to carry part of the superincumbent load, and thus relieve to some extent the softer beds below, which, however, as a consequence, promptly flow in the direction of relief or least resistance, and ever press against the confining arch, and thus do their part, which may be the major part, of carrying the superincumbent load. In a similar manner the strong formations bent into synclines because of the thrust transmitted along their limbs, furnished in part by the weight carried by the adjacent anticlines, will give increased pressure to the softer beds below and add to the ordinary thrust which is already forcing the material to follow the arches

subjected to forces continuing for a short time, it may be doubted whether this property is of importance in considering the slowly acting and long-continued forces of rock folding, except perhaps in the slight flexures of great extent. Single rock beds, when much deformed, are rather to be compared to a wrought-iron bar, which when bent takes a permanent set. In this case there is an actual flowage of material or rearrangement of the particles to the new conditions. The half of the bar on the convex side, subjected to tension, is lengthened, and, to compensate it, is of less cross-section than originally. The half of the bar on the concave side, subjected to compression, is shortened, and, to compensate it, is of greater cross-section than originally. Each homogeneous rock stratum when bent acts like the iron bar to a certain extent. There is rearrangement of its material to new positions, and when the bending occurs without fracture the movements of the rock particles may be like those of the particles of the compressed part of the iron bar. But rock beds are usually composed of different mineral constituents, which differ from one another in strength, in hardness, in

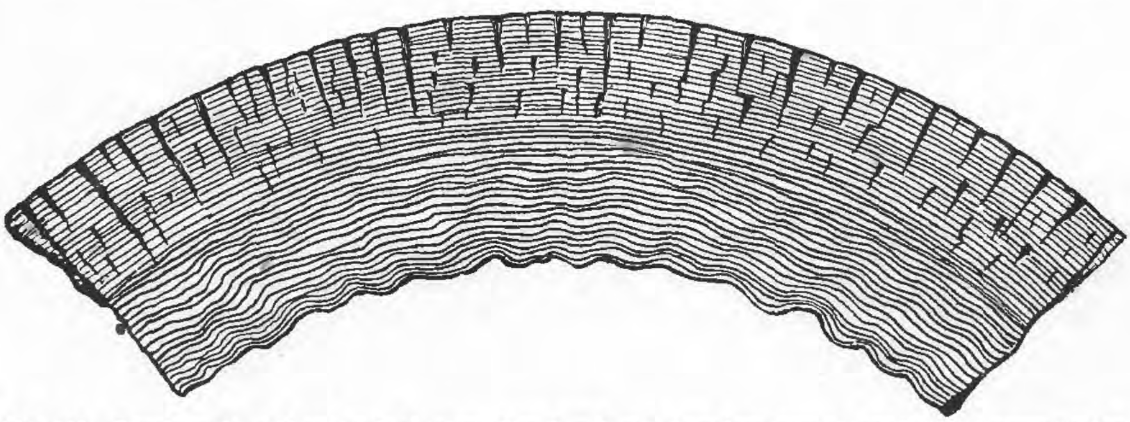

FIG. 102.—Ideal section of bent rock stratum showing fracturing along convex surface and compression along concave surface.

brittleness, in elasticity, and in size. The necessary rearrangement of the mineral particles will more largely affect the weak, small particles than the large, strong ones. However, as shown by microscopical study, when a district is closely folded, no particle of a rock stratum, small or great, simple or complex, weak or strong, escapes the effects or fails to take part in the necessary readjustment of folding (fig. 101).

If a rock stratum could be bent without fracture in such a position that the superincumbent weight were slight, about one-half of the bed, like the iron bar, would be elongated, and the other half would be compressed. Between the two there would be a neutral plane.

As rock beds are brittle they act differently from an iron bar when bent to any considerable degree. Beginning at the middle of the mass in the trough or crest of the fold and passing toward the convex surface, the first lamina is under tension, the second under greater tension, and so on, each stratum being stretched more than the preceding. The tensile force may go beyond the limit of elasticity and radial cracks will be formed (fig. 102). Beginning again at the center and passing

Further, secondary structures nearly parallel to the beds may develop on the limbs, while upon the anticlines and synclines the secondary structures form across the beds. It follows that on the anticlines and synclines, where there is most crenulation and puckering of the laminæ, the original structures will be less altered, and the clastic characters in sediments, such as sandstones and conglomerates, are likely to be preserved. Upo the other hand, upon the limbs of the folds the obliteration of fragmental characters may be complete. We therefore have the paradox that where there is most crenulation there is least meta-

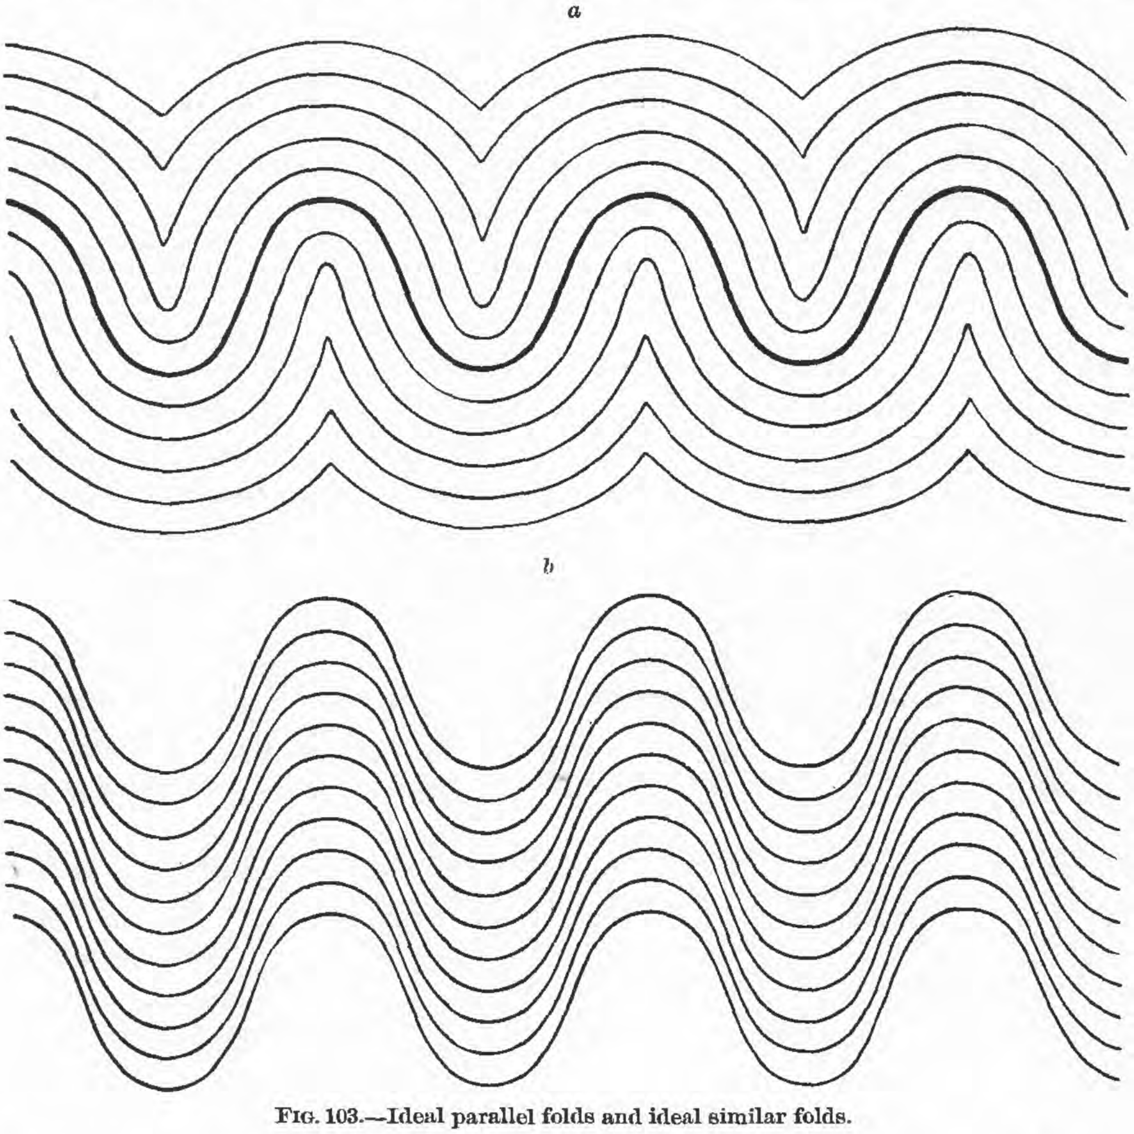

FIG. 103.—Ideal parallel folds and ideal similar folds.

morphism; where least crenulation, most metamorphism. This of course applies only to the different positions of the rock in the fold, not to a gently folded district as compared with a more closely folded area.

But rock beds as they occur in nature differ from the bunch of paper in that they are of varying thickness and strength. The major readjustments of the rock beds occur between the thick and strong strata, and within the weak and soft strata (fig. 133). In these latter, therefore, the rearrangement of the particles is far more profound than would be the case if such beds were folded alone. The polishing effects of

of the comparison is to give at the outset some idea of the complexity of rock folds.

Tangential thrust and gravity are assumed to be the causes of folds. No attempt will be made here to show this or to explain the cause of thrust, although in the last analysis it is probable that thrust is dependent upon gravity. At all times and in all positions rocks are subject to the force of gravity. Thrust and gravity act upon rocks of heterogeneous character. Rock heterogeneity, therefore, modifies the forms of folds. Folds are further modified by igneous rocks. In what follows, the effects of igneous rocks are at first excluded.

We shall now attempt to analyze the rock waves or folds. For convenience, they will first be considered in two dimensions.

SIMPLE FOLDS.

Simple folds are classified by de Margerie and Heim[1] as follows: A fold is upright or symmetrical when the axial plane is vertical, or nearly so, and the limbs have nearly equal dips in opposite directions at corresponding points (fig. 104).

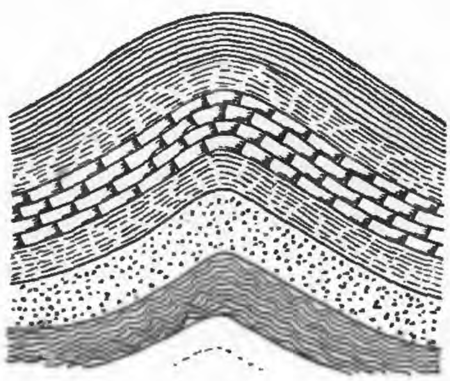

FIG. 104.—Simple upright fold.

A fold is inclined or unsymmetrical when the axial plane is inclined and the limbs have unequal dips in opposite directions at corresponding points (fig. 105).

A fold is overturned or overfolded when the axial plane is inclined and the limbs have equal or unequal dips in the same direction at corresponding points (fig. 106). An overturned fold is lying or recumbent when its axial plane is horizontal, or nearly so (fig. 107). The different parts of an overturned fold are the arch limb, reversed limb and trough limb (*a*, *b*, *c*, fig. 107).

As to closeness of compression, folds are described by de Margerie and Heim as follows: An ordinary fold is one in which the strata diverge from the crest of the anticline and the trough of the syncline (figs. 105–107). Ordinary folds may be described as gentle, open, or close. In close folds, according to Willis, the process has gone so far that the strata are perceptibly changed in

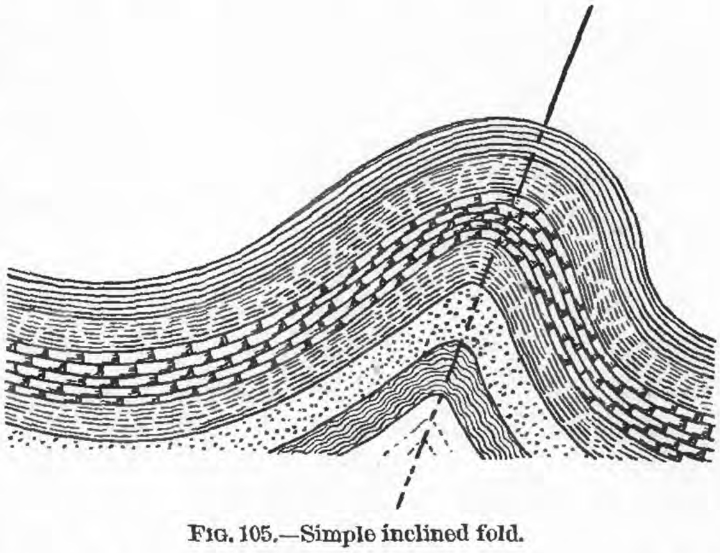

FIG. 105.—Simple inclined fold.

[1] Les dislocations de l' écorce terrestre, par Emm. de Margerie et Albert Heim, Zürich, 1888, pp. 49–63.

thickness in different parts of the fold. An isoclinal fold is one in which the strata are parallel, or nearly so (fig. 108). A fan fold is one in which the strata converge downward from the crest of the anticline (fig. 112). In this case the strata at the limbs of the fold are always greatly thinned, and in some instances the central strata are absent, the material having flowed up and down, forming detached arch cores and detached trough cores. An ordinary, isoclinal, or fan fold may be upright, inclined, or overturned.

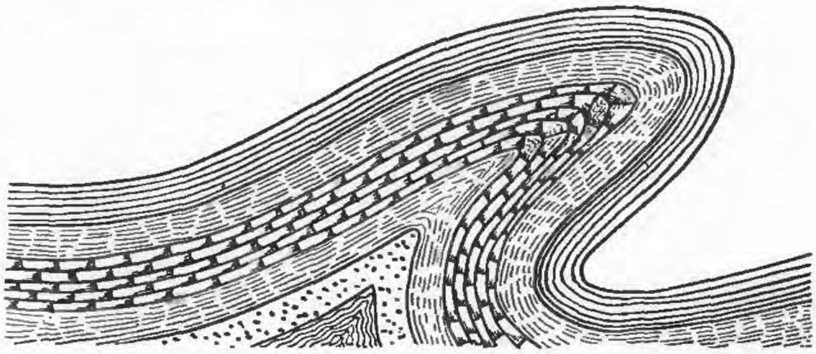

FIG. 106.—Simple overturned fold.

In the formation of the simple fan-shaped anticline the rocks are extremely compressed on the limbs of the fold, while on the anticline the compression is not so severe. This is doubtless due to the partial escape from pressure of the material which rises into an arch, as compared with the deeper-seated material in the limbs of the folds, which constitutes a part of the continuous crust of the earth in which the major thrust must have been transmitted. Another factor is the relative strength of the layers. A strong stratum may deform weaker layers, geologically below, into the fan form by producing

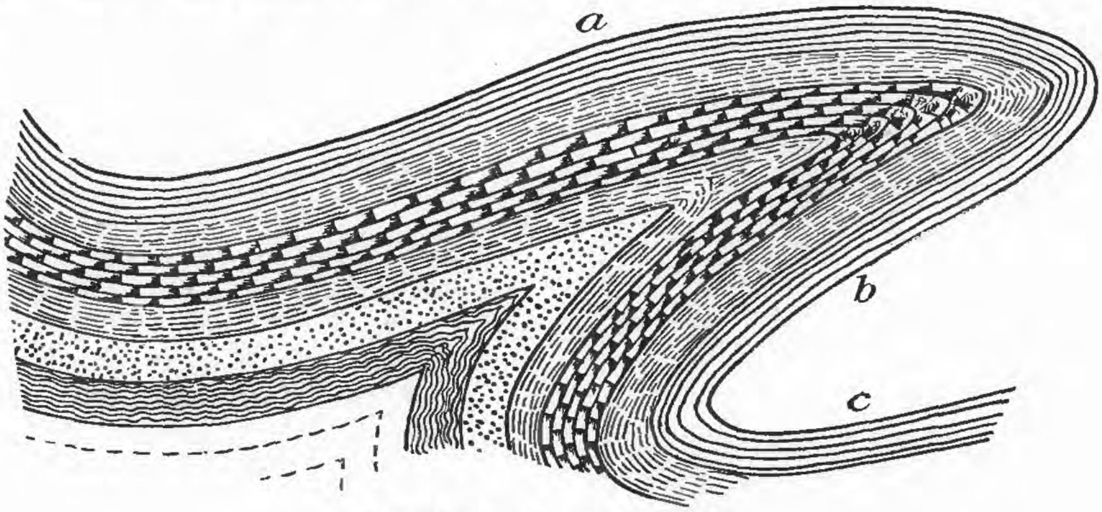

FIG. 107.—Simple recumbent fold.

flowage in them. The formation of the fan fold may be further assisted by the tendency of rocks to bend farther at a place where deformed rather than to bend in a new place. The different phases of the formation of fan folds are illustrated in the Jura. In the folds of certain parts of the Jura one is impressed with the flatness of the anticlinal domes and the synclinal troughs, the steepness of the limbs, and the rapidity of the change from flat dips at the anticlines and synclines to nearly vertical dips on the limbs of the folds (fig. 109*a*). So quick is the change that the folds may be said to have corners, where the beds are bent in a circular fashion almost within their own radius. In the more closely compressed folds the beds constituting opposite limbs of the folds are overturned in opposite directions, thus producing a true fan fold (fig. 109*b*). It is clear that the material of the domes partly escaped the thrusts which were transmitted in the solid rocks below. This thrust from both directions pressed the lower parts of the limbs closer

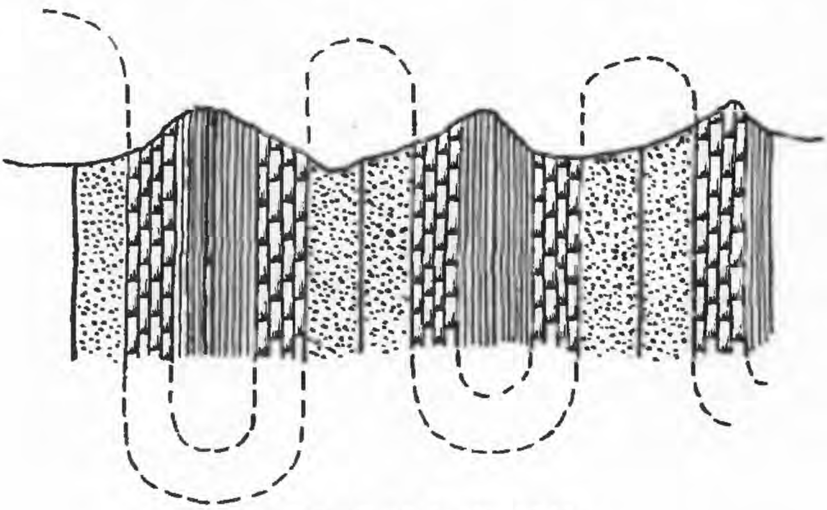

FIG. 108.—Simple isoclinal folds.

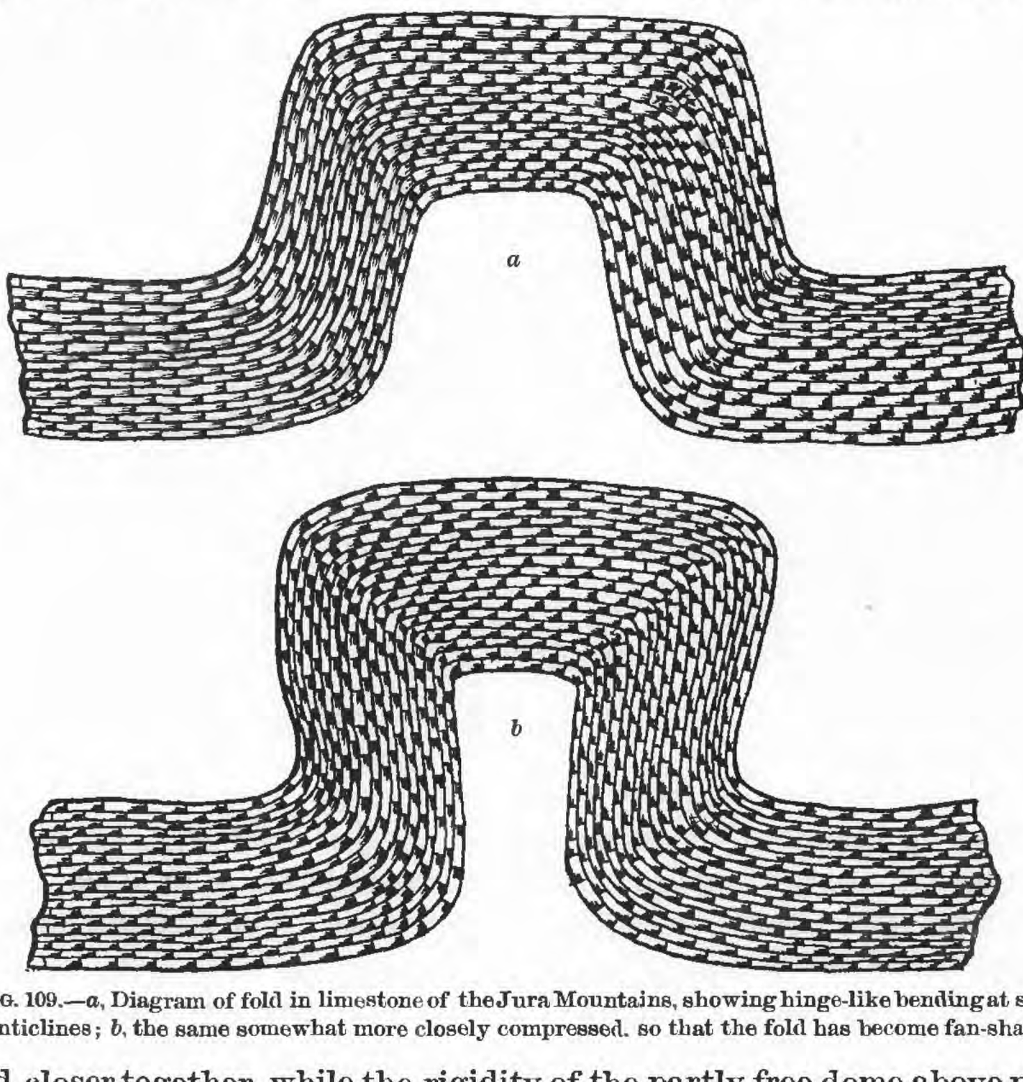

FIG. 109.—*a*, Diagram of fold in limestone of the Jura Mountains, showing hinge-like bending at sides of anticlines; *b*, the same somewhat more closely compressed, so that the fold has become fan-shaped.

and closer together, while the rigidity of the partly free dome above prevented the upper part of the legs from following, and thus the limbs were

the great geological province or basin of deposition of which the Jura, the great valley of Switzerland, and the Alps occupy a part, was a geosyncline. When subjected to orogenic forces the mountain ranges now seen were produced. The Alps and Jura taken as wholes are anticlinoria of the first order, and the great valley between is a synclinorium of the first order.

The various kinds of simple folds may be united to produce a great variety of composite structures. A composite fold may be an anticlinorium or a synclinorium. An anticlinorium or synclinorium, like a simple fold, may be upright, inclined, or overturned, but it is probable that in composite folds of the first order of magnitude the last rarely if ever occurs.

Taking as axial planes the radial planes of the primary fold, the secondary folds may be upright, inclined, or overturned, or on different parts of the same primary fold each form may occur. The radial positions of the axial plane give the proper basis in comparing the dynamic processes and effects of folding, but because we rarely see the whole

FIG. 110.—Ideal section of an upright normal anticlinorium.

of a great anticlinorium or synclinorium at a single view, it is perhaps best to treat both the primary and secondary folds in reference to the plane of the horizon.

Some of the special cases of composite folds are as follows:

NORMAL COMPOSITE FOLDS.

The upright normal anticlinorium.—The primary fold of the upright normal anticlinorium has a vertical or nearly vertical axial plane, and the limbs at corresponding points have nearly equal average dips in opposite directions.

(*a*) The primary fold is composed of a set of secondary folds, each of which is upright or nearly so, taking the radial planes of the primary fold as axial planes of the secondary folds. Referring the axial planes to the horizon, at the crest of the anticline the secondary folds are upright, and in passing in either direction transverse to the primary axial plane the secondary folds are inclined, but not overturned. The two sets of secondary axial planes on opposite sides of the crest of the primary fold diverge upward and converge downward (fig. 110).

(*b*) Composed fan fold. The primary fold is composed of a set of secondary folds which at the crown are upright, and in passing in either direction transverse to the primary axial plane the secondary folds are first inclined and then overturned. The secondary folds may be ordinary, isoclinal, or fan-shaped. The two sets of secondary axial planes on opposite sides of the crest of the primary fold diverge upward and

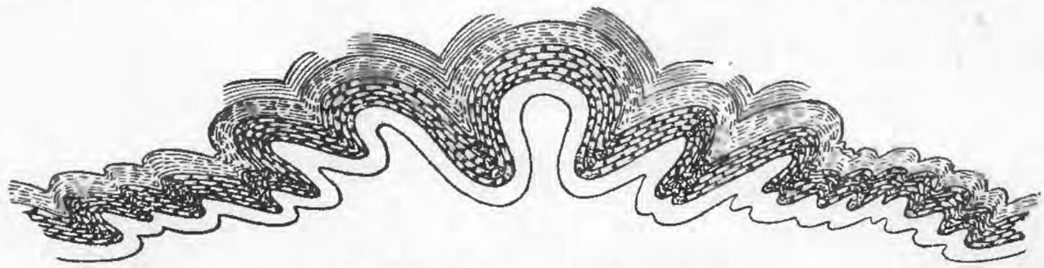

FIG. 111.—Ideal composed fan fold.

converge downward (figs. 111 and 112). Often in extreme cases of compression at the crest of the primary anticline the secondary folds are fan-shaped, and passing in either direction these grade into isoclinal and then into ordinary folds. Such are many of the composite folds of the Alps.

The inclined normal anticlinorium.—The primary fold of the inclined normal anticlinorium has an inclined axial plane and the limbs at corresponding points have unequal average dips in opposite directions. The primary fold is composed of a set of secondary folds which are inclined or overturned. The two sets of secondary axial planes on opposite sides of the crest of the primary fold diverge upward and converge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped.

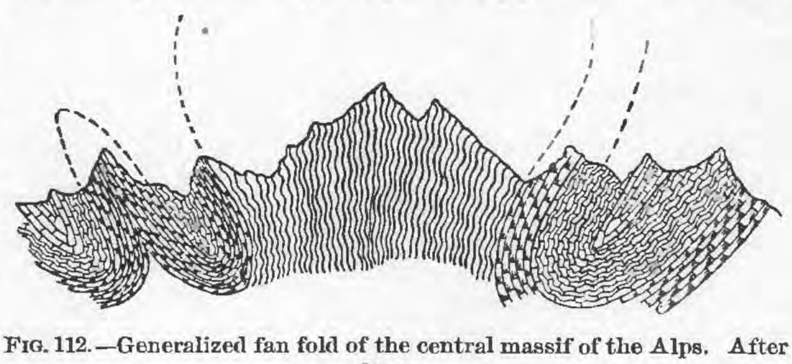

FIG. 112.—Generalized fan fold of the central massif of the Alps. After Heim.

The overturned normal anticlinorium.—The primary fold of the overturned normal anticlinorium has an inclined axial plane, and the limbs at corresponding points have equal or unequal average dips in the same direction. The primary fold is composed of a set of secondary folds, which are overturned in the same direction as the primary fold. The two sets of secondary axial planes on the opposite sides of the crest of the major fold diverge upward and converge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped.

The upright normal synclinorium.—The primary fold of the upright normal synclinorium has a vertical or nearly vertical axial plane, and the limbs at corresponding points have nearly equal average dips in opposite directions.

(*a*) The primary fold is composed of a set of secondary folds, each of which is upright, or nearly so, taking the radial planes of the primary fold as axial planes of the secondary folds. Referring the axial planes to the horizon at the trough of the synclinorium, the secondary folds are upright, and in passing in either direction transverse to the primary axial planes the folds are inclined, but not overturned. The two sets of axial planes on opposite sides of the trough of the major fold converge upward and diverge downward (fig. 113).

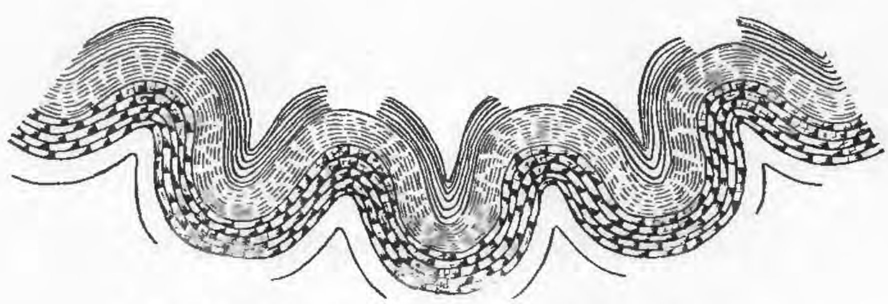

FIG. 113.—Ideal section of an upright normal synclinorium.

(*b*) Inverted intermont trough.[1] The primary fold is composed of a set of secondary folds, which at the center of the trough are upright, and in passing in either direction transverse to the primary axial plane the secondary folds are first inclined and then overturned. The two sets of secondary axial planes on opposite sides of the trough of the major fold converge upward and diverge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped (fig. 114).

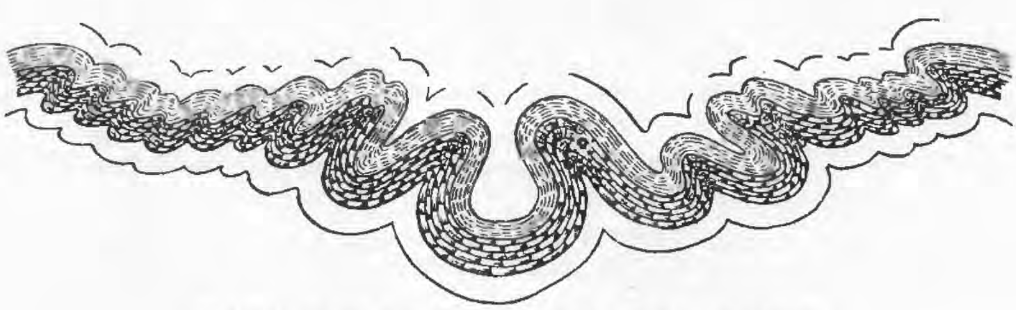

FIG. 114.—Ideal section of an inverted intermont trough.

The inclined normal synclinorium.—The primary fold of the inclined normal synclinorium has an inclined axial plane, and the limbs at corresponding points have unequal average dips in opposite directions. The primary fold is composed of a set of secondary folds, which are inclined or overturned. The two sets of secondary axial planes on opposite sides of the trough of the major fold converge upward and diverge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped.

[1] Les dislocations de l'écorce terrestre, par Emm. de Margerie et Albert Heim, p. 83. Zürich, 1888.

The overturned normal synclinorium.—The primary fold of the overturned normal synclinorium has an inclined axial plane, and the limbs at corresponding points have equal or unequal average dips in the same direction. The primary fold is composed of a set of secondary folds, which are overturned in the same direction as the primary fold. The two sets of axial planes of the secondary folds on the opposite sides of the trough of the major fold converge upward and diverge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped.

ABNORMAL COMPOSITE FOLDS.

The upright abnormal anticlinorium.—The primary fold of the upright abnormal anticlinorium has a vertical, or nearly vertical, axial plane, and the limbs at corresponding points have nearly equal average dips

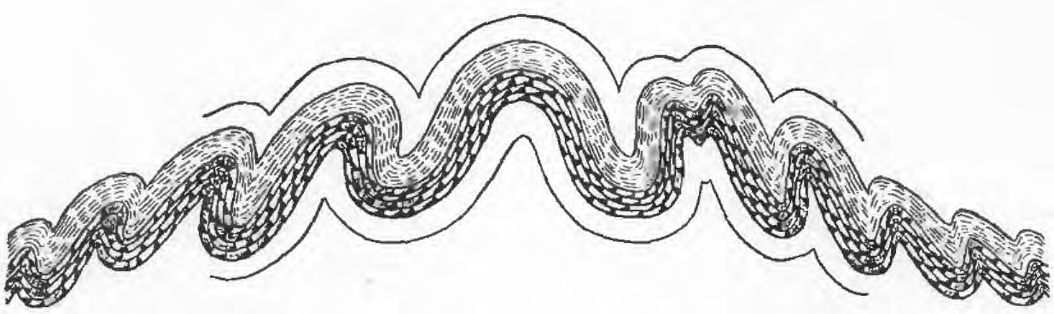

FIG. 115.—Ideal section of an upright abnormal anticlinorium.

in opposite directions. The primary fold is composed of a set of secondary folds, which at the crest are upright, and in passing in either direction transverse to the primary axial plane the secondary folds are first inclined and then overturned. The two sets of secondary axial

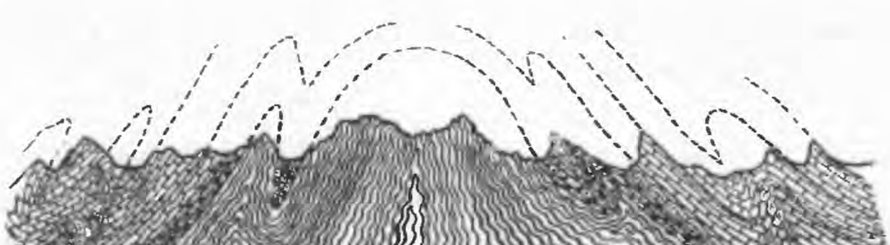

FIG. 116.—General section of roof structure in the central massif of the Alps. After Heim.

planes on opposite sides of the crest converge upward and diverge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped (figs. 115 and 116).

The inclined abnormal anticlinorium.—The primary fold of the inclined abnormal anticlinorium has an inclined axial plane, and the limbs at corresponding points have unequal average dips in opposite directions. The primary fold is composed of a set of secondary folds, all of which are inclined or overturned. The two sets of secondary axial planes on opposite sides of the crest converge upward and diverge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped.

The overturned abnormal anticlinorium.—The primary fold of the overturned abnormal anticlinorium has an inclined axial plane, and the limbs at corresponding points have equal or unequal average dips in the same direction. The primary fold is composed of a set of secondary folds, which are overturned in the same direction as the primary fold. The two sets of secondary axial planes on opposite sides of the crest converge upward and diverge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped.

The upright abnormal synclinorium.—The primary fold of the upright abnormal synclinorium has a vertical, or nearly vertical, axial plane, and the limbs at corresponding points have nearly equal average dips in opposite directions. The primary fold is composed of a set of secondary folds, which at the trough are upright, and in passing in either direction transverse to the primary axial plane the secondary folds are first inclined and then overturned. The two sets of secondary axial

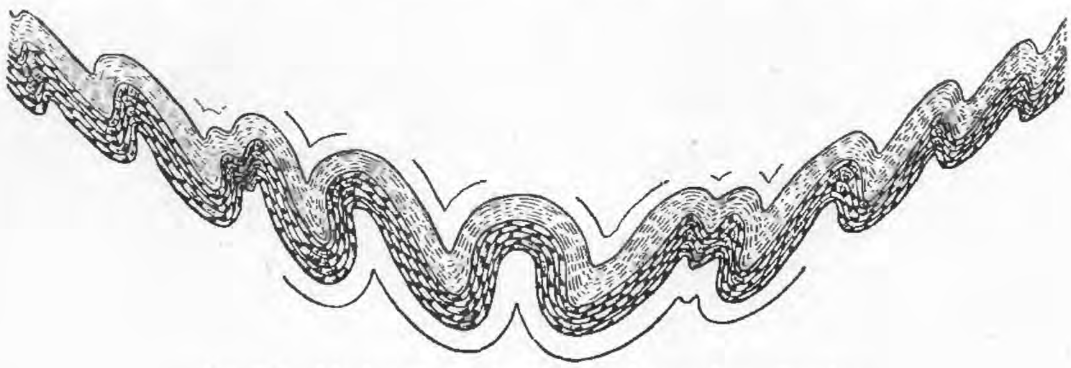

FIG. 117.—Ideal section of an upright abnormal synclinorium.

planes on opposite sides of the trough diverge upward and converge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped (fig. 117).

The inclined abnormal synclinorium.—The primary fold of the inclined abnormal synclinorium has an inclined axial plane, and the limbs at corresponding points have unequal average dips in opposite directions. The primary fold is composed of a set of secondary folds, all of which are inclined or overturned. The two sets of secondary axial planes on opposite sides of the trough diverge upward and converge downward. The secondary folds may be ordinary, isoclinal, or fan-shaped.

The overturned abnormal synclinorium.—The primary fold of the overturned abnormal synclinorium has an inclined axial plane, and the limbs at corresponding points have equal or unequal average dips in the same direction. The primary fold is composed of a set of secondary folds, which are overturned in the same direction as the primary fold. The two sets of secondary axial planes on opposite sides of the trough diverge upward and converge downward.

three-fourths of an inch thick. The sheets may be taken to represent thin beds in a nearly homogeneous rock. Fig. 119 represents this same drawing as it was distorted when the bunch of papers was folded into anticlines or synclines between blocks of wood. It will be seen that, consequent upon the readjustment of the sheets over one another, rendered necessary by the folding, the secondary folds at the crests and the troughs remain upright, although compressed if a secondary anticline or syncline corresponds with a primary fold of the same kind, and dilated if a secondary anticline or syncline corresponds with a fold of the opposite kind, and vice versa. If the secondary folds were slight, the opening might go so far as to obliterate them and the only

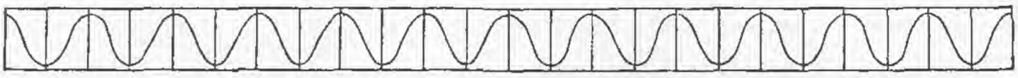

FIG. 118.—Representation of simple symmetrical folds, with their axial planes drawn on the ends of a bunch of smooth paper three-fourths of an inch thick.

remaining effect be to flatten the primary anticlines or synclines. The secondary folds on the limbs of the primary folds are distorted. The readjustment therefore mainly affected the forms of the fold upon the limbs. Taking as their axial planes the radial planes of the primary folds, the secondary folds on the limbs are seen to be inclined. In reference to a primary anticline, the axial planes of opposite folds converge downward; in reference to a primary syncline, the axial planes of opposite folds diverge downward, but both less than they would were it not for readjustment. The above experiment does not exactly represent the conditions in nature, for the accommodations between the beds, instead of occurring parallel to the primary folds, would take place parallel to the secondary folds. However, an examination of the distortion of the axial planes of fig. 118, shown in fig. 119, shows beyond question that when a set of beds are folded which are free to adjust themselves parallel to bedding, the movement of the material in the upper half of the beds is relatively away from a syncline toward an anticline, and the movement of the lower half is away from an anticline toward a syncline; or, stated more generally, the differential movements between the beds on the legs of folds are relatively up in a higher bed or relatively down in a lower bed. It can not be doubted that the sum total of the readjustments between the beds, although they follow the crenulations instead of being exactly parallel to the primary fold, would give the same effect. Therefore there is a tendency in

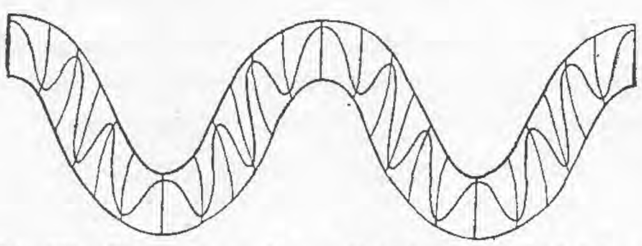

FIG. 119.—The same, as it was distorted when folded into anticlines and synclines.

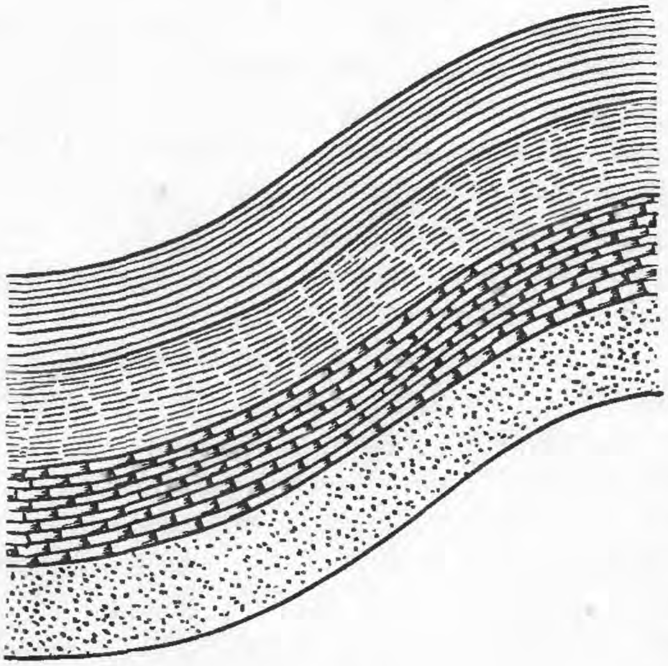
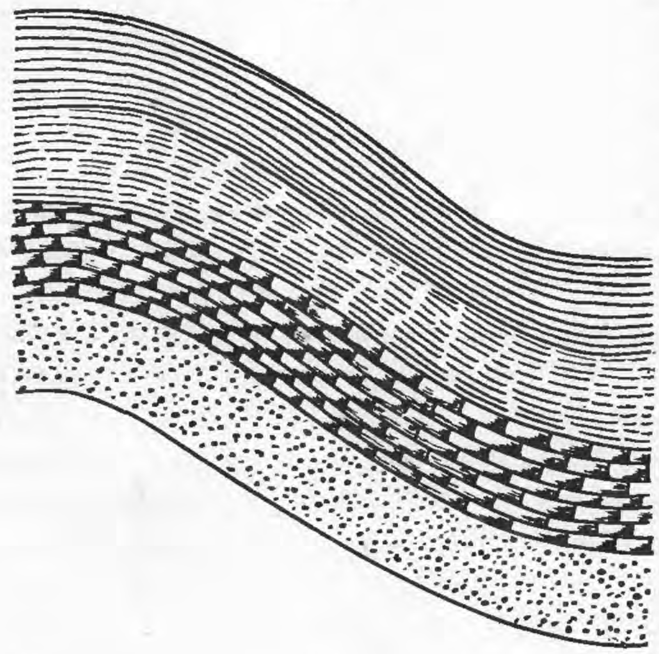
strata and the lessened weight to which the upper strata are subjected are not usually sufficient to prevent thrust and gravity from acting in the ordinary way and producing normal anticlinoria and synclinoria.

In both the abnormal anticlinorium and synclinorium the application of the above causes to their formation are identical. To make this clear the following figures are drawn: Figs. 120 and 121 each represent four strata, the lower two of which are strong and the upper two of which are weak, each figure comprising one-fourth of a wave and the other being its complement. In each case the figure ends on one side at the crest and on the other at the trough of the flexure. There is nothing to indicate whether either is a part of an anticline or a syncline. Each, in fact, may be half of either, for, put end to end in one way, they form an anticline; in the other, a syncline. In both cases the lower rocks constitute a relatively rigid inclined plane. If the superincumbent weight is not too great when thrust occurs, in certain cases the softer rocks above may yield to the forces to a greater degree than do the rigid rocks below, and thus tend to flow over them, and in case the upper strata be much weaker than the lower, or there be a plane of weakness, the differential flow will be largely concentrated along the contact or weak zone, and normal secondary folds which have before developed may be inclined in an opposite direction from their first position, so as to become abnormal. In this case the parts of the composite folds may be represented by figs. 122 and 123.



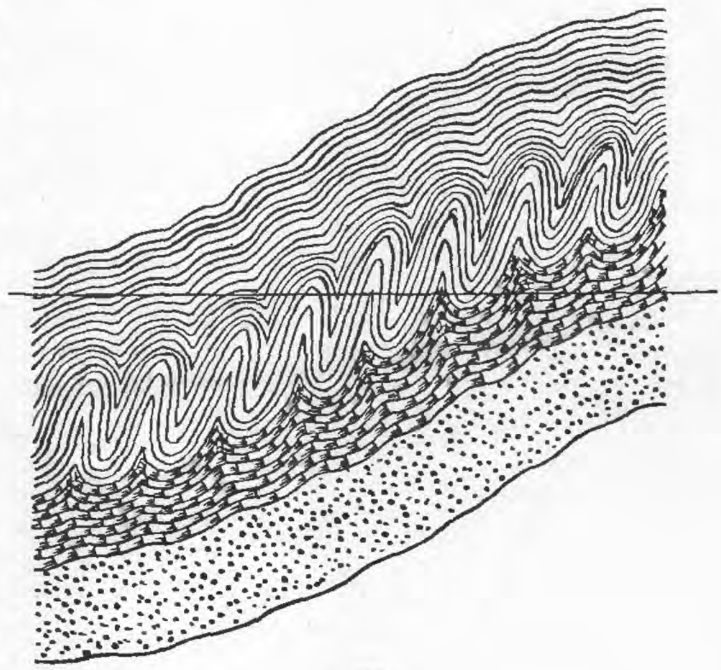
120.



121.

FIGS. 120 and 121.—Obverse halves of an anticline or syncline.

Put together end to end in one way the prominent secondary folds form an abnormal anticlinorium; in the other, an abnormal synclinorium. It will be noted that in passing away from the central zone of plications either into the more rigid rocks below or into the softer rocks above the secondary folds become normal. Considering the two figures put together to represent a great flexed mountain mass, and supposing erosion to truncate the layers to the horizontal line drawn, there would be exposed normal folds at the center of the anticline, abnormal ones upon the flanks, and normal ones at the outer parts of the mountain mass. In nature we can never hope to see such a great composite fold in all its parts. It is only in the great mountain masses where such folds have been dissected that we can get at their character. In such cases the older strata would be expected to show the normal forms, the newer strata the abnormal forms, and the intermediate strata alternations of the two. The change from normal to abnormal and to normal again is apparently that which actually occurs in the Alps from the St. Gothard massif south to the great valley of Switzerland. (See pp. 624–625, and Pl. CIX.)



122.

123.

FIGS. 122 and 123.—Obverse halves of composite folds, showing development of abnormal folds and their relations to normal folds.

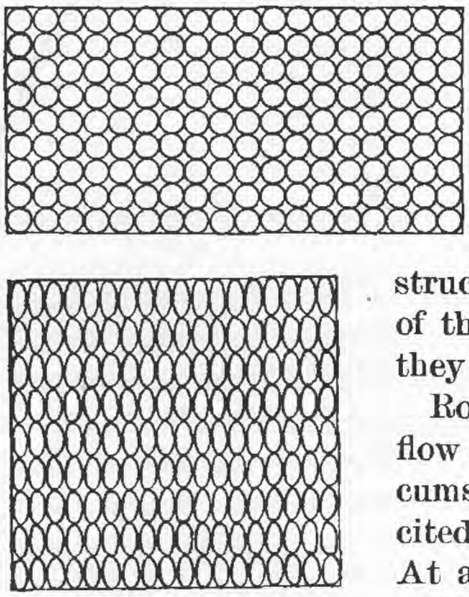
After Heim.

DEVELOPMENT OF CLEAVAGE IN HOMOGENEOUS ROCKS.

Becker has recently rediscussed the origin of cleavage, and concludes that it always develops in the shearing planes rather than in the normal planes. Even in the case of the experimental development of a cleavage structure in wax, which is strictly normal to the pressure, the structure is explained as developing in the shearing rather than in the normal planes.

As will be seen below, it is my own conviction that a structure develops in the normal planes under certain conditions, and that under other conditions structures develop in the shearing planes, as advocated by Becker. The first is believed to be a deep-seated phenomenon of the zone of flowage; the second is believed to be a more superficial phenomenon in the zone of fracture. In other words, as already stated, it is thought that under the term cleavage two entirely distinct structures of different origins have been confused. Theories which explain or partly explain one of these structures have been extended to cover both of them, because it was not understood that they are different.



FIGS. 124 and 125.—Diagrams showing theoretical change in arrangement and form of particles when uniformly shortened by hydrostatic plastic flow.

Rocks when deformed under great weight flow as a plastic solid, and under these circumstances, as shown by the geologists above cited, the property of cleavage is developed. At all times the particles of the rock are welded together (fig. 101). Fissility will not form, for by the supposition the rocks are so deeply buried that no crevices can exist. In the formation of flowage cleavage, or cleavage proper, as the term is here used, the thrust may be from one or more than one direction. It may vary in force both horizontally and vertically. In any case there is flow of the rock mass in the direction of least resistance. If the force be applied so that there is uniform shortening in one direction, as in the case of a rigid piston, the elongation is at right angles to the direction of thrust, or in the normal planes. This may be called *pure shortening* (figs. 124 and 125). By pure shortening is meant the particular kind of nonrotational distortion illustrated. The volume remains unchanged, the shortening in one direction being compensated by equivalent elongation at right angles to this. In this kind of deformation, while there is no differential movement or shearing in the normal planes, shearing does occur along all of the intersecting diagonal planes. It makes no difference whether the movement is wholly from one end of the mass or in part from both ends. But when the lateral force varies greatly at

In case the direction of greatest normal pressure is nearly horizontal, the planes of fissility would be at angles of about 45° with the horizon. However, as no rocks are strictly homogeneous, and as the direction of greatest normal force is always compounded of thrust and gravity, the directions of the shearing may vary considerably.

In case the parting is very close, the rock is foliated. Each lamina moves slightly over the adjacent laminæ. The rubbing of the laminæ over one another, due to the differential movement, gives the slickensided surfaces which are so common on both sides of the parted laminæ. The more intense the movement, the thinner and more brilliant do the folia become. Since the partings are usually inclined to the bedding, this structure may be called *cross fissility.*

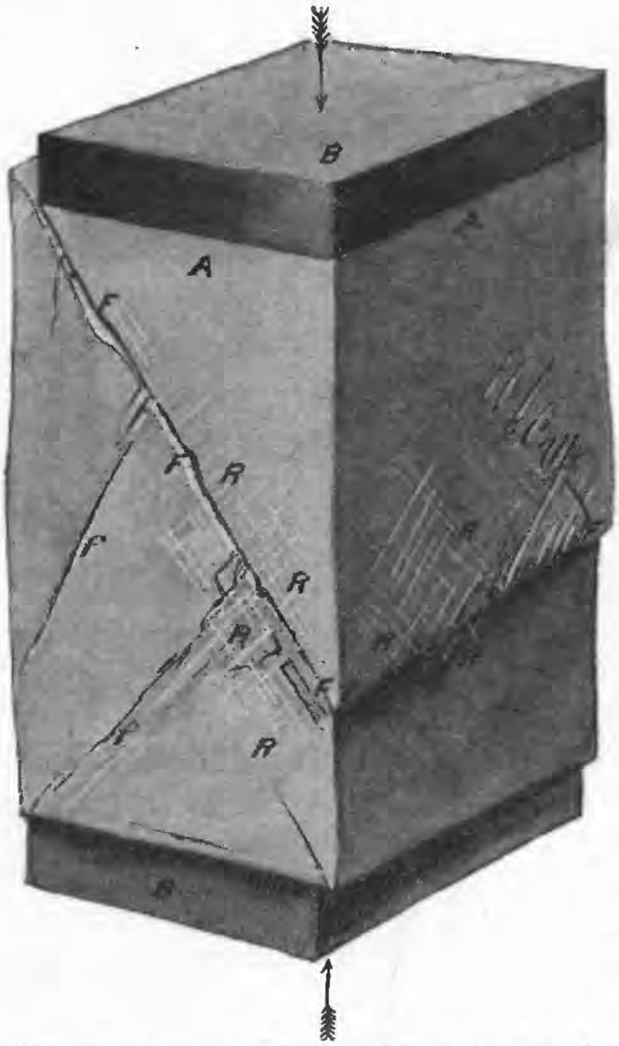


FIG. 126.—Experimental production of fractures along the shearing planes. After Daubrée.

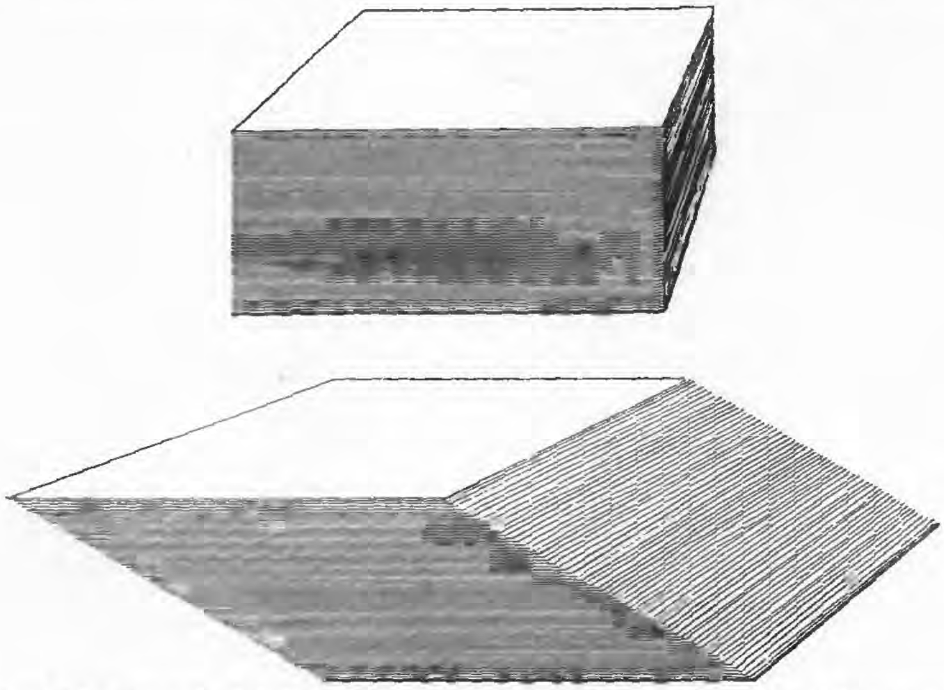
In passing from the zone of fracture to the zone of flow it is to be expected that all gradations would be found between the development of cleavage in the normal planes and the development of fissility in the shearing planes. This point is discussed later. (See p. 654.)

Frequently fissility forms in lithologically homogeneous rocks in which the property of cleavage had already been developed, and which by subsequent denudation are brought so near the surface that the superincumbent weight is less than the strength of the rocks. When subjected to stress under these circumstances numerous fractures develop along the cleavage planes. This occurs because fractures take place so readily along these planes, and because the chances are always that there are shearing planes, although they may not be those of maximum stress.

This may be the case although the direction and force of thrust may not have varied. The direction of greatest normal pressure, combined of gravity and thrust, would be in a different direction when the rocks are in the deep-seated zone of flowage and when they are in the superficial zone of fracture. Thus, cleavage in the normal planes would pass into the shearing planes as denudation progressed.

the laminæ. As a result, the minerals receive an elongation in the direction of greatest movement, a less elongation in the direction at right angles to this and in the plane of movement, but are contracted at right angles to the plane of movement. Also new minerals which develop are controlled in the same manner. If the fissility be second-



FIGS. 127 and 128.—Theoretical deformation of laminated rock by uniform differential movements parallel to a previous structure.

ary to cleavage, the minerals were previously oriented with their two longer axes in the plane of differential movement, and the slipping of fissility but emphasizes an arrangement of the mineral particles which already existed.

DEVELOPMENT OF CLEAVAGE AND FISSILITY IN HETEROGENEOUS ROCKS.

When a set of layers, either sedimentary or not, of different lithological character are folded, and cleavage or fissility develops in them, the process is not simple.

As the case of alternating sediments is the most important one, and somewhat different from any other, this will be first considered.

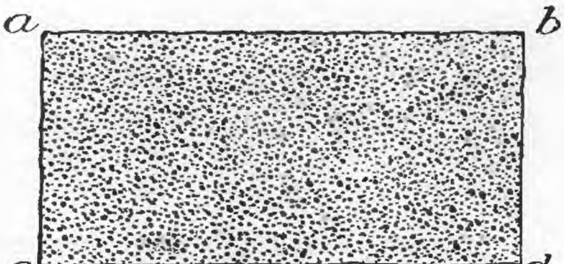
The original series, instead of being homogeneous, is composed of beds of different characters; that is, it consists of alternations of mud, grit, sandstone, limestone, etc. Before these rocks are folded the forces of consolidation, cementation, and metasomatism may have been at work. As a result of these prior alterations, combined with original deposition, the strata may have greatly varying strength. The sandstones may have been transformed to quartzites; the grits may have been changed to graywackes; the muds may have been compacted into shales; and the limestones may have become crystalline.

the limbs of the folds, but the two will be at right angles to each other upon the crests of anticlines and in the troughs of synclines (fig. 133). When the compression is so great as to form plicated folds, the changes in the direction of bedding being very sharp, the discrepancy between bedding and cleavage will be slight. However, the discrepancy is real and important. The cleavage in this case may be about parallel to the axial planes of the folds, and will cut the beds at a very acute angle. In many districts where cleavage has been described as everywhere according with bedding, and the two do approximate but not exactly accord in direction upon the limbs of the folds, a close examination shows that on the crests of the anticlines and in the troughs of the synclines the two structures intersect each other.

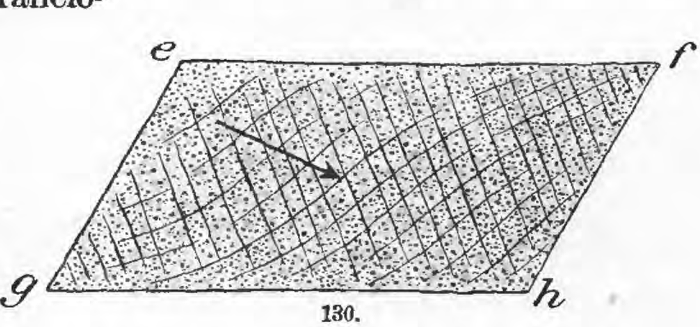
At the beginning of the process it may be noted that the shortening is at right angles to the bedding. At the end of the process the shortening is parallel to the bedding. Thus the work first done is partly undone. The resultant position of the shorter axes of the mineral particles in reference to the bed is intermediate between the two extremes.

DEVELOPMENT OF FISSILITY IN HETEROGENEOUS ROCKS.

The development of fissility in heterogeneous rock beds is still more complicated. The directions of the forces are exactly the same as with cleavage, but as fissility develops along the shearing planes, in the simplest case this structure forms in two general directions. In simple folding, as there is differential movement between the layers, the deformation of a portion of a given layer is that of a rectangle (fig. 129, *abcd*) into a parallelogram (fig. 130, *efgh*). If the layer were exactly homogeneous and the pressure normal, the secondary structures would be nearly at right angles to each other and at an angle of about 45° to the greatest pressure. According to Becker, in the case of inclined pressure the structures would have different positions, but they still would be planes. These conditions are most nearly approached in the center of a bed which at this place is massive. However, in pass-



129.



130.

FIGS. 129 and 130.—Diagram showing development of fissility along the longer and shorter diagonals of a deformed portion of a rock stratum.

In the center of stratum the fractures are in the planes of greatest shearing, but on the outside of the layer the fractures are in lesser shearing planes, the direction of fracture being controlled to some extent by bedding.

ing from the center to the weaker, outer part, the original bedding may largely control the direction of parting, the partings occurring near the planes of bedding rather than in those of greatest tangential stress (fig. 131). The result is that the planes of fissility may change from their diagonal position in the center of the layer, where it is most rigid, to nearly parallel to the bedding on the outer parts, where it is least rigid.

The diagonal *ad* (fig. 129) is shortened to *eh* (fig. 130); therefore the fissility along the diagonal *gf* is formed under conditions of compression. This results in producing many approximately parallel planes of fissility. No sooner does a parting form than the laminæ are sheared over one another, thus producing slickensided surfaces. Across this structure along the longer diagonal, in the plane of the shorter diagonal, there is actual stretching of the layers. The length of the original diagonal *cb* is increased to *gf*. Parallel cracks are therefore produced in this direction. As a crack once formed easily widens, the result is the production of a few cracks of considerable size. The broken parts do not rub over one another, and hence do not produce slickensided surfaces. These peculiarities frequently lead to oversight of the shearing along the planes of the shorter diagonal. The development of the cracks along the shorter diagonal are strictly analogous to the upward-pointing crevasses of a glacier.

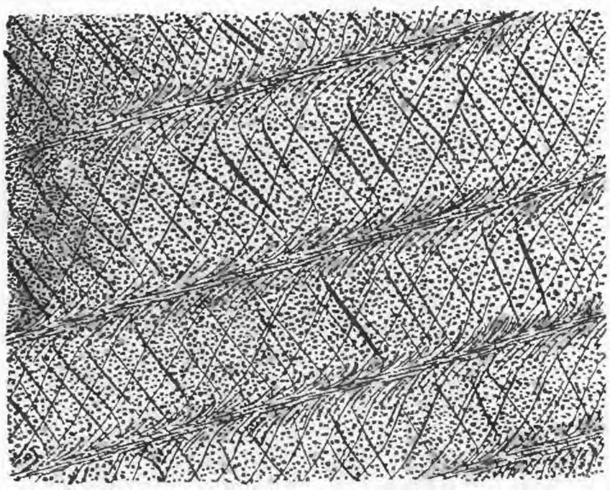


FIG. 131.—Parallel fissility and cross fissility in heterogeneous rock strata.

The planes of fissility near the border of the beds, where the rigidity is less, perhaps originally developed diagonally, may be rotated to a nearly parallel position. This rotation may change the direction of the planes of fissility either in the compressed or the stretched diagonal. The cross fissility will grade into parallel fissility by a gentle curve. On opposite sides of a layer the curves are in opposite directions, just as in the case of cleavage, and by these curves it is easy to determine the relative direction of movement of the layers (fig. 131).

This rotation is explained by fig. 132, which is supposed to represent a bed of rock made up of thirteen layers differing in rigidity. In passing from the outside of the bed to the center the coefficient of rigidity of each layer is supposed to be twice as great as that of the one next adjacent. The greatest stress is supposed to be the same throughout the bed, and in an inclined direction, and, as shown (pp. 647–648), these conditions may be approximately complied with upon the limbs of folds. When the differential stress exceeds the ultimate strength of the rock, parallel fractures along shearing planes will be formed. The fracturing will continue until the stress falls below the ultimate strength of the rock. The differential stress may still surpass the elastic limit of the rock, or if not, it may again accumulate until the elastic limit is exceeded. Flowage will then begin. On account of the varying rigidity the two layers adjacent to the center will have a certain amount of differential movement, which may be called 1. The layers next to them toward the outside will have a movement which would be represented by 2; those next to them, 4; those next to them, 8; and the outside layers a movement of 16. Now, connecting similar points in the different layers, a curve is produced which corresponds very nearly in form to those which have been observed in nature. The structure produced in the diagonal direction, in the centers of the layers, has been rotated to the position indicated. In different rocks the variation of the coefficient of rigidity would be different from that supposed, and it would undoubtedly vary irregularly instead of regularly. A more accurate discussion wonld consider each of the layers as indefinitely thin, and the coefficient of rigidity in passing toward the center of the bed as increasing by a minute increment. If different numerical suppositions be made, curves would be produced differing from those represented by the fignre, but the same in essential character.[1]

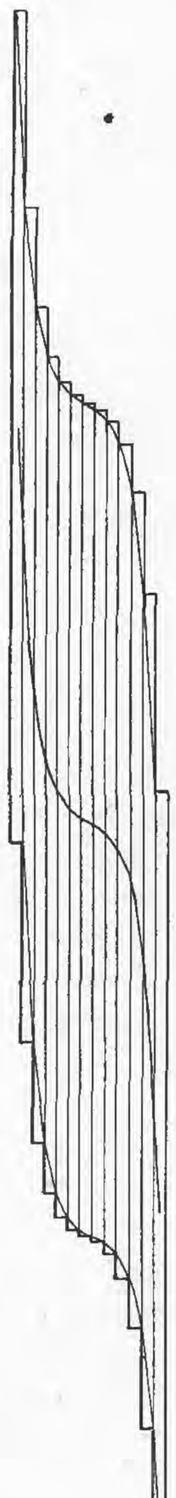

FIG. 132.—Diagram showing rotation of cleavage which originally developed in the normal planes to a position nearly parallel to the bedding.

A third way in which the curved fissility above described may be produced is as a structure secondary to cleavage. That cleavage can be produced having the same curves and relations to bedding as just described for fissility has already been shown (pp. 647–649). Such previously developed cleavage would give parallel curved surfaces of weakness. When the rock passed into the zone of fracture fissility would develop along these shearing planes whether they were those of maximum tangential stress or not.

The above phenomena (probably secondary to cleavage) are finely illustrated in the quartzites of the North Range of Baraboo, Wisconsin (figs. 150–152), and in the massive graywackes of the Ocoee series on the Hiwassee River, Tennessee, combined with cross and parallel secondary structures, as shown by fig. 131. It is possible that in the cases of both

[1] Compare Geology of the Comstock Lode and the Washoe District, by Geo. F. Becker, Mon. U.S. Geol. Surv., Vol. III, pp. 156–178, 1882.

of the interaction of the two (fig. 133). In many cases where there is almost perfect accordance of primary and secondary structures on the limbs, and the rocks are so crystalline that the two can not readily be discriminated, at the crests and troughs both structures may readily be seen intersecting each other.

Formations are but divisions of rock masses greater than beds which are roughly homogeneous. In each formation, considered as a whole, cross secondary structures will usually be produced, while at the contacts between the formations, where major readjustment is sure to occur, nearly parallel structures may be found. In the discussion of each separately it has been seen that in the cases of extreme folding the relations between the different secondary structures and bedding are nearly the same, and therefore that cleavage and fissility developed under each of the laws will merge together, and both be approximately parallel to the reduplicated beds. They are all brought into nearly parallel positions, just as are pebbles in the folding process. In order that this should be done, it is plain that there must be such extreme rearrangement of the rock material that it could not inaptly be compared with kneading.

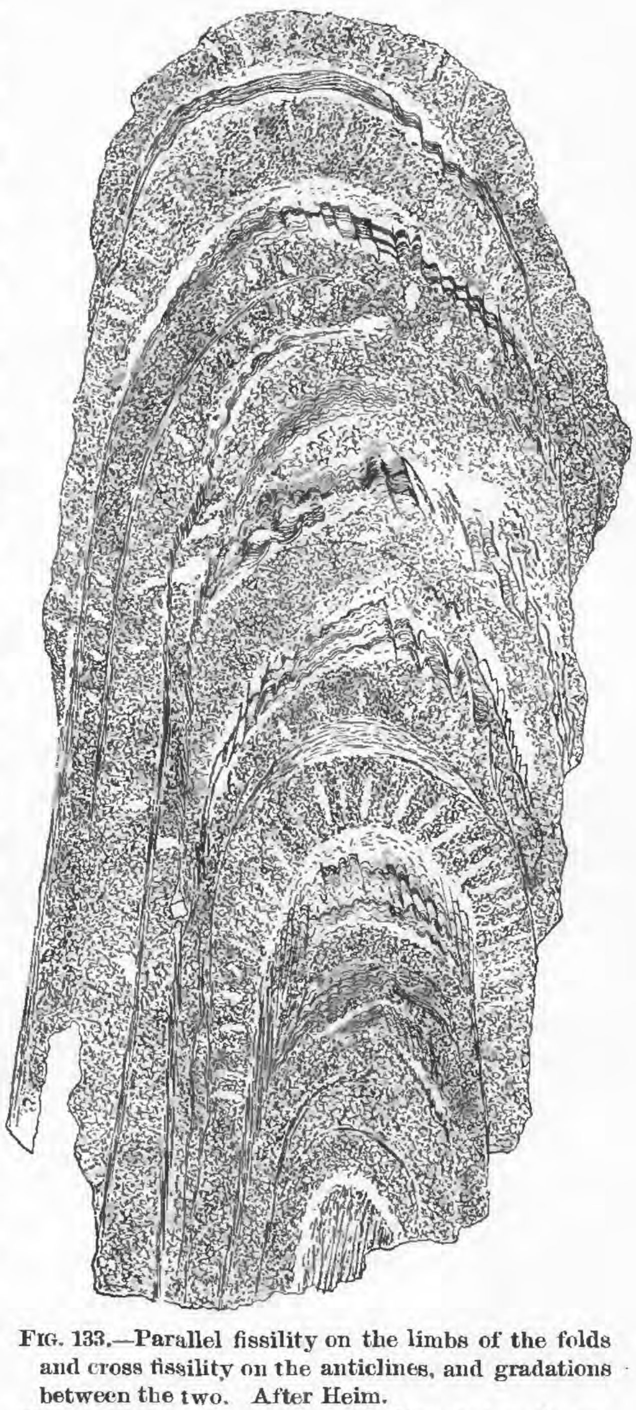

FIG. 133.—Parallel fissility on the limbs of the folds and cross fissility on the anticlines, and gradations between the two. After Heim.
The deformation is mainly by folding, but on the anticlines, where the material is partly relieved from stress, the deformation is partly by the multiple minor slips of fissility.

In rock masses in which the alternating layers of different strength are not beds, the principles of the development of cleavage and fissility are the same as in the heterogeneous bedded rocks. The different layers may be due to secondary structures. They may be due to the flowage of igneous material along primary or secondary planes of weakness, or to secondary water-deposited impregnations along such planes. They may

The quartz laminæ show thinning on the limbs of the folds and thickening at the anticlines and synclines.

represented as extending to a great depth, where it may be comparatively superficial. (Fig. 135.)

The assumption that bedding and secondary structures correspond is still less justifiable when no remaining evidence of bedding is found. If only cleavage or fissility be found, and the relations of the beds with other beds are not such as to give the direction of stratification, no inference in reference to this point should be drawn.

It is apparent that attempts to estimate the real thickness of cleaved or fissile beds must take into account two difficulties: (1) The same bed may be folded on itself many times, and these folds must be followed, or at least some estimate must be made of the thickness of the beds which would be present if the minute plications could be straightened. (2) In the complex folding of the beds there is readjustment, mashing, and consequent lengthening of the layers upon the limbs, and they are, therefore, on the average, thinner than originally. So far as such thinning occurs, it compensates for the reduplication of the beds, but it is believed that this compensation is far short of full correction. To fully overcome the difficulties is often impossible, and estimates of the thickness of the closely folded, cleaved, and fissile beds, even when all the difficulties are wholly understood and allowances made, are usually only approximate.

FIG. 135.—Closely plicated shale underlain by bed of limestone.

DEVELOPMENT OF CLEAVAGE BY OTHER CAUSES THAN THRUST.

Thus far I have considered cleavage developed in connection with and dependent upon orogenic movements. It is probable that this structure develops in other ways. It may be that deeply buried beds may become cleavable with the structure parallel to bedding, where superincumbent pressure, cementation, and metasomatic changes are the predominant forces. Such deep-seated rocks, if below the level of no lateral stress, are in the zone of great vertical compressive stress and circumferential tension. They would, therefore, be shortened vertically. If under the stress of gravity movement goes far enough, this would develop a cleavage parallel to the surface. Such cleavage in sedimentary rocks would be parallel cleavage and would emphasize the bedded structure originally formed. Just below the level of no lateral stress it is probable that the circumferential dilation would be slight, but would increase with depth. Whatever its amount, it is a real cause so far as it goes.

It is not asserted that rocks in which cleavage may thus develop reach the surface by subsequent denudation, but perfectly crystalline schistose rocks in which the cleavage corresponds exactly with the bedding, and which are but gently folded, suggest that such may have

tension caused by cooling, and the mud cracks of sedimentary rocks are due to the contraction and consequent tension caused by desiccation. However, it is probable that neither cooling nor desiccation is important in the production of systematic sets of joints in the sedimentary rocks.

It has already been seen that when rocks are simply folded and not too deeply buried the convex halves of the anticlines and synclines are subjected to simple tension (pp. 597-598, fig. 102). If the tension goes beyond the limit of elasticity, radial cracks will be formed which strike parallel with the rocks. Joints of this class are at right angles to the tensile force. This class of joints is beautifully illustrated in the sharp folds of the graywackes of the Hiwassee River, in the Ocoee series (fig. 136). If the folded rock has planes of weakness of any kind, due either to a primary or a secondary structure, the fracture due to the tensile stress may be controlled by these, and thus deviate from the normal planes.

Joints produced by tensile stress may have smooth or rough surfaces, depending upon the character and strength of the rock. If it is a weakly cemented sandstone, the fracture, as pointed out by Becker, is around the grains. If, however, it is a strong, tolerably homogeneous graywacke, quartzite, or limestone, or similar rock, the fractures may be clear-cut and sharp. After joints due to tensile stress have formed, subsequent movements may press the surfaces together, or may fault the strata in a minor or major way, and thus produce slickensided surfaces.

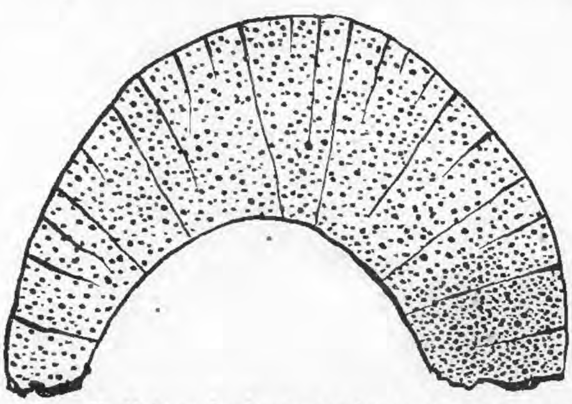

FIG. 136.—Radial cracks due to tension in sharply flexed stratum.

It has been seen in the discussion of folds that, instead of being simple, and, therefore, in a horizontal attitude, they usually have a pitch; or, in other words, the rocks are folded in a complex manner. In such regions there may be tensile stresses in two directions at right angles to each other, thus producing two intersecting sets of joints. One of these sets, that roughly parallel to the more conspicuous folds.would be called strike joints, while the other set of joints, parallel to the transverse folding, would be called dip joints. Both sets would intersect the bedding nearly at right angles. The fact that two sets of joints in these positions so frequently accord in direction with the strike and dip is strong evidence that many joints are produced by the tensile stress of folding on the stretched half of the mass folded. If the folds are nearly horizontal—that is, if the force was mainly in a single direction—the strike joints may be strongly developed and few dip joints produced. If, on the other hand, the folds are important in both directions, the strike and dip joints will both be important.

shearing planes. Faults are, however, usually defined as normal and reverse. A *normal fault* is one in which the overhanging side descends in reference to the other, while in the reverse fault the overhanging side ascends in reference to the other. Another term applied to reverse faults is *thrust faults*, implying that tangential thrust is the controlling factor. As equivalent to normal fault may be placed the *gravity fault*, implying that gravity is the predominant force.

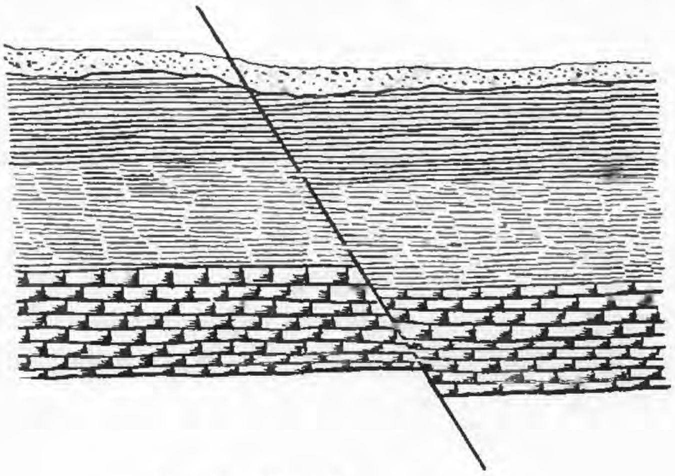

FIG. 137.—Normal or gravity fault.

In the case of the normal fault the overhanging side has a smaller base than the other. Consequently, by force of gravity it descends, as compared with the other side. In all cases, both of normal and reverse faults, gravity is a never-ceasing force. As first explained by Le Conte,[1] the principle of the inclined plane thus applies to these two forces, the hade of the fault giving the inclination of the plane. Where the hade is greater than 45°, if the forces of gravity and tangential thrust are equal the fault is normal, because gravity controls the movement (fig. 137). If, on the other hand, the hade is less than 45°, tangential thrust

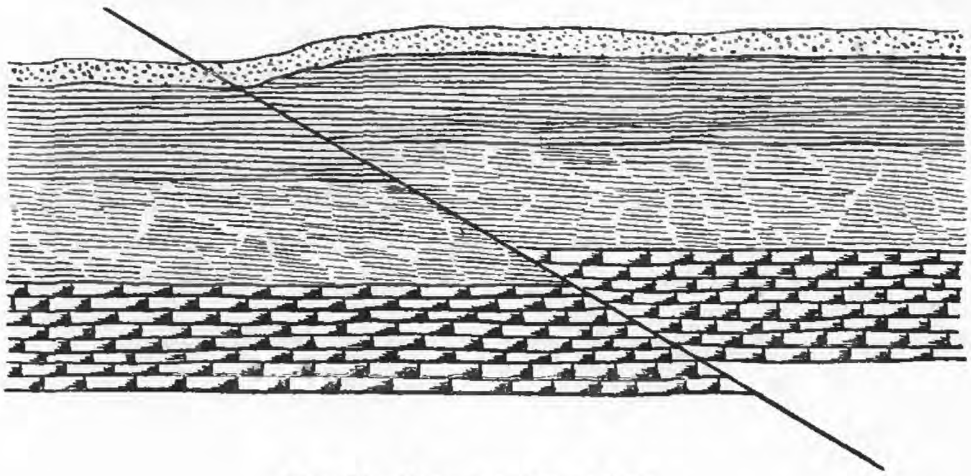

FIG. 138.—Reverse or thrust fault.

is the predominant force, and the fault is a reverse one (fig. 138). As the hade becomes steep, gravity has greater and greater relative power, and if the hade is very steep, gravity may be able to overcome the tangential thrust, even if the latter is several times as great as the former. So, also, if the hade is flat, tangential thrust even much weaker than gravity may overcome it and produce a reverse fault. This is one

[1] On the origin of normal faults, and of the structure of the Basin region. Joseph Le Conte. Am. Jour. Sci. (3), Vol. XXXVIII, pp. 257-263.

arch limbs be thrust over the trough limbs. In a region of overfolds and thrust faults, if it could be determined whether the differential movements are such as to carry the material moved toward the surface or away from the surface, it could be decided whether such folds and faults should be called overthrusts or underthrusts. But the differential movements, the forms of inclined and overturned folds, and the character of the thrusts are identical, whether a given bed above be considered as moving forward and upward as compared with the layer below, or be considered as moving forward and downward as compared with the layer above. In fig. 139, if the force be considered as applied at A, it would be called an overthrust fault; if the force be considered as applied at B, it would be called an underthrust fault; and yet the phenomena are identical. The movements must be such that the material goes in the direction of relief, and it is probable that this is more often toward the surface of the earth (see p. 622) rather than deeper within the earth. It is probable that in certain cases thrust has been transmitted by a strong formation or series and pushed under other strata. This is particularly likely to occur where the lower strata are weaker or where the material in advance of the active strata transmitting the force has been already raised into folds, and thus partly escapes the pressure. (See pp. 606–607, and fig. 109.)

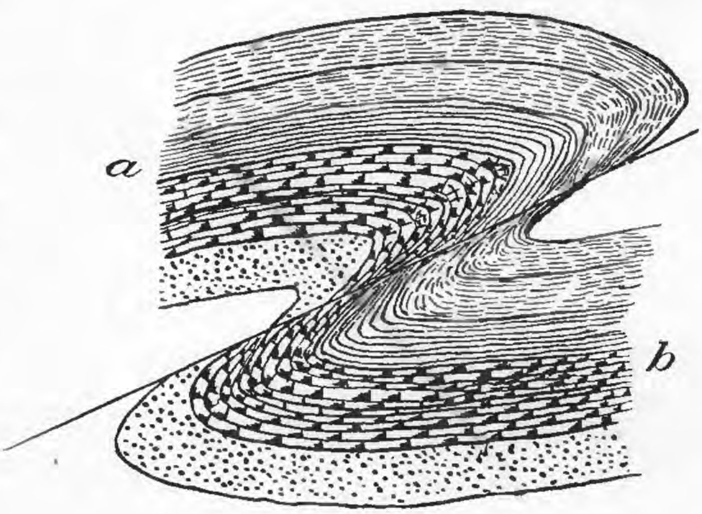

FIG. 139.—Fold passing into fault.

As explained by Willis, in regions which are but lightly loaded the forces producing thrust faults may result in clean-cut fractures, with scarcely any bowing of the layers of the rocks along the shear planes (see figs. 127 and 128, and pp. 659–660). In passing to greater depths the load is greater, and the layers, instead of all having the full movements of the clean-cut thrust faults, adjacent to the fault planes may be found to be in sharp overfolds in opposite directions upon opposite sides of the faults (fig. 139). Where the load is still greater these folds are of increased importance. Under still greater load the rocks may be first bent into an overfold, with little faulting, and finally at a greater depth the deformation may occur altogether by overfolding. It is therefore clear that in the same mountain mass there may be all gradations between clean-cut thrust faults and overfolds without faults. The transition may be longitudinal, as in the case of the Appalachians, where thrust faults which occur in the extreme southeast are gradually

determined with certainty. This criterion may be applied even when the rock has been considerably mashed, and has become a mica slate. But if the mashing was so intense as to make the rock holocrystalline, positive evidence of the direction of the minor laminæ may have disappeared. The geologists working in the Green Mountains have found that where the rocks are holocrystalline the bedding may be indicated by secondary quartz laminæ. (See Dale's fig. 81 in previous paper, p. 556.) These can be relied on, however, only where they cut the cleavage and fissility, and even then it must be certain, in order to demonstrate the structure to be bedding, that there is no prior cleavage or fissility along which the impregnations might have occurred (see Dale's fig. 92 in previous paper, p. 565), for a rock may show cleavage or fissility in one or more directions. Parallel to either of these structures there may be alternating bands of different mineral character or of different color due to secondary impregnation or injection. There may be alternating groups of layers of different character taken as wholes, which suggest beds in a remarkable degree. However, none of these structures or any other can be always relied on as evidence of the direction of bedding in a completely crystalline rock, for it has been seen that such structures are produced by secondary processes, and that two or three different secondary structures may exist in the same rock, none of which are bedding, but all of which are produced by metamorphic processes.

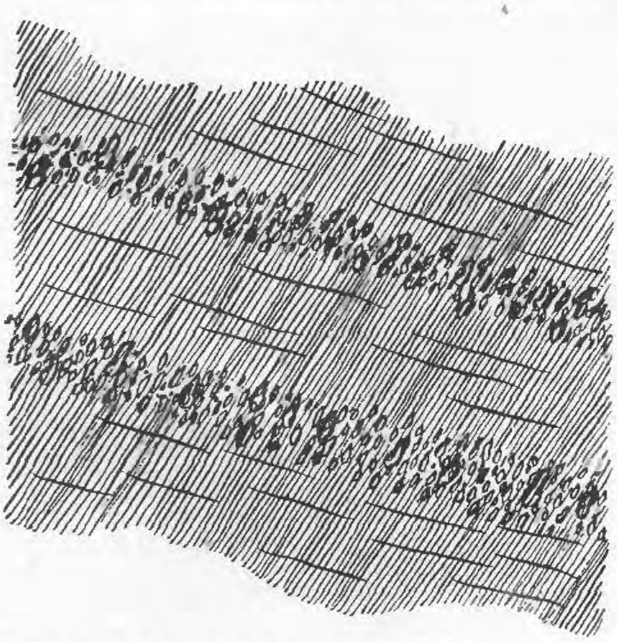

FIG. 140.—Deformation of conglomeratic layers in rock in which a cross foliation is developed.

In sedimentary rocks in which the metamorphism was so intense as to wholly obliterate the clastic characters of the matrix, or of the entire mass where originally a shale, grit, or sandstone, if the rock contained bands of conglomerate, the rows of pebbles may still indicate the direction of bedding (fig. 140). That is, a more intense dynamic action is required to destroy pebbles than to completely granulate the smaller particles (Pl. CXV). Generally, in this case the pebbles are crushed, and they may be rotated. As a consequence the greater dimensions of the pebbles correspond to the secondary structures (Pl. CXV), but the belts of conglomerate occupy their original relative positions (fig. 140). In an advanced stage of change the pebbles are crushed until each becomes a lamina scarcely distinguishable from a bedded layer. Such a rock, when looked at on a surface parallel to the schistosity, may appear completely crystalline. This may even be the case in one plane perpendicular to the schistosity, but the pebbled character may be still discernible in the plane at right angles to both of these (fig. 156).

When the processes of transformation have reached the extreme the pebbles themselves are destroyed, and there is then no way to determine bedding except by the major alternation of sediments; that is, as beds of shale, graywacke, sandstone, and limestone are originally different chemically and mechanically, and as material does not readily migrate in a large way in alteration, when the beds become metamorphosed they do not change into similar rocks. As has been seen, from a bed of shale or grit is produced a mica-schist or mica-gneiss; usually

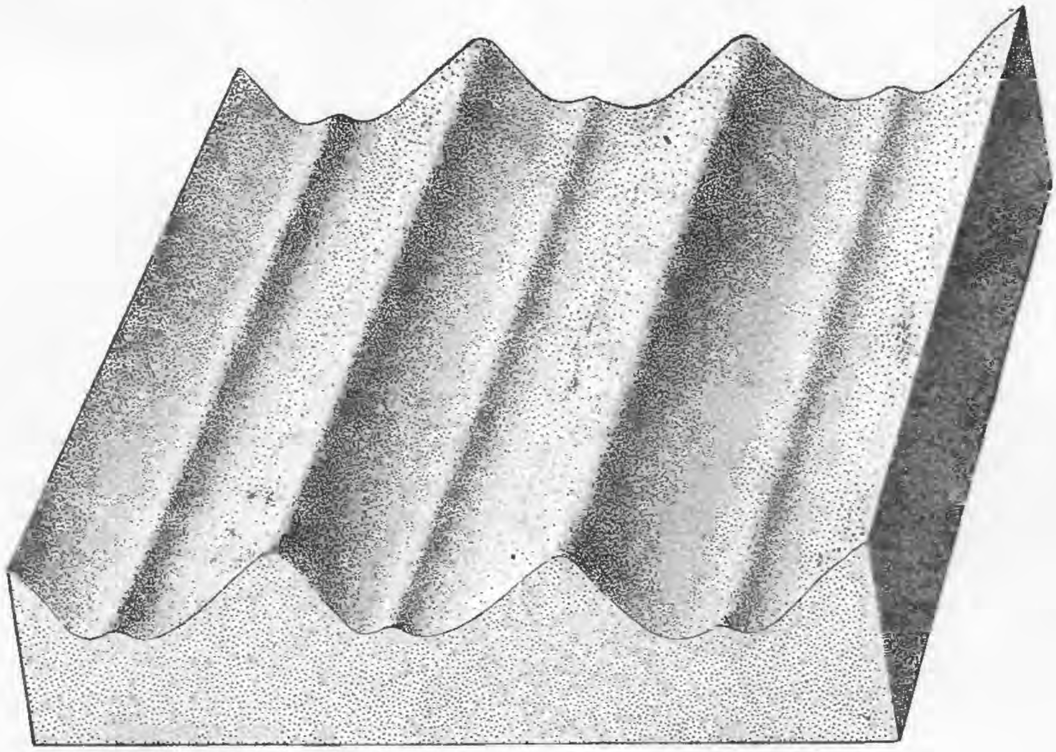

FIG. 141.—Normal ripple-marks.

from a bed of quartzose sandstone is produced a quartzose schist; from a bed of limestone is produced a marble. We conclude that in the case of extreme metamorphism the only safe guide as to the direction of bedding is the contact between formations which are thus dissimilar.

Certain of the completely crystalline gneisses are in layers which simulate beds to a remarkable degree. Viewed from a distance the layers have the exact appearance of beds of sandstone. It is only when the rocks are closely examined that their crystalline character is discovered. It has been seen under Cleavage and Fissility that there is a tendency for secondary structures to be produced parallel to bedding, both in the deep-seated zone of flow and the middle zone of fracture and flow. In many cases it is probable also that deep-seated metamorphic processes, under the pressure of the superincumbent beds, preserve the original structures. In some places it is therefore probable that the layers of crystalline schists are really fossil beds, but until this is shown by the criteria above given it can not safely be assumed in structural work.

RIPPLE-MARKS.

The forms of ripple-marks may sometimes be of assistance in deciphering stratigraphy. Normal ripple-marks consist of a series of sharp ridges separated by rounded hollows, each of which, however, often has a slight, sharp ridge in its center. The appearance is shown by fig. 141. The obverses or casts of such ripple-marks have an entirely different appearance. They consist of broad rounded ridges, each of which has a slight depression in its center, and the ridges are separated by steep depressions. This appearance is shown by fig. 142. The

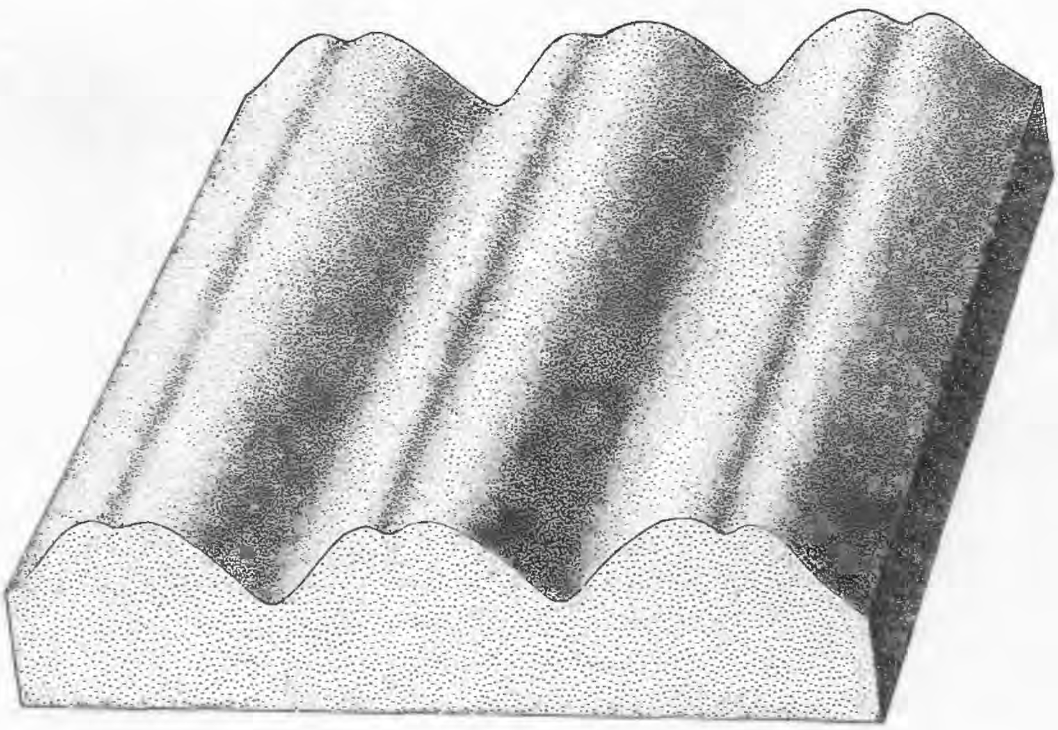

FIG. 142.—Casts of normal ripple-marks.

profile of either of these figures is shown by fig. 143, which is placed in a vertical position. One side represents the ripple-marks as normally formed, the other their cast or obverse. In case the beds of a steeply inclined formation bear ripple-marks, these determine at once which way the formation was uplifted. The profile (fig. 143) should be turned to the right in order to bring it back to its original position. The decision may be as easily made even when the minor elevations in the hollows are absent. In this case in normal position the depressions are gently rounded, while the elevations are of the same form as in the previous case.

This criterion may be of assistance in working out the structure of a difficult area. It often happens that in regions of closely folded rocks, if the manner of upturning of a formation can be determined at a certain locality, the structure of a considerable area at once appears. Conversely, if the structure is believed to be determined the discovery of ripple-marks on the steeply inclined layers gives a test as to the correctness of the conclusions reached. This principle was explained by Jukes and Geikie[1] many years ago, but is neglected in modern text-books.

FIG. 143.—Profile of normal ripple-marks.

BASAL CONGLOMERATES.

By a basal conglomerate is meant a conglomerate deposited upon an eroded, previously consolidated, or modified rock by the encroachment of the water upon the land. The material for the conglomerate is largely derived from the subjacent formation, although shore currents usually bring some material from other and distant sources. Immediately adjacent to the underlying formations the blocks composing the conglomerate are mainly from the inferior formations, and they are often angular, but this phase usually passes quickly upward into a phase containing well-waterworn bowlders, and from this to phases containing bowlderets and pebbles, and from these into sandstone or shale. A basal conglomerate may vary in thickness from a few inches to many feet, depending upon the character of the shore and upon the rapidity of the transgression of the sea. In case cliffs have to be worn away, the basal conglomerate has a very considerable thickness. If, on the other hand, the sea transgresses over a region which has been baseleveled, or nearly so, the advance is marked only by a thin bed of conglomerate, and it is possible that under these conditions no basal conglomerate may form. As a marked instance of a thin conglomerate may be mentioned the occurrence on the Potato River, in the Penokee series of Wisconsin. Resting upon the upturned edges of the Archean schists is a conglomerate containing bowlders as large as 3 or 4 feet in major diameter. This bowlder bed varies from 2 to 4 feet in thickness, and passes quickly into the ordinary slate of the quartz-slate formation. So sudden is the transition that if a belt 4 feet wide were covered the schists of the basement complex would be seen upon one side and the slate upon the other, the fibers of the schist being nearly at right angles to the strike of the fine-grained slate (fig. 144).

[1] Student's Manual of Geology, Jukes and Geikie, 3d edition, 1871, p. 63.

A true basal conglomerate, where it exists, implies that between the two series there has been an erosion interval or an unconformity. The significance of this phenomenon will be considered later.

There are certain phenomena which may be mistaken for genuine basal conglomerates:

(1) Coarse volcanic fragmental material may be deposited upon a bed of ash, lava, or sedimentary rock, or dropped upon the water over ordinary sediments. If the formations are later buried and then somewhat altered by the metamorphosing processes the conclusion may be drawn that such a conglomerate is a true basal conglomerate. This is

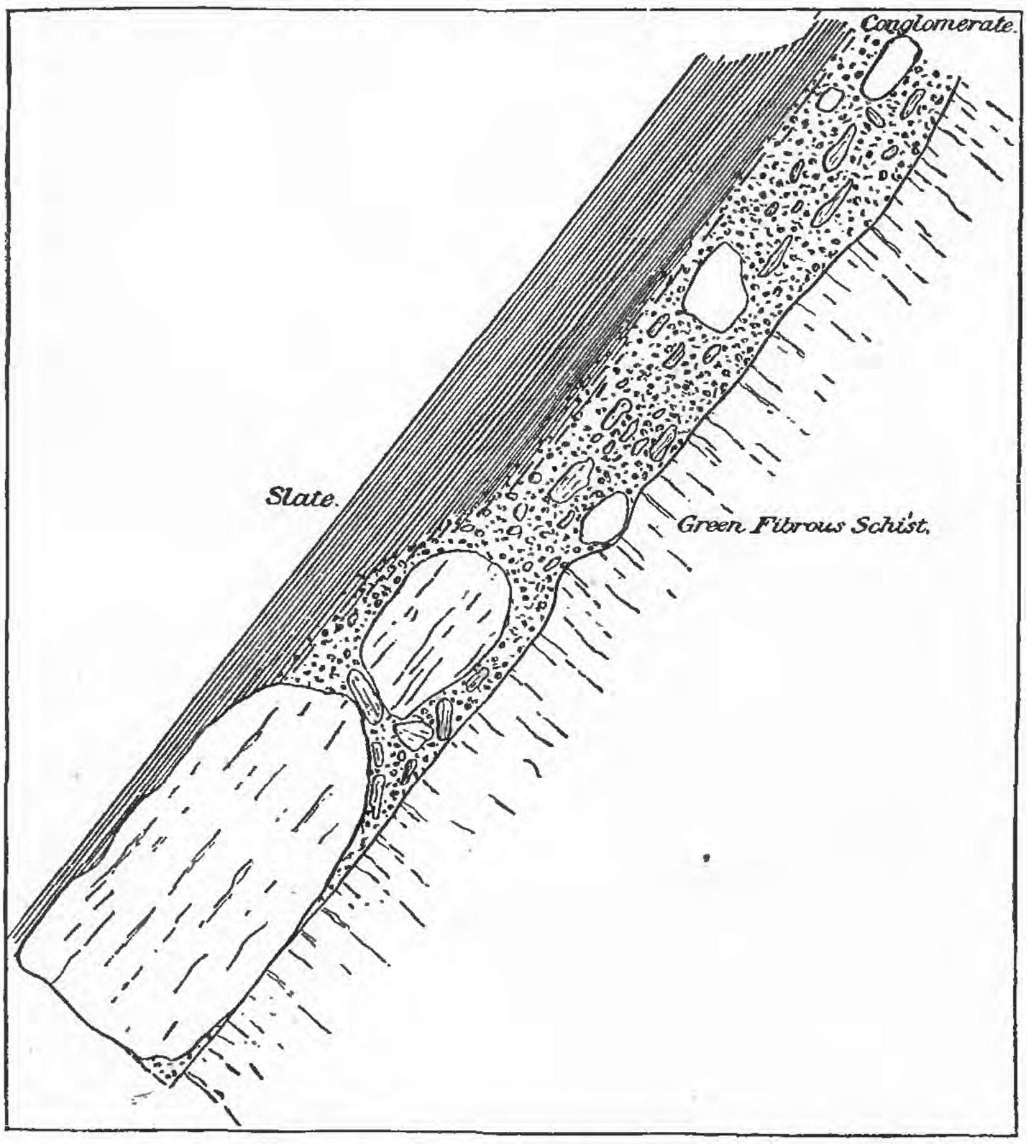

FIG. 144.—Basal conglomerate of Upper Huronian resting on green schist of Archean.

especially likely if the phenomena are not closely examined. Such a conglomerate, however, differs from a true basal conglomerate in that the blocks which compose it are not of the same character as the subjacent formation; and if they have not been too profoundly metamorphosed they will be recognized as having the characters of volcanic bombs rather than of waterworn pebbles. Further, if the contacts are

JASPILITE FROM NEGAUNEE FORMATION OF LOWER MARQUETTE SERIES.

In all of the series and districts the folding is complex. The complexity increases in passing downward from newer to older series. The great east-west Keweenawan synclinorium has important but gentle cross folds. The Upper Huronian of the Penokee, Mesabi, and Animikie districts is almost as simply folded. The folding of the Lower Huronian rocks is exceedingly complex, and in some districts the Upper Huronian rocks are included in the complex deformation. In these districts the character of the folding has been worked out only in the Marquette and Steep Rock Lake areas. In the first the chief longitudinal fold is an abnormal upright synclinorium, the abnormal character of the folding being due to the unequal rigidity and the consequent differential movements between the Archean and the Lower Huronian (fig. 146). The transverse folding is also severe, so as to give steep dips in places. A map of the outcrops of the formations in the more closely crumpled areas is extremely complex (fig. 147). The folds are often overturned (fig. 148). In the Steep Rock Lake district, as shown by Smyth, the Lower Huronian was first bent into a steep monocline, which was subsequently closely buckled by

FIG. 145.—Shattered slate cemented by vein quartz in Wewe slate of Lower Marquette series.

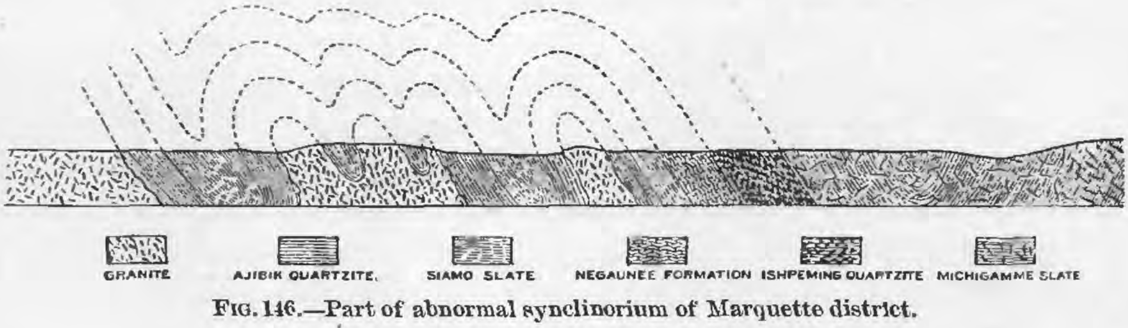

FIG. 146.—Part of abnormal synclinorium of Marquette district.

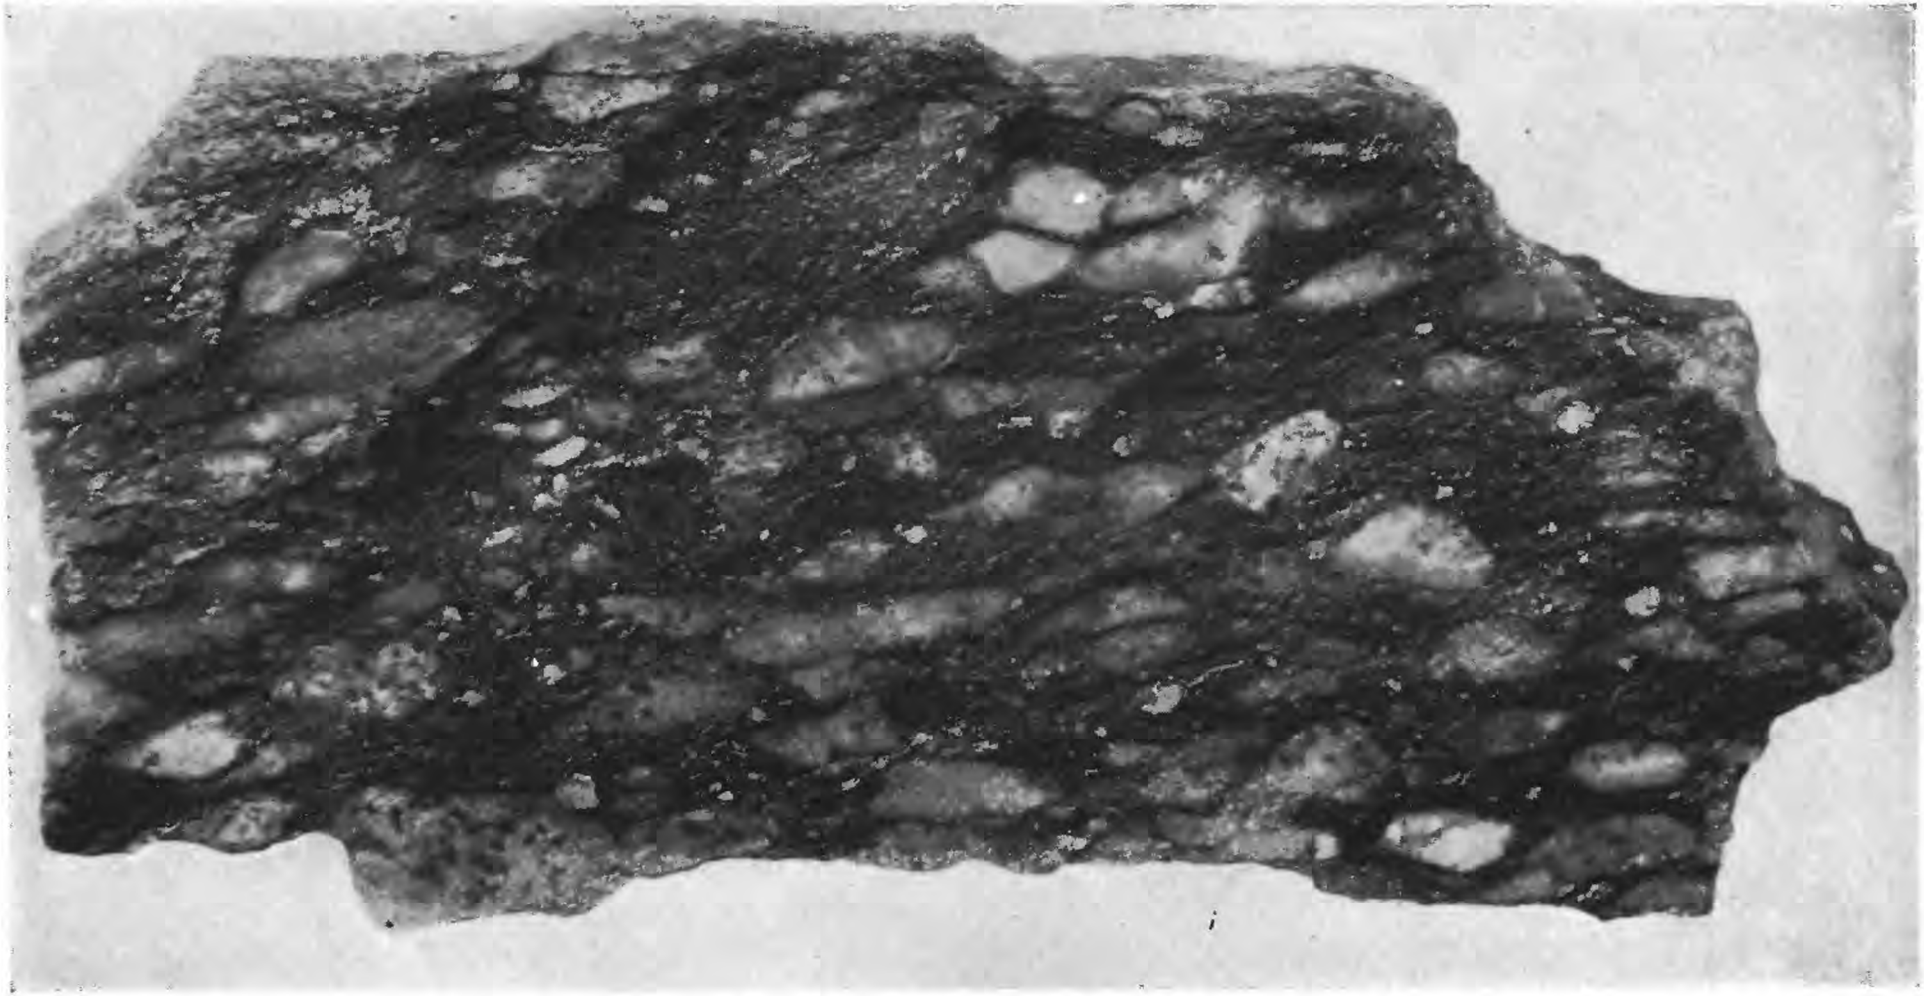
transverse forces. In many of the other districts, while as yet the character of the folding has not been worked out, it is certain that it is even more complex than in the Marquette and Steep Rock Lake areas. The anticlinoria and synclinoria in all of the complex districts are of a very composite type, having folds of a higher order superimposed on those of the next lower order up to microscopical plications.

Cleavage or fissility almost everywhere affects the Archean and the Lower Huronian rocks, and in some districts, as for instance in the



SCHIST-CONGLOMERATE FROM FELCH MOUNTAIN DISTRICT.

Marquette and Menominee districts, is fully developed in the Upper Huronian rocks. Cleavage often occurs in a soft layer and is absent in a harder one (fig. 149). All the different varieties of cross and parallel cleavage and fissility are exhibited, and all combinations of them. In the Baraboo quartzites, and especially at the Upper Narrows of the Baraboo River, fissility in shearing planes, diagonal stretching explained (pp. 651–655) as due to the unequal movement of the opposite sides of beds, and the relations of the same, are beautifully illustrated (figs. 150, 151, and 152).

In the Felch Mountain conglomeratic gneiss, mentioned below, the flattened pebbles in all stages of deformation and the schistosity are in perfect accordance, showing that the secondary structure developed normal to the pressure (Pl. CXV). Northwest of Lake Superior the peripheral cleavage, everywhere parallel to the intrusive batholites in each case, gives further fine illustrations of the development of a secondary structure normal to the pressure. The cleavage of the Berlin (Wisconsin) microgranite (see p. 789) is a beautiful illustration of the development of cleavage normal to the pressure in the case of an igneous rock. The fibrous structure found in the green schists of the Archean gives an illustration of a rock deformed where two of the principal stresses were nearly equal and the third less than these two (see p. 641).

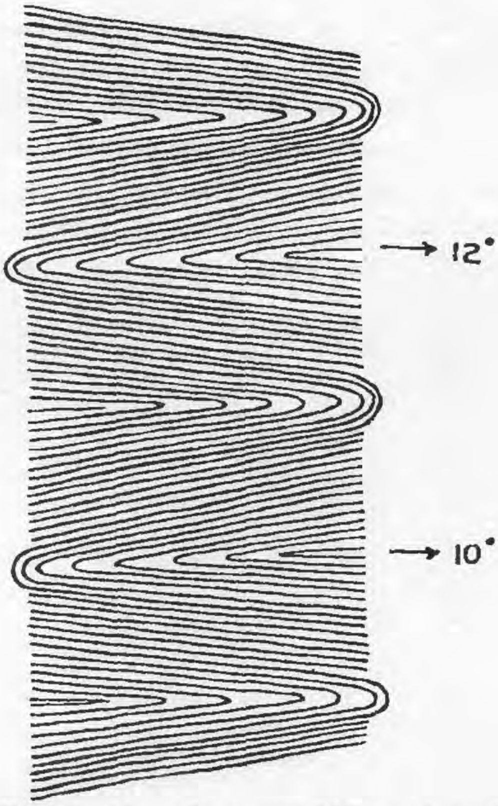


FIG. 147.—Map of outcrop of Wewe slate of Lower Marquette series southeast of Goose Lake.

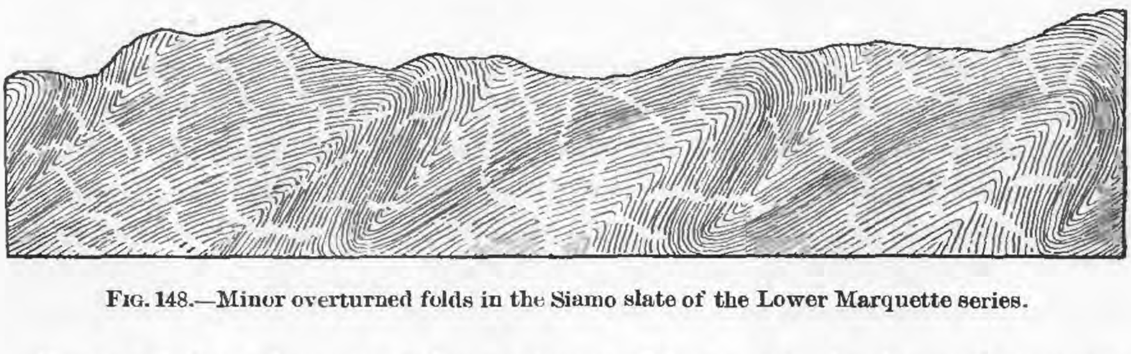

FIG. 148.—Minor overturned folds in the Siamo slate of the Lower Marquette series.

Some of the phases of the metamorphism of both the sedimentary and the igneous rocks are as follows: The rocks have everywhere been consolidated or welded. In many areas the sandstones have been cemented to quartzites, and in some cases in the Keweenawan the arkoses have been cemented by the growth of both quartz and feldspar. Certain of the volcanic tuffs, as at Kekekabik and Ogiski lakes, show also enlargement of hornblende. Metasomatic processes have everywhere affected the argillaceous, calcareous, and ferruginous rocks. Wherever cleavage and fissility occur, there the rocks have also been mashed, and slates or schists have been developed. Large porphyritic minerals, such as garnet, staurolite, chlorite, and chloritoid, have an extensive development, especially in the Upper Huronian mica-schists. In numerous localities the chlorite and chloritoid occur in crystals, the cleavage of which is at right angles to the cleavage of the rock, and this gives evidence of their development under static conditions after movement had ceased. Silicification has profoundly

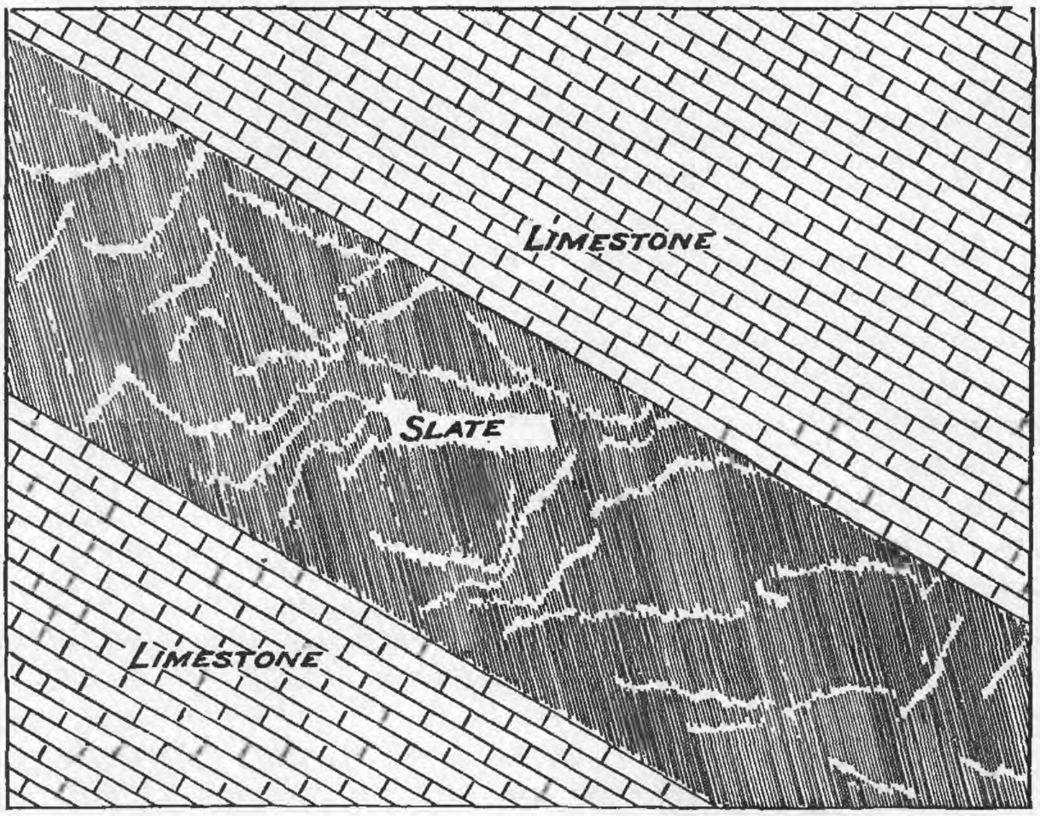

FIG. 149.—Cleavage in slate between two dolomite beds which do not show cleavage, in Kona dolomite of Lower Marquette series.

transformed the iron-bearing formations and the limestones. In the Felch Mountain district there are regularly banded mica-gneisses which can not be discriminated in the hand specimens from gneisses derived from a mashed granite. However, in the field they are traced step by step, both laterally and vertically, back to places where they become very distinctly a conglomeratic gneiss, bearing granite, quartz, chert, and other pebbles. In the closely folded mica-schist south of Michigamme Lake pegmatite veins in minute stringers occur, and a good deal of feldspar is found in the rock, so that it is now a veined mica-gneiss. As extraneous granitic injections have nowhere been discovered in the Marquette district, apparently the pegmatization was due to extreme dynamic metamorphism. In the Felch Mountain area of the Menominee district granite dikes occur in the Algonkian. In northeastern Minnesota and in Canada northwest of Lake Superior intrusive granites are found on a great scale, and the pseudo-conglomerates of intrusion are known at many places.

As a result of the alterations in the Lake Superior region, nearly every variety of metamorphic sedimentary and metamorphic igneous

FIG. 150.—Diagonal fissility of quartzite beds of the north range of Baraboo. Looking west.

rock mentioned in the discussion of principles is found at numerous localities.

All varieties of bedding and all degrees of obliteration of bedding are illustrated.

Basal conglomerates occur at various widely separated places in the Lake Superior region at four different horizons. The basal conglomerates at the lower horizons show all gradations of the process of obliteration.

As proofs of unconformity, all of the phenomena given as evidence of physical breaks (pp. 724–729) have been found at the four great unconformities existing in the region. Also in the Lower Huronian formations are found nearly all of the phenomena which might lead one to falsely infer unconformity. As one kind may be mentioned the dolomite of the Marquette district, the folds of which are truncated by dynamic action, the eroded edges being overlain by an autoclastic rock (fig. 153).

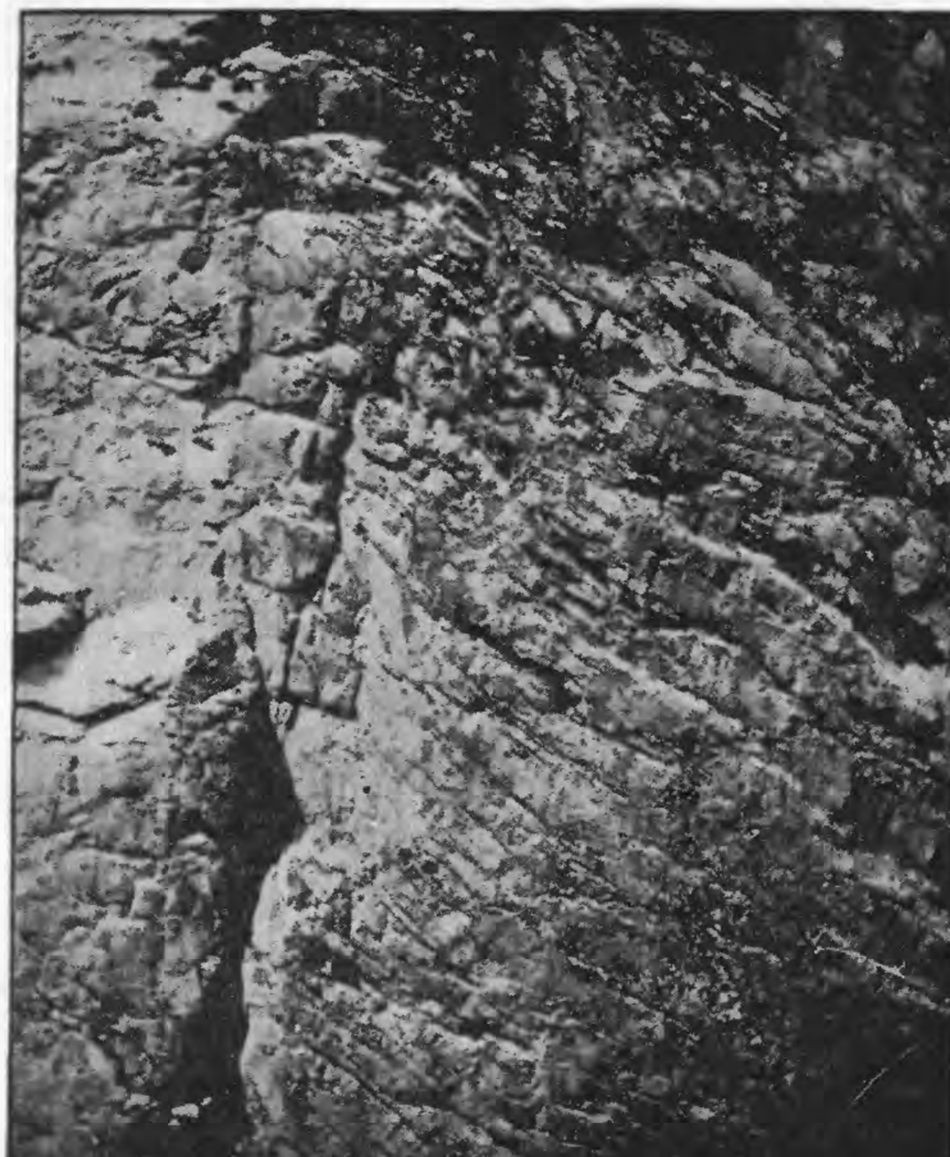

FIG. 151.—Details of one layer of fig. 150 having diagonal fissility. Looking west.

As the phenomena upon which the belief in unconformity is based are somewhat different at different horizons, each case may be mentioned separately. The statement that an unconformity exists between the Archean and the Lower Huronian is based upon: (1) the completely crystalline character of the former and the semicrystalline character of the latter; (2) the intricate folding of the former as compared with the latter; (3) the discordance of the foliation of the Basement Complex with the bedding of the Lower Huronian; (4) the presence in certain districts of abundant granitic intrusives in the Archean which nowhere penetrate the Lower Huronian; and (5) actual contacts at many places, basal conglomerates of the Lower Huronian being found to rest upon

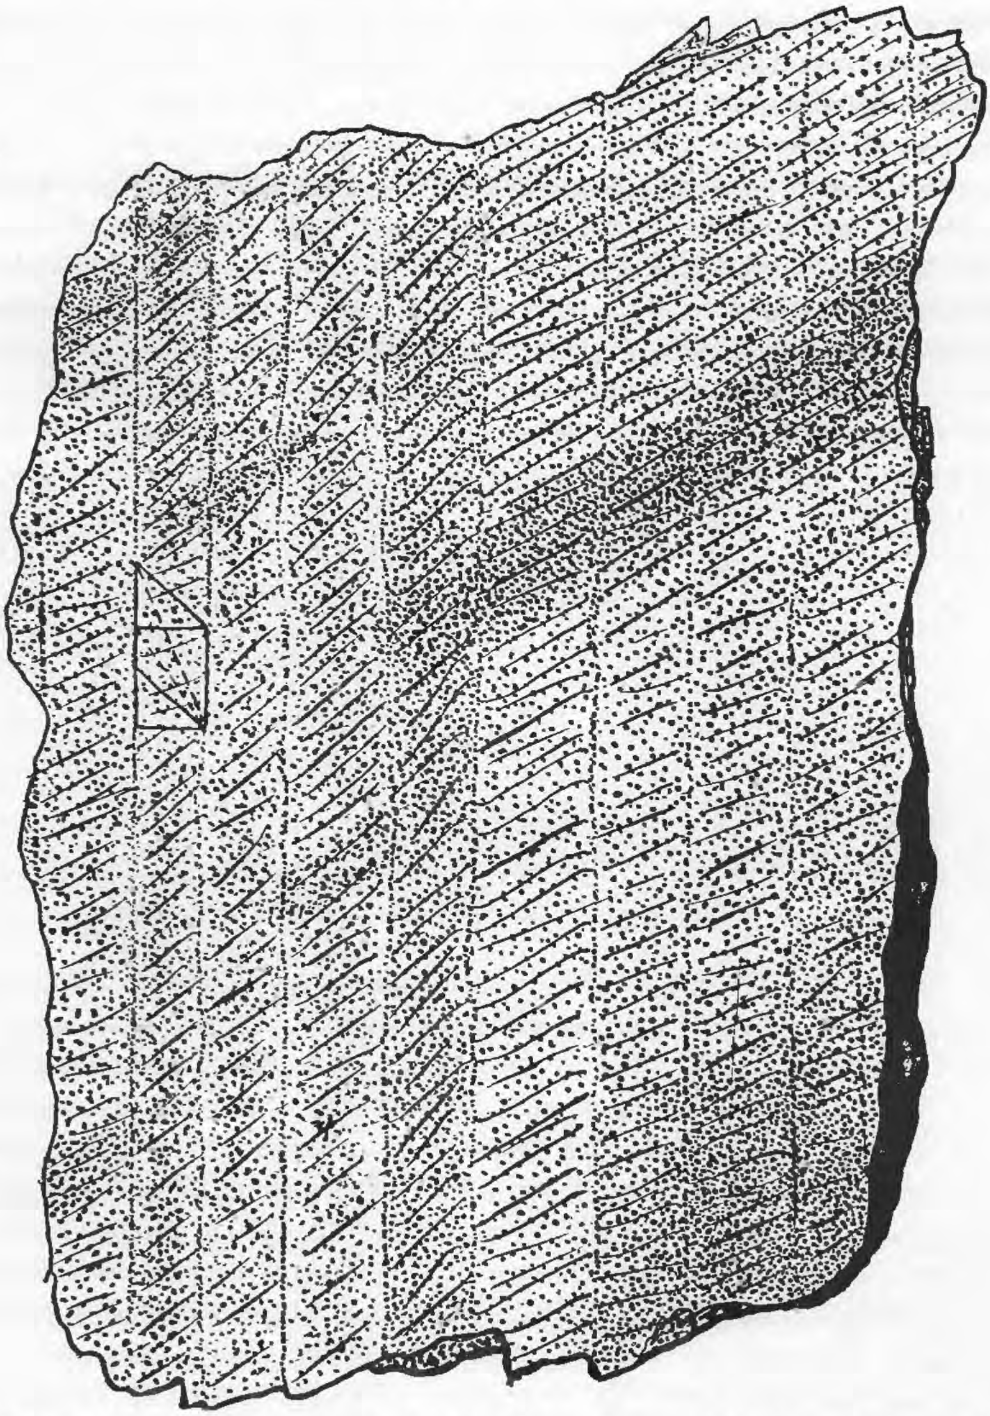

FIG. 152.—Diagonal fissility of quartzite beds of the north range of Baraboo. Looking east.

the foliated and truncated edges of the Archean and being composed wholly of detritus derived from it. All of these phenomena are found in some districts north and south of Lake Superior, but in some of the districts a part only have as yet been detected. As to the time represented by this unconformity, we have no definite knowledge, but it must have been great, since, whatever the origin of the rocks of the Archean, they were intricately folded, metamorphosed, intruded by various eruptives, and deeply truncated, before the Lower Huronian was deposited.

The unconformity between the Lower Huronian and the Upper Huronian is based upon the less crystalline character of the Upper Huronian as compared with the Lower Huronian, upon the very numerous contacts between the two, where discordance of bedding and basal conglomerates are found, and in some districts upon general field relations. The degree of crystallization would have but little weight alone, and it can be applied only in a broad way, for in certain areas in which the folding was intricate the Upper Huronian is more crystalline than is the Lower Huronian in other areas, so that in comparing the crystalline character of one with the other it must be in each case for the same locality. The contacts between the Upper Huronian and the Lower Huronian are found in scores of places. In some cases the formation below the Upper Huronian is a conglomerate, quartzite, quartz-schist, mica-slate, or mica-schist; in others a cherty limestone; in others the iron-bearing formation; and in

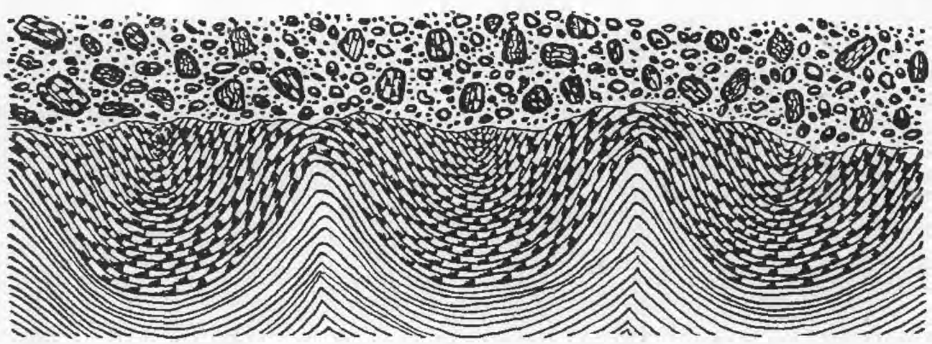

FIG. 153.—Chert-breccia, an autoclastic rock, resting upon truncated minor folds of limestone.

others the igneous rocks of the Lower Huronian. In other words, the inter-Huronian erosion cut to different depths, so that the basement formation of the Upper Huronian rests now upon one member of the Lower Huronian, now upon another. The most numerous contacts are between the Upper Huronian and the iron-bearing formation of the Lower Huronian. The predominant detritus of the basal conglomerate depends, of course, upon the formation with which it is in contact. The amount of discordance in bedding depends upon the closeness of the inter-Huronian folding. In some places the folding was so acute that the bands of jasper were plicated, and in this case the Upper Huronian beds cut those of the underlying jasper at any angle. The discrepancy varies from acute unconformity to but a slight discordance. The unconformity in the last case is discoverable only by the irregular erosion contacts and the basal conglomerate, rather than by discrepancy of strike and dip between the two series. In certain districts where the Lower Huronian is closely folded and the Upper Huronian gently folded, the field relations render the unconformity manifest. Where the Lower Huronian is entirely removed the Upper Huronian

the Archean gneisses, we have no certain evidence as to their real relations. The district has not been closely enough studied to ascertain whether the gradation is real or apparent. In these relations we have the same problem as in so many other regions. The apparent conformity of the Cherry Creek series and the Archean may in the future be explained by any one of three hypotheses: obliterated unconformity, downward metamorphism, or intrusion of the gneissic series.

While the Cherry Creek Algonkian is not anywhere in contact with the Belt series, its extreme metamorphism and common structure with the Archean gneisses make it highly probable that it is unconformably

FIG. 154.—Regularly laminated gneissoid granite of Madison Canyon.

below the Belt series, since the latter rests upon the truncated edges of the Archean gneiss. As to the age of the Belt series, nothing definite can be said, for no fossils have been found in it.

In this series we have a problem of correlation somewhat different from that of any area before considered. A set of clastic rocks bearing Cambrian fossils passes conformably downward into a great series of rocks devoid of fossils, which from their lithological characters ought to contain an abundant fauna. Repeated search for fossils has been made by skilled paleontologists in the area, and in other areas correlated with the Belt series, but always without success. It is possible

That the Mendon series and the Lower Cambrian quartzite, although apparently conformable, are really unconformable, is supported by the following reasons, among others: The extreme lithological diversity of

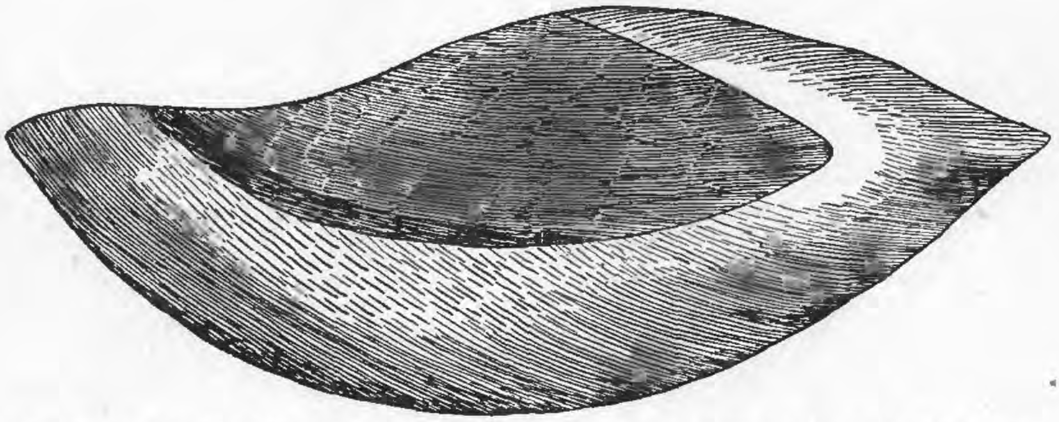

FIG. 155.—Indented pebble from schist-conglomerate; from Plymouth, Vt. After Hitchcock.

the Mendon series as compared with the quartzite; a close folding in the Mendon series not observed in the quartzite; and the fact that the quartzite reposes discordantly upon granitoid gneiss to the southward.

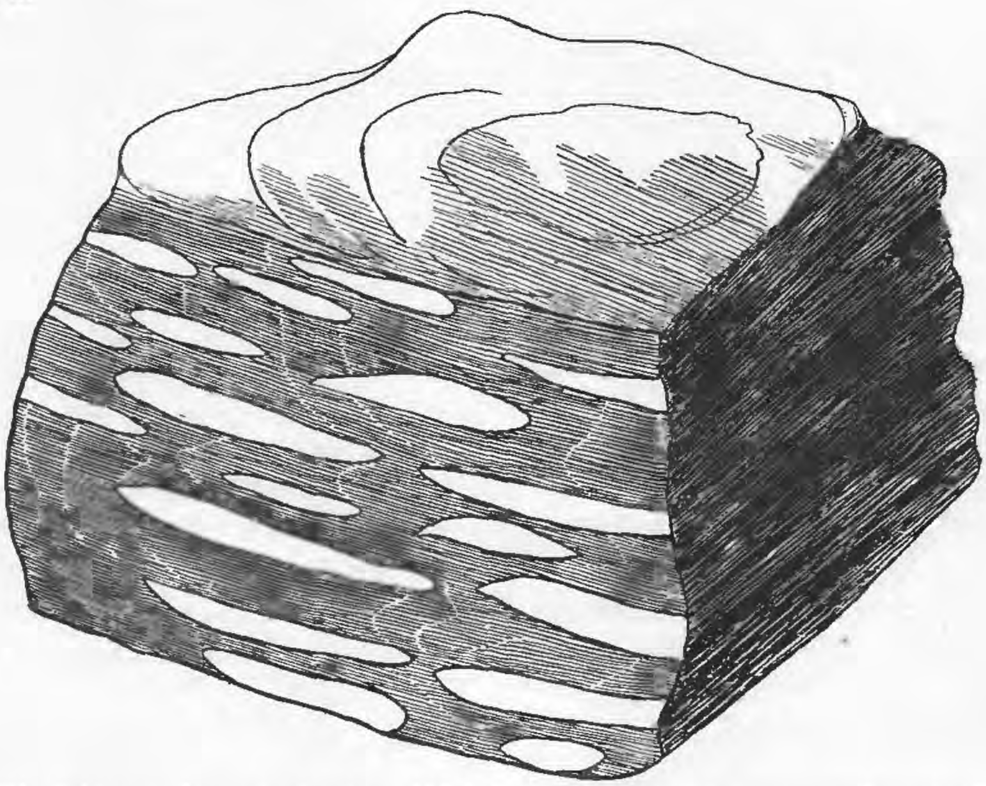

FIG. 156.—Schist-conglomerate, showing pebbled character when cut transverse to the major direction of elongation and gneissoid character when cut in other directions; from Plymouth, Vt. After Hitchcock.

The main axis of the Green Mountains is described as a series of sharply compressed folds striking approximately north and south and overturned to the west in most localities, so that induced schistosity and stratification dip eastward.

The Green Mountains are of great interest in geology as furnishing

Natural Scale $\frac{1}{62.500}$. 1 inch = 1 mile.

clinorium, Mount Greylock being a synclinorium of the second order upon the eastern flank of the great primary anticlinorium, while the Taconic Mountains are another synclinorium upon the western flank of the same. The axial planes of the secondary folds of Mount Greylock, as compared with the axial planes of the secondary folds of the Taconic range, diverge upward and converge downward. Carrying the section still farther east (fig. 157), the Greylock folds and the secondary folds on the west side of Hoosac Mountain may be considered as a normal synclinorium, the axial planes on the opposite sides of the synclinorium converging upward and diverging downward. If Hoosac Mountain be taken by itself, and the secondary folds on its flanks making a part of the synclinorium be considered as a part of the Hoosac anticlinorium, the folds are again in a normal position and Hoosac Mountain is a normal anticlinorium. In the sections secondary folds are not figured as occurring on the eastern flank of Hoosac Mountain. As another illustration of a normal anticlinorium may be mentioned Mount Washington, of Massachusetts, the structure of which has been worked out by Hobbs. The central section is a typical normal anticlinorium (fig. 158).

Fig. 157.—Transverse section through Greylock and Hoosac mountains. After Pumpelly.

Fig. 158.—Cross-section of Mount Washington, Mass. After Hobbs.

These composite folds are also complex, the transverse folding in some cases being rather severe. This cross-folding is well illustrated by Hoosac Mountain, by Greylock Mountain, and by Mount Washington, and perhaps best of all by the flexures of the Riga schist, worked out by Hobbs (fig. 159). At many localities folds of many orders may be seen, from the greatest anticlinorium mentioned, the Green River anticlinorium, to microscopic plications. On any of the mountains above mentioned the different orders of folds may be well observed.

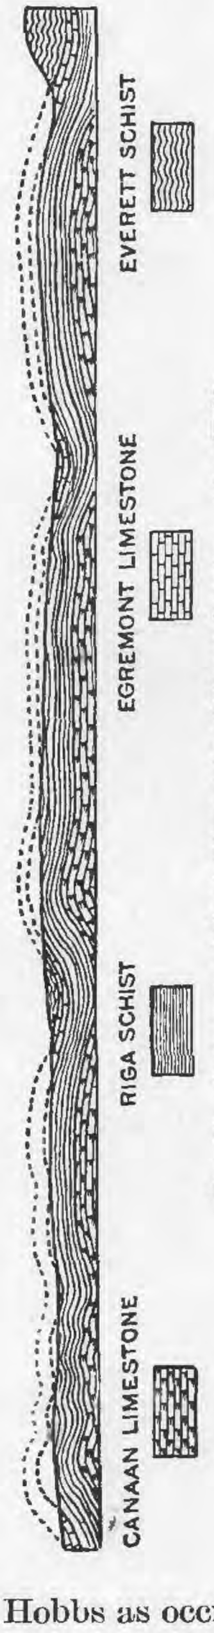

FIG. 159.—Transverse folds of Riga schist of Massachusetts. After Hobbs.

The rules for the working out of the structure of complexly folded districts are fully exemplified. At the north and south ends of Hoosac Mountain and south of Clarksburg Mountain, because of the cross folding, transverse strikes characteristic of pitching folds may be found (fig. 160). The folding of the Riga schist (fig. 159) shows the advantage of examination of the crests of ridges. The low ground at the north and south ends of Hoosac and Greylock and the south end of Clarksburg Mountain illustrate the cross topographic breaks which are likely to occur in districts which are complexly folded. In the schists of Greylock Mountain the discordance between the strike of cleavage and the strike of bedding may be observed. On the flanks of Washington, Hoosac, and Greylock mountains are found many minor folds, the degree and direction of the pitch of which correspond with the major folds.

The obliteration of unconformity by folding is nicely illustrated at Hoosac Mountain upon the flanks of the fold. The structure of the granitoid gneiss and that of the Cambrian quartzite are identical, and one appears to grade into the other; and yet on the crest of the anticline, which is an area of little differential movement, there is, as has already been said, complete evidence of unconformity.

Nearly all of the relations described between cleavage and fissility and the original structures and their different methods of production are illustrated at many localities in this district. Many of these have been described by Dale, others by Hobbs. Dale has especially illustrated fault-slip cleavage, or, as it is here called, fissility (figs. 161, 162; see also figs. 90 and 91, Dale, in previous paper, pp. 563–564). The modification of the secondary structures by infiltration, thus producing banding, has been described by Hobbs as occurring at Searles quarry in a gneiss (Pl. CXVII), and by Dale, in a slate. The Searles gneiss is at the bottom of a syncline, where the primary and secondary structures are likely to be found cutting each other, while upon the legs of the fold a short distance away the two

The plicated layers are probably beds, and these are cut by the secondary banding Photograph by Hobbs.

structures are in accordance. The relations of faults to fissility or slip cleavage are well illustrated by the accordance of the fissility with the *repeated faults in the Housatonic Valley, described by Hobbs.*[1]

mountains and of the Housatonic Valley. To point out in detail the particular localities in which each principle is illustrated, and in what manner it is illustrated, would very greatly extend this paper.

SOUTHEASTERN NEW YORK.

In southeastern New York the following summary has been kindly furnished me by Mr. F. J. H. Merrill:

The crystalline rocks of southeastern New York occur in Dutchess, Putnam, Westchester, and New York counties east of the Hudson River, and in Orange and Rockland counties on the west of that river. The lowest rock in this district is a coarse hornblende-granite, which forms the central axis of the range of mountains known as the "Highlands of the Hudson." On the flanks of these granite masses, which are probably intrusives of great age, are laminated biotitic and hornblendic gneisses, consisting chiefly of quartz and orthoclase feldspar.

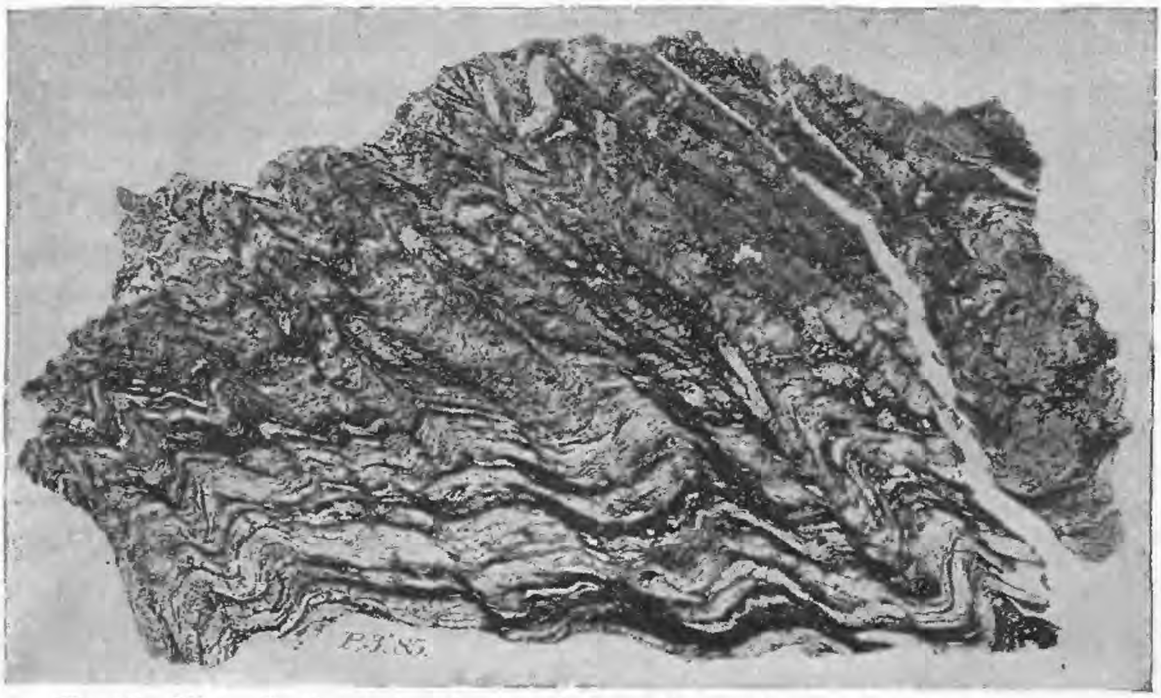

FIG. 162.—Minor plications in trough of Greylock syncline cut by cross fissility. After Dale.

These gneisses contain numerous masses of magnetic iron ore. They are probably of pre-Cambrian age.

On the northern slope of the "Highlands" these gneisses at many places in Dutchess County are overlain unconformably by a basal quartzite, which is believed to be of Lower Cambrian age. The quartzite is bordered by Ordovician limestone, and over this are schists or slates. To the southward, in Westchester and New York counties, the old gneissoid granite, which has been called the Fordham gneiss, is found in anticlinal folds trending northeast and southwest. This is overlain by two formations, limestone and mica-gneiss. These occur in synclines between the anticlinal ridges. Beneath the limestone is a thin layer of quartzite, rarely exceeding a foot in thickness, which may be regarded as the base of the Paleozoic in this district. The limestone designated the Inwood limestone is dolomitic, and in general is highly metamorphosed, coarsely crystalline, and at many places contains silicates. At

be observed that on this view a fibrous structure might develop under certain conditions, there being approximately equal shortening in two axial directions and an elongation in the third.[1] A tendency to this structure is seen in certain schists. But probably in the majority of cases there is a predominant pressure in one direction, causing a shortening in this direction and an elongation in all directions perpendicular to it. (Pl. CXV.)

This seems a simple and adequate explanation of the development of slaty cleavage in any small volume of rock, since the strain is practically homogeneous throughout a volume sufficiently small. It can not be supposed, however, that this homogeneity exists throughout any considerable volume. If a body of rock of great extent is subjected to a great compression in a certain direction, there will be not only a tendency to shortening in that direction but generally also a tendency to bending, because of unequal support in transverse directions. The result will be that, simultaneously with the shortening, there will be folding of a more or less complex character. If the supposed conditions continue for a sufficient time, the shortening in the direction of

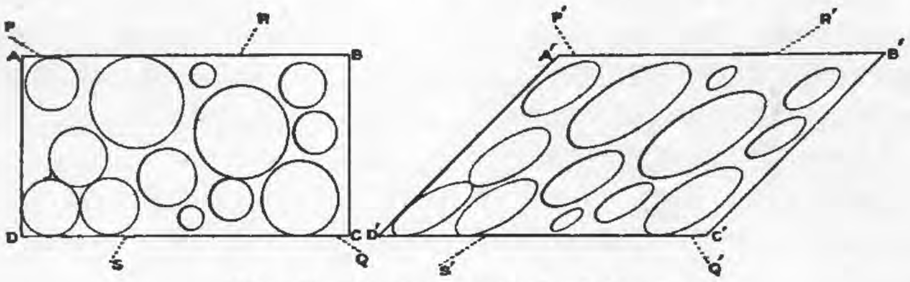

FIG. 169.—Cleavage due to simple shear.

the prevailing pressure may ultimately so far predominate that cleavage will develop in approximately parallel planes, irrespective of minor deformations of the particles due to the folding. On the other hand, there will doubtless be cases in which the local deformation predominates over the general, or is at all events of sufficient amount to modify the direction of greatest shortening of the particles, and thus to produce local variations in the direction of the cleavage planes. It is, indeed, possible that cleavage should be wholly due to local deformation, and should therefore affect only limited volumes. In discussing this local variation in the direction of cleavage, it is useful to consider the relation of cleavage to the shearing planes.

In fig. 167 let the circle represent a small spherical fragment of a sedimentary rock, and let it be supposed that the rock is under such conditions that it flows without rupture and that it undergoes a shearing strain such as is represented in the figure; the spherical fragment becomes an ellipsoid, one of whose sections is the ellipse shown. If the process of shearing were continued, the ellipsoid would be still
