feldspar, nearly always greatly decomposed, is in part lath-like, in part more anhedral, the widespread alteration making it difficult to obtain good determinations; on the whole the structure is only partly normal diabasic, and shows approximation to the dioritic.

Augite- and hornblende-porphyrites are also present in this area, as, for instance, north of the Fair-ground. Here the grayish-brown or greenish porphyrites contain small feldspar crystals and hornblende needles 3 mm. long in a groundmass composed chiefly of laths and short prisms of plagioclase, probably labradorite. Another rock in the same vicinity is an altered augite-porphyrite with phenocrysts of plagioclase and pyroxene in a groundmass of micropoikilitic structure characterized by microlites and grains of feldspar in larger quartz grains. This structure is very unusual.

The best exposures are found at the tunnel on the south side of Deer Creek, 900 feet below the Home mine, where the contact with the Mariposa slates happens to be laid bare in the bed of the creek. Fig. 1 illustrates the exposures and affords a key to the whole complex series.

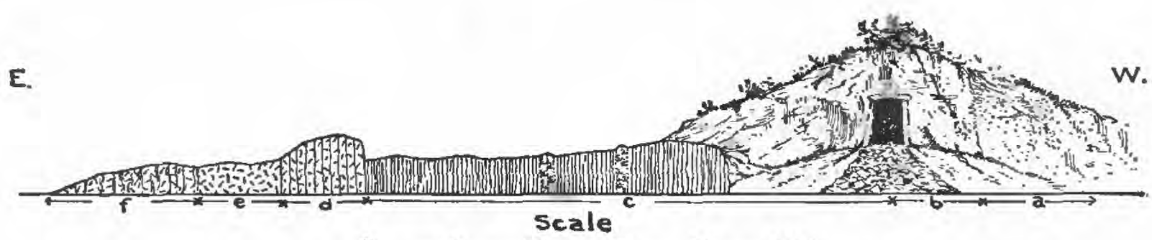

FIG. 1.—Section at tunnel 900 feet below Home mine, south side of Deer Creek. *a*, gabbro; *b*, serpentine; *c*, black mariposa clay-slate with tuffaceous sandstone; *d*, diabase-tuff; *e*, hornblende-porphyrite; *f*, augite-porphyrite, somewhat schistose.

The black Mariposa clay-slates begin at the tunnel and adjoin the serpentine on the west; they contain layers of tuffaceous sandstone and are again adjoined on the east by a dark-brown, fine-grained tuff. This tuff shows under the microscope colorless fresh augite fragments, in part altering to greenish uralite; between the augites lie fragments and aggregates of feldspar. The rock is greatly altered by development of secondary amphibole, biotite, etc.

Adjoining this tuff is a dike of normal greenish-gray hornblende-porphyrite with black hornblende phenocrysts and smaller white feldspars. East of this again is a greenish-brown, distinctly schistose augite-porphyrite greatly altered by secondary mineral growth.

On the whole, it appears probable that the hornblende-porphyrites are in part later dikes in the tuffs and diabases, though they undoubtedly in general belong to the same period of eruption.

Pyrite and pyrrhotite do not appear extensively in these rocks in the Nevada City tract.

The rock appears to be a very typical diabase. Considering that several per cent of the CaO must belong to the augite, it is at once apparent that the average composition of the feldspars does not reach (Ab_1An_1), but is rather that of an andesine. Sulphide has in the analysis been calculated as FeS_2, only that compound being present in the sample; in the specimen from the same outcrop from which the thin sections were taken a large quantity of pyrrhotite was identified by Dr. Stokes.

FIG. 2.—Primary pyrrhotite in augite; in diabase, 121 G. V. Magnified 60 diameters. Black=pyrrhotite; *a*, augite; *b*, uralite; *c*, chlorite.

Other rocks in the vicinity are similar, but usually contain more chlorite; in some the pyrrhotite is more or less completely replaced by black iron ores.

The diabasic rocks from the hanging wall of the Idaho-Maryland vein are grayish-green, extremely chloritic rocks, often containing much carbonates and sericite. In thin section the all-pervading chlorite generally veils the original character, but it is suspected that several varieties of rocks are present. The rock from the hanging wall, fifteenth level (145 G. V.), shows chiefly a mass of feldspars of imperfect lath-like form, between which lies much chlorite. The extinctions indicate a rather acid plagioclase. Other slides, from the sixteenth level near the incline, show a chloritic mass in which lie very long and narrow lath-like feldspars, the structure in fact approaching the pilotaxitic groundmass of some of the porphyrites. Still another specimen, from the mine dump, shows a distinct tuffaceous character. This is not so surprising, for the workings of the mine now extend under the area indicated on the surface as schistose porphyrite, which area in fact is largely composed of pressed porphyrite-tuff.

A partial analysis of No. 145 G. V., by Dr. H. N. Stokes, gave·

	Per cent.
SiO_2	57.94
CaO	1.85
K_2O	.21
Na_2O	8.95

The large percentage of Na_2O and the small amount of CaO are very unexpected, but the rock is much altered and it is not safe to draw any conclusion as to its original composition.

The principal rock exposed in the shaft of the South Idaho is a very

products, and probably also to scapolite, by the ordinary metamorphic processes. Thermal waters have in addition produced abundant calcite and pyrite.

It appears as if the final result of the metamorphic processes would have been a serpentinoid rock consisting of serpentine, chlorite, and actinolite, in which lie larger bastite crystals.

THE NORTH STAR DIABASE AND PORPHYRITE AREA.

Extent.—This area extends in roughly rectangular form from near the North Star up toward the northwestern andesite area. It is bounded

FIG. 3.—Intergrowth of primary pyrite and pyrrhotite with titanic iron ore; in diabase (34 G. V.). Magnified 112 diameters. *a*, augite; *b*, hornblende; *c*, plagioclase; *d*, titanic iron ore; *e*, pyrite; *f*, pyrrhotite.

by the Calaveras formation on the west and by the granodiorite on the east, north, and south.

Description of rocks.—In the southeastern portion of the area medium-grained diabases prevail, in part very fresh and unaltered rocks. Typical specimens were obtained 1,600 feet southeast of the North Star mine (32 G. V.), 3,000 feet north of the Omaha mine (34 G. V.), and 1,300 feet north of the same mine (108 G. V.).

RHYOLITIC TUFFS.

Above the auriferous gravels lie, in the deeper parts of the depressions, a series of light-colored or white clayey or sandy rocks, more or less perfectly consolidated, and commonly described as pipeclay and sand. These are largely rhyolitic tuffs, more or less pure. Certain of the beds consist nearly exclusively of minute fragments of glass, while others are so admixed with mainly granitic detritus as to nearly mask their tuffaceous character. The fragments, both of glass and of granitic minerals, are generally very sharp and angular. Besides, bodies of gravel are also included in the tuffaceous series, and, on the whole, it is impossible to draw a distinct line between the auriferous gravels and the rhyolitic tuffs. On the southern face of Cement Hill the line between the two formations is fairly sharp, separating 60 feet of gravel from over 200 feet of rhyolitic tuff. A little rhyolitic material is found in the sands of the main channels down to a distance of 40 feet, or even less, from the bed rock. The occurrence of the rhyolitic tuff is practically confined to the northern part of the Banner Hill and Nevada City tracts.

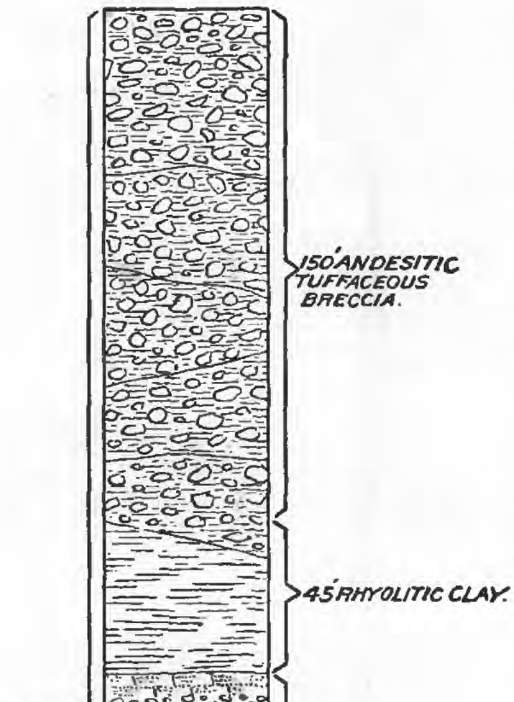

FIG. 4.—Section of superjacent formations at Manzanita mine, Nevada City.

The composition of several tuffs and sandstones is shown by the table on the next page; the partial analyses were made by Dr. H. N. Stokes.

It is apparent that the purest tuff has very nearly the composition of a rhyolite. Grains and flakes of a brownish translucent mineral, with faint double refraction, are abundantly developed, especially in the rocks poor in alkalis. This is undoubtedly the same kaolin mineral recognized by Mr. H. W. Turner in his Ione sandstone.[1]

[1] Fourteenth Ann. Rept. U. S. Geol. Survey, Part II, 1894, p. 464.

Table of partial analyses of clays, sandstones, and rhyolitic tuffs.

2 N. C.: Odin mine, 2 feet above bed rock. Sandy clay containing no rhyolite fragments.
5 N. C.: 800 feet south of Sugarloaf reservoir. Yellowish sandstone with rhyolite fragments; 100 feet above bed rock.
7 N. C.: West Harmony drift mine, 4 feet above bed rock. Sandy clay; no rhyolite fragments.
8 N. C.: 850 feet west of West Harmony incline. Pure rhyolite tuff.
10 N. C.: Manzanita pit, 10 feet above bed rock. White sandstone; a few rhyolite fragments.
14 N. C.: Hydraulic pit, west of Odin mine. Crumbling white sandstone; a few rhyolite fragments.

At the Cement Hill diggings, in the northwest corner of the Nevada City area, sandstones and gravel occur cemented by an almost pure, yellowish opal.

ANDESITIC TUFFS.

It has already been mentioned that the high, gently sloping ridges of these districts are covered by andesitic flows, and their general character as tuffs and tuffaceous breccias has also been described. As a

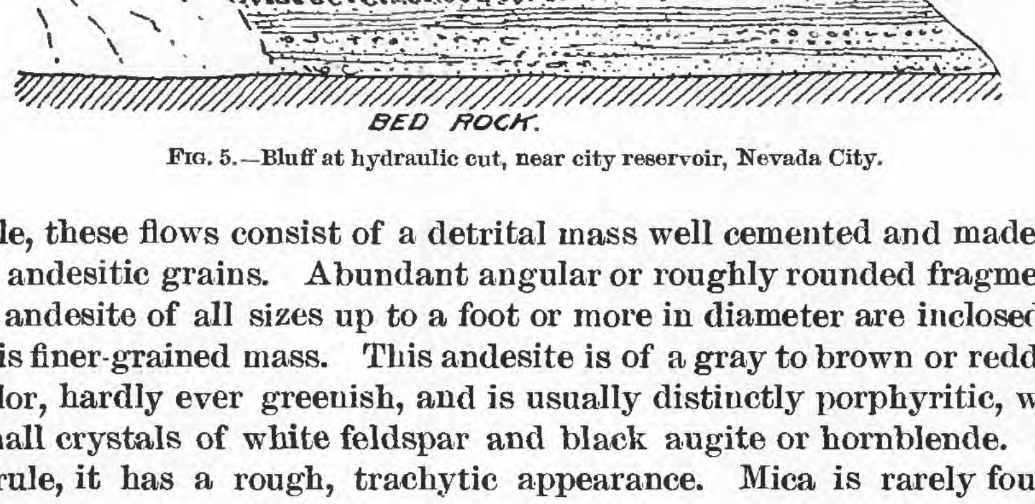

FIG. 5.—Bluff at hydraulic cut, near city reservoir, Nevada City.

rule, these flows consist of a detrital mass well cemented and made up of andesitic grains. Abundant angular or roughly rounded fragments of andesite of all sizes up to a foot or more in diameter are inclosed in this finer-grained mass. This andesite is of a gray to brown or reddish color, hardly ever greenish, and is usually distinctly porphyritic, with small crystals of white feldspar and black augite or hornblende. As a rule, it has a rough, trachytic appearance. Mica is rarely found.

Pyroxene (both augite and hypersthene) is almost invariably present. Black basaltic hornblende frequently occurs with the pyroxene, and usually in larger crystals. The groundmass is partly glassy, or of a very fine grained, holocrystalline structure. The thickness of the volcanic flows ranges from 400 feet in the Banner Hill district to about 200 feet in the Nevada City district. The easily disintegrating cement renders the exposures unsatisfactory, and a deep, reddish soil usually covers the tops of the ridges. This disintegration, and the tendency of the decomposed material and residual andesitic bowlders to slide downhill, often make the contacts with the underlying formations obscure and difficult to trace. Good exposures are found in the vicinity of the Harmony gravel mines. The best exposure, though practically inaccessible, is in the bluff of the Manzanita hydraulic pit north of Nevada City. Resting unconformably on the sloping surface of the white clays and sands, there are here at least four separate flows of andesitic tuff, each 20 to 30 feet thick and separated by irregular, worn

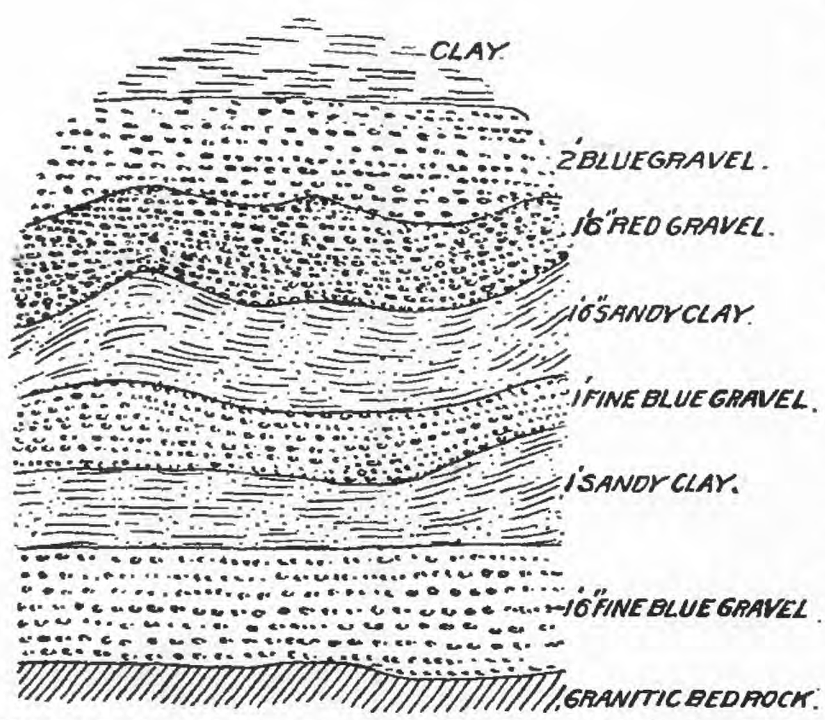

FIG. 6.—Section of breast of workings, West Harmony drift mine, 300 feet east of main drift.

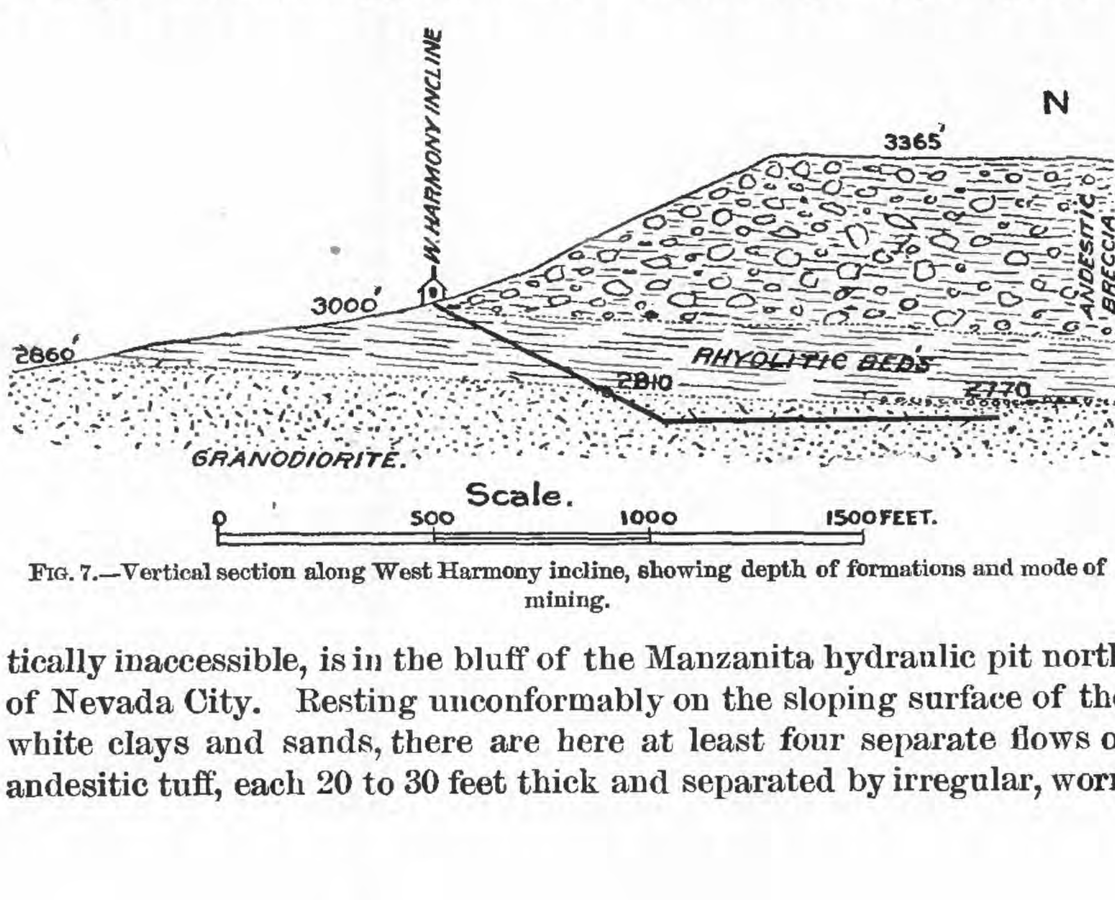

FIG. 7.—Vertical section along West Harmony incline, showing depth of formations and mode of mining.

surfaces. The amount of angular andesitic bowlders is not constant, and some flows consist entirely of the fine, detrital, cementing tuff. Of such character are the tuffs overlying the clays and gravels exposed in the hydraulic pit just north of Grass Valley.

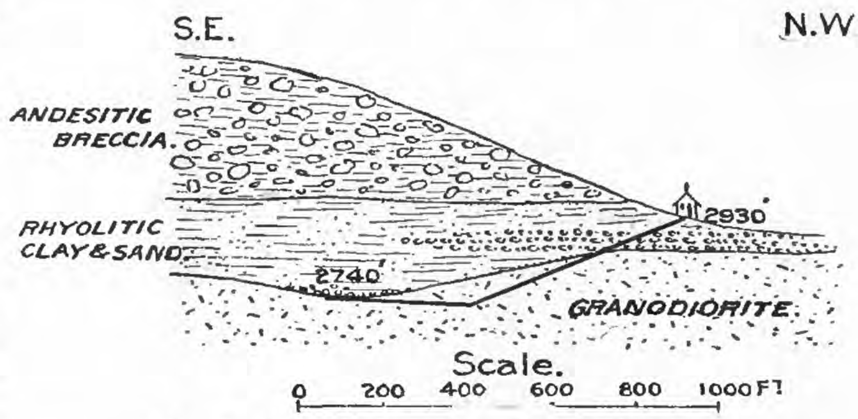

FIG. 8.—Vertical section along Yosemite incline.

ALLUVIUM.

The alluvial deposits are of small extent, and consist principally of a few gravel flats along Deer Creek, Little Deer Creek, and Wolf Creek. Many of these bodies of gravel are formed of débris from hydraulic gravel mines.

Alluvial sands and clays have accumulated in several swampy flats to the south and southeast of Nevada City, and also to some extent near the race-track. The largest alluvial deposits lie in Deer Creek below the Providence mine, and consist of well-washed gravel of quartz and metamorphic rocks, with some sand. They are made up largely of the débris from the extensive hydraulic mines just north of Nevada City, which had their principal outlet through the first gulch emptying into Woods Ravine from the east. In the Grass Valley district extensive flats of sand and clay occur on both branches of Wolf Creek above the city, and smaller gravel flats are found at intervals along the creek below the city. In the southwestern part of the district there are at the headwaters of the gulches a number of shallow alluvial flats of sand and clay, usually of a marshy character. The largest is found south of the North Star mine.

CHAPTER XIV.

DETAILED DESCRIPTIONS.

BANNER HILL DISTRICT.

VEINS OF THE DEER CREEK BASIN AND WILLOW VALLEY.

General features.—These veins have in general an east-west strike and flat medium northerly or southerly dip. The ores are frequently of high grade and the fissures narrow. The gold is associated with much silver, and there is a considerable amount of sulphurets. A few veins having a north-south strike and flat westerly dip intersect the

FIG. 10.—Sheeted zone in granodiorite, Deer Creek, Bellefountain mine.

prevailing system. The east-west veins are in closest genetical connection with a system of joints or a sheeting of the country rock; this sheeting begins to show very strongly a little beyond the Deadwood mine, and may be seen to best advantage all along the rocky canyon of Deer Creek. Fig. 10 illustrates this structure; granodiorite is divided in benches or sheets from 1 to 4 feet thick and dipping north at slight

hanging wall of the vein is not well defined, but the foot wall continues unbroken and distinct. Numerous seams dipping north at various angles, but carrying no quartz, are noted, as illustrated on fig. 11. The mineral spring on the fourth level is described in Chapter IX. The filling of the vein consists of the usual milky-white quartz, occasionally containing grains of calcite. Fragments of the country rock, sharp and angular, though converted into carbonates and sericite, are very frequent in the quartz, and around these fragments the sulphurets often cluster, as illustrated in Pl. VII, fig. *b*. The ore contains the large amount of 6 per cent of sulphurets, which have a very high percentage of arsenopyrite and are of medium grade, containing somewhat more gold than silver by weight. (For analysis of concentrates, see p. 127.)

Arsenopyrite and pyrite prevail, while galena, zincblende, and copper pyrites are very subordinate.

The ore shoots are somewhat irregular, but the best pay is found in a chimney in the vicinity of the shaft, dipping about 70° E. on the plane of the vein. The value of the ore is stated to be $15 per ton.[1] The gold is 675 fine.

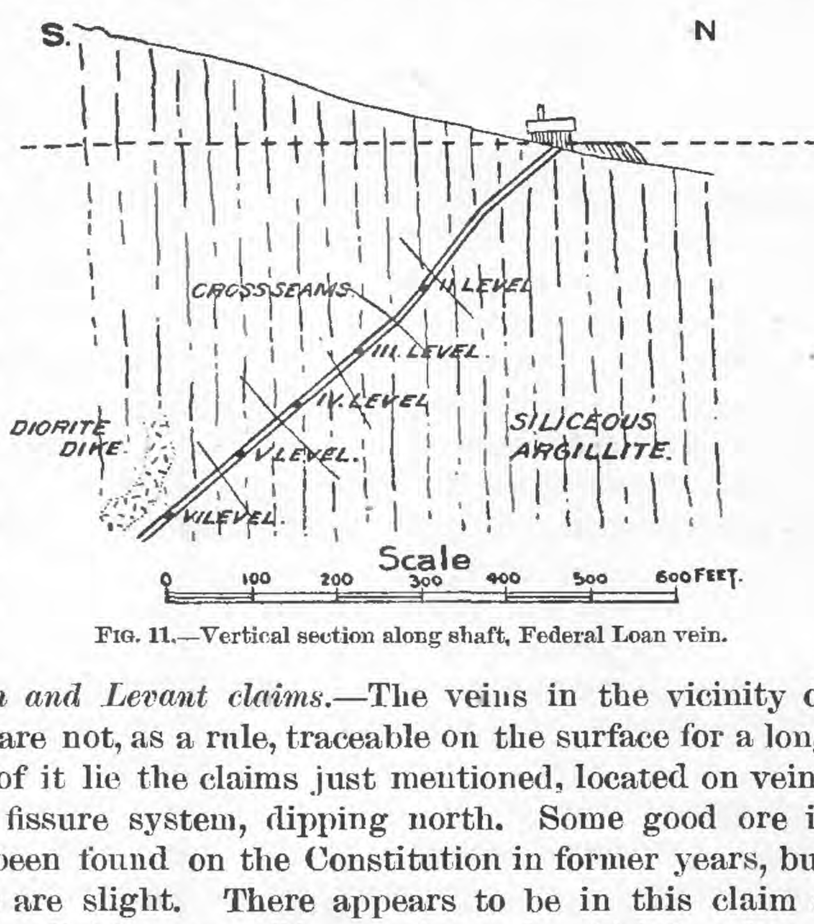

FIG. 11.—Vertical section along shaft, Federal Loan vein.

The Constitution and Levant claims.—The veins in the vicinity of the Federal Loan are not, as a rule, traceable on the surface for a long distance. North of it lie the claims just mentioned, located on veins belonging to the fissure system, dipping north. Some good ore is reported to have been found on the Constitution in former years, but the developments are slight. There appears to be in this claim a number of small parallel fissures. The country rock, which is a dense, siliceous argillite, is impregnated with iron pyrites along the veins. In the mint report of 1880 the vein is stated to be 1 foot thick, heavily sulphureted, and similar to the Lecompton.

The Lecompton vein.—The Lecompton is situated on the south side of Deer Creek, almost adjoining the Federal Loan. It was located in 1857, and up to 1863 the gross yield of the mine was $220,000. From 1863 to 1866 it was also a considerable producer; in 1867, however, the incline situated near the bed of Deer Creek was flooded by a freshet,

[1] Eleventh Rept. State Mineralogist.

depth, on account of which the outcrop can not be readily traced on the surface. The vein is narrow, from 3 to 16 inches, and yields some very high grade ore, the value sometimes reaching $300. Generally similar to the Lecompton, the bullion contains some antimony and much silver, being only 750 fine. The strike is N. 73° E., and the dip at first 45° N. At a depth of 200 feet a cross vein is struck, belonging to the Federal Loan system of fractures, and, according to Mr. Lyons, the vein leaves the original fissure and continues on the one dipping south (fig. 12). This is of great interest as proving that the two vein systems are contemporaneous.

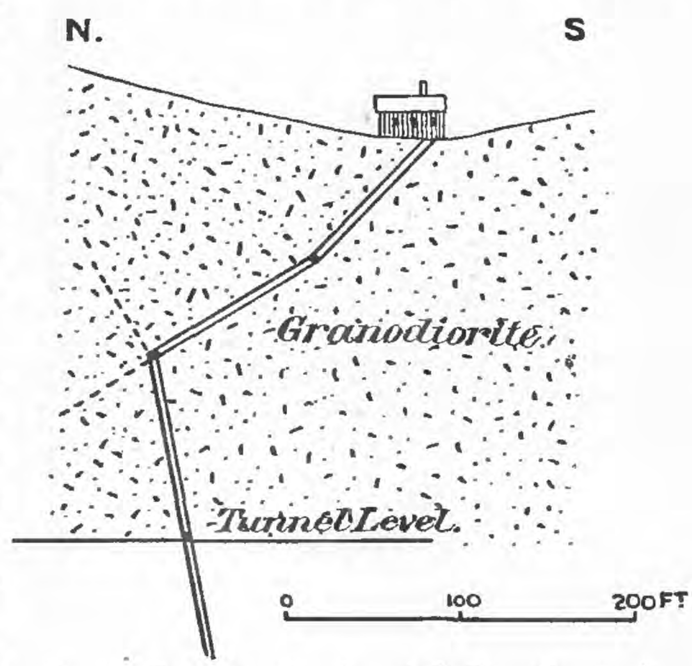

Fig. 12.—Vertical section along shaft, Never Sweat vein.

Near Willow Valley there are a considerable number of veins, none of which, however, have been worked very extensively.

The Montana vein.—This has been worked intermittently and has produced some good ore. It is developed by an incline shaft 400 feet long; strike northeast, dip 22° NW. The vein is from 6 to 8 inches wide, and can be traced for a considerable distance across the contact line. The ore, which is heavily sulphureted, forms two pay shoots pitching to the southwest on the plane of the vein, one on each side of the shaft and from 100 to 200 feet wide. In the claim are three more parallel ledges of less importance.

The Willow Valley vein (*Tolbert*).—Located in 1865, but little work has been done on this vein since 1867; 800 tons were taken out in 1866, yielding an average of $22 per ton.[1] It is developed by a 200-foot incline; the vein strikes northeast and dips 45° to the northwest; its width is from 1 to 4 feet. The country rock is granodiorite, the eastern end of the claim crossing the contact.

At the forks of the Washington and Scotts Flat roads is a small vein, striking N. 72° W. and dipping 70° N., on which a little work has been done.

The Franklin-Hussey vein.—Not much work has been done on this vein since 1884, when some very rich ore, going as high as $150 per ton, was produced. It is developed by an incline and drifts 230 feet long and extending 90 feet on each side. The strike is northeasterly and the dip 45° NW. The vein is in places from 1 to 2 feet wide.

[1] Bean's Directory.

Floyd and the Mayflower. None of the intersections being visible at the time of my visit, I rely upon the statements of Mr. W. H. Martin, for many years owner and superintendent of the property. The relation of the east-west veins to the Beckman is shown by the diagram, fig. 13, indicating a relative downward movement of perhaps 20 feet of the sheets between the Big Blue and the North Star. A horizontal projection of the Floyd and the two faulting veins shows the relation indicated in fig. 14, the amount of the faults not exceeding 20 feet.

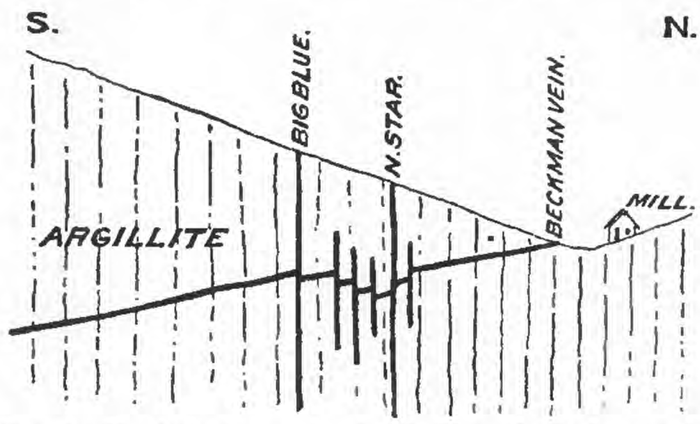

FIG. 13.—Vertical section, showing faults on the Beckman vein, Mayflower mine.

The Canada Hill (Charonnat) vein.—This vein was worked from 1854 to 1863, but the most extensive work on it was done between 1879 and 1887, in which period the mine produced 19,810 tons of ore, containing about $18 per ton; the exact percentage of sulphurets was 2.8, averaging $90 per ton. The ore yielded $14.80 per ton in amalgamated gold bullion, containing 73 per cent of gold and 27 per cent of silver, and $3.20 per ton in concentrated sulphurets, probably containing much silver. The Canada Hill incline is 1,300 feet deep on the vein and there are over 9,000 feet of drifts; the country rock is a normal granodiorite. The vein strikes north and south, bending to the northwest north of the shaft, and dips 15° to 20° W.; in places it is almost horizontal. It is 15 to 18 inches wide, frequently, however, closing down to a seam. The ore contains, like the Grant, besides free gold, much arsenopyrite, zincblende, galena, and pyrite, and is beautifully ribboned by alternating streaks of sulphurets. Near the cross veins this sulphureted ore is said to change to a more quartzose character, with occasional rich bunches at the intersection. An analysis of the ore showed the presence of tellurium (Mint Report, 1882).

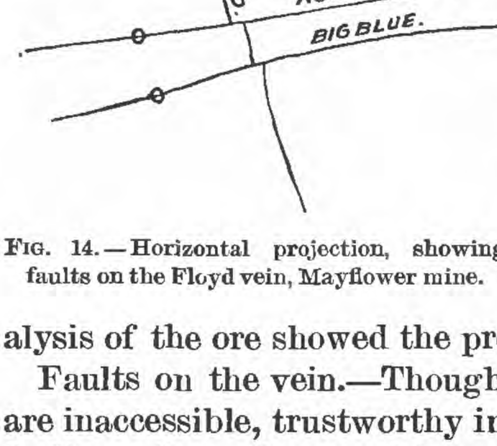

FIG. 14.—Horizontal projection, showing faults on the Floyd vein, Mayflower mine.

Faults on the vein.—Though at present the underground workings are inaccessible, trustworthy information in regard to the well-defined faults on this vein was obtained from Mr. Charonnat, and his information is verified by the underground maps and by inspection of the cross-seams on the surface. The Canada Hill is crossed by the heavy St. Louis vein, as well as by a great number of other fissures, rarely carrying quartz, striking a little north of east and perpendicular or dipping slightly north. All these throw the Canada Hill vein to the left, going north on the vein. The greatest fault is that produced by the St. Louis, which amounts to 150 feet on the surface and in the drain tunnel, measured in a horizontal direction, which corresponds to a vertical displacement of 45 feet. Between the St. Louis vein and the shaft there are at least two and probably more faults, throwing the Canada Hill an aggregate amount of about 150 feet in horizontal distance; the vein is often cut off as with a knife, as is shown by a portion of the map of the mine given in fig. 16. The rule for finding the faulted vein in the Canada Hill mine is, clearly, to drift in the hanging wall when going north on the vein.

The Grant vein, parallel to the Canada Hill, but dipping east, is apparently not faulted to any notable extent by these cross veins.

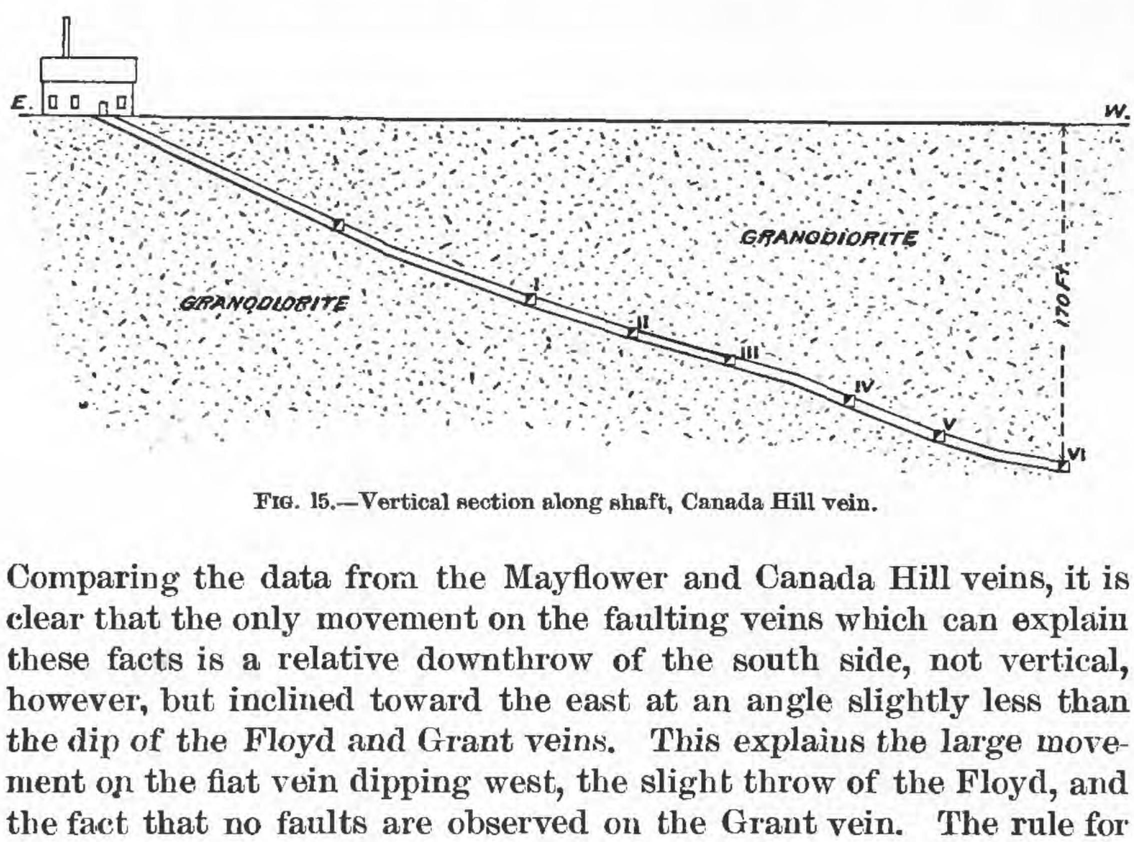

FIG. 15.—Vertical section along shaft, Canada Hill vein.

Comparing the data from the Mayflower and Canada Hill veins, it is clear that the only movement on the faulting veins which can explain these facts is a relative downthrow of the south side, not vertical, however, but inclined toward the east at an angle slightly less than the dip of the Floyd and Grant veins. This explains the large movement on the flat vein dipping west, the slight throw of the Floyd, and the fact that no faults are observed on the Grant vein. The rule for finding the faulted parts of the veins dipping east is thus to drift in the foot when going north on the vein. Many of the faulting fissures are vertical, so that no distinction can be drawn between normal and reversed faults. The St. Louis, however, dips about 85° N., and the fault produced by it is therefore a reversed or overthrust fault.

The Greenman vein, a short distance west of the Canada Hill, dips to the east and, according to Mr. R. Sharpe, intersects the latter without faulting or being faulted. Drusy quartz, galena, pyrite, arsenopyrite, blende, and molybdenite were noted on the dump.

The Wide West is a small vein parallel to the Canada Hill and cropping in Little Deer Creek. It is said to be 1 foot wide and to contain good quartz, but a heavy influx of water in the shaft stopped the developments.

The Union vein.—Located about a mile east of Canada Hill, on the north side of Little Deer Creek, this vein is the most westerly of the

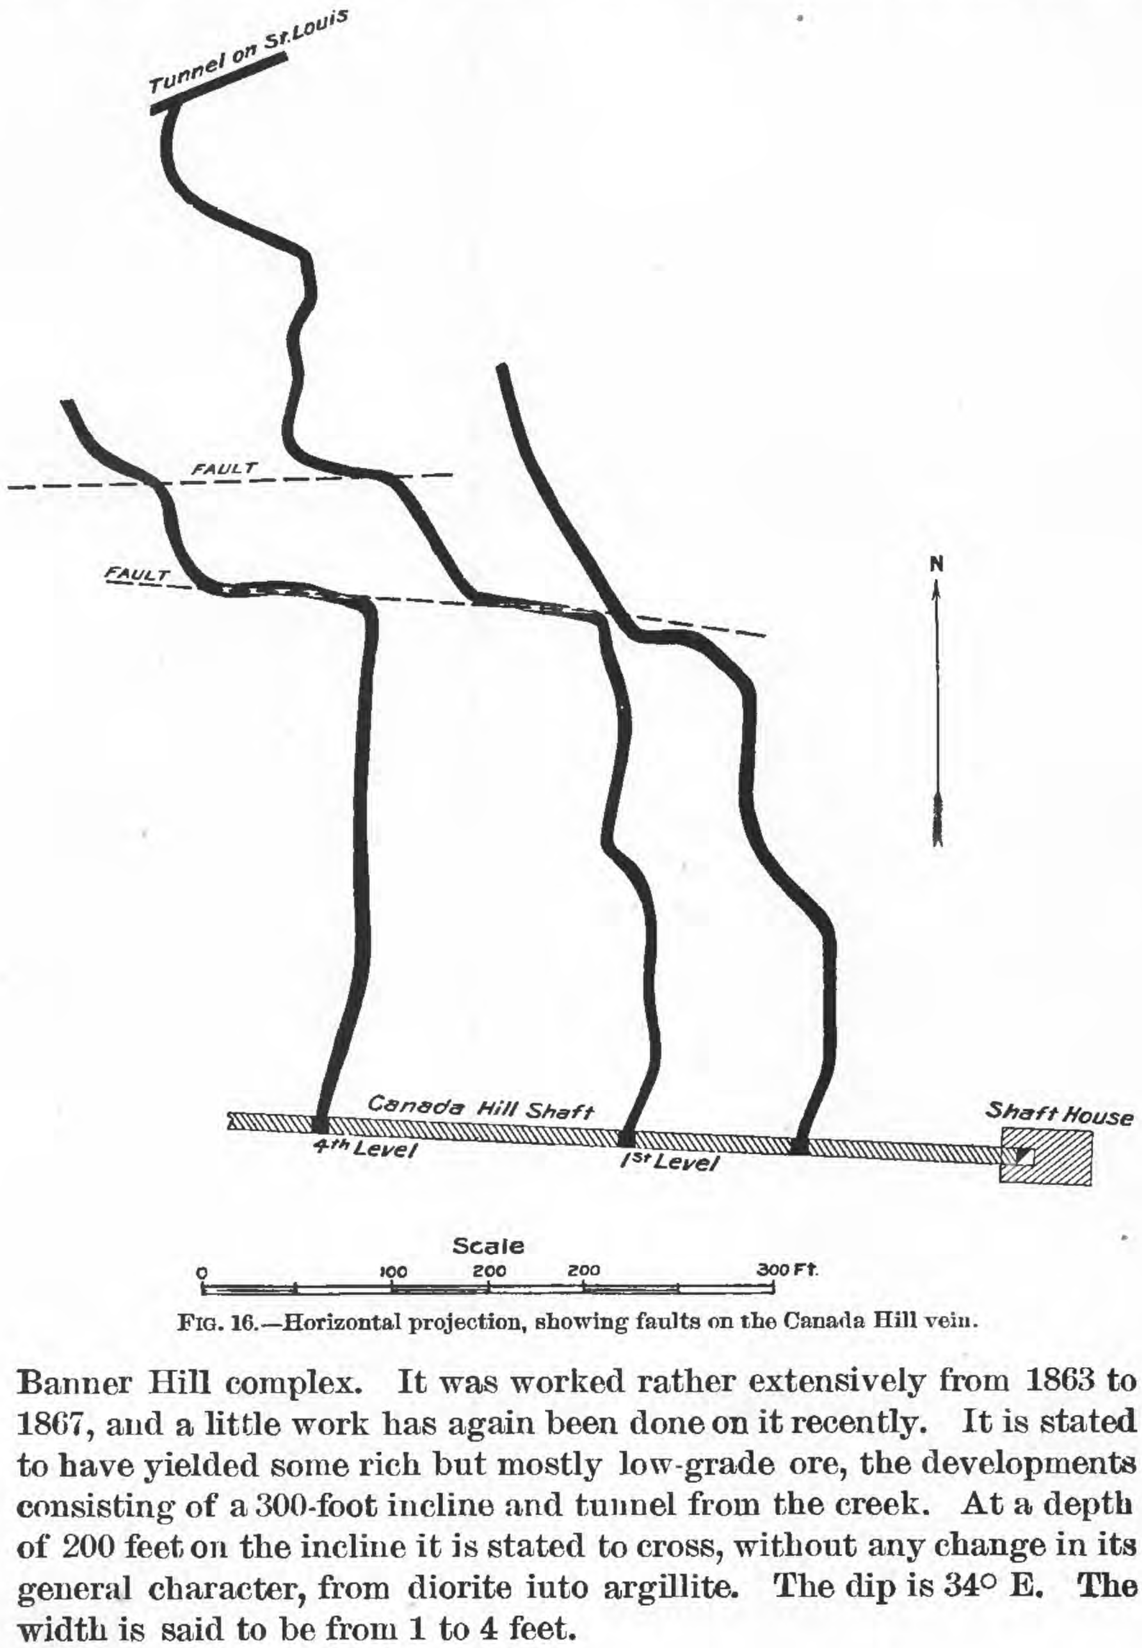

FIG. 16.—Horizontal projection, showing faults on the Canada Hill vein.

Banner Hill complex. It was worked rather extensively from 1863 to 1867, and a little work has again been done on it recently. It is stated to have yielded some rich but mostly low-grade ore, the developments consisting of a 300-foot incline and tunnel from the creek. At a depth of 200 feet on the incline it is stated to cross, without any change in its general character, from diorite iuto argillite. The dip is 34° E. The width is said to be from 1 to 4 feet.

VIEW OF SUGAR LOAF AND CEMENT HILL FROM NEVADA CITY.

is clear that the pay shoot in this part of the mine has contracted and split in two, one on each side of the shaft. As a whole, the wide shoot may be said to dip to the northeast on the plane of the vein.

The developments to the southwest have generally stopped when a series of fissures faulting the vein was encountered, but, as shown by the work of the last few years on the fifth level, good ore occurs in and beyond the faults. The faulting fissures strike east-west, are nearly

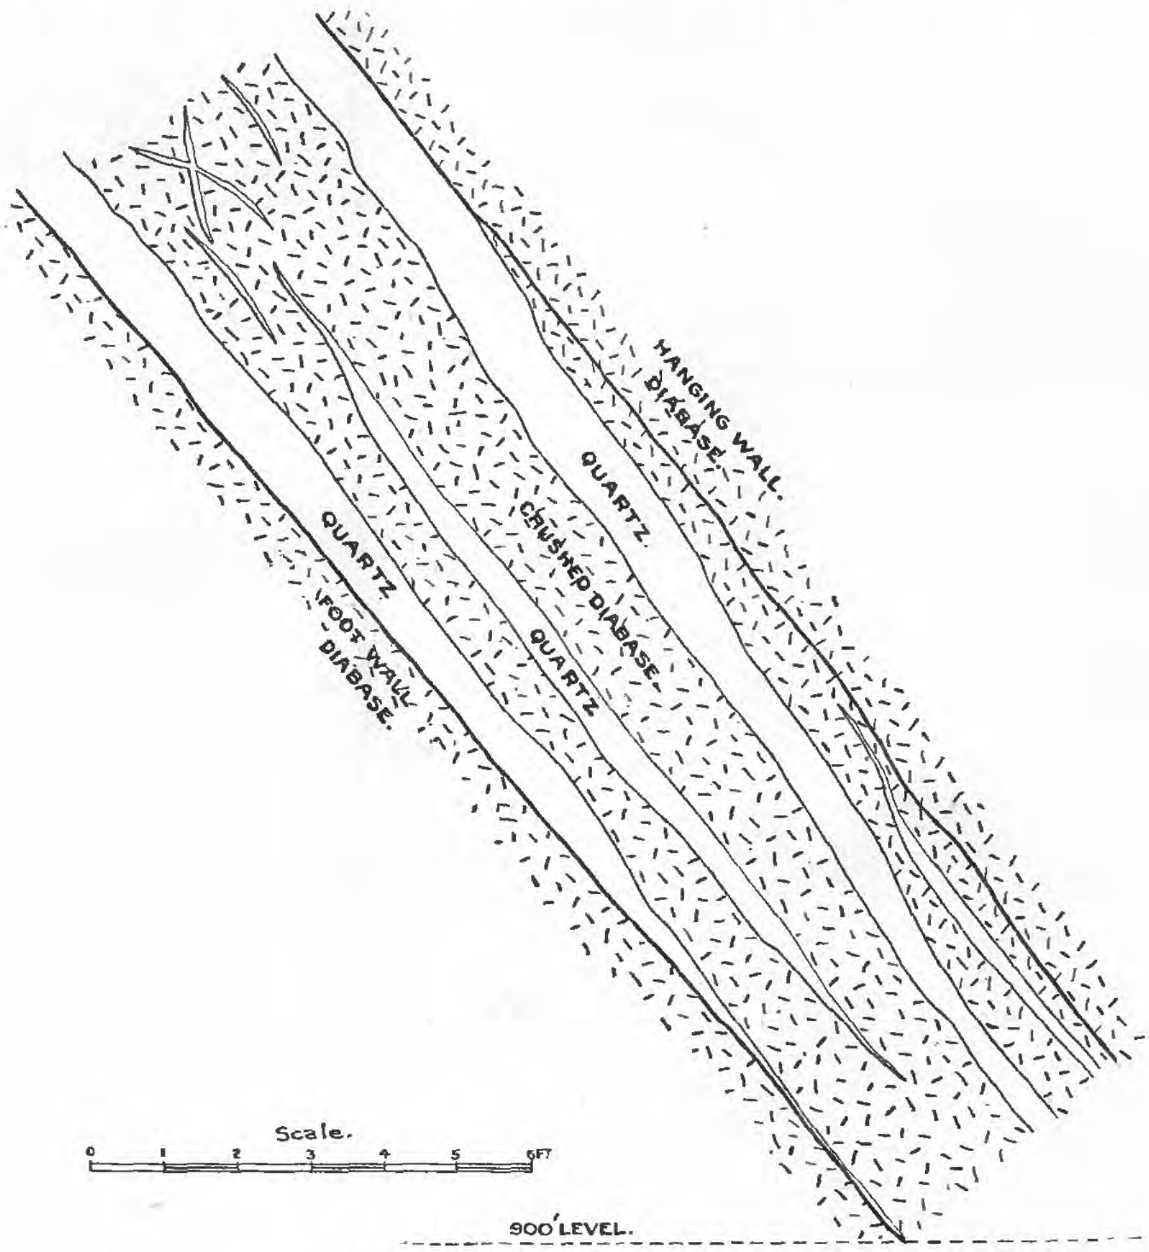

FIG. 19.—Section of Pittsburg vein, ninth level.

perpendicular, and contain no quartz; at least three of them have been recognized, and Hague mentions that the vein south of the old shaft down to the fourth level has been traced through three of these faults and appears to be somewhat enriched by them. Below the fifth level the vein has not yet been followed through the faults. The same fissures are found to fault the adjoining Gold Flat vein. The throw of the faults measured along the drifts does not exceed 40 feet, the north

the *Cadmus* mines are located. In the former several small veins have been found, dipping northwest, southeast, and east at angles of 30° to 40°, and some of them carrying coarse gold. At the Cadmus, the works of which were started in 1895, there are also several veins, one of them up to 1 foot wide and dipping west. Some coarse gold has been found on them.

ORO FINO, YELLOW DIAMOND, AND OTHER CLAIMS.

Though the great Ural vein can not be traced much farther than to the limits of the special sheets, there are to the west-northwest of the Coan shaft several veins, usually dipping east and extending down toward the river. None of them follow the contacts, and, as the sketch, fig. 20, shows, they are inclosed in different kinds of rocks. The Oro

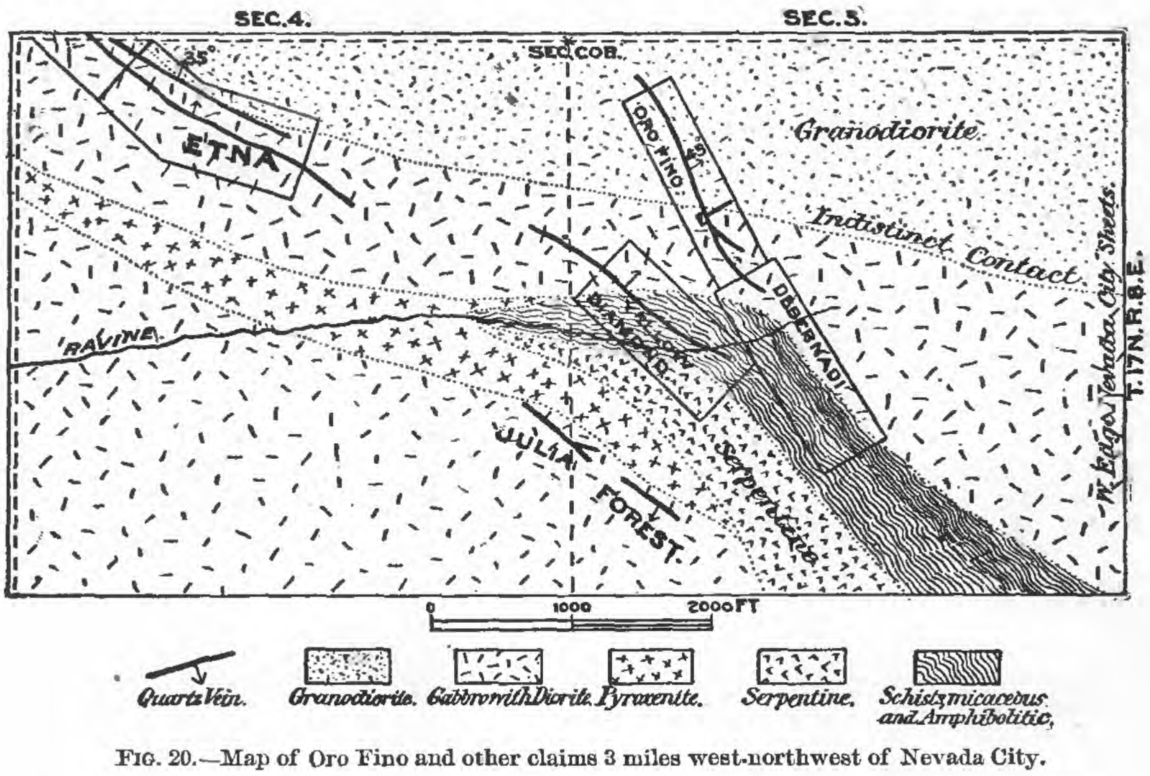

FIG. 20.—Map of Oro Fino and other claims 3 miles west-northwest of Nevada City.

Fino is the most important, and is developed by a shaft 300 feet deep on the incline. The vein dips from 45° to 32°, and strikes north-northwest. The width is said to be about 2½ feet, and there are three pay shoots, one north of the shaft, one at the shaft and 100 feet wide, and finally one narrow but rich shoot south of the shaft. The northern part of the vein lies in granodiorite, while at the shaft it is in a granular rock closely allied to a gabbro. There is a small amount of sulphurets. The Yellow Diamond has a northwest strike and lies chiefly in amphibolitic schists, with serpentine not far away in the foot wall. Several smaller shoots of ore have been found on the Yellow Diamond. In one place the vein is cut and faulted by a steep cross fracture, striking east-northeast. The Julia is a heavy, perpendicular, thus far barren vein; it lies in gabbro and carries some copper pyrite. The Forest

western part there is in the foot wall a rather heavy dike-like mass of an extremely chloritic and altered diabase. The Spring Hill is from 2 to 5 feet wide and contains a small amount of sulphurets in fine distribution. The ore is generally low-grade; though several smaller lots of high-grade ore were milled in 1870.[1] Some work was done on it in 1892 with encouraging results.

THE COE VEIN.

This deposit is on the west side of the road from Grass Valley to Nevada City, about one-half mile from the former. It has been idle for many years past, but was extensively worked twenty years ago. It is said[2] to have yielded $500,000. It is developed by a shaft 554 feet deep on the incline, and three levels run from the same. The vein,

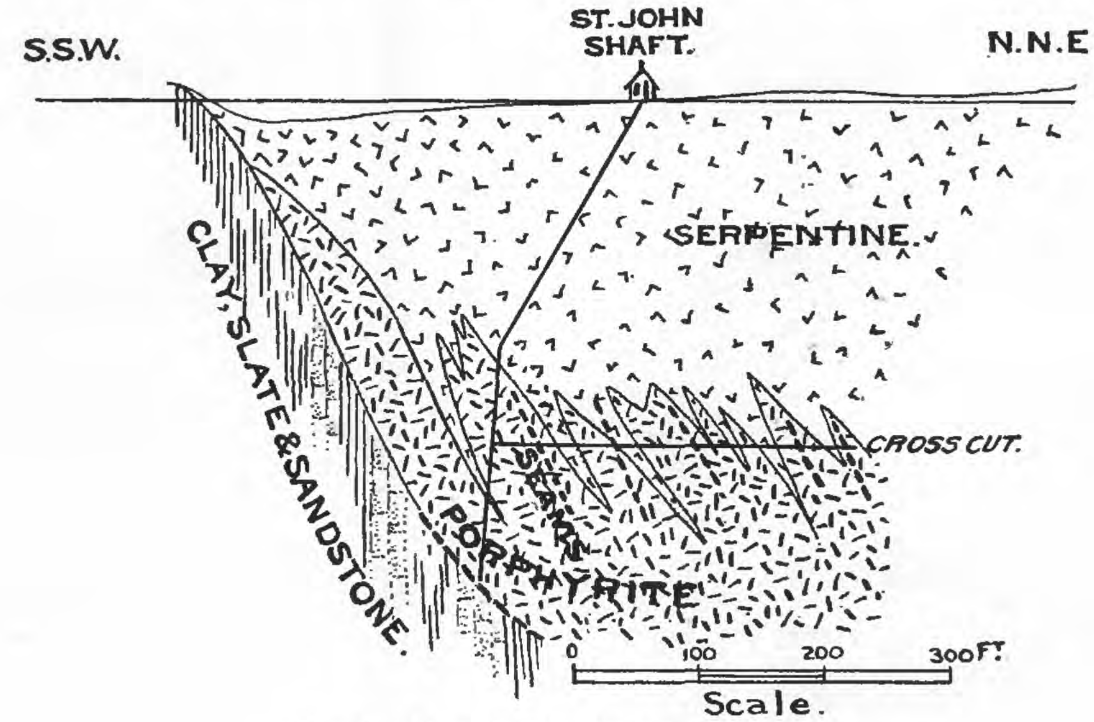

FIG. 21.—Vertical section through St. John shaft.

which lies in serpentine, can be traced for only 1,000 feet west of the road. The strike is parallel to that of the Idaho-Maryland, but the dip is 60° N. It is not, as often asserted, an extension of the vein just mentioned. The outcrops are remarkably strong, showing 3 feet or more of solid quartz. On the west it is said to continue up to the St. John, but there is not sufficient evidence to support this view. Some croppings show at the head of the gulch in which the Coe is located, but it is not beyond doubt the same vein. The ore is said to contain only 1 per cent of pyrite and galena. The extent of the pay shoot is not known; it is reported to pitch to the west.[3]

[3] Tenth Ann. Rept. State Mineralogist.

THE ST. JOHN MINE.

This property, which lies three-fourths of a mile north of Grass Valley, was actively prospected in 1893 and 1894, but is at present closed down. The geological features shown in the workings are of great interest. At the point where the shaft is sunk some quartz appeared on the surface, but no continuous vein could be traced. The shaft goes down to a depth of 220 feet, dipping south at 70°, and from there on to the bottom at a depth of 500 feet it is nearly perpendicular. The serpentine of the surface is found to be replaced by porphyrite, traversed by seams of serpentine (fig. 21). In the bottom of the shaft the contact with the black clay-slate was unexpectedly struck, and on this contact a quartz vein, in one place nearly 10 feet thick. Drifting east the heavy body of quartz soon contracted, and the relations at the face of the drift are illustrated by fig. 22. Between the slate in the foot wall and the serpentine in the hanging wall lie a few feet of slaty serpentine with stringers of quartz, the latter containing some galena and free gold. West of the shaft the vein, or at least a branch of it, goes in the clay-slate, but in a little crosscut in the foot wall it shows again the relations illustrated in fig. 23, the serpentine resting on the clay-slate and separated from it by a polished seam and a small quartz vein. All these facts point strongly to the existence of an overthrust fault along the contact of slate and serpentine. In a long crosscut, shown in fig. 21, a number of seams were met with, almost forming a sheeting of the porphyrite, and most of these carry a little free gold, as shown by prospecting the crushed matter in the pan.

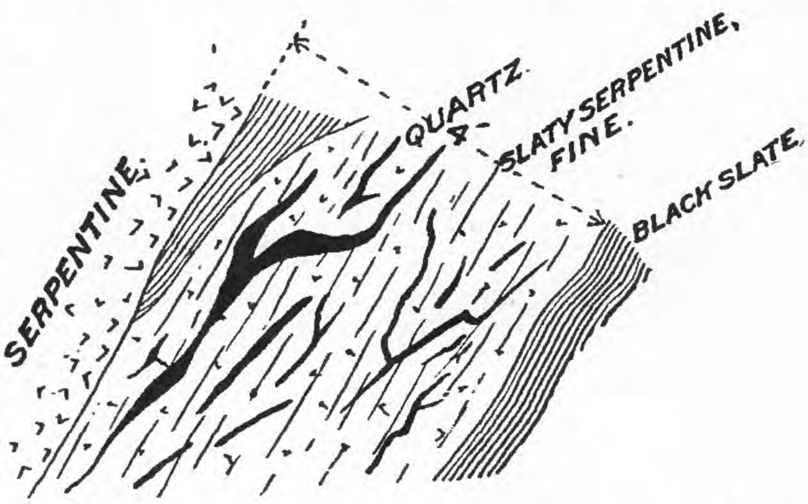

FIG. 22.—Vein in St. John mine, fifth level, 150 feet east of shaft.

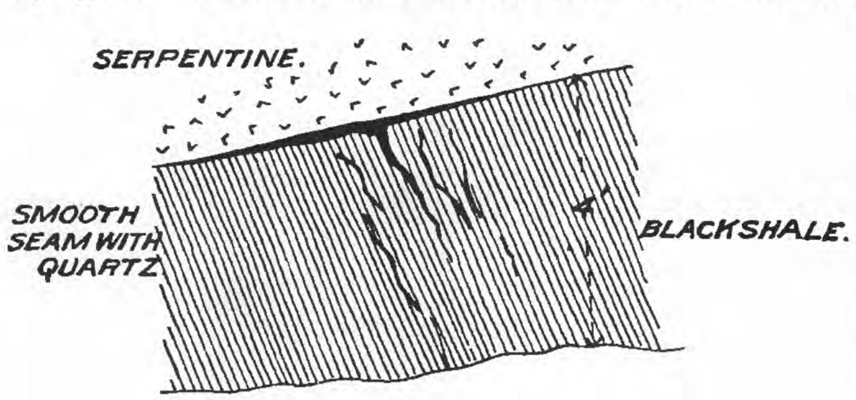

FIG. 23.—Vein in St. John mine, fifth level. 100 feet west of shaft.

the Eureka ground as very strong croppings of white, massive quartz. Toward the east, in the vicinity of the old Eureka shaft, indications of a chloritic and decomposed diabase appear in the hanging wall; the outcrops are very much less prominent, and are not seen at all east of the Idaho-Maryland shaft. A diabase dike outcrops in Wolf Creek, in serpentine, about where the vein would be expected. At the Idaho shaft a coarse-grained uralite-gabbro appears in the hanging wall, but a short distance east of the shaft the vein must outcrop in serpentine. It probably continues in serpentine all the way up to beyond the Maslin shaft, but until near that point no outcrops are visible; nothing definite can be seen on the hillside, which is covered by deep, red soil; it is possible that a diabase dike follows the vein here, too. At the Maslin shaft, however, the croppings of white quartz in serpentine are distinct, and there can be little doubt that these represent the vein in question. A short distance beyond the Maslin shaft the line of the vein, if continuing straight, would enter coarse, white gabbro, or it may bend a little southward and follow the line between serpentine and gabbro. The old Maryland shaft, 300 feet deep, was sunk southwest of the Maslin shaft to intercept the vein, but encountered nothing but serpentine. Three thousand feet southeast of the Maslin shaft the Chevanne shaft is now being sunk in the serpentine to find the continuation of the vein; nothing but serpentine has thus far been met with, at a depth of a few hundred feet. A quarter of a mile farther southeast, near the Brunswick mill, the Chevanne tunnel, 1,200 feet long, was driven in a northeasterly direction, but without result; the tunnel is in gabbro and serpentine. Small croppings, which may possibly represent the croppings of the Idaho-Maryland vein, have been found 650 feet north-northwest of the Chevanne shaft, near the contact of serpentine and gabbro. Under ground, the vein lies, in many places at least, on the contact of diabase and serpentine, but sometimes the determination of formations is not easy without crosscutting in hanging and foot walls. The average strike is N. 77° W., and the dip is about 70° S., occasionally, however, flattening out to 50°.

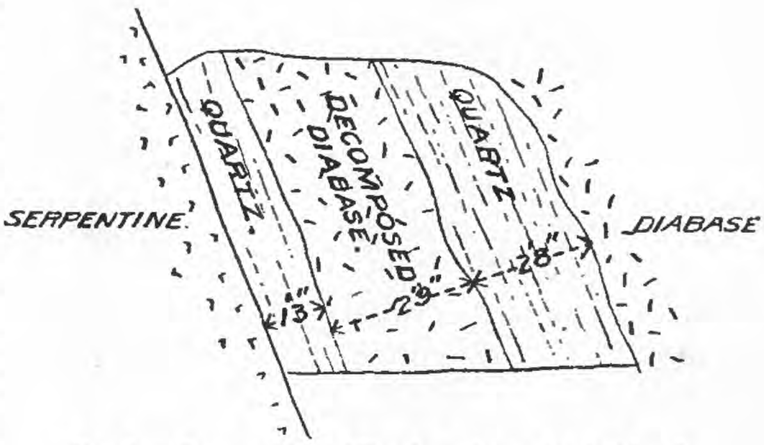

FIG. 24.—Cross section of Eureka vein, on 300-foot level.

In the Eureka ground there are, according to Professor Silliman, two veins, separated by a mass or dike of greenstone 30 feet thick. The smaller of these veins, on the south, has never been worked. The main vein lies, as indicated by fig. 27,[1] between a serpentine foot wall and

[1] Copied from Mellville Attwood in Phillips's Mining and Metallurgy of Gold and Silver, London, 1868.

a dike-like mass of diabase in the hanging wall. The vein is heavy, varying from a few inches to 6 feet, and averaging 3 or 4 feet of solid quartz. On the 300-foot and 400-foot levels in the Eureka a horse of decomposed diabase was met with, dividing the vein in two, as illus-

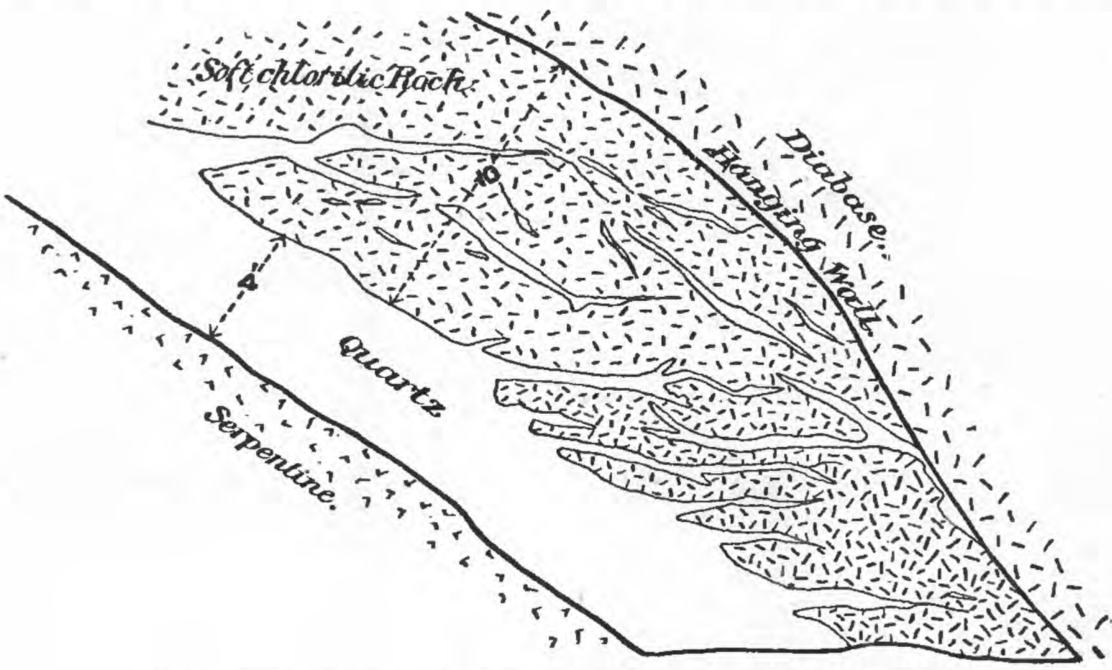

FIG. 25.—Cross section of Maryland vein in stopes above the 1,500-foot level.

trated in fig. 24.[1] The dip for the first 300 feet is 78°, which below decreases to 65° to 70°. This horse varies in thickness from a few inches to 6 feet, and is often filled with quartz stringers, so that the whole mass may be mined. In a few localities both layers of quartz

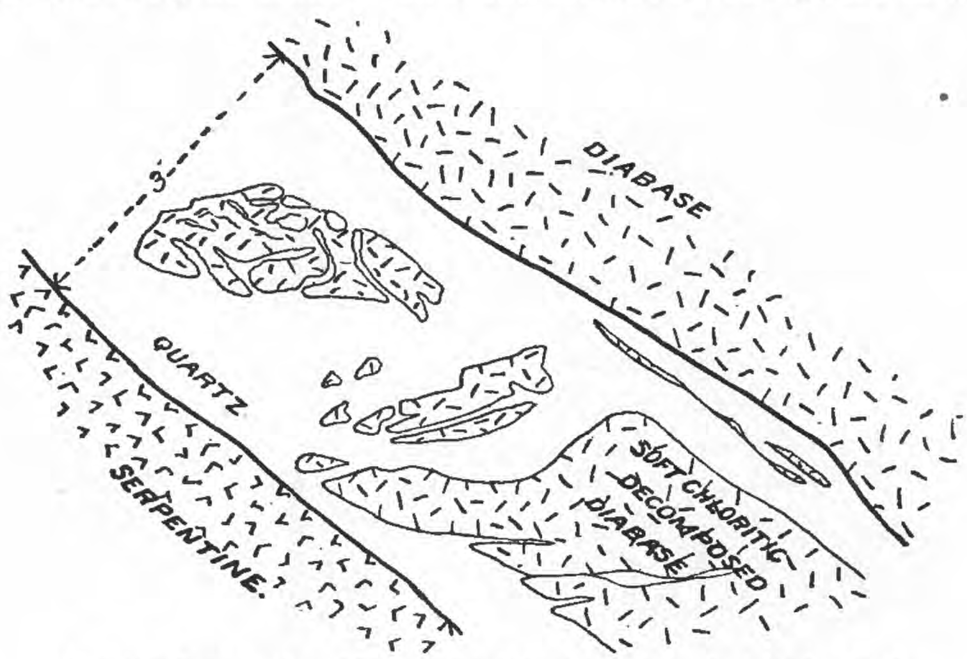

FIG. 26.—Cross section of Maryland vein in stopes above the 1,500-foot level.

come together in the width of the vein, without having the horse between. In these cases there is a line of quartz crystals visible which fill the narrow cavity sometimes left.[2] On the hanging wall there is a

[1] Copied from Melville Attwood in the Eighth Ann. Rept. State Mineralogist.
[2] Raymond's Report, 1872, p. 41.

distinct clay selvage. Concerning the western extension, Professor Silliman makes the following statement (Bean's Directory, p. 233): "The Eureka vein, going west, faults in the Whiting ground, and, having previously become almost vertical, has to the west of the fault a northerly steep dip."

In the Idaho and Maryland mines the vein is equally well defined; the dip is from 73° to 55° S., and the strike very regular; the width of the ore—that is, of the quartz—probably averages 2½ feet. The serpentine is often well exposed in the foot wall, but the diabase is not always distinct. Flaky, chloritic, or serpentinoid soft rock, filled with calcite and cubes of pyrite, often forms the hanging wall; comparatively fresh diabase was noted at the shaft in the seventh and fifteenth levels and at a few other places. A long crosscut, starting from the seventh level and extending 800 feet in the hanging wall, begins in diabase; 25 feet from the vein coarse gabbro begins to appear and continues for 200 feet, mixed with what are probably dikes of diabase; then southward to the face the crosscut is diabase, cut by seams in many directions, but not showing any distinct veins or mineralization. On the whole, the vein was very regular in width and character; in a few places it showed signs of splitting up, but soon increased in strength again. Such places were found in 1875 below the 800-foot level, when the hanging wall went down flat and the ledge broke up in stringers; again in 1882 and 1883 the ore became poor on the 1,100-foot level and the vein irregular; some distance east of the Maryland line, on the 1,500-foot level, the vein splits in two parts, but it has in every case been found beyond strong and reunited. The vein is frequently accompanied in the foot wall by a characteristic gangue of dolomitic rock, sometimes colored green by mariposite, which is to be regarded as a completely altered serpentine. These and other rocks from the Idaho-Maryland are described in detail in Chapter XI. Mr. Attwood states that this dolomite carries a little gold.

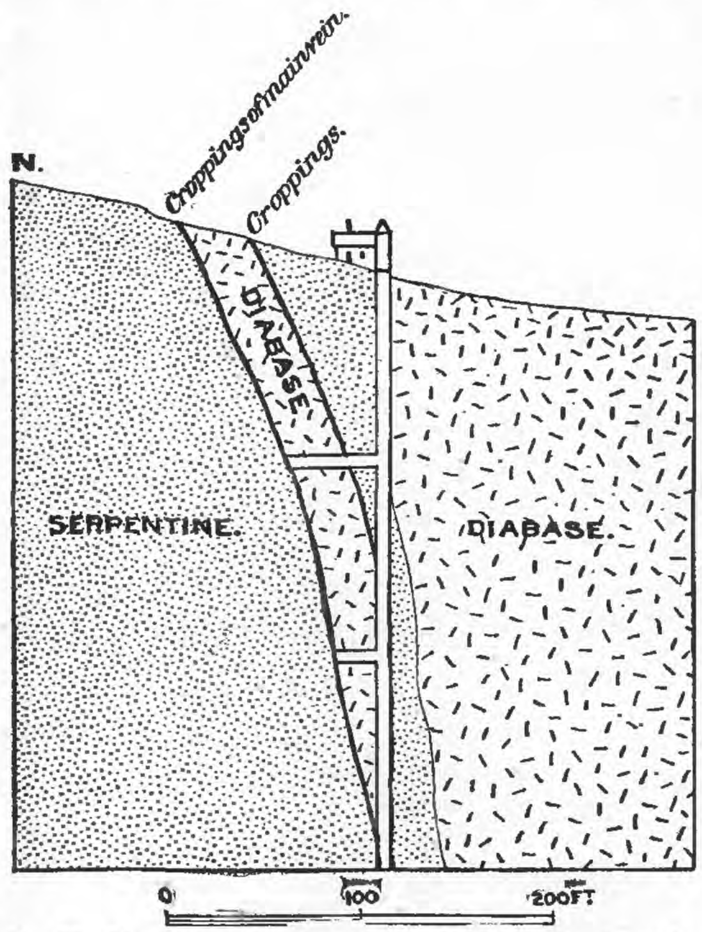

FIG. 27.—Vertical section through Eureka shaft, showing veins.

The ore.—The ore consists exclusively of the solid quartz in the pay shoot, except when the adjoining country rock is impregnated with quartz stringers, as sometimes happens. The chief value in the ore is in the free gold, which as a rule is in fine distribution. Sometimes, however, rich "specimen rock" is met with showing abundant coarse gold. The ore has varied, as stated, from $60 down to $10 and $13 per ton, but an average would probably be about $20. It would appear as if the western part of the pay shoot were somewhat richer than the extension toward the east. The gold is 848 fine; the amount of sulphurets is small, having varied from 1¼ per cent in the Eureka to three-fourths of 1 per cent and 2 per cent in the Idaho and Maryland. The value of the concentrated sulphurets is about $100, sometimes reaching $400. The amount of silver in the sulphurets is small, being stated to be 1.5

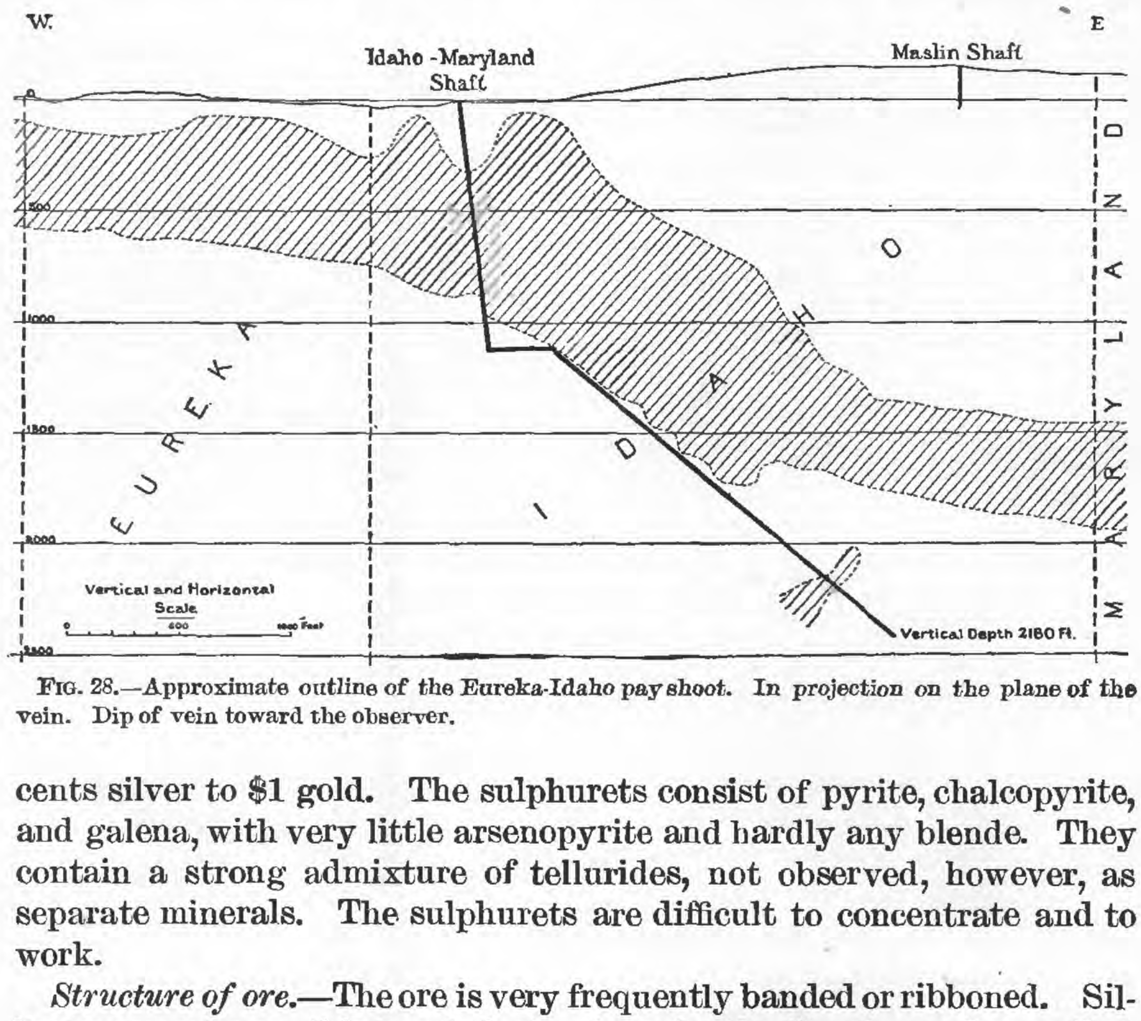

FIG. 28.—Approximate outline of the Eureka-Idaho pay shoot. In projection on the plane of the vein. Dip of vein toward the observer.

cents silver to $1 gold. The sulphurets consist of pyrite, chalcopyrite, and galena, with very little arsenopyrite and hardly any blende. They contain a strong admixture of tellurides, not observed, however, as separate minerals. The sulphurets are difficult to concentrate and to work.

Structure of ore.—The ore is very frequently banded or ribboned. Silliman remarks on this banded structure in the Eureka and says that the joint surfaces are often coated with gold. A banded structure by arrangement of the pyrite in parallel streaks is also noted. Pls. XI and XII[1] show the structure of the Maryland vein. In Pl. XI the ribbon structure is illustrated, due without much doubt to the sheeting of the vein subsequent to its formation. In Pl. XII the vein consists of

[1] From photographs by Victor Dorsey, the superintendent of the Maryland, whose untimely death in 1895 was due to a falling slab of the treacherous hanging wall in his mine.

which down to 400 feet is 45°, then becoming 60°, and finally at 600 feet 70°, was located early and has been worked with varying success for a long time, the upper levels containing some good ore shoots. For the last seven years the mine has been extensively prospected, and some good bunches of ore have recently been found in the lowest level. The mine is developed by a shaft 700 feet deep on the incline, and drifts extending 300 feet toward the west. The vein is contained in a chloritic schist derived by dynamo-metamorphic processes from a porphyrite-breccia, and intersects the strike of the schist at an acute angle. There are usually two well-defined walls, 2 to 4 feet apart. The space between the walls is only locally wholly filled with massive quartz, being generally occupied by soft chloritic schists, extensively altered by hydrothermal processes; the schists are either parallel to the walls or, as is frequently the case, broken and irregular; they contain streaks and ramified veins of massive quartz (fig. 29), which sometimes increase in thickness and occupy the whole space between the walls. East of the shaft the vein closes down to a mere seam. Free gold is rarely visible in the quartz, and the sulphurets, which generally are rich, consist of pyrite, chalcopyrite, and galena.

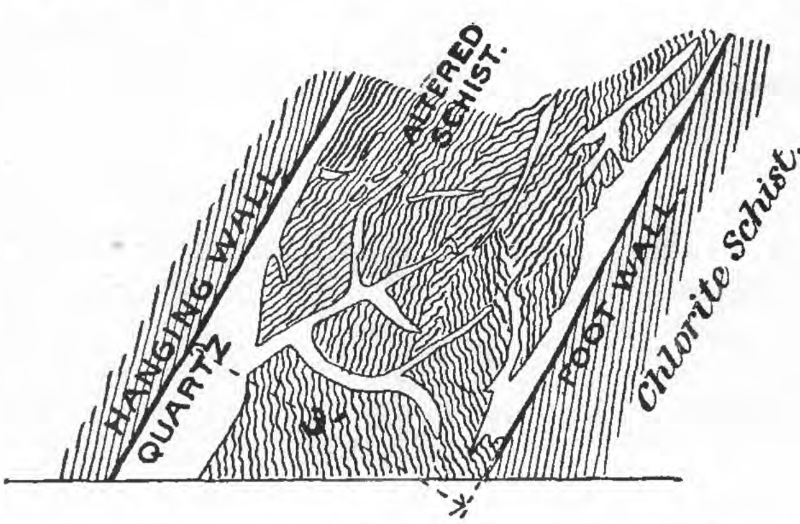

FIG. 29.—Cross section of the Brunswick vein, on 700-foot level.

The Gold Point is a vein parallel with and south of the Brunswick. The heavy croppings, dipping 70° S., can be traced for over 2,000 feet. It is opened by a tunnel from Wolf Creek connecting with inclines from above. To the west of the tunnel the vein is very heavy and contains large masses of low-grade ore. The country rock is a schistose porphyritic breccia, less chloritic than that of the Brunswick.

The Union vein, the croppings of which are visible in places on the north bank of Wolf Creek, is one of the earliest-located veins in Grass Valley. The ore was worked with an arrastra up to 1854. In 1865 mill and hoisting works were erected, and the mine was worked with profit until 1870. The total product is given as $250,000. From January 1 to August 1, 1869, the mine produced 7,200 tons, yielding $75,569, or about $10 per ton. The vein, which is continued in schistose porphyritic breccia, dips 50° S. and has been developed by a shaft 268 feet deep on the incline. The width is said to be considerable, averaging 3½ feet. The extent of the stopes is shown on fig. 30, taken from

Raymond's Report for 1869-70. The gold is 822 fine. Galena is said to predominate in the sulphurets.

The Cambridge vein is located on the south side of Wolf Creek. The Lucky and the Cambridge mines were located on this vein and worked extensively about 1865 to 1868. The Lucky mine, on the west, had a 15-stamp mill and was exploited by a shaft 400 feet deep on the incline, 10,000 tons of ore being extracted from 1865 to 1867. The Cambridge, adjoining on the east, was opened by a shaft 200 feet deep, and a 10-stamp mill was erected on the property; 75 tons of ore per week were crushed for a long time, averaging $20 per ton (Bean's Directory). The vein lies in chloritic schist, dips 50° SW., and is generally wide, averaging 2 to 3 feet. According to Professor Silliman, free gold is rarely visible in the ore. If these reports are correct, this vein, as well as the Union, may be rendered productive again. The gold is from 817 to 820 fine.

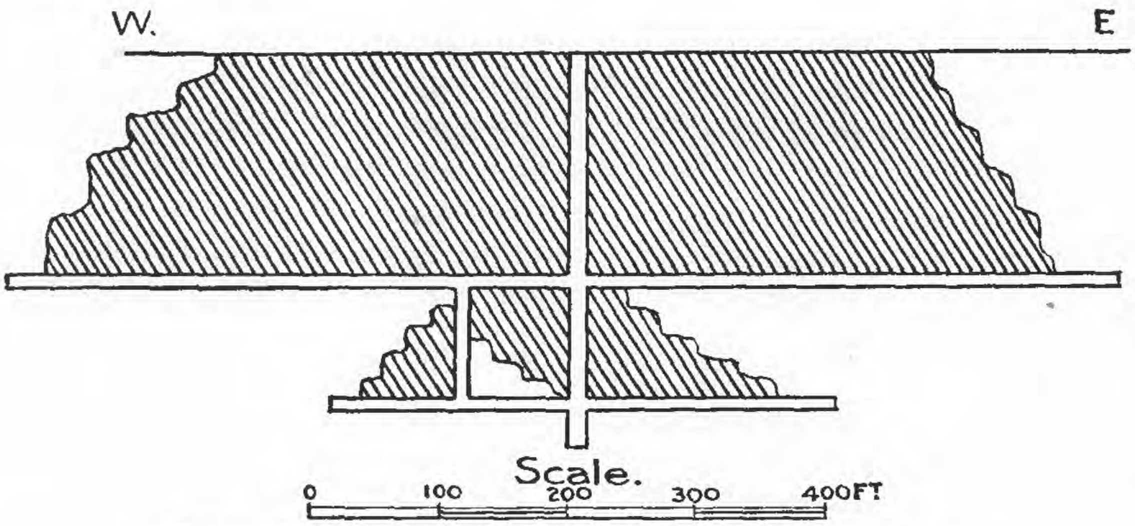

FIG. 30.—Longitudinal section, Union Hill mine, showing areas stoped.

The Francfort vein, about 800 feet south of the Cambridge, is said to have produced some good ore from the croppings.

THE CROWN POINT VEIN.

This deposit, located on the south side of Wolf Creek, half a mile east of the center of the city, has been worked at intervals since 1886. The production is stated to have been $130,000, of which $80,000 was found in one bunch of ore with much coarse gold. The shaft is 400 feet deep on the incline, with levels extending east and west, only the upper two levels being accessible in 1894. The vein, which strikes northwest and dips 70° to 80° N., lies in serpentine or serpentinized porphyrites, the width of quartz and vein matter varying from a few inches to 4 feet. There are considerable amounts of magnesic and calcic carbonates produced from the serpentine by thermal alteration. A thin sheet of quartz, still adhering to the foot wall near the shaft in the drift, shows beautiful polish, with nearly horizontal striation; in

granite-porphyry (quartz-porphyry) are met with. The vein is said to usually become poor when incased in this rock. The tenth level extends 1,000 feet northward, some good ore occurring in it in bunches, but farther in the vein is disturbed by crossings and shows signs of splitting up.

The vein is narrow, probably averaging 1 foot, and lies between well-defined hanging and foot walls without much inclosed altered country rock. Outside of the pay shoots the vein generally closes to a seam, so that practically all quartz is good ore. The granodiorite next to the vein is impregnated with pyrite, but on the whole is unusually fresh and hard. Calcite occurs to only a limited extent in the wall or in the vein. There is very little banded or ribbon quartz, most of it being massive, with sulphurets in irregular distribution. The ore is of high grade,

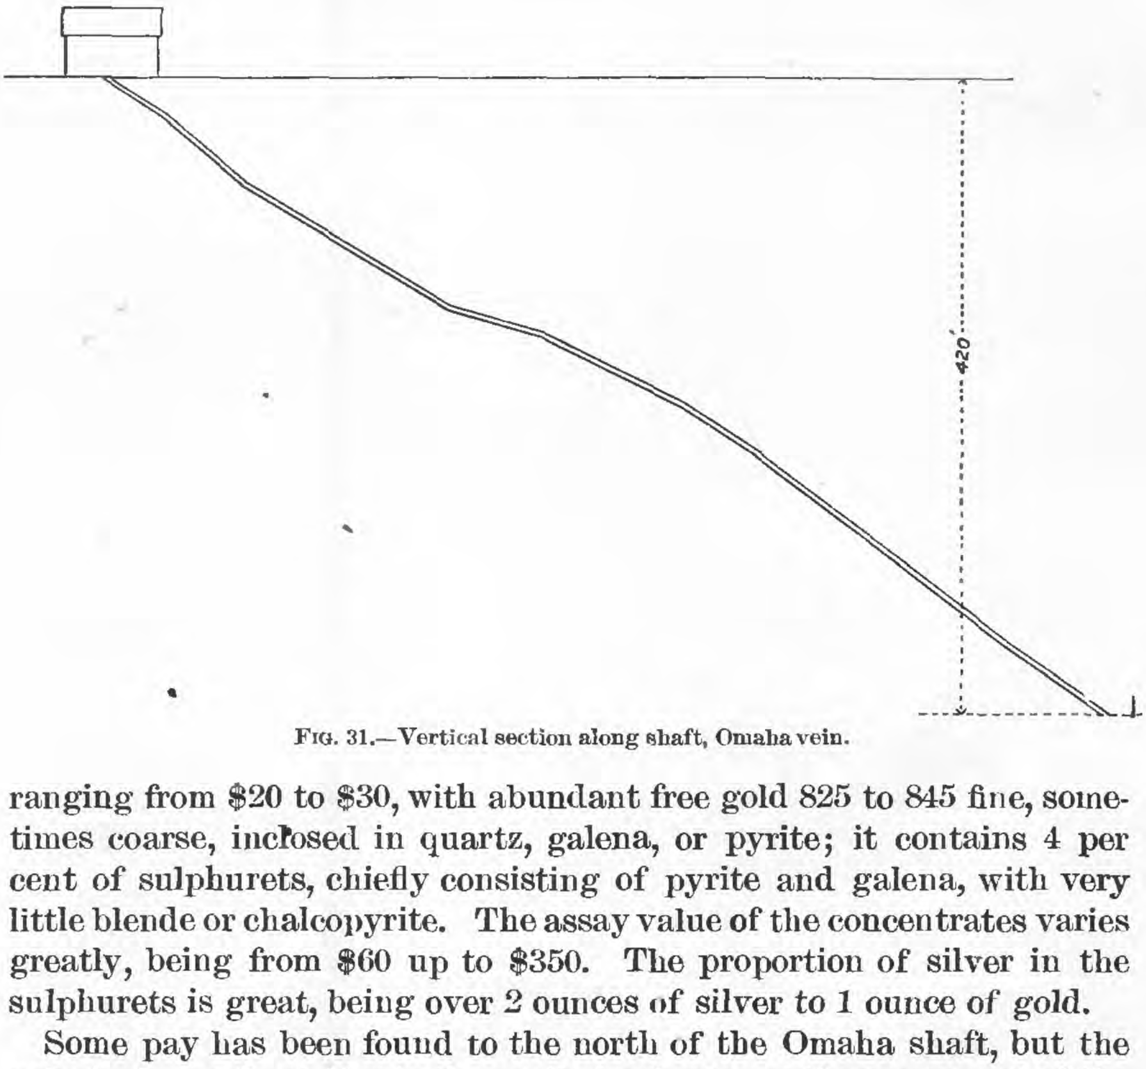

FIG. 31.—Vertical section along shaft, Omaha vein.

ranging from \$20 to \$30, with abundant free gold 825 to 845 fine, sometimes coarse, inclosed in quartz, galena, or pyrite; it contains 4 per cent of sulphurets, chiefly consisting of pyrite and galena, with very little blende or chalcopyrite. The assay value of the concentrates varies greatly, being from \$60 up to \$350. The proportion of silver in the sulphurets is great, being over 2 ounces of silver to 1 ounce of gold.

Some pay has been found to the north of the Omaha shaft, but the principal pay shoot dips to the south, beginning at the upper part of the Omaha shaft and extending toward the bottom of the Lone Jack. Very rich ore was extracted from this shoot in 1894 on the fourteenth level. Another pay shoot, also dipping south, has been found south of the Lone Jack. A strong "crossing" or barren fissure traverses the vein along the principal pay shoot, with a steep dip to the south. It does not seem to affect the tenor of the ore. On the twelfth level the vein is faulted about 1 foot by this crossing, with a relative downthrow of the south side, and on the fourteenth level the curious relation illustrated in fig. 32 obtains at the crossing, showing a differential movement of the sheets constituting the crossing. A similar cross seam, faulting and dragging the vein, is found at the end of the tenth level north.

The Homeward Bound mine lies to the south of the Lone Jack. Only superficial developments were made up to 1867, the vein having been worked along the surface for 200 feet. The shaft at present on the property has been sunk to a depth of 350 feet, the incasing rock being very hard. Two levels are turned at 165 and 268 feet from the surface, the drifts extending a maximum distance of 350 feet southward and 750 feet northward, four distinct pay shoots having been found. The vein is said to be large. The mine was worked in 1889–90.[1]

The Hartery mine has worked two parallel veins. The old shaft is sunk on the southern end of the Omaha vein to a depth of 600 feet on

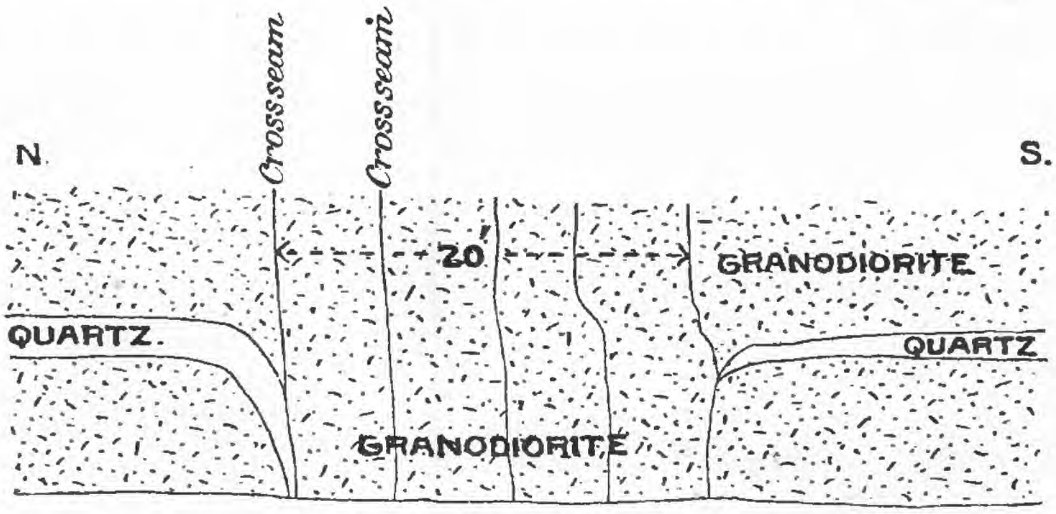

FIG. 32.—Longitudinal section, showing fault, Omaha mine, fourteenth level.

the incline. "The vein, which was located in 1853, has been worked at intervals since that time, but not more than ten or twelve years of continuous work has been spent on the property. Over $300,000 have been taken from the mine, some of the ore consisting of extremely rich specimens of coarse gold."[2] The mine was idle in 1893 and 1894. Productions ranging from $19,000 to $39,000 are credited to the mine in the United States reports for 1869, 1890, and 1891. "Three levels are turned, at 368, 508, and 600 feet, extending north a maximum distance of 300 feet and south 400 feet. A drain tunnel from Wolf Creek, 1,200 feet long, intersects the shaft 250 feet from the collar."[1]

The vein dips 30° W. and is inclosed in hard granodiorite; it averages somewhat over a foot in width. The ore is of high grade, probably averaging about $30 per ton. The amount of sulphurets is said to be small and their value $50 per ton. In the mint reports of 1890 and

[1] Tenth Ann. Rept. State Mineralogist.
[2] Nevada County Mining Review.

1891 the mine is credited with a considerable amount of silver, the relation being for the first year 1,635 ounces of gold and 871 ounces of silver.

The Hartery Consolidated shaft is sunk to a depth of 500 feet on the incline, on a parallel vein a short distance east of the Omaha vein, but comparatively little development work has been done from it. The incasing granodiorite is reported to be very hard.

THE WISCONSIN-ILLINOIS VEIN.

This is parallel to the Omaha vein, and crops a few hundred feet to the west. It was worked at its northern end from 1854 to 1856 and again from 1866 to 1870, during which time it produced a considerable amount of high-grade ore. In 1869 the old shaft was sunk to a depth of 500 feet on the incline, and the extent of the stopes is shown on fig. 33, copied from Raymond's report for 1869–70, page 47.

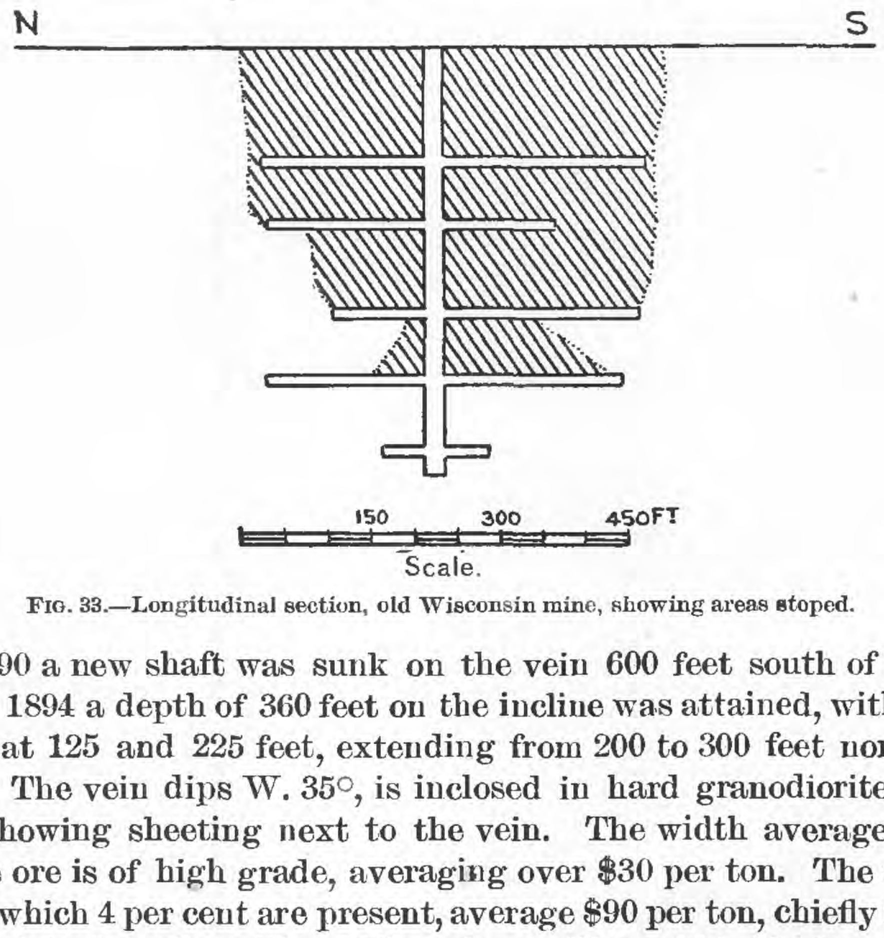

FIG. 33.—Longitudinal section, old Wisconsin mine, showing areas stoped.

In 1890 a new shaft was sunk on the vein 600 feet south of the old one; in 1894 a depth of 360 feet on the incline was attained, with levels turned at 125 and 225 feet, extending from 200 to 300 feet north and south. The vein dips W. 35°, is inclosed in hard granodiorite, sometimes showing sheeting next to the vein. The width averages 1 foot and the ore is of high grade, averaging over $30 per ton. The sulphurets, of which 4 per cent are present, average $90 per ton, chiefly in gold, and consist of pyrite, with a little galena. The gold is 854 fine. In the old shaft there was an extensive pay shoot supposed to dip to the south, and the present shaft is sunk to intercept that in depth. There are also two smaller pay shoots of high grade, one on each side of the new shaft. A cross seam cuts the new shaft without disturbing the vein perceptibly.

THE MINNESOTA VEIN.

The Minnesota vein, upon which the Surprise shaft was sunk long ago, may represent the southern continuation of the Wisconsin vein.

OTHER VEINS.

Almost due north of the Allison Ranch shaft, a distance of 1,500 feet, is the Franklin vein, on which in early days considerable work was done and a large mill once erected.

The Allison Ranch Ford–Horseshoe vein is located on the west bank of Wolf Creek and probably is a continuation of the Franklin or an adjoining parallel vein. The Horseshoe shaft is 3,500 feet north of the Allison Ranch and 240 feet deep on the incline. The vein is from 10 to 20 inches thick.

THE FOREST SPRING GROUP OF MINES.

Four miles south of Grass Valley and 1¼ miles south of Allison Ranch there is, on the east side of Wolf Creek, a series of veins of some importance.[1] The ores are similar to those of Osborne Hill.

THE NORAMBAGUA VEIN.

The Norambagua was worked extensively between 1855 and 1867. Its total production is said to amount to $1,000,000 (Bean's Directory).

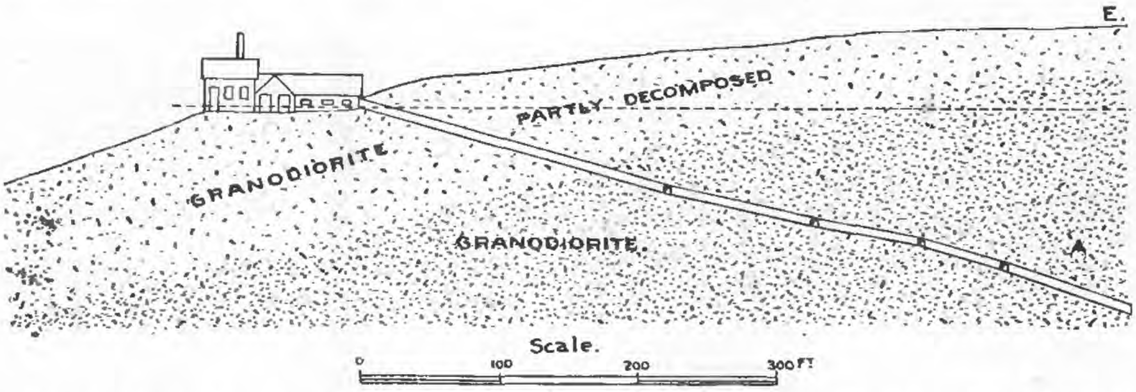

FIG. 34.—Vertical section along shaft. Norambagua vein. After Melville Attwood in Phillips's Metallurgy of Gold and Silver.

In 1866 the production was $80,000. The mine was reopened for a short time in 1892 and is credited with a production of $2,500 in that year. During the principal period of exploitation the cost of mining and milling was $30 per ton. This very high figure is evidently due to the narrow character of the vein. The incline is 567 feet long down to the fifth level, attaining a vertical depth of 120 feet at that level. The levels extend 1,000 feet south and 500 feet north from the shaft, and a drain tunnel joins the shaft 490 feet from the croppings. The Norambagua has a northerly strike and a dip of 15° E., thus belonging to another system than the Omaha. It is contained in a blocky granodiorite and is very narrow, rarely over 10 inches wide and more frequently 4 or 5. The ore is a bluish quartz, seamed and banded with pyrite and arsenopyrite arranged in parallel zones, producing a ribbon-like structure. The gold is rarely visible to the naked eye. The tenor of the ore is from $40 to $100 per ton, and frequently about $65 per ton (Phillips).

[1] See Geologic Atlas of the United States, folio No. 18, Smartsville, Cal.

ago, as is indicated by the pits along the croppings. The total production is said to have been $125,000, and the ore contained from $35 to $50 per ton.[1] On the summit of the hill is a shaft 300 feet deep on the incline, on which work was resumed in 1895 under the name of Hecla mine. The vein dips 45° W. and is inclosed in hard granodiorite.

THE CRESCENT VEIN.

The Crescent vein is located 600 feet east of the Kate Hayes, and dips to the east.

THE PENNSYLVANIA VEIN.

A few hundred feet farther west the Pennsylvania vein is met with. The vein has been exploited at various times and produced a large total amount. Work of development has been going on for the last five years, and in 1894–95 a considerable amount was produced.

The vein, which is inclosed in granodiorite, can be traced on the sur-

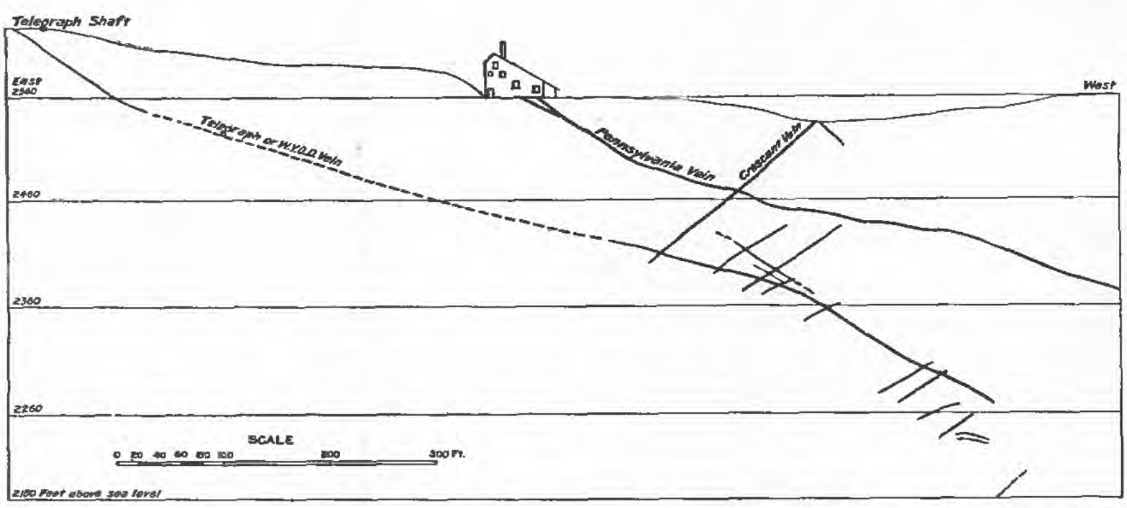

FIG. 35.—Vertical section along shaft, showing veins and cross fissures, in the Pennsylvania mine.

face for 1,000 feet north of the shaft, while to the south the continuity of the surface croppings is doubtful. The shaft is sunk to a depth of 600 feet on the incline, the vein dipping west at an average angle of 20°. A part of the shaft, continued down at a steeper angle, struck a parallel vein believed to be the Telegraph, though this would necessitate a a very flat dip for the latter. The vein averages a little less than 1 foot in width; the ore carries frequently coarse gold and a small percentage of pyrite and galena. The wall rock is generally fresh, or at least not extensively altered. The sheeting and fracturing are very extensive and render the work of exploitation very difficult; the vein frequently pinches to a mere seam, difficult to follow. The system of fissures dipping east is very prominent; at 220 feet on the incline the Crescent vein intersects the Pennsylvania, and throughout the mine there is a constant tendency of the main vein to throw out stringers dipping east. These relations are illustrated in fig. 35. Besides, there

[1] Nevada County Mining Review.

is high, ranging from $20 to $50 per ton. The ore shoot, which was narrow in the upper part of the mine, rapidly widened between the sixth and ninth levels, attaining a maximum length of 850 feet; below this it showed a lower grade of ore for some distance, and then improved again greatly. The shoot, though very irregular in its details, dips on the whole to the south on the plane of the vein. Thus far the largest ore bodies have been found in the diabase. There are a number of seams dipping east, as in the Pennsylvania, and there is a tendency of the vein to fall back in the foot wall on these seams. A great number of "crossings," or barren seams, follow the ore shoot down, with a general southwesterly strike and steep or vertical dip; they do not appear to throw the vein to any noticeable extent.

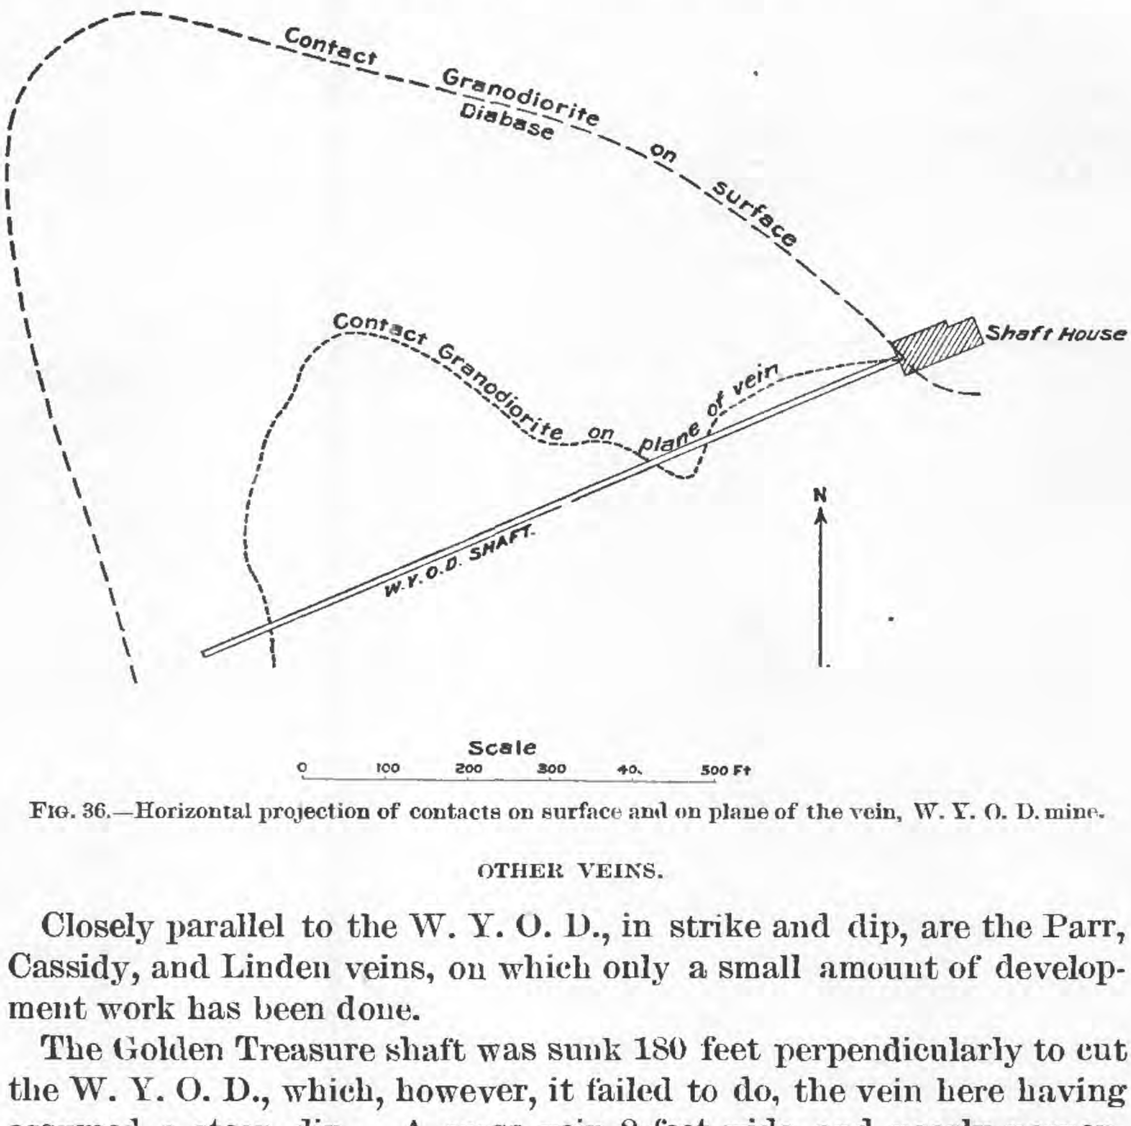

FIG. 36.—Horizontal projection of contacts on surface and on plane of the vein, W. Y. O. D. mine.

OTHER VEINS.

Closely parallel to the W. Y. O. D., in strike and dip, are the Parr, Cassidy, and Linden veins, on which only a small amount of development work has been done.

The Golden Treasure shaft was sunk 180 feet perpendicularly to cut the W. Y. O. D., which, however, it failed to do, the vein here having assumed a steep dip. A cross vein 2 feet wide, and nearly perpendicular, outcrops just west of the shaft.

THE DIAMOND, BULLION, AND ALASKA VEINS.

Following the western foot of Osborne Hill, there are a number of veins with an easterly dip of about 45°. It is very likely that they may in reality be one continuous vein with a general north-northwest

consists of quartz with often coarse, free gold 805 fine. The quartz is partly ribboned, partly massive, and contains 3 per cent of sulphurets, chiefly pyrite, with little galena and occasionally blende and chalcopyrite. Arsenopyrite is absent. The concentrated sulphurets contain from 3.5 up to 5 ounces of gold and about 2 ounces of silver. Large parts of the pay shoot have averaged $30 to $50 per ton. The main pay shoot extends on both sides of the shaft and is somewhat irregular in shape, though it is stated that the richest ores are from shoots dipping south on the plane of the vein. The greatest length of stoped ground is 2,000 feet. On the thirteenth level the vein is split into three parts, the division extending several hundred feet north and south. This break, occurring in the main shoot, made the exploitation very difficult and diminished the tenor of gold in the veins. Excellent ore 18 inches wide was, however, stoped on the twentieth level north in 1894. The distance between the branches makes it doubtful whether they will join again in depth. Several strong cross seams run through the northern part of the mine, and have been observed to fault the vein a little. The relations illustrated in fig. 37 were shown in the stopes a little below the twentieth level.

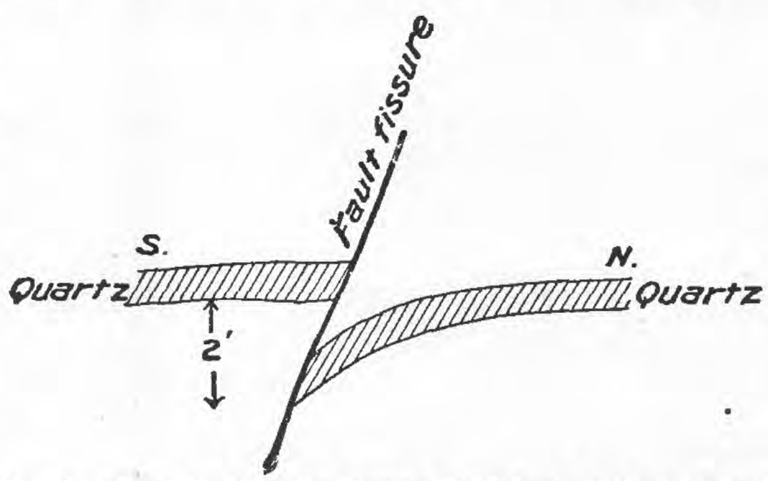

FIG. 37.—Longitudinal section, showing fault, Ophir Hill vein, twentieth level, Empire mine.

The Rich Hill vein, dipping 30° W., and approaching the Ophir Hill in depth, has been opened to a less extent by an incline shaft and by means of a crosscut from the sixth level on the Ophir Hill shaft. Good ore was stoped from this vein in 1894 on the so-called Rush and Laton shoot, which is said to be 200 feet long. For some distance above the sixth level the vein is divided in two, joining again above the fifth level. The hanging vein is the better, showing about 12 inches of massive quartz with pyrite and galena, and is inclosed in diabase, hard and fresh close up to the vein. This complete absence of crushed or altered wall rock is somewhat unusual. Brown opal containing coarse gold has been noted from this shoot.

The Rich Hill continues southward through New Ophir and Daisy Hill claims, on which the developments are not extensive. A shaft, 300 feet on the incline, was sunk on the latter many years ago, and the mine is reported to have been reopened in 1895. A branch vein is said to connect with the Ophir Hill vein at the Prescott shaft.

but its dip varies from 45° to 70°. The shaft has followed the average dip of the vein (i. e., 60°) to the fourth level, where it split. Bowlders of granite and gneiss could occasionally be observed completely inclosed in the andesite country rock. Down to the fourth level (400 feet on the dip) the vein is comparatively regular. Below that level a horse of country rock about 30 feet wide divides it into two. The northeastern vein gradually assumes a steep dip and becomes reversed, having a pitch to the north. For some distance it is said to have gone down in a series of steps that were alternately very shallow and very steep. From the fifth level down the northeasterly vein had granite on the hanging or northeastern wall and on the other wall breccia gave place to porphyry. The ore became mostly pyrite of rather low grade—20 to 30 ounces of silver per ton. The southwestern or main vein, on the other hand, grew shallower in dip, and diverged from the other until at the eighth level they were nearly 800 feet apart. The crosscuts between the two were in broken rock until the seventh level was reached, when it became solid porphyry, which showed a regular sheeting parallel to the southeastern vein. The northeastern vein gradually died out, and the southeastern or main vein was thought at one time to be lost, but was recovered on the eighth level. Here the breccia had disappeared and the same even-grained porphyry appeared on both walls. In the vein were found here and there rounded fragments of red granite

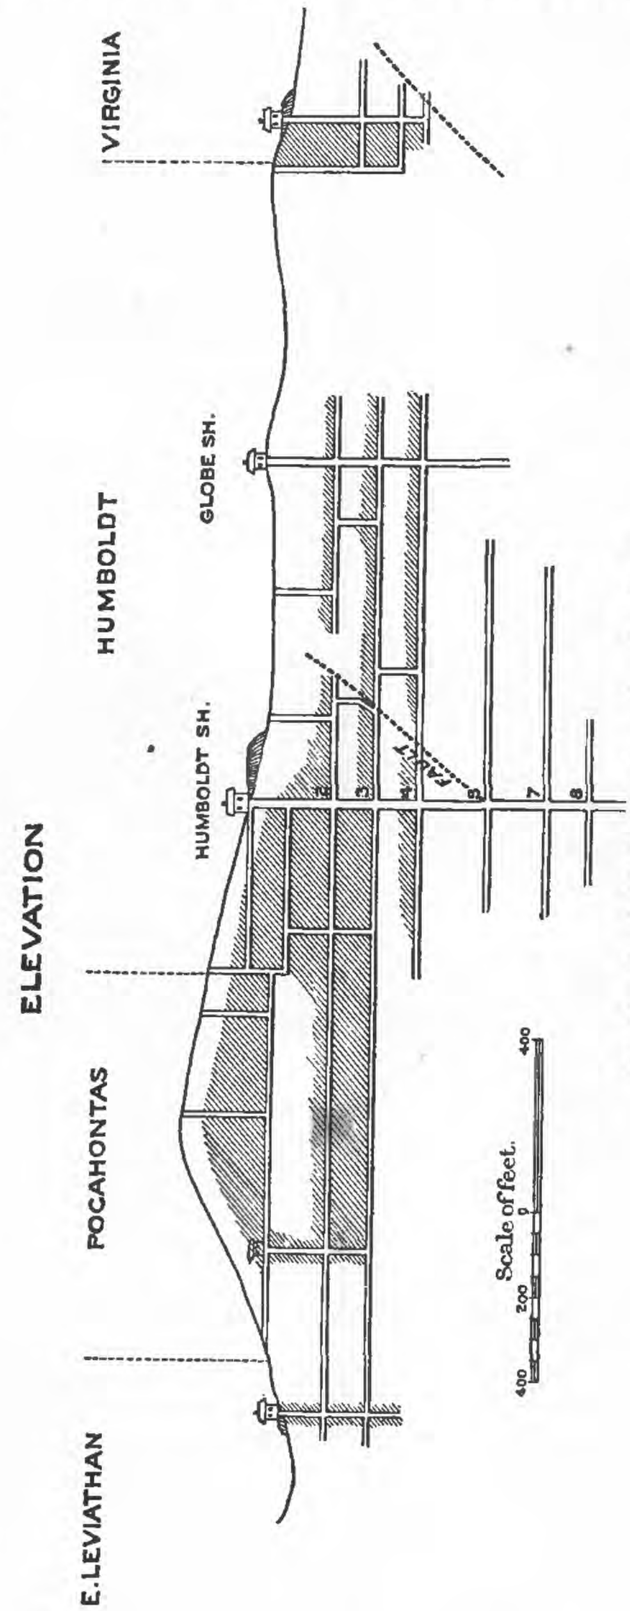

FIG. 38.—Humboldt-Pocahontas vein; elevation.

of various sizes, sometimes entirely coated by gray copper. In one case the granite fragment was so large that it took quite a long time to cut a drift through it.

The facts with regard to these lower workings were obtained in 1887 from the manager, Mr. Thornton, an extremely careful and intelligent observer. At that time they were full of water, having been abandoned by the owners on account of the low grade of the ore and of the shallow angle of the vein, which rendered the drift difficult to ventilate and drain. The lowest point accessible at time of visit was the fifth level, where, 50 feet south of the shaft, a body of porphyry (presumably trachyte) cut off the breccia and vein at right angles. A crosscut along this body found, 50 feet to the northeast, an irregular contact of porphyry with a breccia containing large fragments of granite. This contact or vein had the normal strike of the Humboldt vein, with a vertical or slightly reversed dip. A cross cut to the southwest found the contact between porphyry and breccia at 80 feet from the line of the shaft, which dipped 30° to the southwest and was apparently the normal continuation of the Humboldt vein. Between these two veins the rock was porphyry, but so altered that it was impossible to determine whether it was trachyte or andesite. It was crossed by small stringers or slip planes parallel to the main vein, which carried a little ore, and in the middle was so broken up as to resemble a friction breccia. It is possible that the porphyritic rock is a portion of an offshoot from the trachyte dike which forms the low ridge between the Humboldt shaft and the town of Rosita, and which, if it extends vertically downward, would be cut by the southwestern branch of the Humboldt vein (see fig. 39). This dike, as shown on the map, crosses the line of the vein just west of the Virginia shaft, which may account for its barrenness at that point.

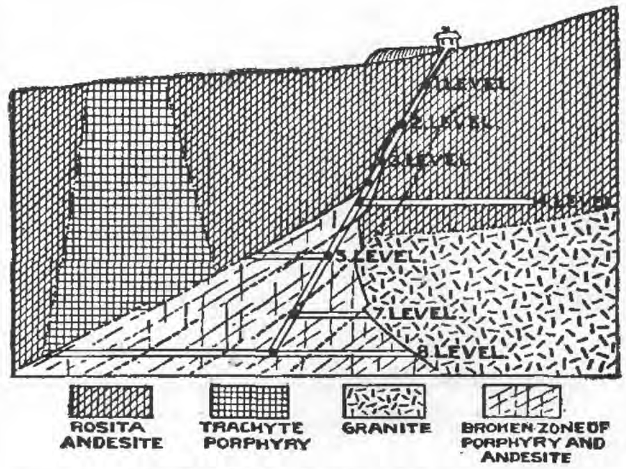

FIG. 39.—Humboldt-Pocahontas vein; cross-section.

In the upper workings the Humboldt ore body is said to have extended in practical continuity nearly to the Virginia line, a distance of about 1,600 feet. The Virginia mine was not accessible at the time of visit, and the only data obtained with regard to it were taken from Mr. Clark's description, already quoted. It appears from these statements that where the trachyte crosses the vein it pinches and becomes poor, and this appears to be the case in the lower part of the Humboldt. How far, if at all, the vein has been explored in the lower levels in the Pocahontas and Virginia grounds is not known, bnt it may be assumed

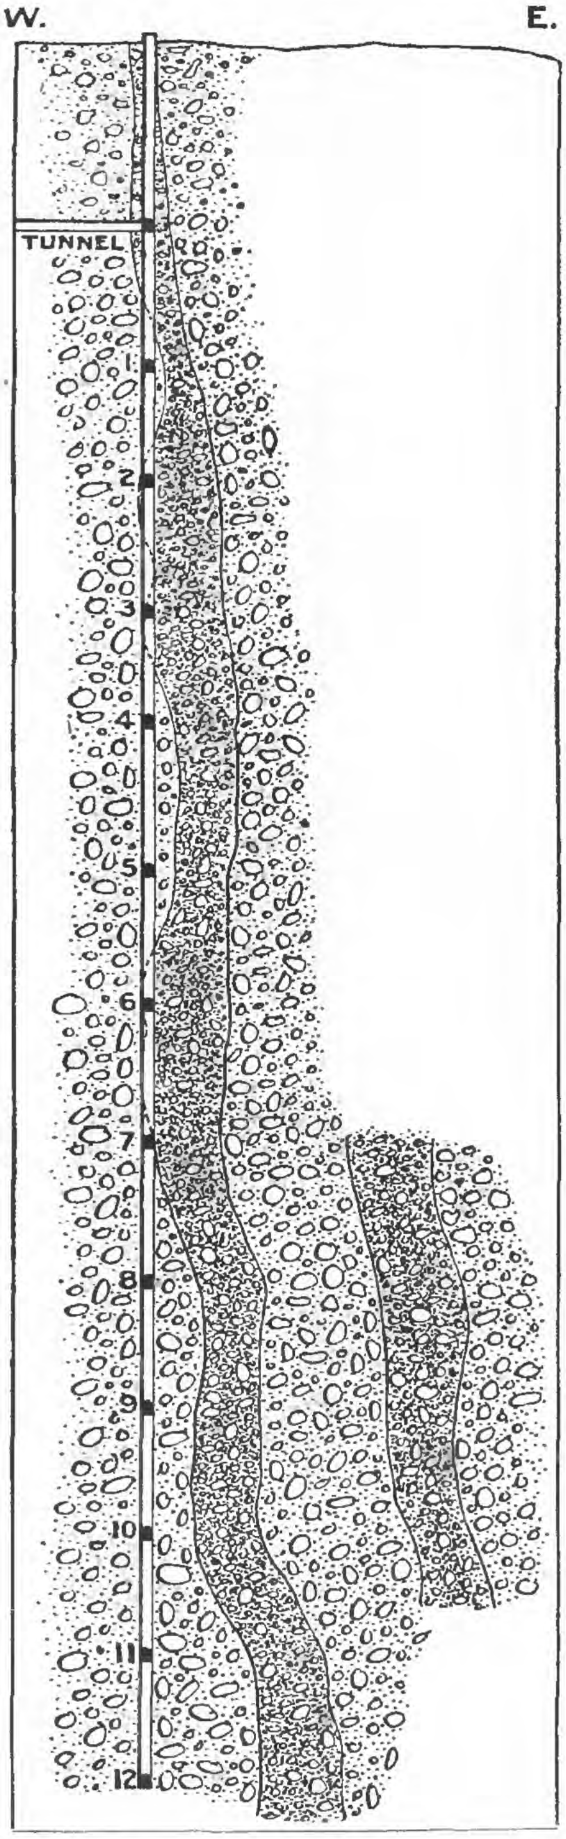

FIG. 40.—Bassick mine; cross-section of ore body on an east-west line.

hand, they are very frequently impregnated with pyrite, which, coarser and more abundant near the periphery, decreases and becomes finer grained toward the interior.

In the barren breccia surrounding the ore body, the interstitial spaces between the larger fragments of andesite are filled by a bluish siliceous mass which incloses, also, smaller fragments of the country rock. It is in part a finely granular mass, in part compact, approaching chalcedony. The latter contains no metallic minerals, but fine-grained pyrite is scattered through the granular portions, and still more abundantly through the interior of the fragments where it seems preferably to replace the basic silicates, but never completely to fill the spaces originally occupied by them.

Although there is no definite boundary between the ore and the barren breccia, it was observed that there were several fracture plains or joints in the agglomerate, cutting each other in such a way as to rudely outline the form of the ore shoot.

As the mine was permanently closed down before a second visit to the district was made, no personal observations of the lower levels were possible. From the superintendent and foreman the following facts with regard to them were, however, obtained: A second ore body or shoot was struck to the east of the main body when the shaft was down to the tenth level. and the two ore bodies

by the great heat of the burning roof and tore a hole 6 inches long in the top of the boiler. The machinery was at once disabled by the loss of steam pressure, and the air compressor which furnished air to the men who were sinking the shaft at the 550-foot level was stopped, so that, overcome by want of air and by the products of combustion, ten miners were suffocated.

After this the mine was worked somewhat intermittently, but closed down in 1889. In 1890 it was opened again by parties who took a long lease of the property, and was worked for awhile at a profit. It was visited by the writer during this year, and the workings on the 550-foot level examined. Since that time it has been again closed down.

PRODUCTION.

Data with regard to the product of the Bull-Domingo mine are, if anything, even more incomplete than those of the other mines here noticed. The Silver Cliff Mining Gazette gives $290,000 as the value of the product up to January 1, 1881, and the Mint reports credit it with $300,000 to $400,000 up to the summer of the same year. For the following years up to 1890 no segregated product is given, but for the subsequent years, when it was working under lease, a product of about $100,000 in silver and $75,000 in lead is given. It can only be said, therefore, that the total product has probably been something between $500,000 and $1,000,000 worth of silver and lead.

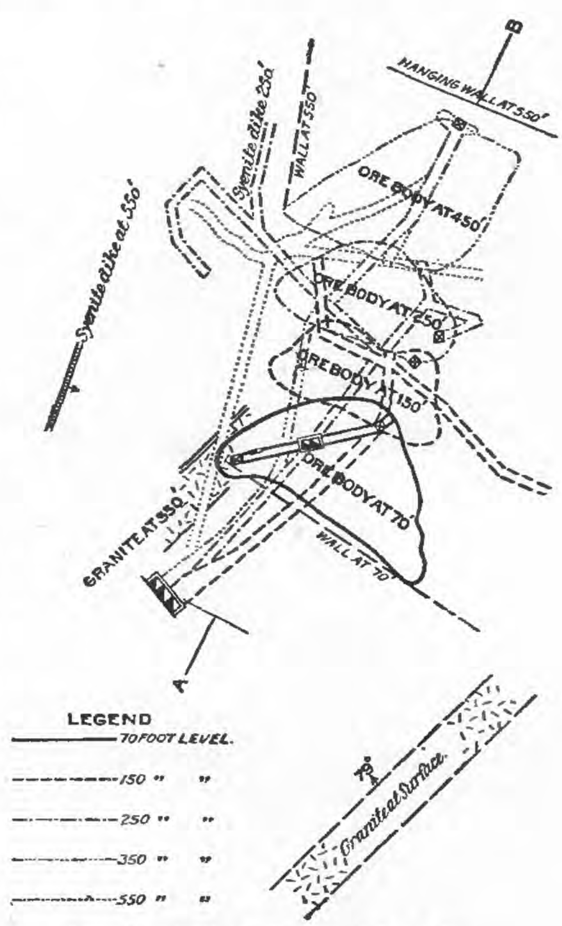

FIG. 41.—Bull-Domingo mine; plan.

MODE OF OCCURRENCE OF THE ORE.

The Bull-Domingo ore body has been generally classed with that of the Bassick mine as a deposit in a volcanic neck, a very unusual form of ore deposition. The ore itself is even more striking in appearance than that of the Bassick mine, consisting of concentric shells of brilliant crystalline galena and spar forming coatings around rounded bowlders of country rock.

The studies of this deposit made by us have been somewhat less unsatisfactory than those of the Bassick mine, consisting of two or three visits made in different years when the mine happened to be in active operation, but still have admitted of a very incomplete examination of the deposit, as the workings soon become inaccessible after the ore has been extracted, owing to the crumbling nature of most of the country rock.

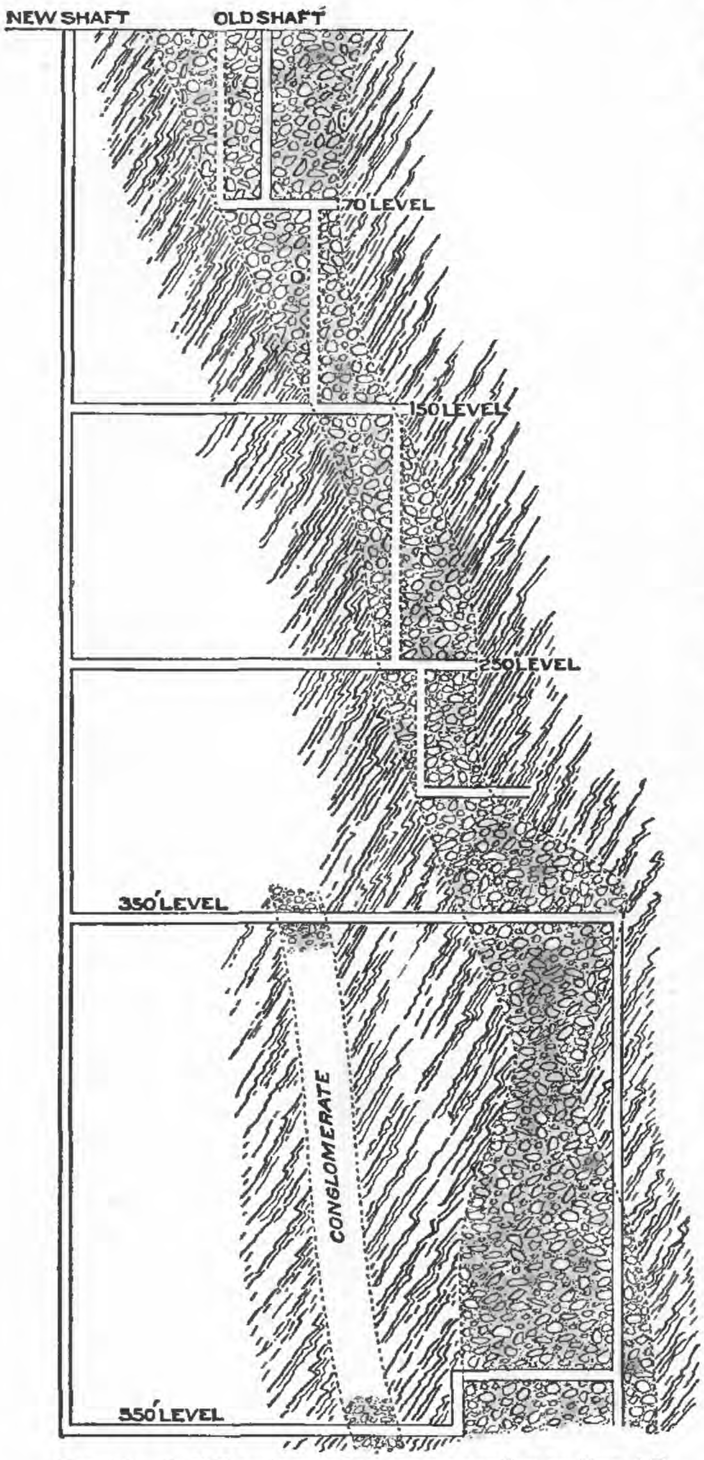

FIG. 42.—Bull-Domingo mine; cross-section on line AB.

A general idea of the form and character of the deposit will be best obtained by reference to the plan and section in figs. 41 and 42 respectively. In fig. 41 is given all the reliable data it has been possible to obtain with regard to the phenomena on the principal levels of the mine, projected on a horizontal plane. The outlines of the ore body there given are those furnished by the mine surveyor, as it was impossible to obtain them by personal observation. They indicate, therefore, rather the limit of pay ore than the actnal geological boundary of the area of ore deposition, but are necessarily within the limits of the latter.

In the section on line AB, fig. 42, is given the form of the pay ore body as constructed from similar data. It has been impossible, however, to determine accurately the form of the conglomerate body which incloses this ore body and contains disseminated through it more or less ore in scattered grains and crystals.

MINERALOGICAL CHARACTER OF THE ORE.

The bowlders or rock fragments which, though they carry no metallic minerals within their mass, constitute the largest and most striking

SILVER CLIFF QUARRY.

occasional vein minerals. The ore was said to average 10 to 11 ounces of silver to the ton, which was enriched by concentration to near 100 ounces for shipment. The ore extended also in thin cracks and seams into the wall rock on either side, but was not worked there, because of the hardness of the rock.

DEEP DEPOSITS OF THE GEYSER MINE.

The only mine workings that have extended to any considerable depth on the plateau, say over 100 feet, are those of the Secnrity-Geyser mine. As far as is known, the ore of all the plateau deposits had given out or been lost trace of within considerably less than 100 feet of the surface. The ore was always chloride of silver where its character could be distinguished. That from the Kate (Silver Bar) claim, worked in early days, is said to have contained some gold also, but this is the only case known, and it has not been verified. It does not seem likely that the silver would be accompanied by gold in one place and free from it in all the others. As will be seen later, of the two shipments to smelters of ore from the bottom of the Geyser shaft, one contained only one-tenth of an ounce of gold per ton, the other but a trace.

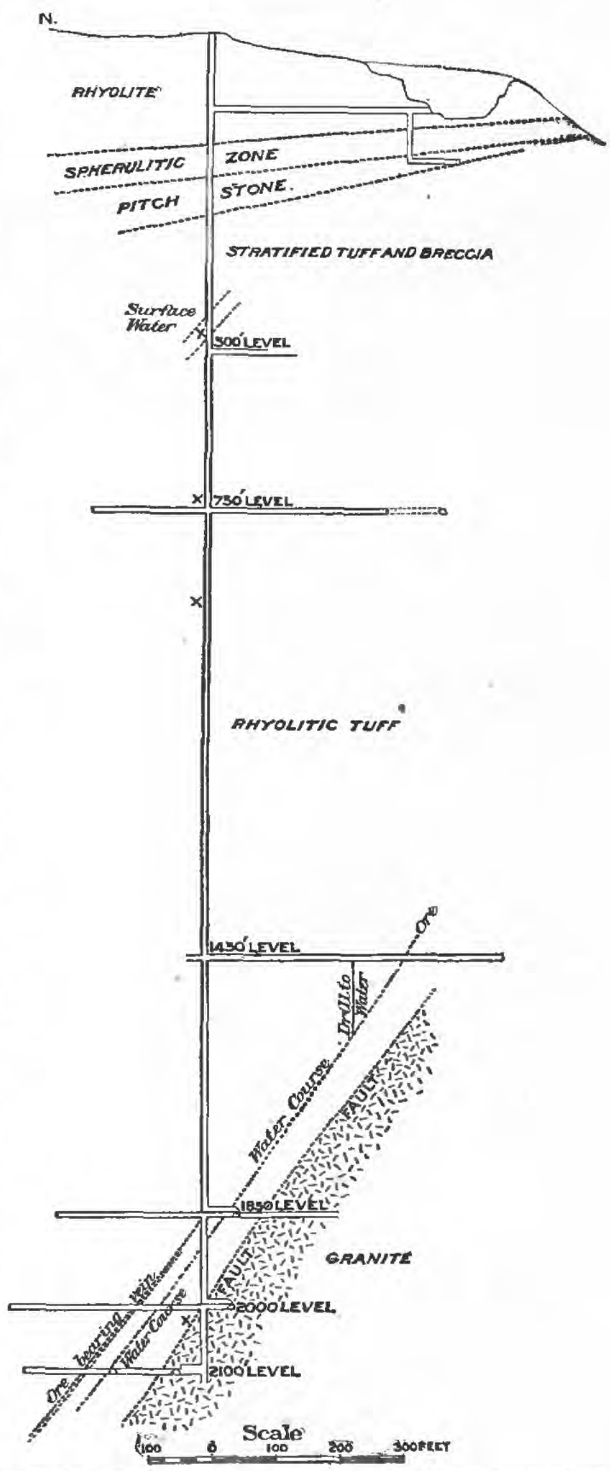

FIG. 43.—Geyser mine; cross-section through shaft on north-south line. Crosses indicate localities where charcoal was found.

It is only through the underground workings of the Geyser shaft, therefore, that it has been possible to obtain any information with regard to the conditions of ore deposition in depth. The data that it has been possible to obtain with regard to them in occasional visits during the past years will therefore be given in considerable detail.

The Geyser shaft, as it is now called, is a thoroughly built 3 compartment shaft, located 350 feet north,

RED BANK AND TERRAPIN CREEKS.

Showing Location of White Phosphate Deposits.

Scale.

0 ½ 1 2 miles

Contour interval 25 feet.

100 feet above the river valley, near the top of a sharp point of land between two ravines. The deposit must be quite small, since the siliceous limestone is exposed a short distance back in both ravines. Between the phosphate and the limestone, cutting across the narrow point, is a well-defined vein of limonite containing many inclusions of chert. Other thin veins of limonite are seen cutting the siliceous limestone at various angles.

TOMS CREEK DISTRICT.

Toms Creek is in the northern part of Perry County, flowing westward into the Tennessee River. At two points in its valley considerable deposits of white phosphate have been discovered. Their location is shown on the accompanying sketch map, fig. 44. The easternmost of these localities is a short distance above the main division of the stream upon the north branch. The deposits occur on the Cotton place and adjacent properties. They are confined to the northwest side of the valley and are distributed through a distance of about half a mile, following the windings of the valley side around the heads of the

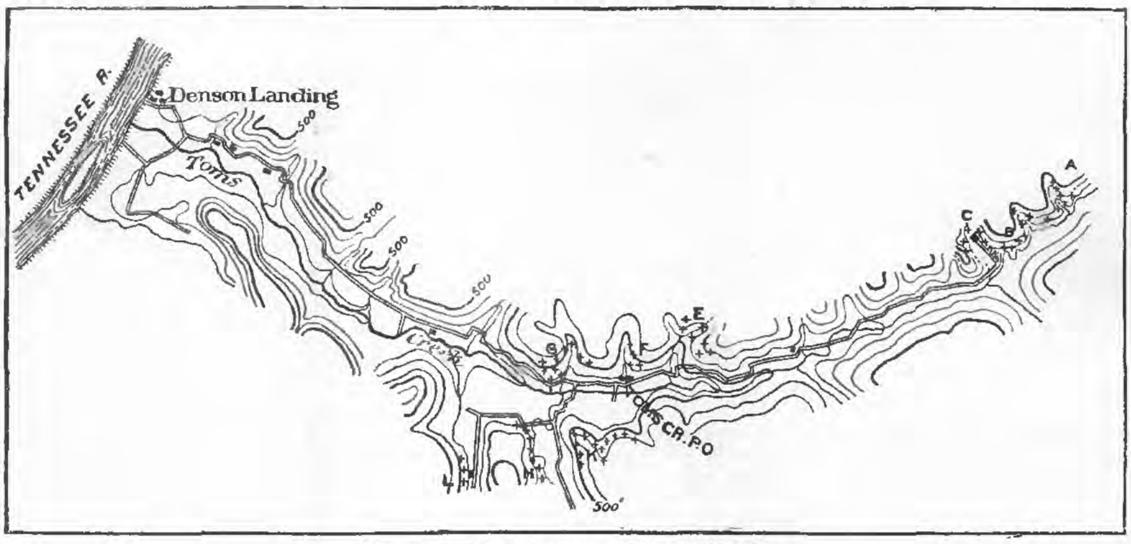

FIG. 44.—Sketch map of Toms Creek.

smaller ravines. The exposures are by no means continuous through this distance, but the extent of the deposits is indicated by occasional fragments on the surface, as well as by larger outcrops forming considerable bluffs. The phosphate appears to be confined to 30 or 40 feet in vertical range. It is not found in the bottom of the valley nor on the tops of the spurs.

The phosphate in this locality consists entirely of the breccia variety, although there is some which approaches the lamellar, but nothing resembling the stony variety. At some points, particularly in the northeastern of the three ravines in which the deposits occur, at the locality marked A on the map, the phosphate forms the matrix of a very coarse breccia. The silica in the original limestone was evidently well segregated, so that the original formation consisted of a tolerably pure limestone in which were embedded many thin beds or plates of chert. Upon the solution of the lime the chert beds settled down with

and snowdrift in the mountains, passes to the plains at the narrow end of this tongue, traverses its middle, and flows eastward. Its principal affluents outside the mountains are Fountain Creek, rising in high mountains west of Colorado Springs; St. Charles River, draining Greenhorn Mountain and neighboring uplands; Huerfano River, draining Huerfano Park, a more southerly embayment of the Rocky Mountain front; Apishapa River, flowing from Spanish Peaks; and Purgatoire River, rising on the eastern slope of the Culebra Range. Of these mountain-born streams, the Fountain alone traverses the northern slope of the Arkansas Valley and holds a southerly course; the others flow on parallel lines toward the northeast. All tributaries east of the Fountain and the Purgatoire head within the plains.

For half of its course between Canyon and Pueblo the Arkansas is closely hemmed in by rock bluffs 200 feet high, with cliffs of limestone at top. Elsewhere its immediate valley is more open, usually with a

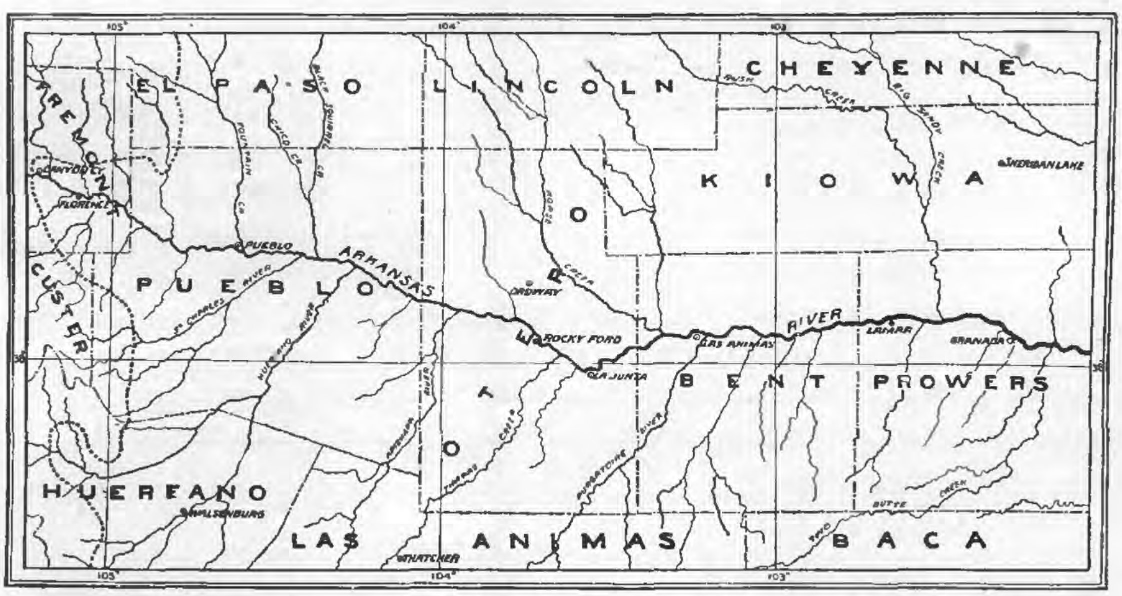

FIG. 45.—Map of part of Colorado, including the district to which this report pertains.

sharp ascent on one side to a gravelly mesa, and a long, gradual slope on the other. Farther back the ascent is broken by terraces of gravel or sand or by tracts of clayey bad lands, and here and there by rocky cliffs and mesas. East of the Fountain the northern slope is characterized chiefly by broad, gently undulating plains, illustrating the typical character of the Great Plains region. On the southern slope similar plains occur east of the Purgatoire, but the topography is in general more accented. The Purgatoire runs for 50 miles in a canyon between sandstone walls, and the Apishapa and Huerfano have shorter canyons of the same character.

At the city of Canyon the altitude of the river is 5,325 feet; at the Kansas line, 3,350 feet, the total fall being 1,975 feet. The distance by rail is 189 miles, but by river it is 218 miles, giving an average grade of 9 feet per mile. Considering the stream in three sections, the fall

2

INOCERAMUS CRIPSII AND SCAPHITES NODOSUS, FOSSIL SHELLS CHARACTERISTIC OF THE TEPEE ZONE OF THE PIERRE SHALE.

Inoceramus cripsii (Fig. 1) is a bivalve shell shaped something like the fresh-water clam. The valves may be found separate or together. The individual figured is of moderate size.

Scaphites nodosus is a coiled shell, and Fig 2 shows a large individual.

he is able, by the aid of the preceding descriptions, to recognize the particular formation occurring at the locality in which he is interested. For his aid a scale of heights has been added to the diagram at one margin, the zero mark being placed somewhat below the top of the Dakota group, at about the level where a water-bearing bed is to be

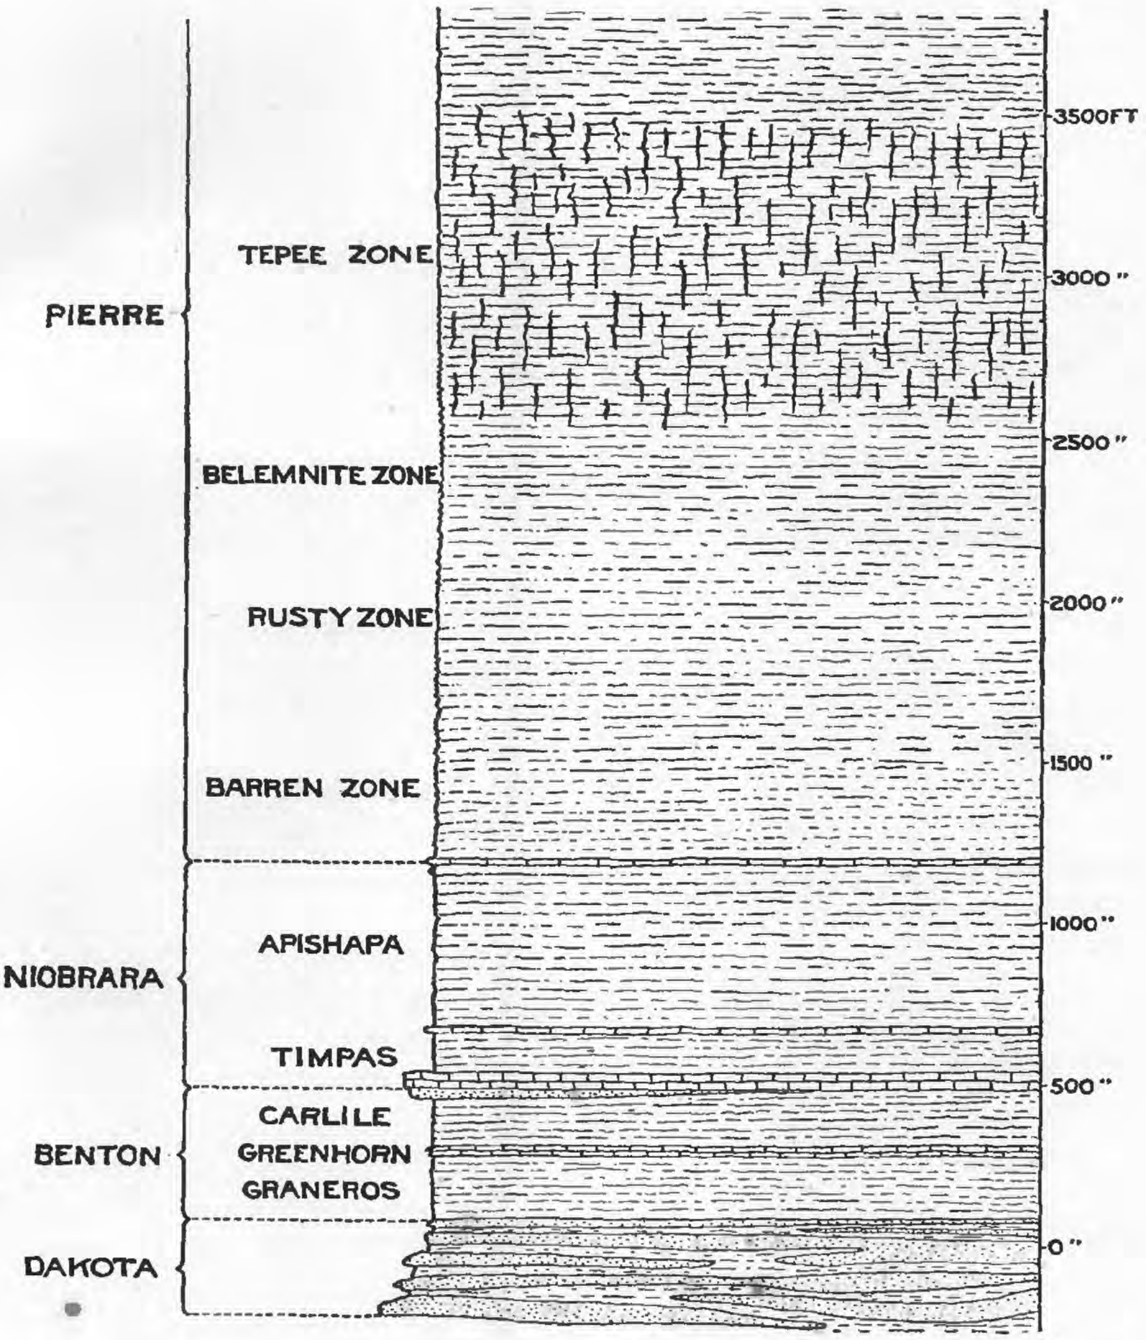

FIG. 46.—*Diagrammatic section of the Cretaceous strata* (except the Fox Hills group), showing the relative thicknesses of the formations. Shales are indicated by broken lines, sandstones by dots limestones by oblong blocks. In the Tepee zone the vertical marks represent tepee cores, but are, more thickly set than in nature. Names of groups are given in the first column, names of formations and zones in the second.

expected. The higher gradations of the scale indicate the approximate depth of this water-bearing horizon below the corresponding elements of the rock series. For example, if one finds at his locality a whitish limestone made of heavy beds separated by only a few inches of shale,

1

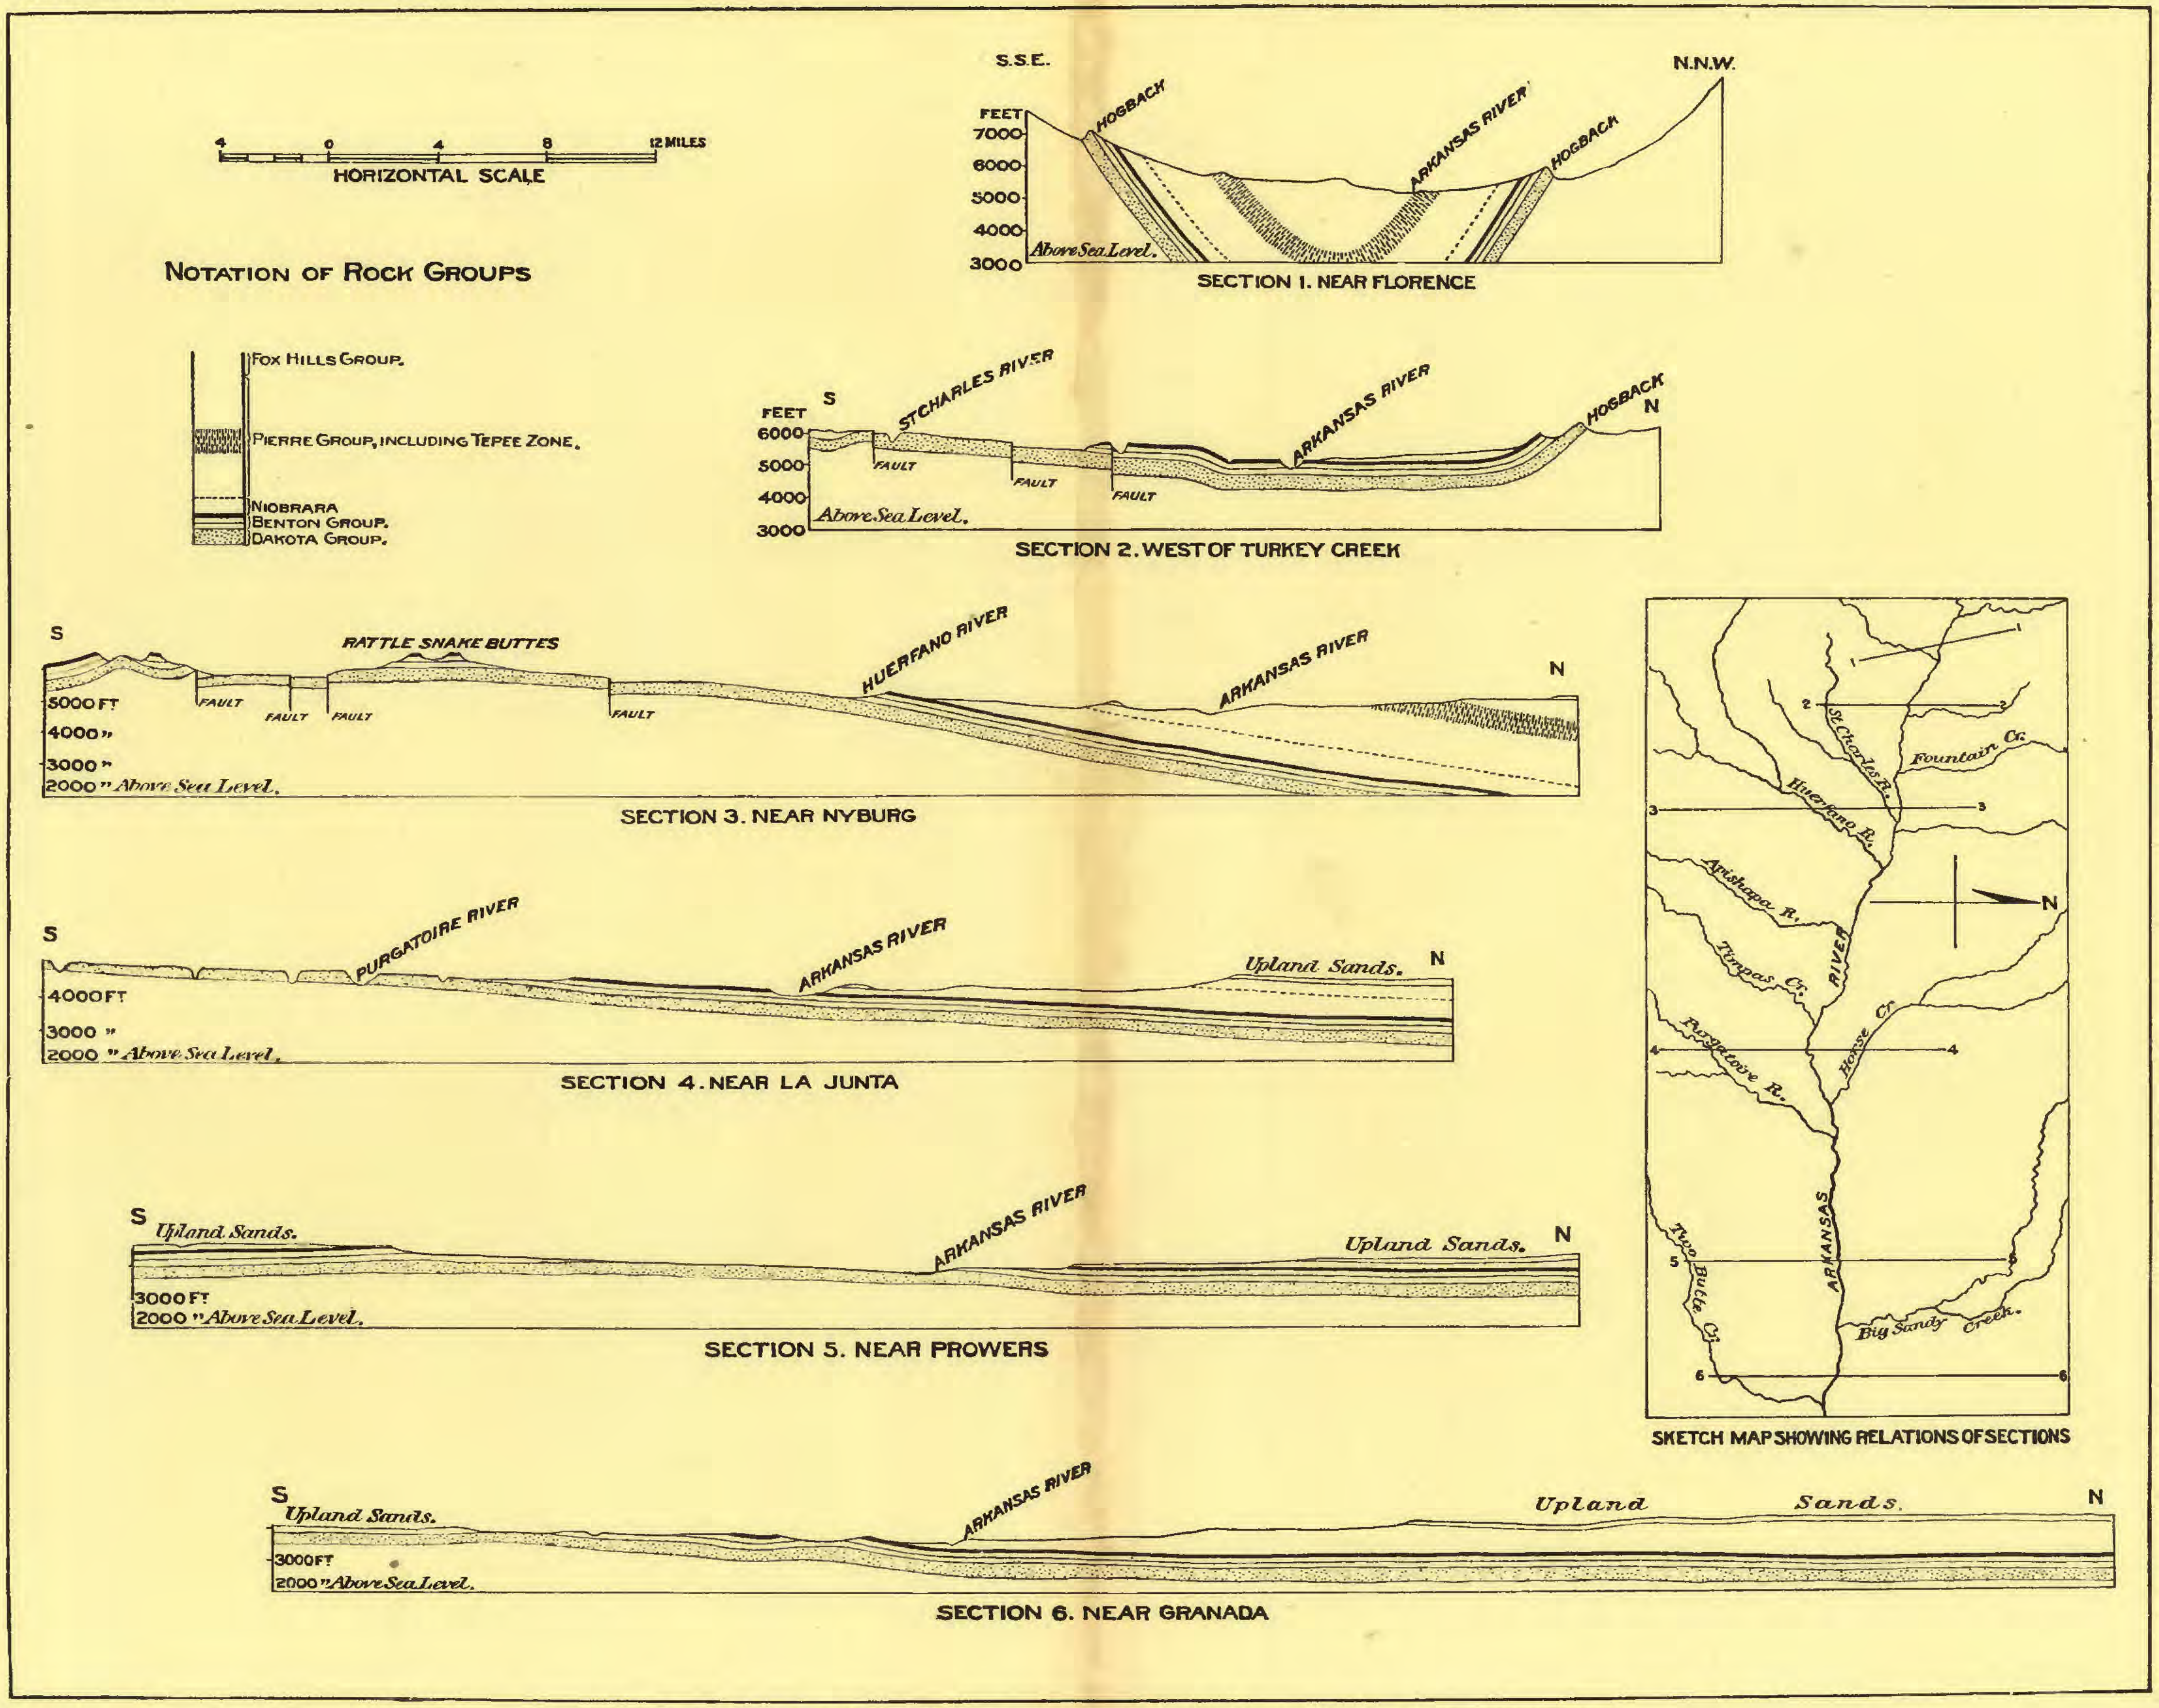
2

LUCINA OCCIDENTALIS AND INOCERAMUS SAGENSIS.

Lucina occidentalis (Fig. 1) is a small bivalve shell occurring in great abundance in the limestone cores of the Tepee Buttes. The figure shows a side view. Natural size.

Inoceramus sagensis (Fig. 2) is characteristic of the Tepee zone, but is rarely found in the limestone cores. The individual figured is young. The adult form spreads into a broad, smooth shield, often a foot in diameter.

A TEPEE BUTTE.



SECTIONS ACROSS THE ARKANSAS VALLEY FROM SOUTH TO NORTH, SHOWING THE ARRANGEMENT OF THE CRETACEOUS ROCKS.

shales and other rocks of the Cretaceous system, but there are many local belts of gravel and sand. Except where the sand has been disturbed by the wind, these belts are flatter than the neighboring slopes, and they are usually sharply limited toward the river by steep slopes or bluffs so as to constitute benches or terraces. Much of the irrigated land of the valley lies on these terraces. In some cases the gravel and sand are covered by a few feet of loam, and their presence is then discovered only through wells or by an examination of the terrace at its margins.

These terraces were all made by the river and its branches during the progress of the excavation of the valley, and it is easy to understand them if one notes the present condition and habits of the river. The river is a great carrier of mud, sand, and gravel. This work it performs chiefly at time of flood, and the finer part of its load can then be seen in the water as the torrent rolls along. The gravel can not be seen in motion as it is dragged and rolled along the bottom in the deeper parts of the channel, but its presence may be noted here and there at low stage.

On the outside of each curve of its course the torrent digs into the

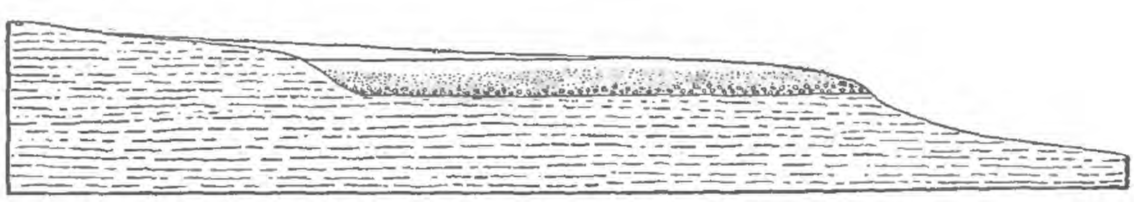


FIG. 47.—Diagrammatic section across a terrace. The dots show sand and gravel, the broken lines bed rock.

bank, so that the river encroaches on the land; but the channel does not grow broader, because in the quieter water on the inside of the curve some of the sand settles from the water, and new land is thus built up. At first the accumulating sand makes only a shoal, but as the main current works farther and farther away, sand and mud are gradually added until the level of the bottom land, or flood plain, is reached. In fact, the whole flood plain of the river has been formed in this way. Some of the bends lie wholly in the flood plain, so that what they dig out is merely alluvium that the river had previously deposited; other bends touch bed rock, and by digging in that make the flood plain broader.

As the stream thus gradually shifts its channel all over its flood plain, it leaves behind an assorted deposit. The lowest layer is gravel, and this rests directly on the Cretaceous bed rock; then comes sand, and, above the sand, clay or loam.

Each of the terraces of the valley slopes is part of a river flood plain, formed when the valley had been dug only to that level. The oldest are those lying highest, and the newest of all is so near the modern flood plain that it is called the "second bottom." As a result of this

Rocky Ford, and continues north of the river to the Kansas line. It is probably as much as 15 miles north of Lamar, but is comparatively near the river in the vicinity of Granada. Between this line and the gathering grounds already mentioned the depth of the artesian water is believed to be everywhere less than 1,000 feet. Farther north it is more than 1,000 feet.

In fig. 49 a rough map is given of the artesian district. A subdistrict is shown in which the depth of water is estimated as less than 1,000 feet, and another in which the depth is estimated as between 1,000 and 2,000 feet. North of the 2,000-foot line, and in an oval tract about Florence the depth to the Dakota water is supposed to be more than 2,000 feet. I confess that I have drawn this map with much reluctance, because it is impossible in such delineation to give adequate expression to doubt, and the data at hand are too imperfect to fix the lines definitely except at a few points. When the region has been thoroughly

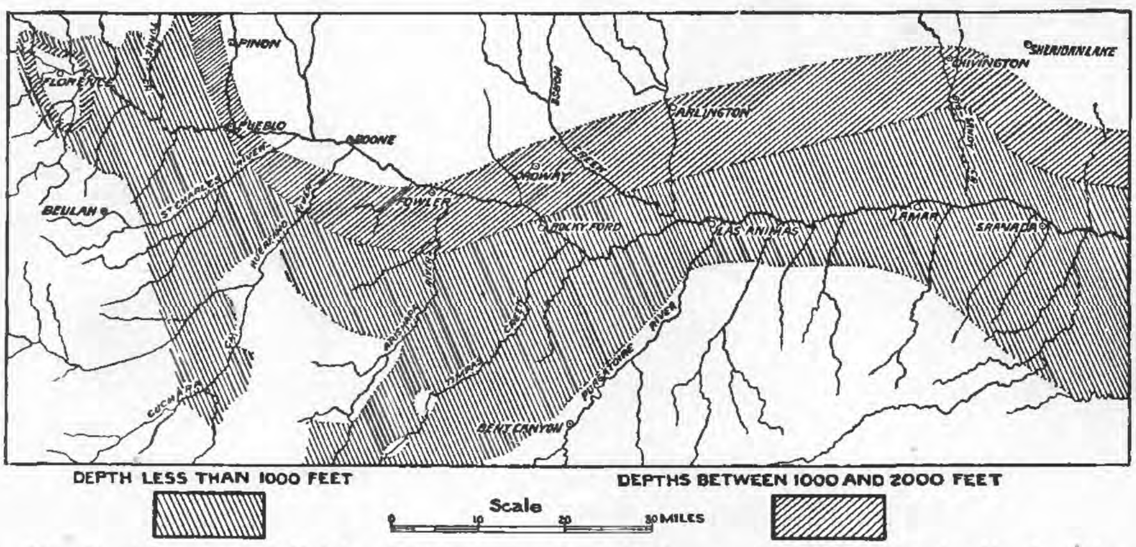

FIG. 49.—The artesian district, showing approximately the area in which the water lies less than 1,000 feet below the surface, and the belts in which its depth is between 1,000 and 2,000 feet.

surveyed, the free-curving boundary lines of each belt as here drawn will be replaced by more sinuous lines, and doubtless the general position of each one will be in some parts materially changed. The reader is warned that he must place no reliance on the local details of the map, but regard it merely as the expression of certain general facts as to the accessibility of the artesian water. The area in which artesian water is available at depths of less than 1,000 feet is nearly 4,000 square miles, and the corresponding area of depths between 1,000 and 2,000 feet is about 1,500 square miles.

The determination of the areas in which the water may be expected to reach the surface without pumping is a more difficult matter. It depends partly on the comparative porosity of the rock in different regions, a character which can not be directly observed; and for this reason trustworthy prediction can not be carried far in advance of experimental boring. There is, however, a general principle in regard

MAP OF ARTESIAN BASIN IN EASTERN S. DAKOTA AND A PORTION OF N. DAKOTA. BY N. H. DARTON

Scale: 0 5 10 15 20 25 50 miles

JULIUS BIEN & CO. N.Y.

clear insight into the general relations, and as it is necessary to understand these relations in considering the conditions of underground water supply, a brief description of the geology is desirable. East of the vicinity of the Missouri River the surface is occupied to a greater or less thickness by gravel, clays, and sands, which were deposited by or in connection with the great continental glaciers of the Glacial period. These formations vary in thickness from 40 or 50 feet to over 100 feet, and they are so continuously spread over the surface that exposures of underlying formations are relatively few, particularly to the east and northeast. Lying beneath the drift and occupying the surface over the plains region westward in South Dakota are clays or shales of the Cretaceous period. Their thickness averages 1,000 feet over the greater part of the area, but they thin rapidly east of James River. In the region adjoining White River and extending thence southward through Nebraska this clay formation is overlain by a much younger series of Tertiary clays and sandy clays which occupy the surface in the Rosebud and Pine Ridge Indian reservations and in the Bad Lands. They have a thickness of between 300 and 400 feet in their greatest development. North of the Cheyenne River, and extending thence far to the north and eastward into North Dakota, the Cretaceous clays are overlain by sands and sandstones known as the Laramie formation.

FIG. 50.—Vertical section from eastern portion of the Black Hills across South Dakota, showing the attitude and relations of the water-bearing Dakota sandstones; looking north; 300 miles long; vertical scale considerably exaggerated.

In the southern portion of South Dakota the Cretaceous clay series includes an extensive deposit of calcareous material about 300 feet above its base, which is known as the Niobrara chalk. This chalk formation outcrops extensively along the Missouri Valley below Chamberlain. The underlying beds are known as the Benton clays, and the overlying beds as the Pierre clays or shales.

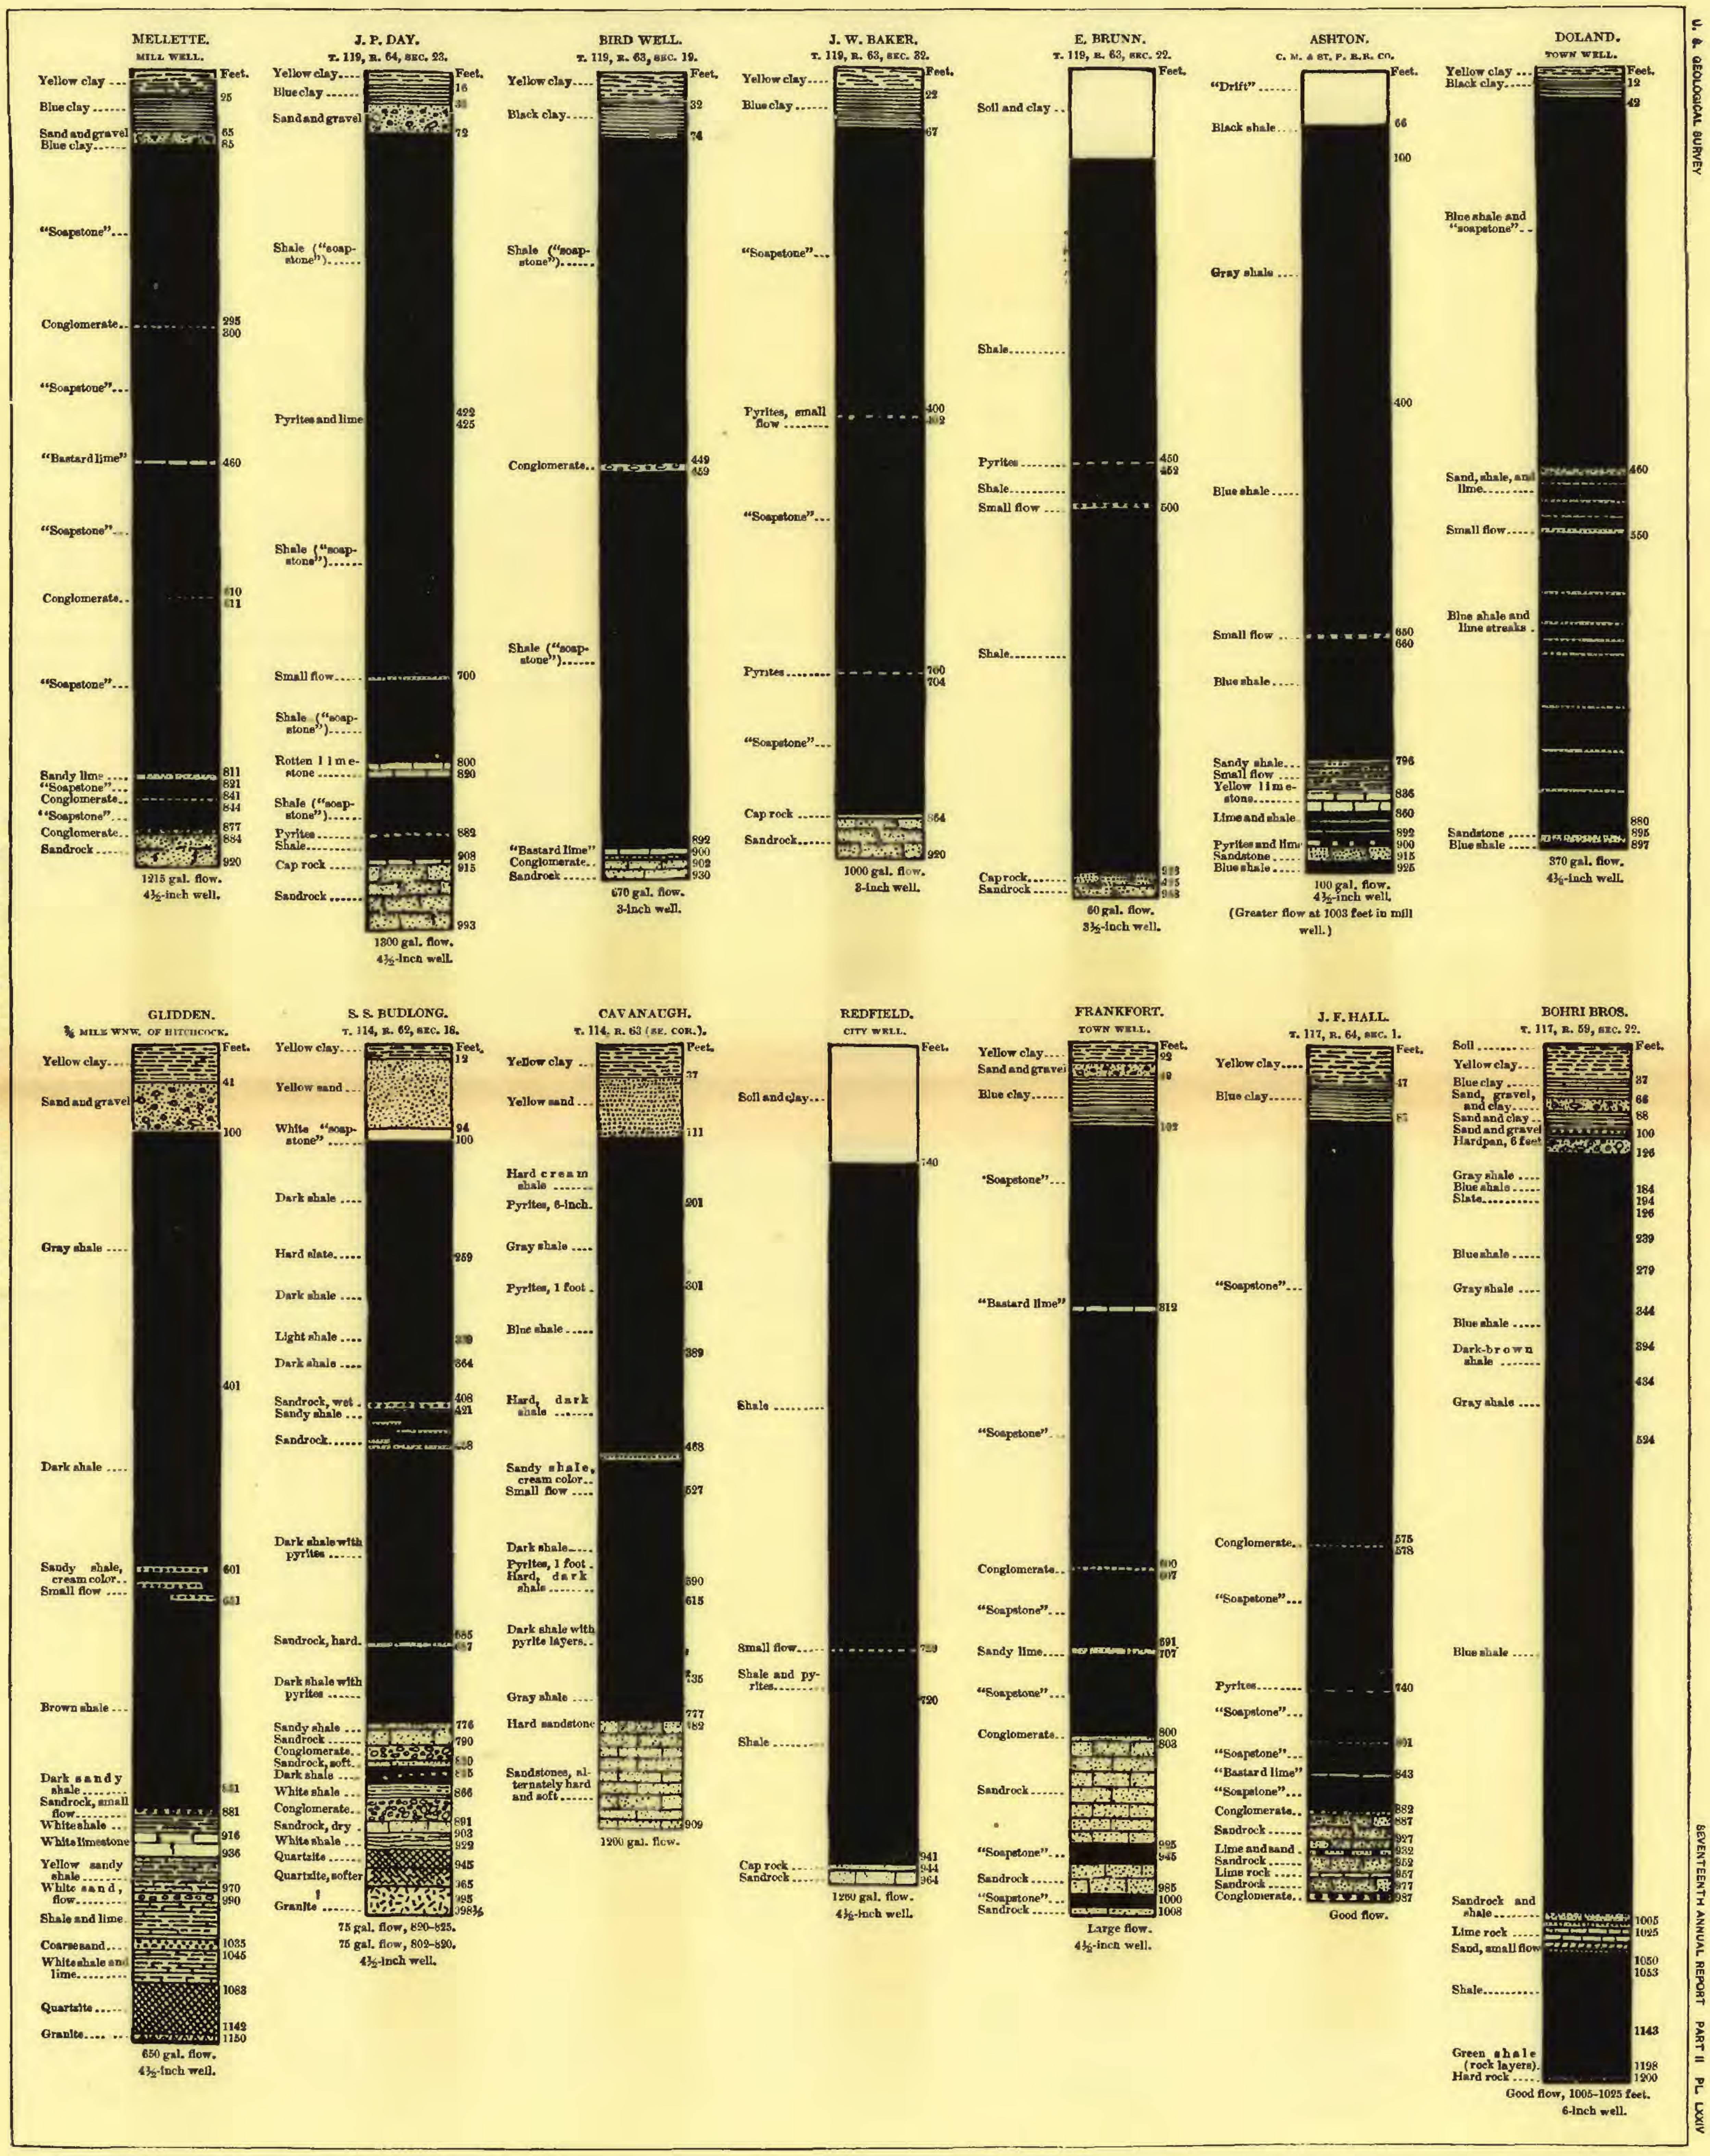
LOGS OF WELLS IN SOUTHERN HALF OF BROWN COUNTY, SOUTH DAKOTA.

LOGS OF WELLS IN SPINK AND CLARK COUNTIES, SOUTH DAKOTA.



RISDON WELL, NEAR HURON, SOUTH DAKOTA, THROWING A 10-INCH STREAM TO A HEIGHT OF 12 FEET.

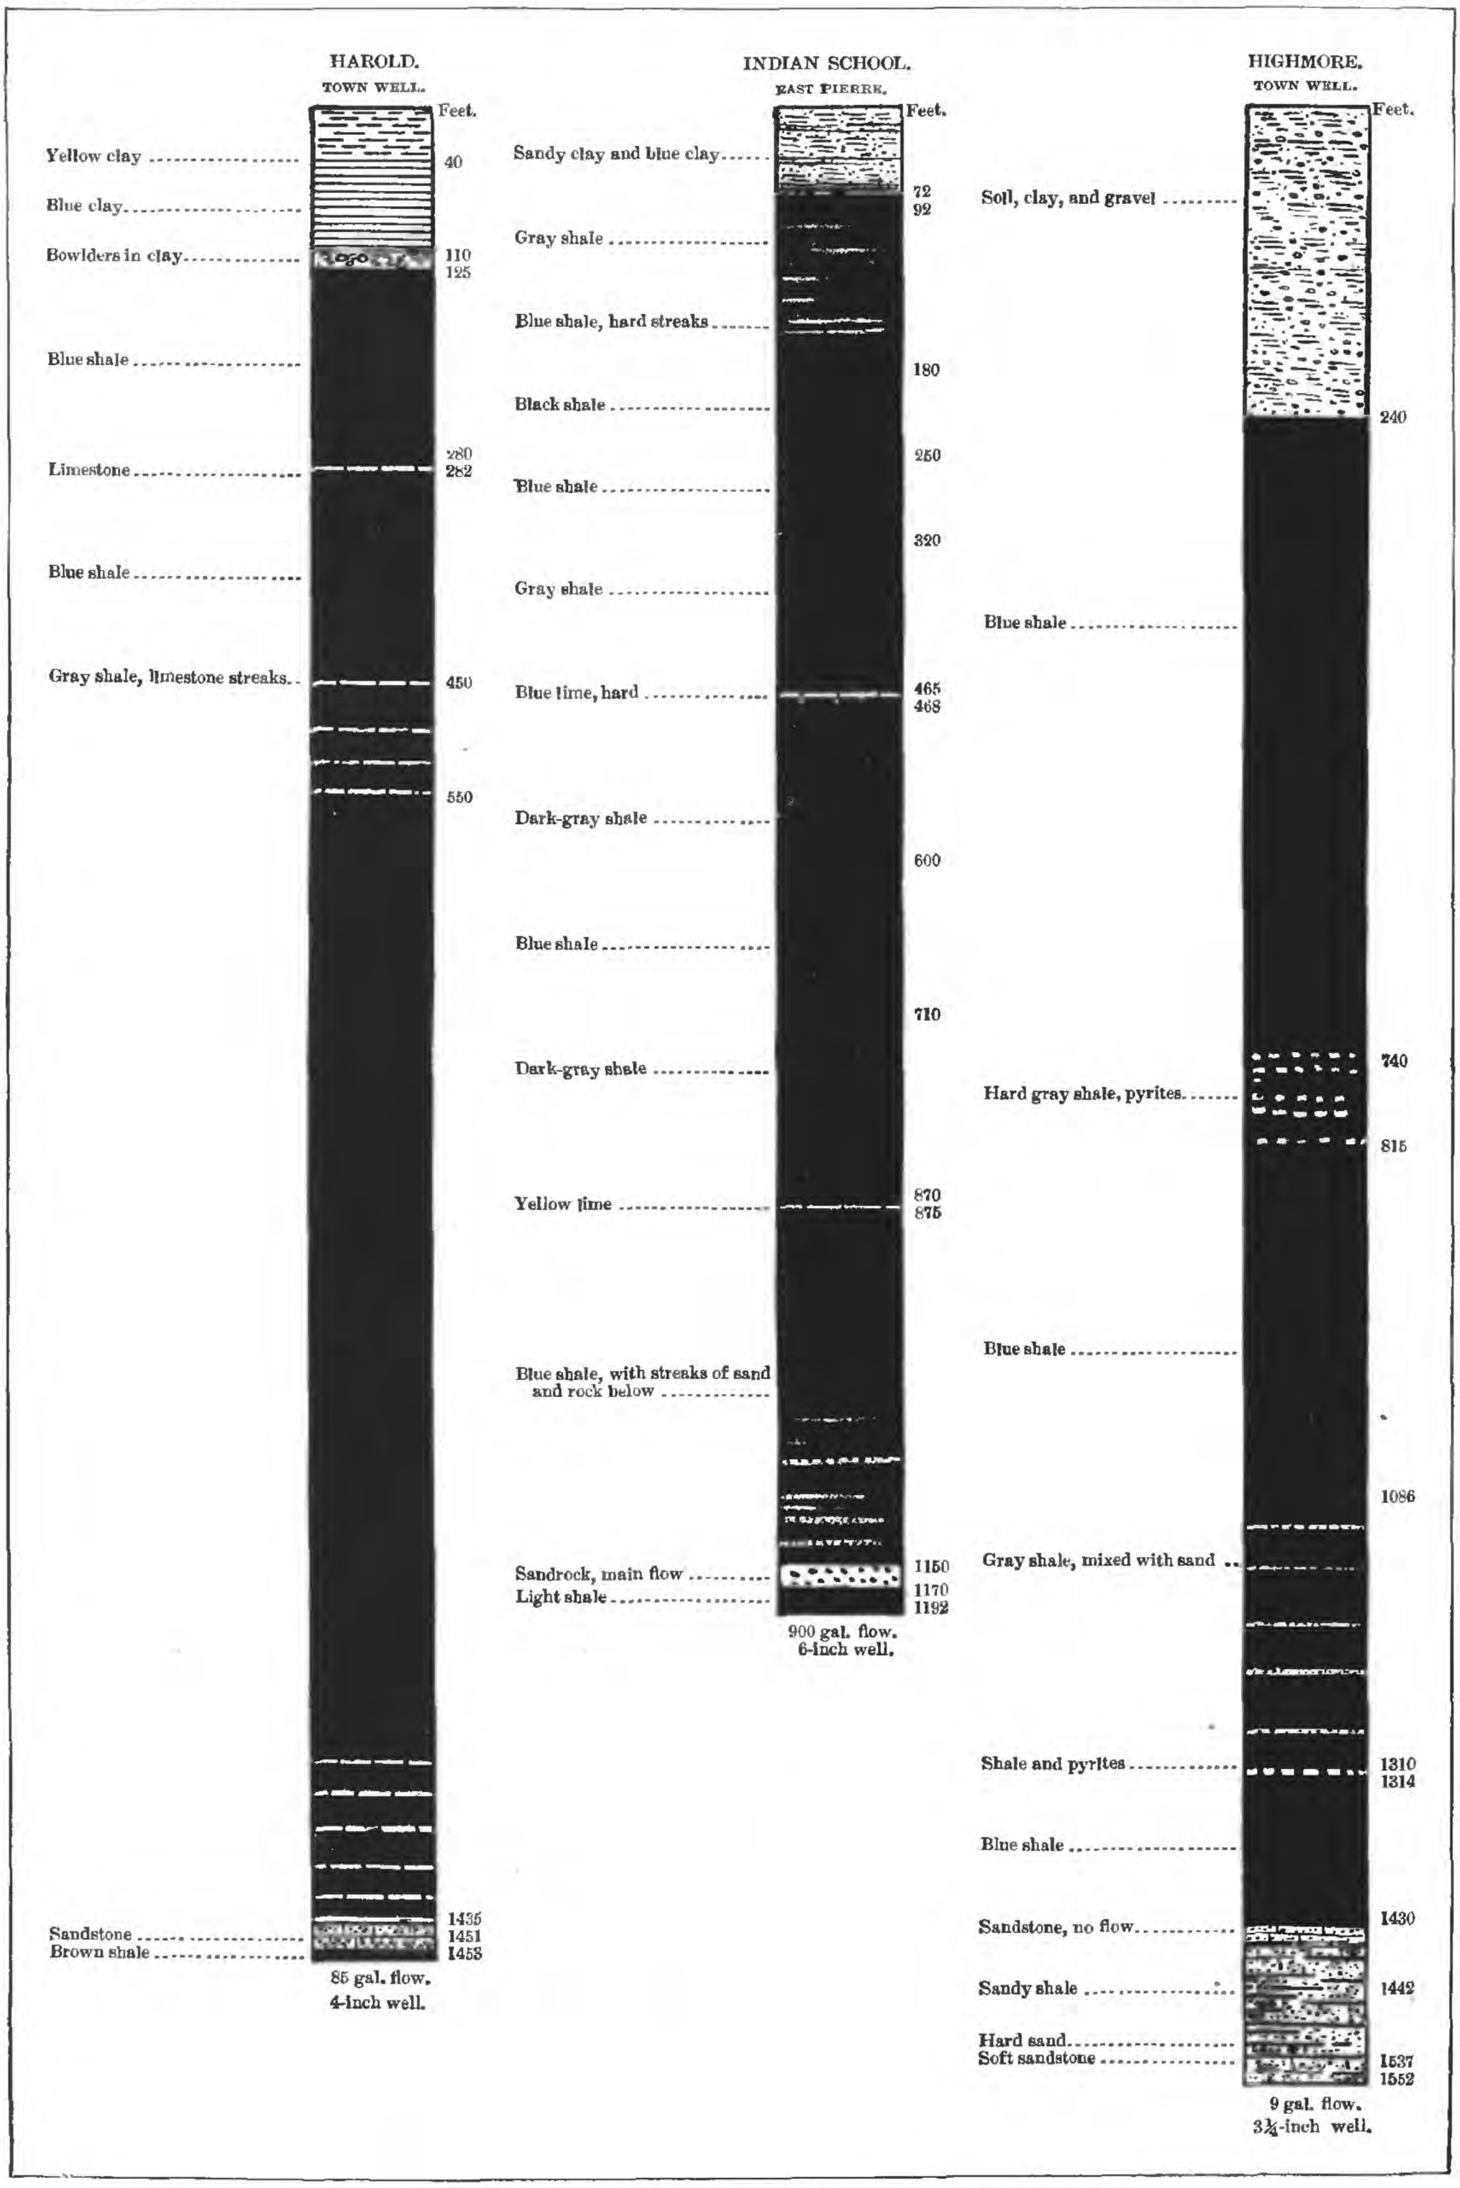
section 3, Pl. LXXI, the water-bearing beds probably lie at a depth of about 1,300 feet at Clark, but the head is not sufficient for a surface flow at that locality. No doubt a well to this depth would obtain a large volume of water, which would rise to within about 110 feet of the surface at Clark and afford very satisfactory force-pump wells.

FIG. 53.—Log of well in T. 117, R. 68, sec. 18, near Orient, Faulk Co., S. Dak.

FAULK COUNTY.

Only two deep wells have been sunk to the artesian waters in this county, but their experience was satisfactory. They were near the central part of the area, and indicate the extension of the waters westward from the James River Valley, where, in the adjoining county of Spink, they furnish large supplies to many wells.

The well at Faulkton is stated to draw its waters from a depth of 1,032 feet, but the contractors claim that its original depth was 1,296 feet. It was not properly constructed, and at one time completely clogged up. The flow is estimated at 100 gallons per minute, and the pressure varies from 25 to 34 pounds per square inch. The other well is about 4 miles north by east of Orient. It had a depth of about 1,215 feet, a flow of 950 gallons per minute, a pressure of 130 pounds to the square inch, a diameter of 6 to $5\frac{1}{4}$ inches, and a temperature of 75°. It is now clogged up. It is reported that several flows were found, those at 394, 1,050, 1,070, and 1,165 feet being the principal ones. Its log is given in fig. 53. As shown in section 3, Pl. LXXI, the lowest waters in the Orient and Faulkton wells were in the same horizon in the Dakota sandstones, which is probably the same one as at Redfield and Frankfort. The upper horizons are less definitely correlated, but they appear to be at the top of the irregular upper surface of the Dakota sandstone. The pressure exhibited in the Orient well is sufficient to raise the waters to an altitude of 1,865 feet. Possibly the original pressure at Faulkton was equally great. This head is sufficient to yield an artesian flow in all except the western tier of townships of the county, and T. 117, R. 71, which are elevated considerably above 1,850 feet in greater part. In the eastern portion of the county, where the country is less elevated, abundant water supplies may be expected at a depth of between 1,000 and 1,100 feet, and although the head of the waters



LOGS OF WELLS IN HYDE AND HUGHES COUNTIES, SOUTH DAKOTA.

WELL AT WOONSOCKET, SOUTH DAKOTA, THROWING A 3-INCH STREAM TO A HEIGHT OF 97 FEET.

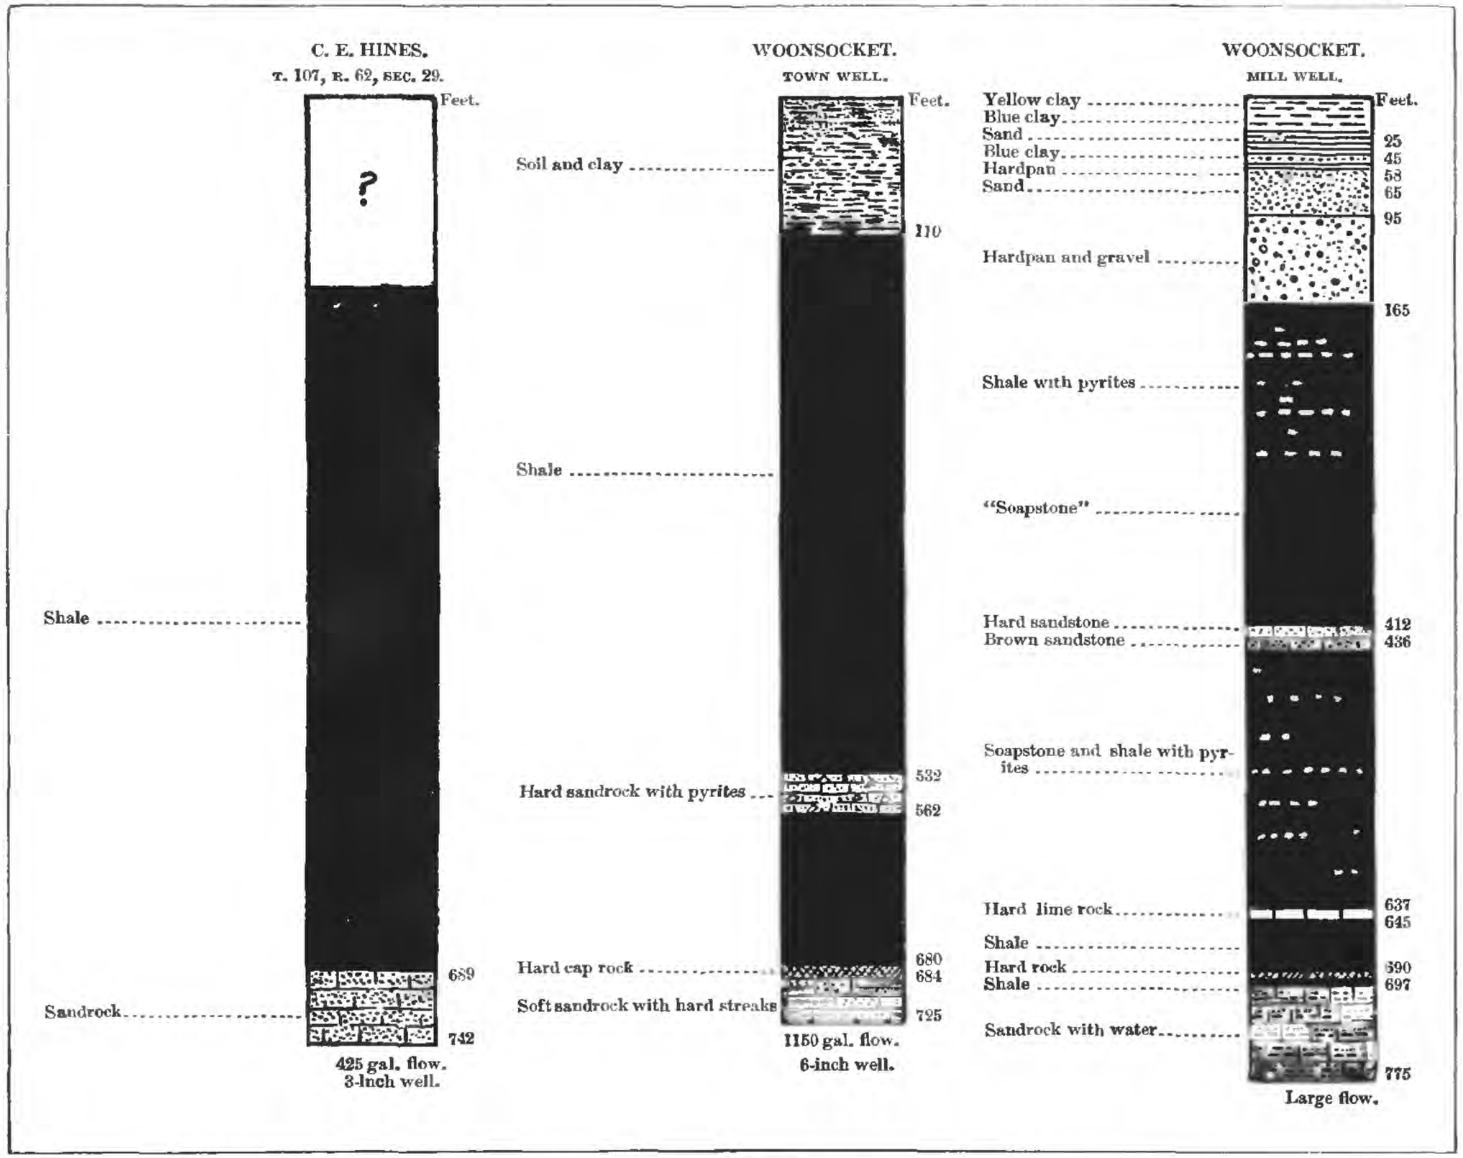
HYDE COUNTY.

There is but one deep flowing well in this county, but it throws important light on the artesian-well prospects in this portion of the western Coteau. The well is at Highmore, at an altitude of 1,890 feet. Its depth is 1,552 feet, diameter 6 inches, flow about 9 gallons per minute, and the pressure is stated to be 12 to 15 pounds per square inch. In the Resources of Dakota for 1887 its flow was given at 14 gallons and pressure 25 pounds, but later measurements reported by Mr. Coffin give smaller figures. The temperature of the water is 72°. The water-bearing bed was entered at 1,537 feet. Water was found also in a bed extending from 1,430 to 1,442 feet, but it did not flow out of the well. The log is given in Pl. LXXVII. While the pressure of the water in this well is relatively low, it indicates a greater head above sea level than that of any other well in the region. It is equivalent to a rise of the waters to an altitude of 1,920 feet above sea level. This head is sufficient to bring waters to the surface over a limited area on the slopes of the high ridge which passes through the center of Hyde County. Of course this head may decrease in the regions north and south of Highmore, as it does to the west, as indicated at Harold, so that we can not make a definite prediction as to the precise altitude at which artesian waters may be expected in the higher lands in Hyde County. In Pl. LXIX, I have attempted to indicate approximately the area of which the elevation appears to be sufficiently low for artesian flows, but it should be borne in mind that this is only an approximation and is not based on very definite topographic information or knowledge as to the possible variation of the head of the waters.

FIG. 54.—Log of town well in Miller, Hand Co., S. Dak.

HUGHES COUNTY.

There are three deep flowing wells in this county—two in the Missouri bottom at Pierre and East Pierre, and the other on the relatively high lands at Harold. The well in Pierre is at the Hotel Locke, to which it furnishes water at a temperature of 92° for the bathing pool. Its depth is 1,160 feet. The flow is stated to be about 600 gallons per minute. The well at East Pierre is at the Indian school, and is



LOGS OF WELLS IN NORTHWESTERN PORTION OF SANBORN COUNTY, SOUTH DAKOTA.

The experience of these wells indicates that the water-bearing bed lies nearly horizontal or rises slightly to the south and east. Its depth is about 715 feet along the eastern edge of the county, and it lies correspondingly deeper as the land gradually rises westward. There may possibly be two horizons of water-bearing beds, but if so they are not far apart. In the southeastern corner of the county there are also

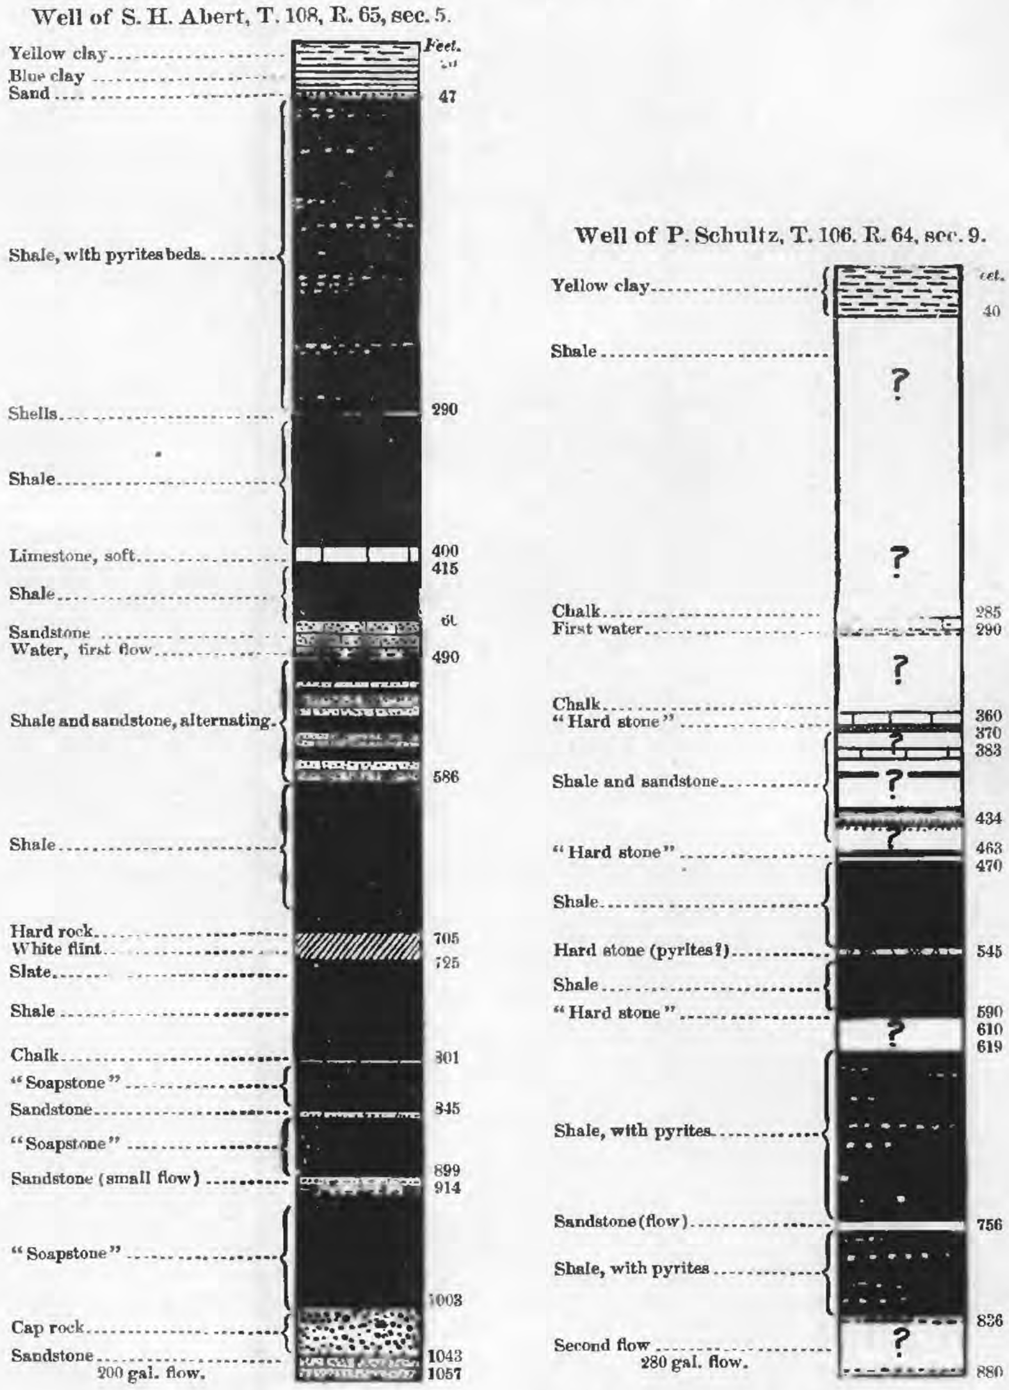


FIG. 55.—Logs of two artesian wells in Jerauld County, S. Dak.

prospects for moderate water supplies at a depth of about 550 feet, such as are found in a few wells in the adjoining counties. Their existence, however, can not be definitely predicted. The relatively small supplies of water in the wells in the above list are due mainly to the small diameters of the casings. Only two logs of Jerauld County wells were obtained; they are given in fig. 55.

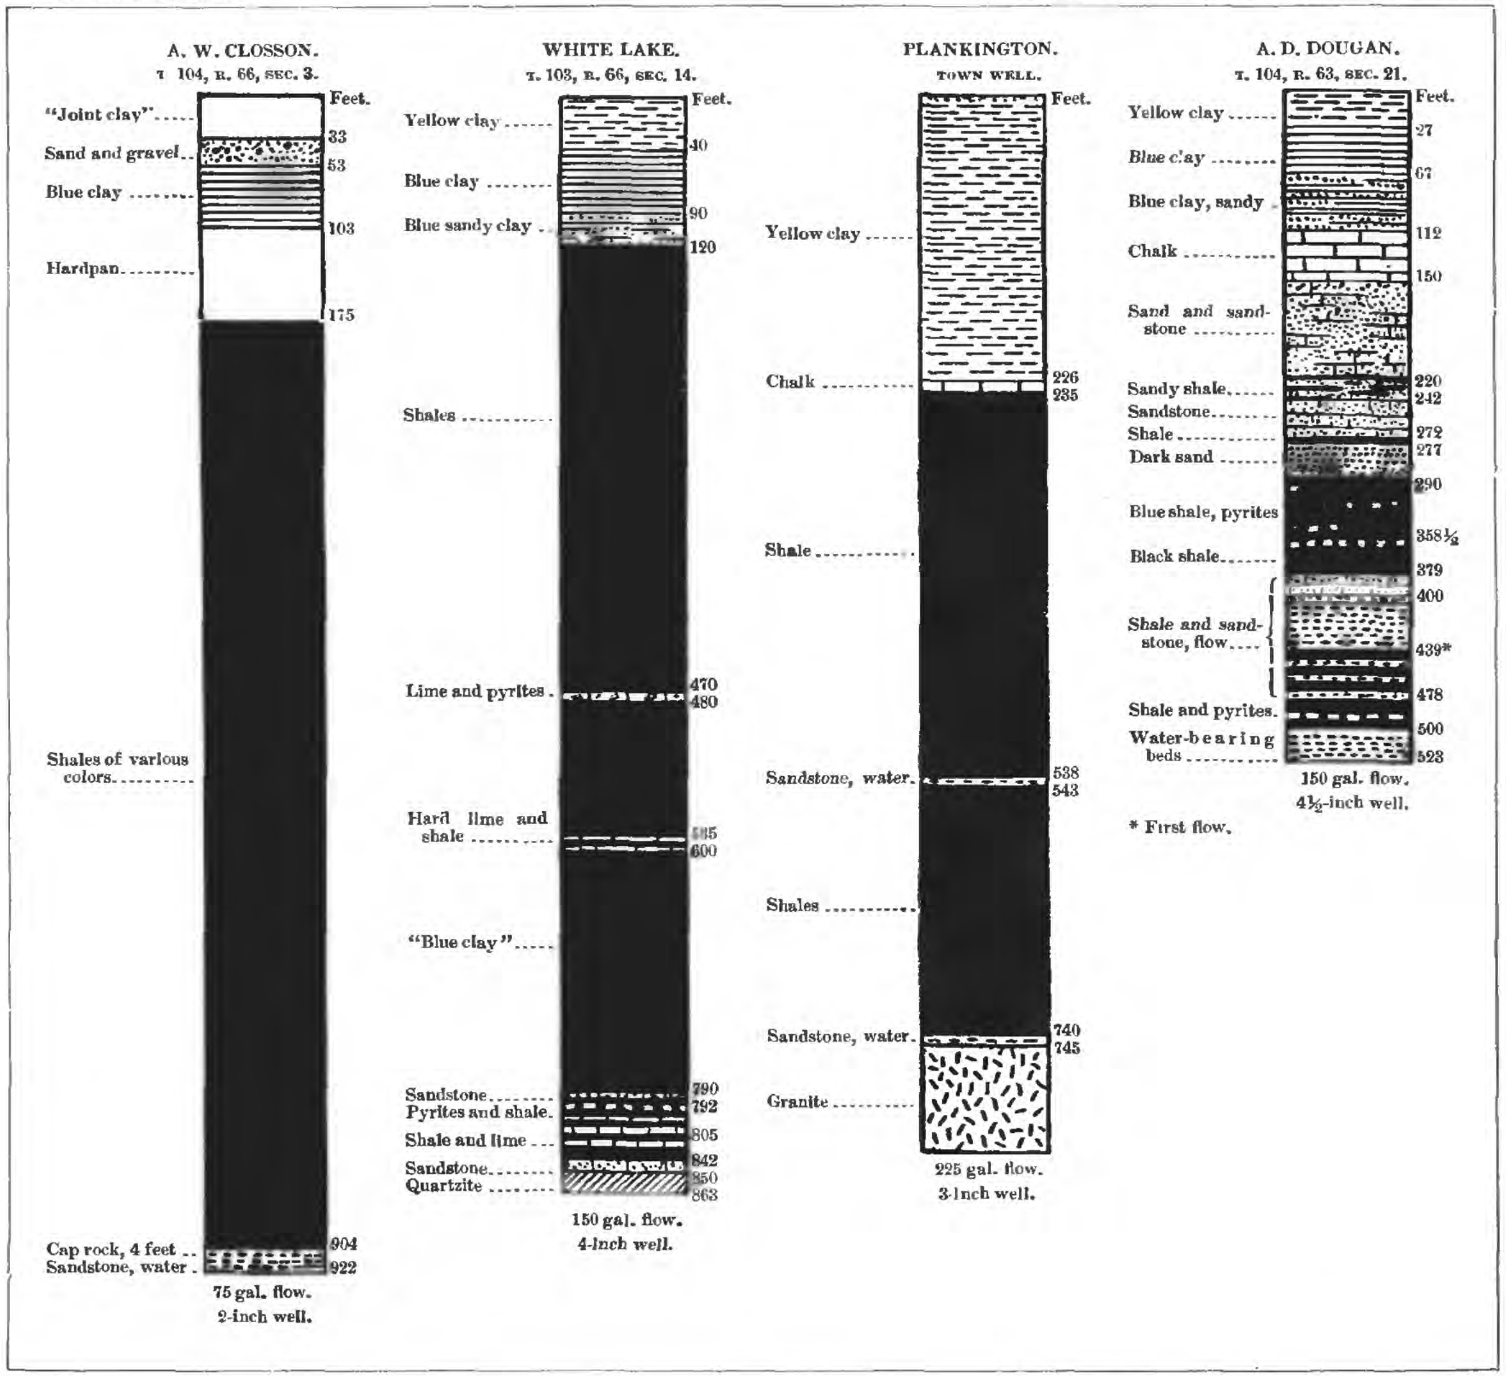
552–556	sand rock, third flow, 15 gallons per minute.
556–577	gray shale.
577–579	sand rock, fourth flow, 30 gallons per minute, soft water.
579–641	gray shale full of lime and pyrite streaks 2 to 12 inches thick.
641–651	sand rock, very soft, 3,000-gallon flow, hard water, 70° F.

DOUGLAS COUNTY.

The wells in Douglas County are quite numerous, and they are so scattered over the area as to indicate the probable extension of the artesian waters throughout the county. It is possible that in the extreme northwestern corner of the county the land is too high for an artesian flow, but this area, if it exists at all, is very restricted in extent. The wells from which we have received returns in Douglas County are given in the list on the following page, which is thought to be very nearly complete.

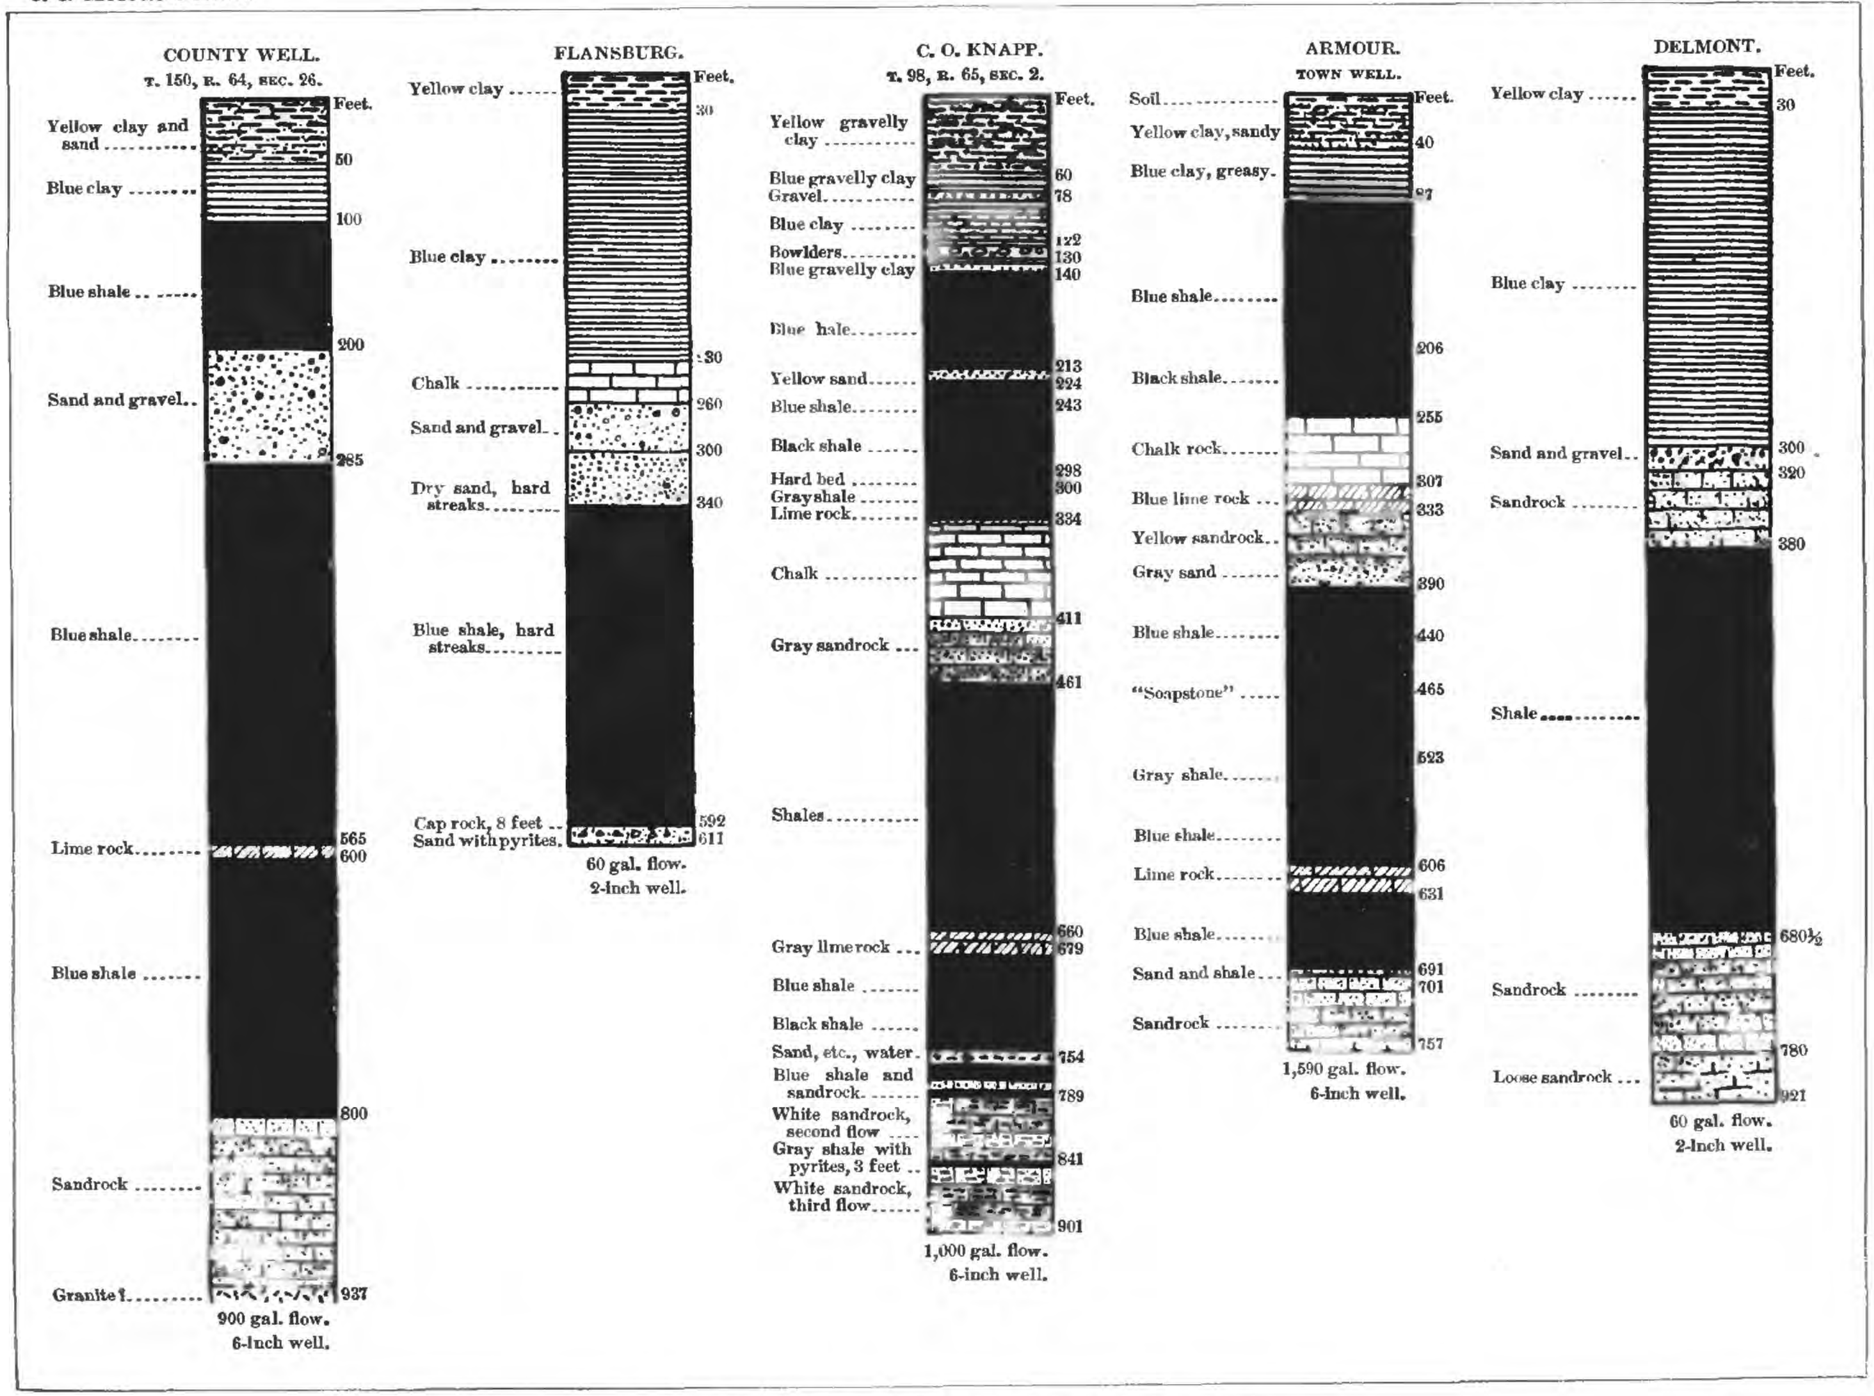


LOGS OF WELLS IN AURORA COUNTY, SOUTH DAKOTA.

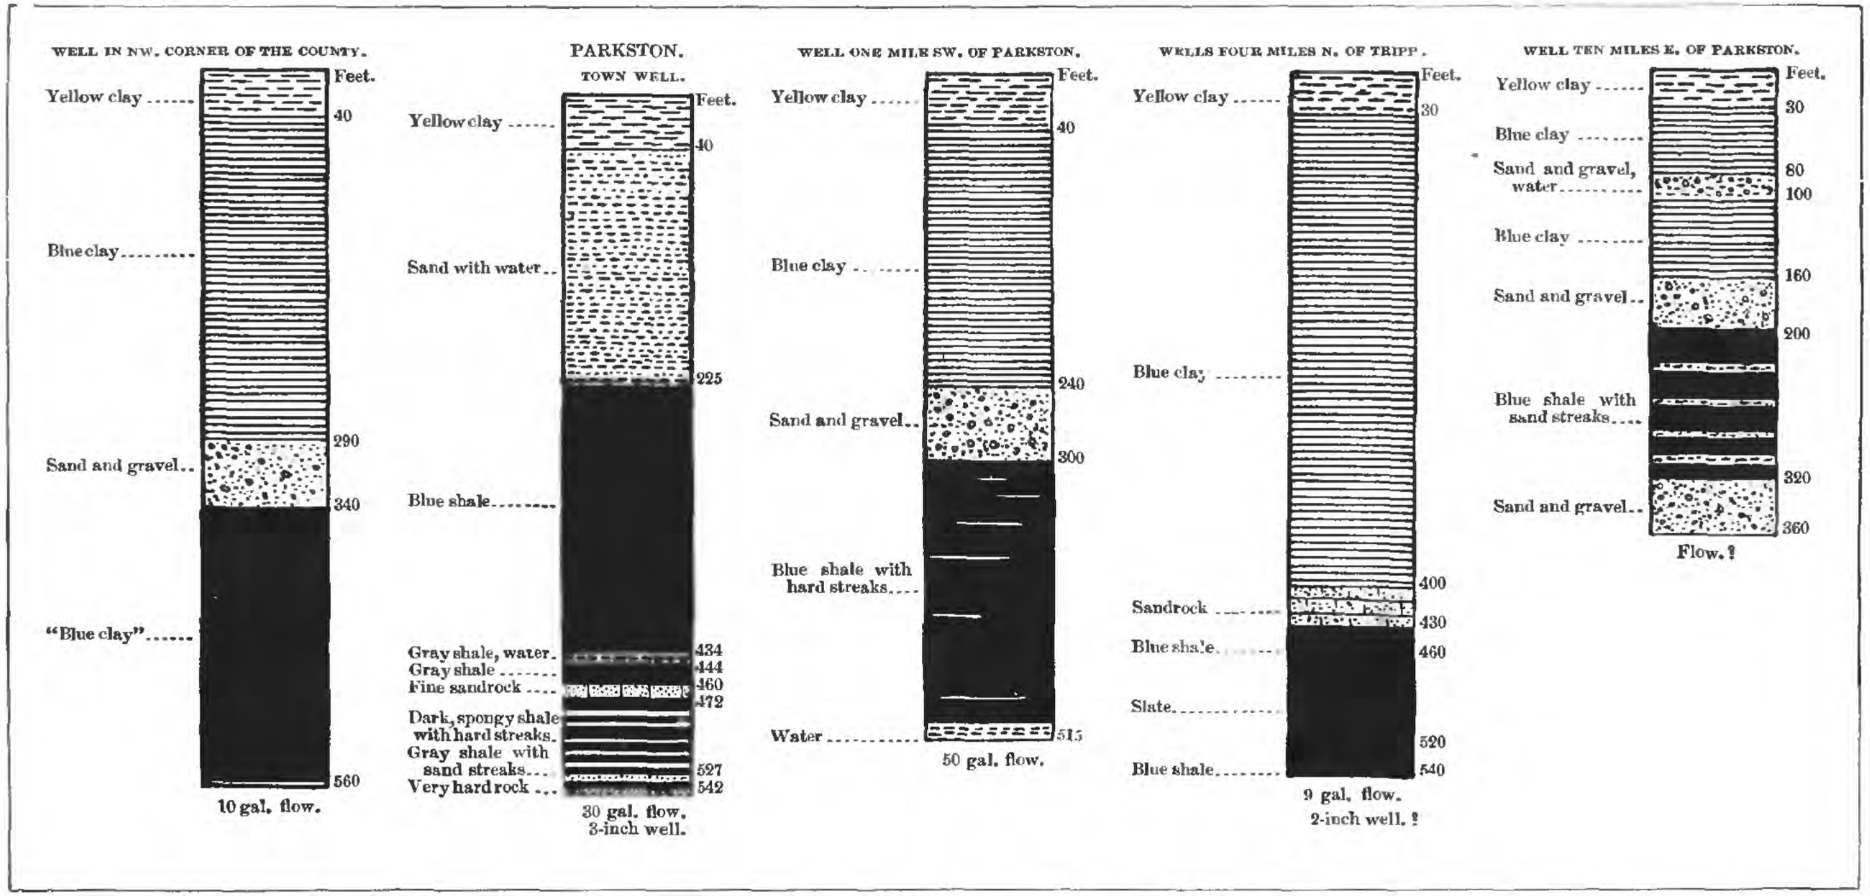
at 590 feet, but obtained no increase in flow. The Layson well was sunk on the high ridge lying between Emanuel Creek and Choteau Creek to a depth of 1,074 feet and 8 inches. Only a feeble flow was found, and the pressure was sufficient to raise the water only to about 7 feet above the surface. The wells at Tyndall, those in the southeastern corner of the county, and those in the Missouri bottom near the mouth of Choteau Creek yield more satisfactory supplies. The

FIG. 57.—Artesian well at mill in Springfield, S. Dak.

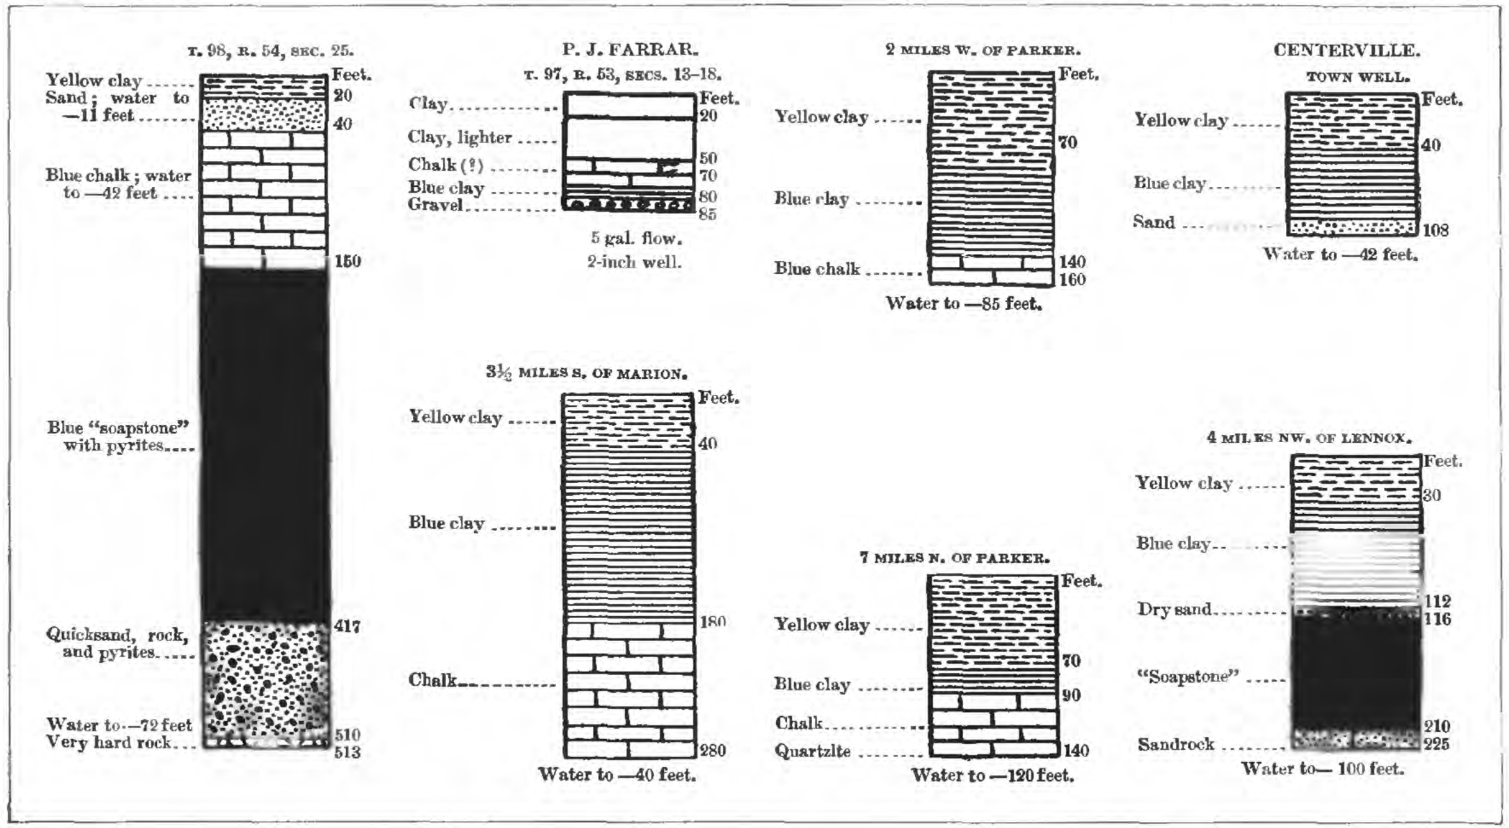
artesian waters in Bonhomme County all appear to come from approximately the same horizon excepting those at Scotland, Layson, and the mouth of Choteau Creek. At Scotland the waters appear to be largely cut off by a ridge of the quartzite bed rock, as shown in sections 1 and 6, Pl. LXXI. The Layson well appears to have been sunk to a horizon considerably below that of the group of successful wells to the east and south. The low pressure at the surface is due to the height of the



LOGS OF WELLS IN DOUGLAS COUNTY, SOUTH DAKOTA.



LOGS OF WELLS IN HUTCHINSON COUNTY, SOUTH DAKOTA.



LOGS OF WELLS IN TURNER COUNTY. SOUTH DAKOTA.

All of Clay County appears to be underlain by the water-bearing beds, but, owing to the greatly decreased head of the water, they afford flowing wells only in the lower-lying lands. The limit of the area of flow in the Missouri bottom appears to be in the extreme southwestern corner of the county, and in the valley of the Vermilion River it extends to the northern boundary of the county.

Logs of a number of Clay County wells are reproduced in Pl. XCV.

THE REGION WEST OF THE MISSOURI RIVER.

Very few attempts have been made to obtain artesian waters in the region west of the Missouri River. Two small wells opposite Chamberlain and a well at Fort Randall are the only ones in the vicinity of the river. In the Plains country westward a boring is now in progress on the Rosebud Indian Reservation, at a point 22 miles northeast of Rosebud Agency. In April, 1896, it had gone to a depth of 2,075 feet, but had not reached the Dakota sandstone formation. Calcareous beds were penetrated between 1,500 and 1,650 feet below the surface, which are believed to represent the chalk deposits of the Niobrara formation. It was expected that the underlying Benton shales would be found to have a thickness of about 400 feet, so that the depth to the Dakota sandstone would be about 2,050 feet. The boring is situated on the divide between branches of Oak Creek of White River and the Keya Paha River. It is being sunk by the Indian Bureau of the Interior Department to supply water to the creeks for the watering of stock. It is believed, however, that the boring has but little prospect of obtaining a flow of water, although with the increase of head westward the waters may rise to within a moderate distance of the surface. The region has an elevation of about 2,700 feet above sea level.

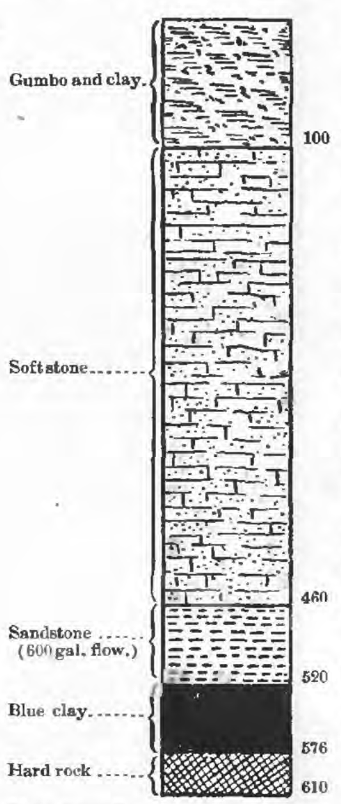


FIG. 58.—Log of well at Fort Randall, Todd County.

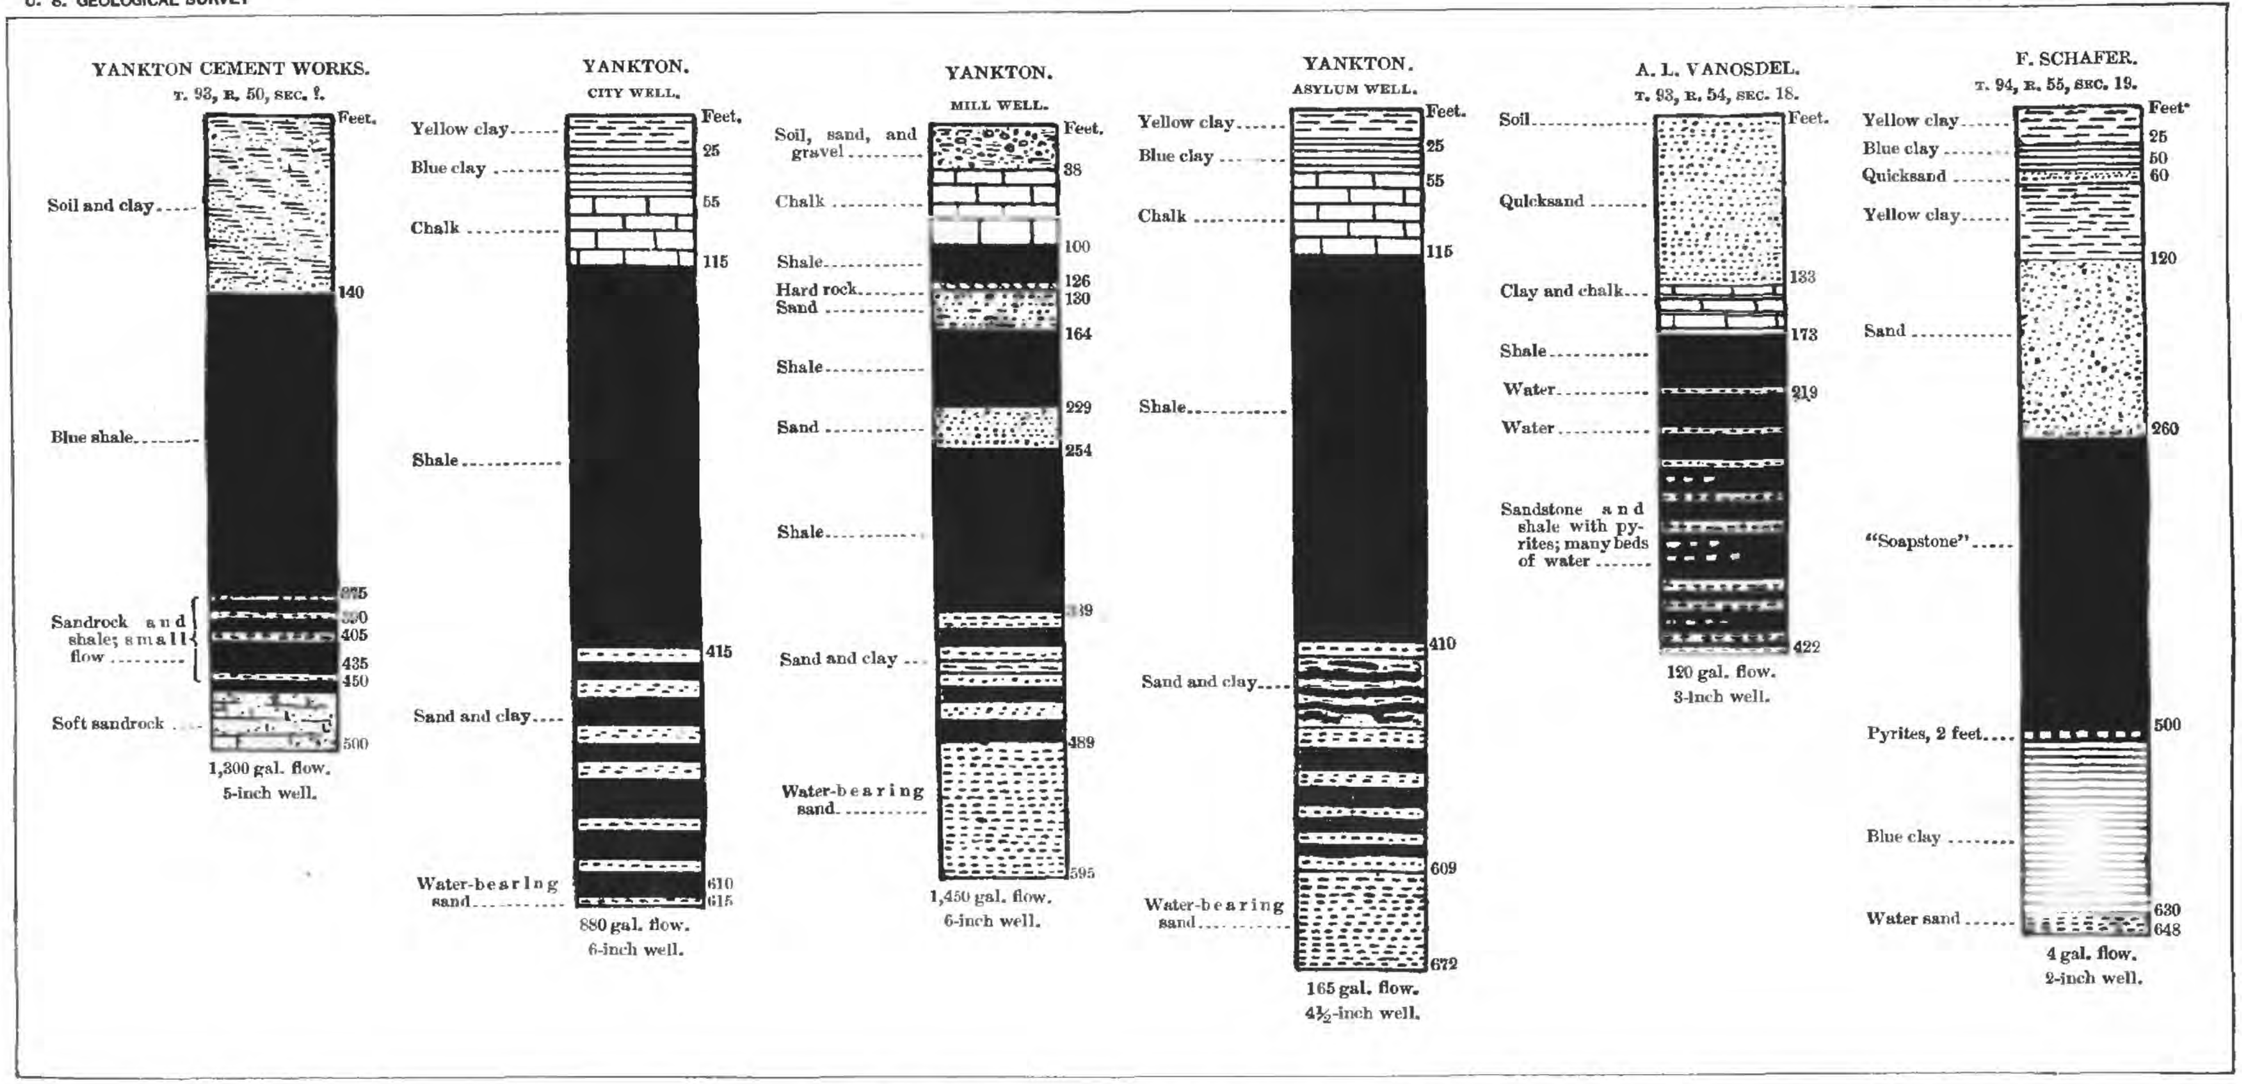
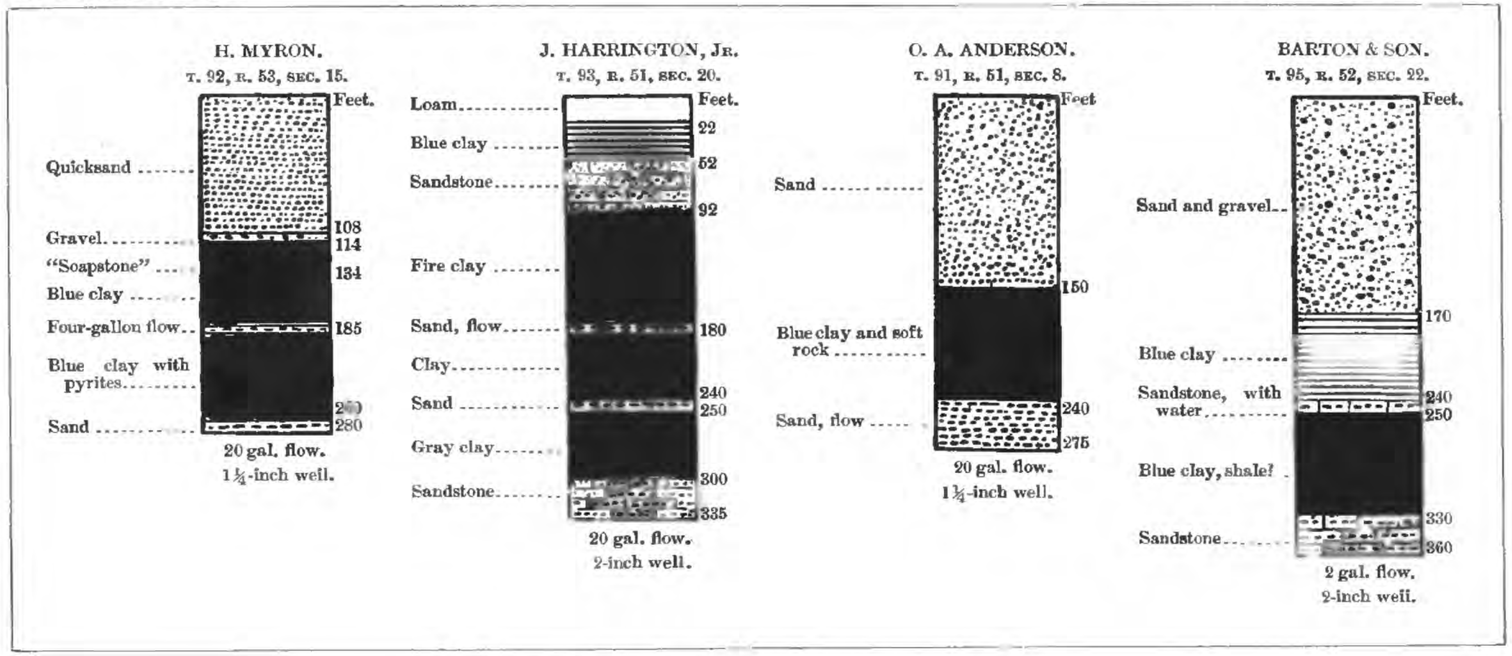
The wells opposite Chamberlain yield flows for irrigation. One is on the farm of G. S. Grant, in T. 104, R. 72, sec. 14. It has a depth of 563 feet and a diameter of 2 inches. The first flow was reported at 360 feet, a second flow at 460 feet, and a third at 560 feet. The other well is on the farm of E. A. Barlow, on the bench a mile back from the river, in the southern part of T. 104, R. 71. Its depth is 600 feet and its diameter 2 inches. Its flow is reported to be 2 gallons per minute, and increasing. A flow is reported at 450 feet, which is quite alkaline. Both of these wells draw from a water horizon which was found in the Chamberlain wells at about the same depth, or slightly lower.

The well at Fort Randall, in Todd County, was sunk by the Government for the use of the military reservation. Its depth was 610 feet, its diameter 4 inches, and its original flow 600 gallons per minute.



LOGS OF WELLS IN YANKTON COUNTY, SOUTH DAKOTA.



LOGS OF WELLS IN CLAY COUNTY, SOUTH DAKOTA.

surface by the widely extended sheets of drift clays. The general structure is shown in fig. 59.

Many artesian and other wells are sunk to the waters in the Red River Valley, and in the aggregate a large supply is obtained. No doubt some of the waters in this valley have a local source under the drift, but it is thought that much of the supply and nearly all of the pressure are derived from the edge of the Dakota sandstone. This formation has been recognized in some of the deeper wells, notably at Castleton, which lies well within the area underlain by the Dakota sandstone. The descent of the water-bearing bed from Castleton to Jamestown appears to be at a relatively uniform rate, as indicated by the wells at Staples and Tower City. The principal features are shown in fig. 59.

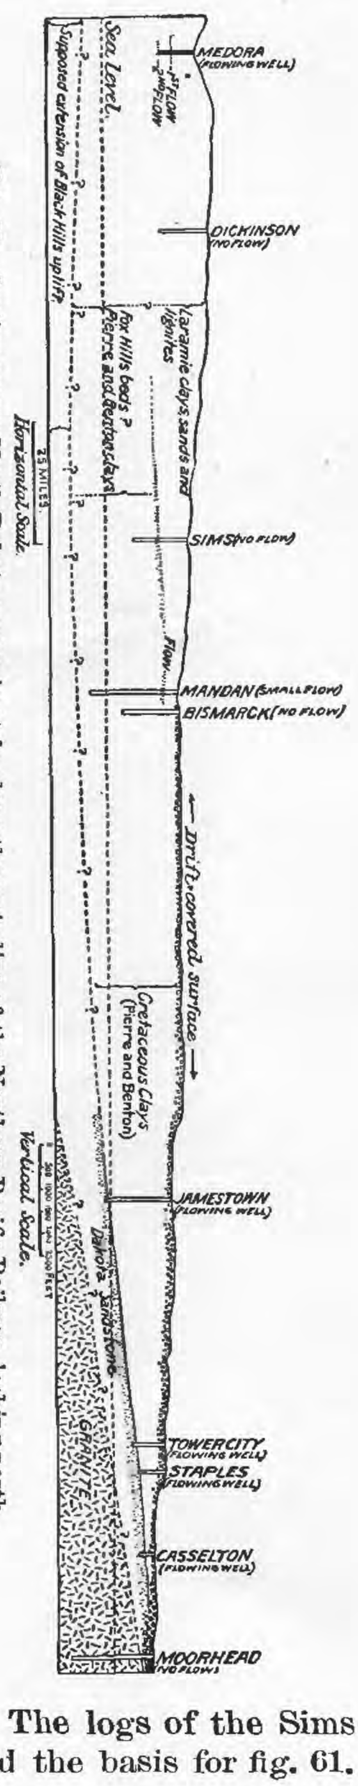


Fig. 59.—Section across North Dakota approximately along the main line of the Northern Pacific Railway, looking north.

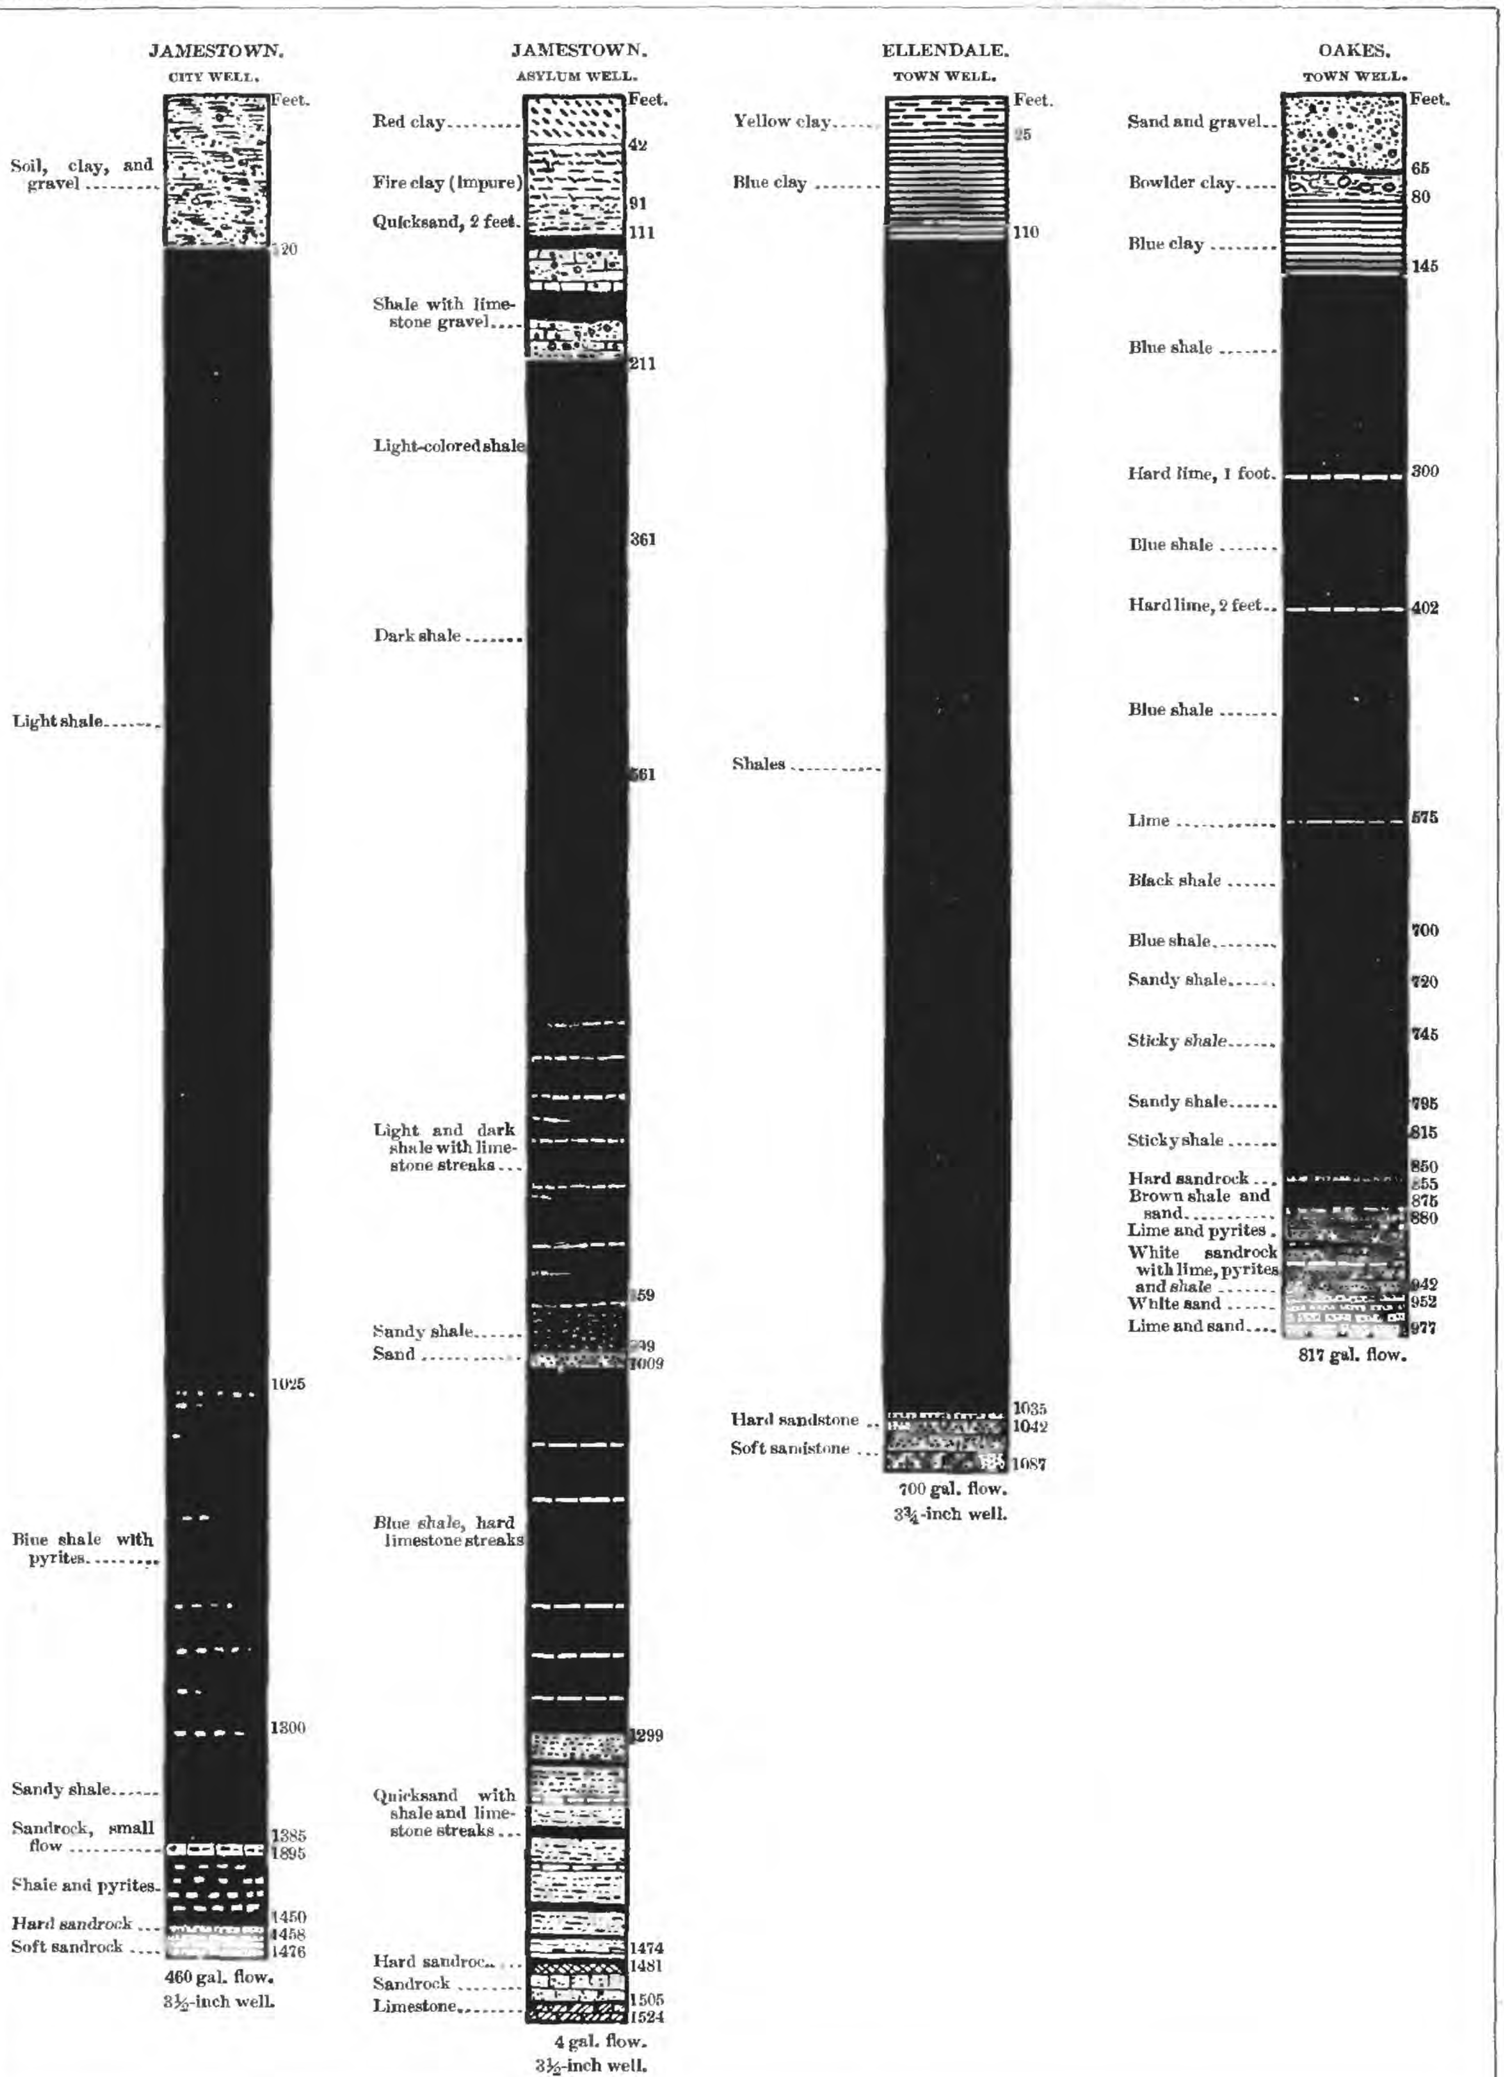
This section also sets forth all available information which we have regarding the general structural relations in the western portion of the State. Unfortunately, the 2,000-foot boring at Mandan was apparently not quite deep enough to reach the Dakota sandstone, so that the rate of descent of this formation west from Jamestown can be shown only approximately. It may be greater than I have suggested in this section, but probably not very much so. There is a fair degree of probability that there is a northward prolongation of the Black Hills uplift in the western portion of the State, which has at least some effect in North Dakota, as suggested in this section. The Medora, Dickinson, and Sims wells throw some light on the conditions in the higher formations in the western part of the State. The two flows in the Medora well are from sandstones in the Laramie formation; the borings at Dickinson and Sims are as yet unsuccessful. According to Mr. Barrett, the first flow at Medora rises 45 feet above the surface, and the second flow to over 100 feet. The water is soft, somewhat sulphurous, and is in good supply. Diagrams of the logs of the Medora and Dickinson wells were kindly supplied by Mr. McHenry, of the Northern Pacific Railroad Company, and they are reproduced in fig. 60. The logs of the Sims well, as given from memory by the driller, afford the basis for fig. 61.



LOGS OF WELLS IN JAMES RIVER VALLEY, NORTH DAKOTA.

this formation in the southeastern corner of the State and southward. I believe this suggestion fully accounts for the phenomena, which, so far as I can now see, are all accordant. It may be noticed in fig. 62 that the line of head above sea level passes beneath the Missouri River between Vermilion and Elk Point, in the vicinity of the outcrops of the top of the Dakota sandstone formation as it first rises to the surface. The declivity from Huron and Woonsocket toward Mitchell is also explained by the supposed approach of the Dakota sandstone near to the surface in the Mitchell region, where, no doubt, considerable leakage occurs. A depression of the line is also indicated by the Day well near Mellette, but this indication is probably due either to erroneous data, such as a leak in the well, or to some other defect which would record too low a pressure. The narrow area of low pressure north of Hitchcock is apparently directly related to a local cause—a ridge of granite, which will be considered later in this chapter. From Aberdeen to Jamestown the head above sea level, as shown in Pls. LXX and LXXI, drops to 1,544 feet at Frederick, rises to 1,727 feet at Ellendale, is 1,631 feet at the asylum near Jamestown, and 1,614 feet in Jamestown. As these calculations all include the variations of head due to the rise and fall of the water-bearing stratum, Pl. XCIX has been prepared to show the variations of pressure calculated at a plane of uniform altitude, so as to exclude the factor of the position of the water-bearing stratum. A plane 1,000 feet above sea level has been the one selected, and to the surface pressures have been added the calculated pressures from the surface to this plane. Of course only those wells have been indicated which are known or supposed to draw from Dakota sandstone horizons.

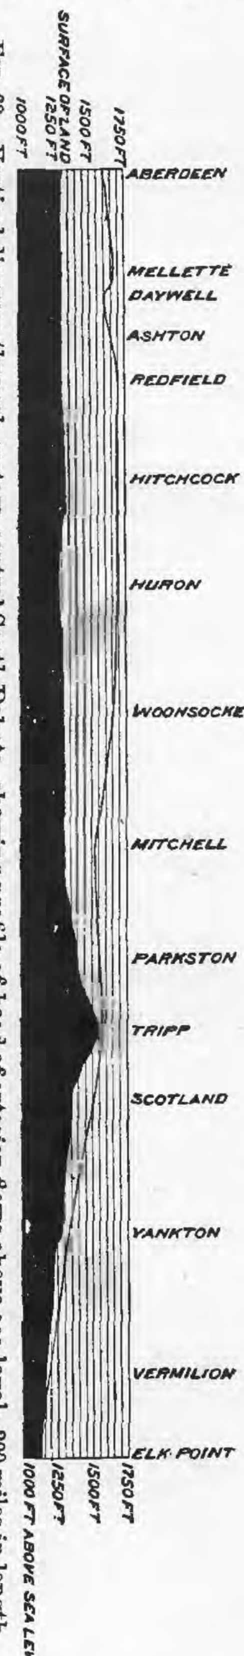

Fig. 62.—Vertical diagram through eastern-central South Dakota, showing profile of head of artesian flows above sea level; 200 miles in length.

In descending a well the pressure increases directly in proportion to the weight of a corresponding column of water, or 1 pound, approximately, for each 2.3 feet; so that, for instance, in a well 1,203 feet above sea level, with a surface pressure of 100 pounds per square inch, the total pressure at 1,000 feet above sea level is 200 pounds per square inch. This is of course independent of the position of the water-bearing bed, and gives the direct means of comparing the true rate of diminution of pressure due to leakage. Pl. XCIX shows the result of such calculation for all the wells of which we have suitable data, with the areal relations brought out by tints. The most prominent feature in this illustration is the regular decrease of pressure to the eastward. This is probably equally regular in all the region lying between the James River Valley and the eastern border of both South Dakota and North Dakota north of latitude 42° north, but data are lacking for this belt, except in the vicinity of the Northern Pacific Railroad. The amount indicated at Highmore may reasonably be expected to increase to the northwestward, but we shall have to await further developments of wells in that direction before this can be determined. No doubt the well now in progress on the Rosebud Reservation will throw light on the rate of increase to the southwestward, but unless this rate increases in rapid ratio west of the Missouri River the Rosebud boring will be found to be on land too elevated for a surface flow. Assuming that the elevation at this well is 2,700 feet, which is the best estimate now available, there will have to be a pressure of 740 pounds to the square inch at 1,000 feet above sea level in order to give a surface flow.

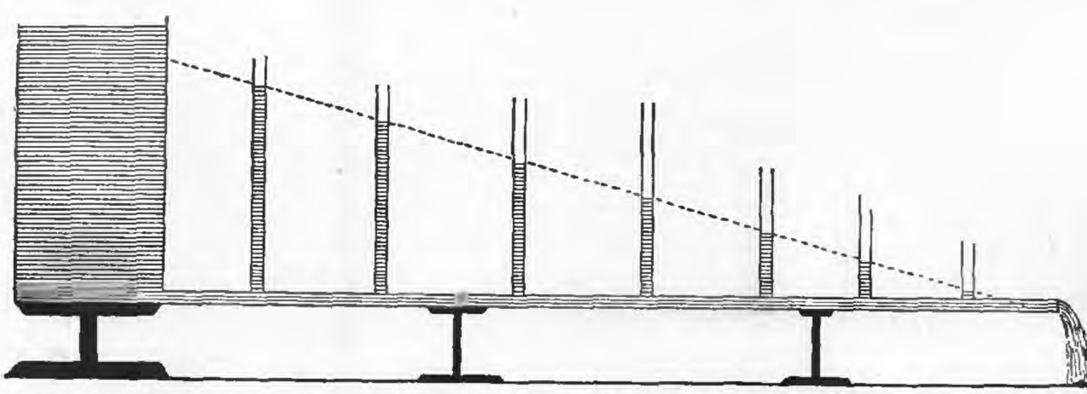

FIG. 63.—Diagram of apparatus for illustrating the declivity of head of liquids flowing from a reservoir.

As illustrating some known conditions under which pressures gradually diminish toward a leak, I have introduced in fig. 63 a diagram from Daniell's Text-book of the Principles of Physics, page 286.

This illustration appears to be closely parallel in its conditions to those which we find in the Dakota artesian basin, although, of course, the same regularity could not be expected under the more variable conditions that occur in nature as is found in a carefully constructed physical apparatus.

Returning to Pl. XCIX, it will be seen that there are a number of exceptional features for which no explanations are evident, but they have no important bearing on the general relation. The local decreases of altitude of head at Frederick, Aberdeen, and in the new power well at Chamberlain are the most anomalous of these, and they can not at present be explained. We should have expected a much higher actual pressure than 110 pounds (104 pounds at last reports) in this power well, for it is on land far lower than the Chamberlain city well, which was reported to have a considerably higher actual pressure.

GENERAL VIEW OF RESERVOIR AND WELL ON RICHARDS'S IRRIGATION FARM, NEAR HURON, SOUTH DAKOTA.

VIEW FROM BANK OF RESERVOIR ON RICHARDS'S FARM, NEAR HURON, SOUTH DAKOTA, SHOWING DITCH AND IRRIGATED FIELDS.

BEADLE COUNTY.

Irrigation with artesian water has been practiced in this county for several years past, but on only a few farms. The results have been eminently successful, and they have afforded encouragement to many persons in adjoining regions. The configuration of the region is very favorable for irrigation, and a large supply of water under great pressure throughout the county renders the conditions all that could be

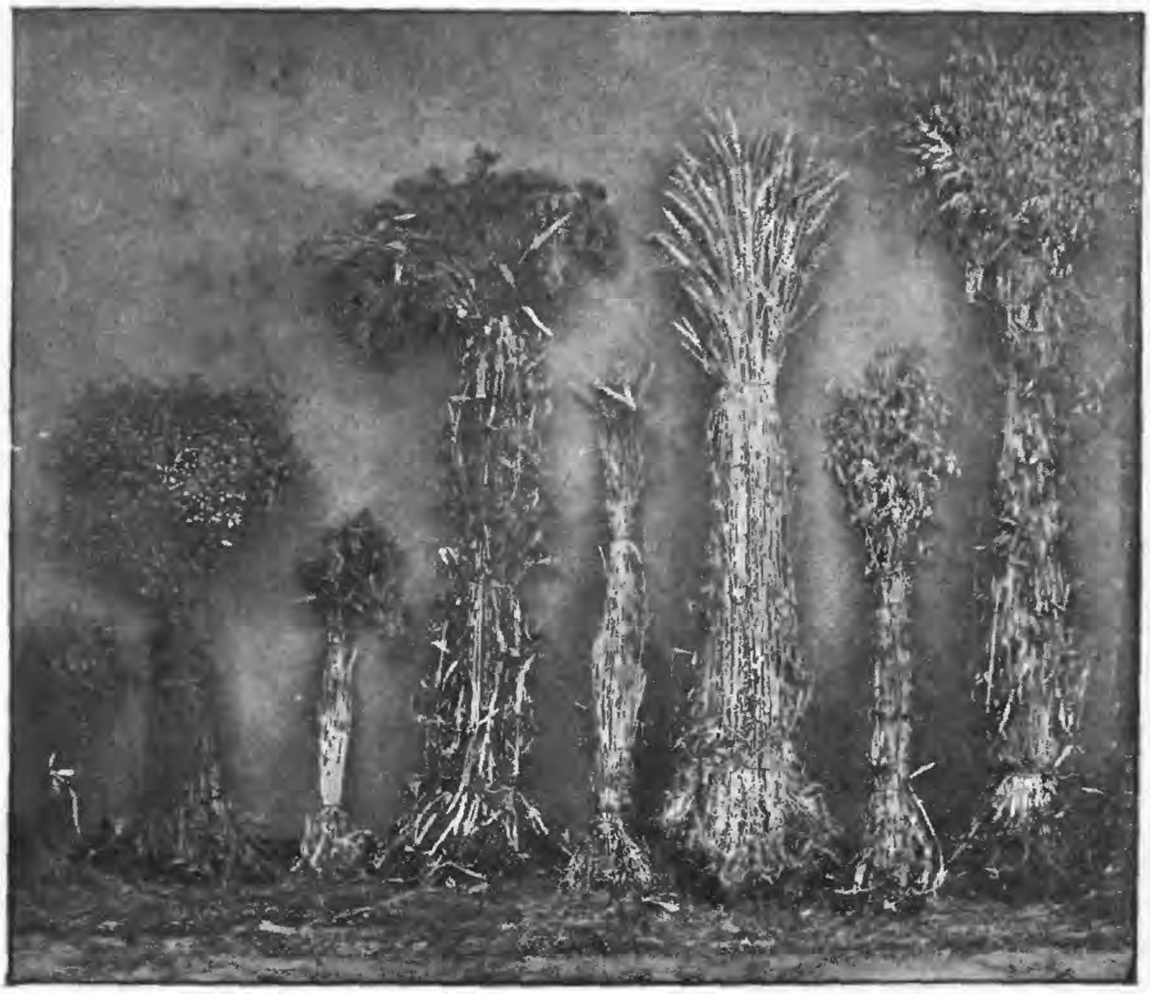

FIG. 64.—Results of irrigation on Richards's farm, near Huron, S. Dak. Shows samples of certain nonirrigated and irrigated crops. The larger bunch of each pair was irrigated. From a photograph kindly furnished by Mr. Richards.

desired. The principal operations have been in the vicinity of Huron, where there are several irrigation farms. Some results obtained are as follows: T. A. White, about 3 miles northwest of Huron, reports a very large production of irrigated crops. His beets averaged at the rate of 2,480 bushels per acre; corn, about 50 bushels; onions, 500 bushels; rutabagas, 846 bushels: sugar corn, 1,000 dozen; squashes, over 4,000; potatoes, 175 to 200 bushels; cabbage, 4,000 heads; and pumpkins, from 2,000 to 2,500. His land has been irrigated for the past three seasons. Several other crops also produced abundant returns, notably beans, melons, corn, pop corn, and a hedge of cottonwood trees.

VIEW ON RICHARDS'S IRRIGATION FARM, NEAR HURON, SOUTH DAKOTA.

have begun seeping up around the outer casing until they have finally made a sufficient space to emerge in large volumes, and after that the life of the well usually is soon terminated. There are other cases, too, in which the water would seep up along the outer side of the well casing and find its way, in whole or in part, into some higher horizon, so as to decrease or totally lose its head and volume. A relation of this character is shown in fig. 65.

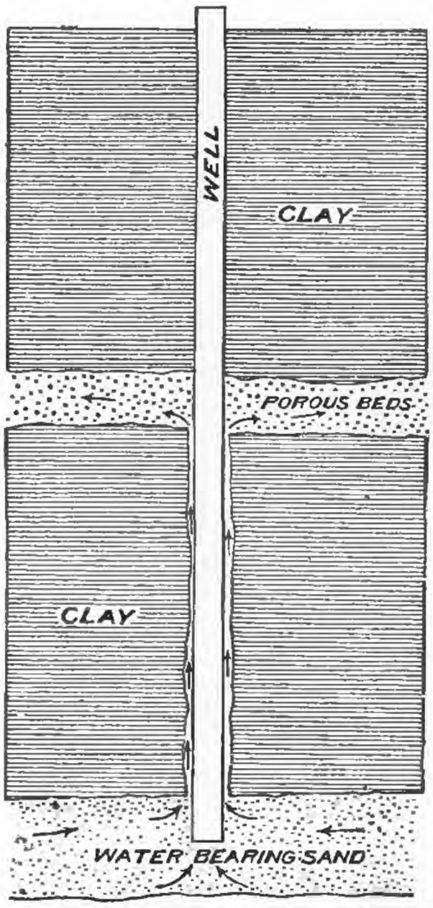

FIG. 65.—Diagram illustrating the escape of waters from a lower into a higher horizon along the outer side of the casing in an artesian well.

It is probably due to this cause in more wells than we suspect that the pressure is so much less than we should expect from the depth and experience of wells in the surrounding district. In many wells, some of which have failed and others of which now, owing to their favorable conditions, are working satisfactorily, the casing supplying the water reaches through the cap rock and has neither an extension into the water-bearing beds nor any anchorage excepting the thin layer of cap rock. This is a dangerous feature, and has caused the clogging or displacement in a number of wells. It is always much safer—and I should advise it in every case—to sink the inner pipe of the well completely through the water-bearing beds to some hard stratum lying next below them, and then sufficiently far into that stratum to hold the pipe rigidly. As it is necessary to have the portion of the pipe that is in the water-bearing beds perforated, to admit the water, it is further desirable to have this portion of the casing of extra heavy piping, to compensate and much more than compensate for the weakness caused by the perforations.

I must acknowledge that there is often great difficulty in managing the completion of the well after a great volume of water has been struck, but I believe that a skillful well borer can in every case properly insert the perforated pipe or strainer and anchor it firmly in bed rock below. The difficulties of working in water having a great pressure are very great, and frequently the well is damaging itself during the delay incidental to its final completion; but there are now so many expedients known to the skillful well borer that he surmounts most of these difficulties with relative ease.

It is very important in constructing and managing a well to prevent the discharge of any large volume of solid matter from the water-bearing beds, for this has been the cause of the clogging up of the greater

CHAPTER VIII.

ARTESIAN WELLS.

GENERAL STATEMENT.

Since the essential conditions for obtaining artesian wells have been discussed at some length by Prof. T. C. Chamberlin in a report of this Survey,[1] only a brief outline of these conditions is here attempted. That report now being out of print and perhaps not accessible to every-one interested in the subject, reference is also made to Johnson's Cyclopædia, which contains a brief discussion of artesian-well conditions by Mr. F. H. Newell.[2] A similar discussion, by Mr. Robert T. Hill, appears in a recent number of the Popular Science Monthly.[3]

The essential conditions for artesian wells are: (1) A suitable exposure of a porous rock in a humid region, i. e., a favorable absorbing area; (2) the extension of this porous bed from the absorbing area out underneath regions having a lower altitude, i. e., a favorable transmitting area; (3) a partial or full obstruction to the escape of the waters at

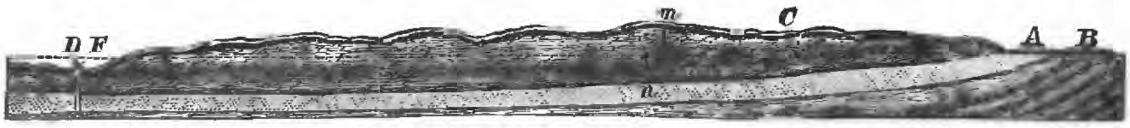

FIG. 66.—Section illustrating the aid afforded by a high water-surface between the fountain head and the well. (After T. C. Chamberlin; see Fifth Ann. Rept. U. S. Geol. Survey, fig. 15, p. 140.)

a lower level than the absorbing area. The porous rock is usually confined between beds which are less porous and which act as a partial or complete obstruction to the escape of the waters. It is not necessary, however, that these beds should be perfectly water-tight; indeed, such is rarely the case. It is only necessary that the confining beds should be such as to prevent most of the water from escaping.

In some cases the water contained in semiporous beds overlying the porous rock aids in preventing the escape of water from the porous bed at points between the absorbing area, or fountain head, and the well. This is illustrated in the section (fig. 66), and as it is a condition which prevails quite extensively in northern Illinois the subject is worthy of discussion in this place.

The absorbing area for the artesian waters of northern Illinois is in southern Wisconsin, the porous rock thence dipping southward to

JULIUS BIEN & CO. N.Y.

as known to the writer, there is no marked disturbance along the Mississippi north from that point.

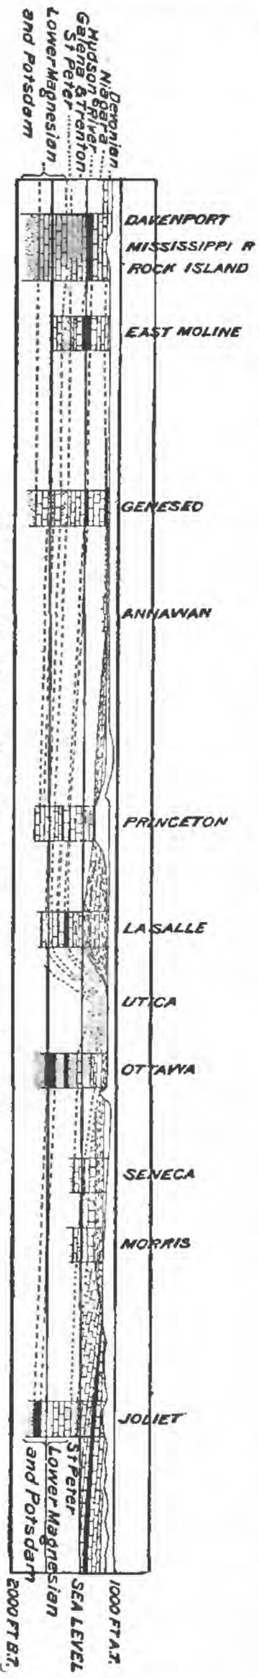

Fig. 69.—Section C-C, from Davenport, Iowa, to Joliet, Ill. This section shows the monoclinal fold which passes just east of Lasalle, with the nearly horizontal blocks on either side. Vertical scale is 20 times the horizontal.

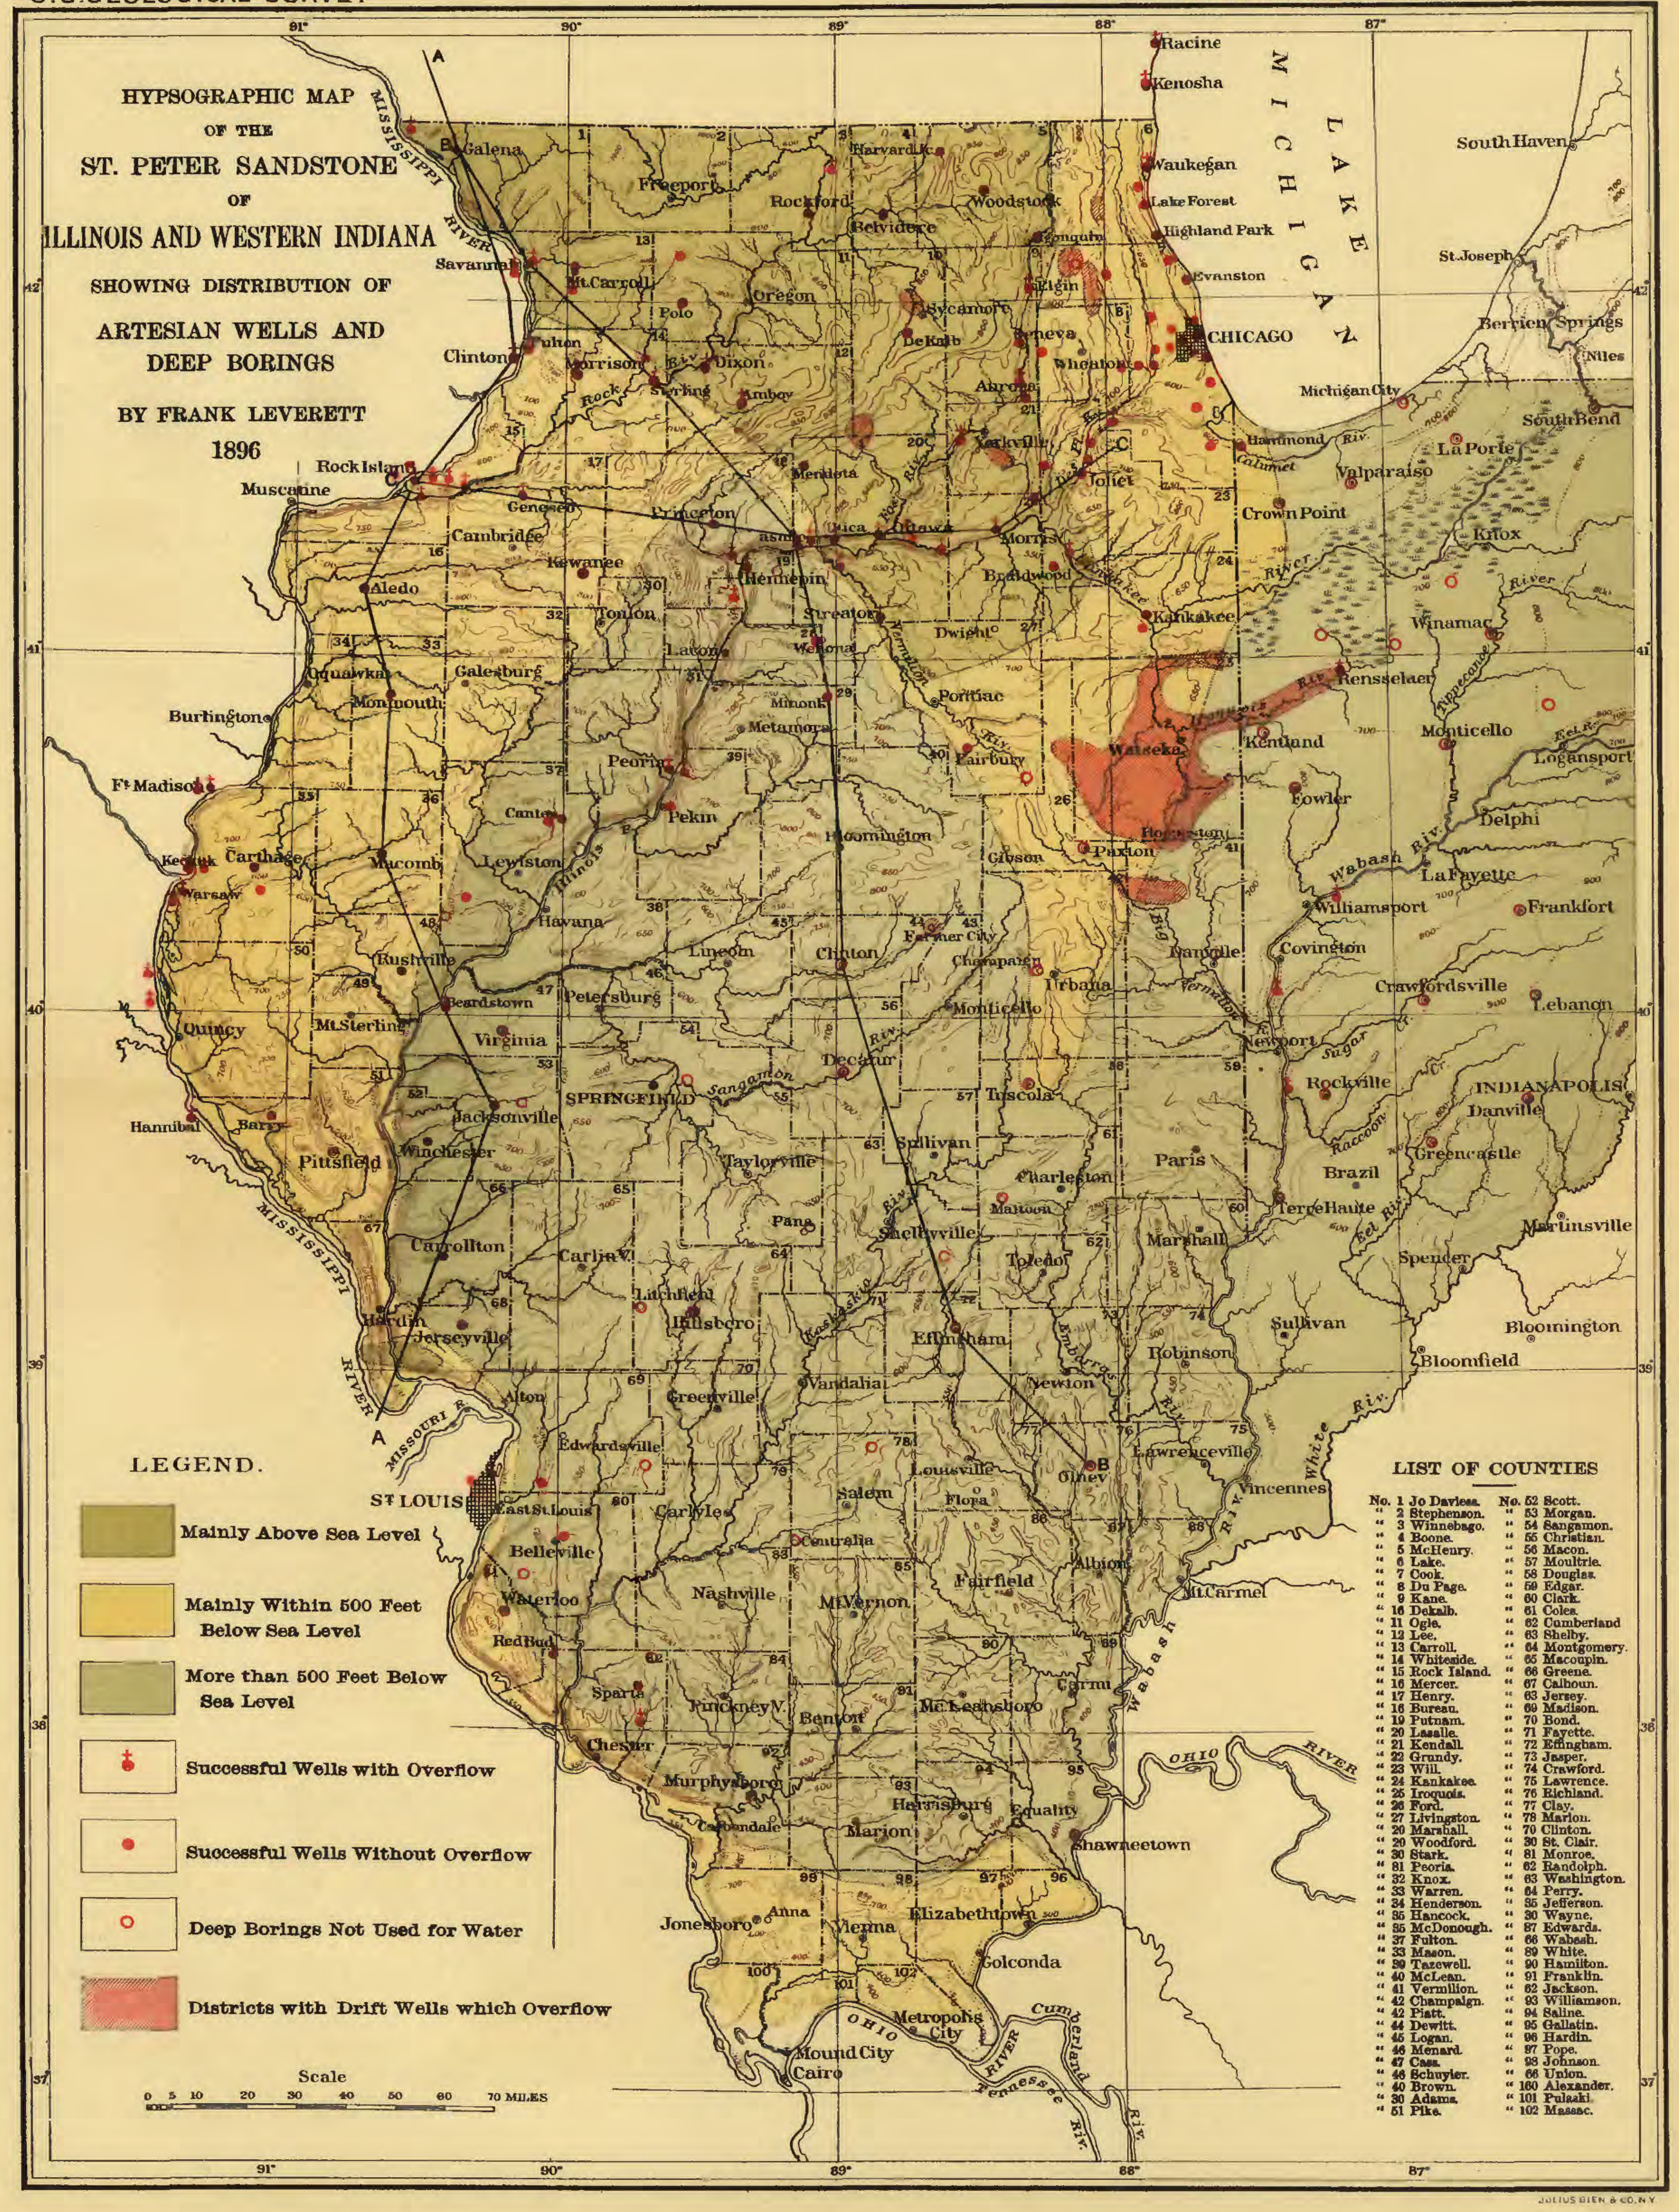
From the Cap au Grès disturbance southward to the Ozark ridge, in southern Illinois, a different field is entered. Disturbances are frequent along the Mississippi. There is also in this district a great descent in the floor of the Coal Measures within a few miles east of the Mississippi. Thus, in passing from the east bluff of the river in western St. Clair County eastward to Belleville a descent of 650 feet is made within a distance of 10 miles. In the vicinity of Murphysboro the Coal Measures floor ranges from 200 feet below sea level to 800 feet above within a distance of 10 miles. The deep portion of the Coal Measures basin seems, therefore, to approach the Mississippi closely from near the mouth of the Illinois southward, and, so far as can be learned from borings, extends eastward at least to the Indiana line. The lowest known points in the Coal Measures floor are in the southeastern part of the State—their level at Olney being about 800 feet and at Shawneetown 1,100 feet below sea level. A great depth is reached in southwestern Illinois, however, the floor at Coulterville, in Randolph County, only 25 miles from the Mississippi, being 325 feet below tide, and at Highland, about 25 miles from East St. Louis, the level is apparently 477 feet below tide.

ALTITUDE OF THE BASE OF THE COAL MEASURES.

In the following table an alphabetical list of the principal borings in the coal field of Illinois is presented which throws light upon the altitude of the floor of the Coal Measures basin. Where borings reach a definite horizon near the base of the Coal Measures, estimates have been made for the level of the floor, and are so indicated. When borings have apparently reached the lower coal, but not the rock floor, a minus sign is affixed to indicate that the base is still lower.



JULIUS BIEN & CO. N.Y.

been examined. Fortunately, Prof. J. A. Udden has had opportunity to carefully examine drillings from several of the wells in the vicinity of Rock Island, and his report upon this study is presented herewith. (See Chapter X.) This report, with the sections which accompany it, serves to indicate the character of the formations from the Devonian to the Potsdam in that part of Illinois.

From records in the writer's possession, together with those which have already appeared in print, sections have been made which set forth the structure along several lines traversing the State in various directions. One of these sections passes through Rock Island in a north-to-south course and indicates the changes in thickness and structure of the formations which occur in that direction (see fig. 67). Another leads eastward from near Rock Island to Joliet, showing the changes in dip, structure, and thickness in that direction (see fig. 69). A third section leads from Galena southeastward beneath the Coal Measures basin (see fig. 68). A section across southern Wisconsin from Prairie du Chien to Milwaukee, obtained from Professor Chamberlin's geological map of Wisconsin (see fig. 70), is also given.

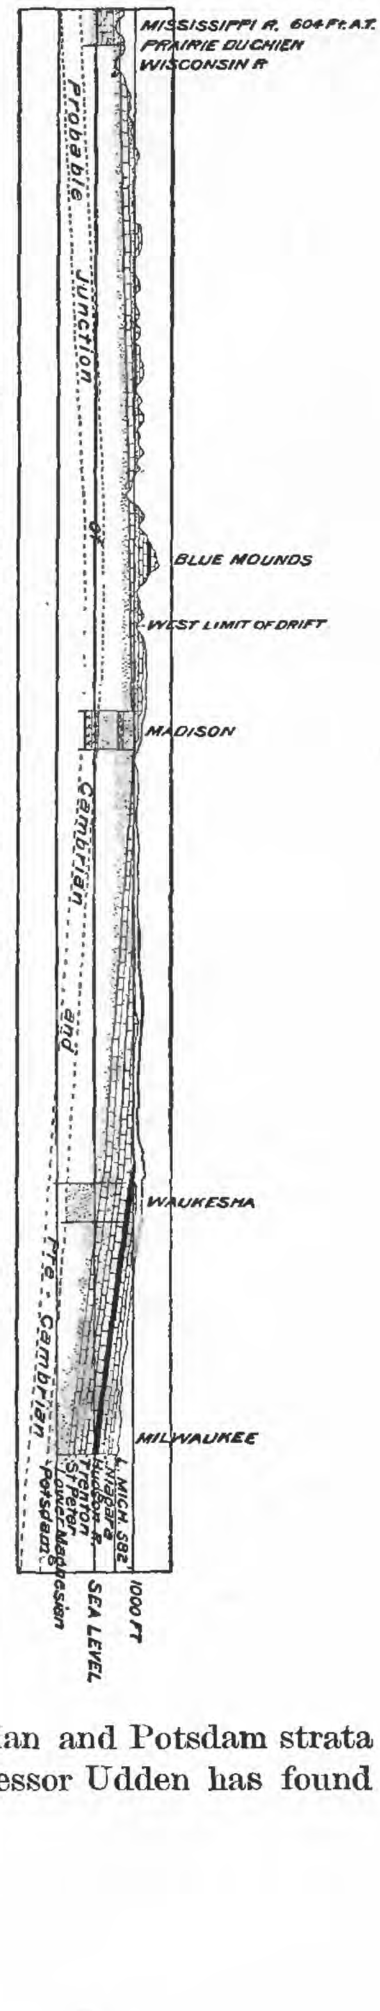


FIG. 70.—Section D-D, across southern Wisconsin from Prairie du Chien to Milwaukee. This section is reduced from Professor Chamberlin's section accompanying his geological map of Wisconsin, published by the Wisconsin Survey. The St. Peter and Potsdam are here separated by only a thin limestone formation. Vertical scale is 25 times the horizontal.

It will be observed that shale constitutes but a small part of the sections outside the Coal Measures area, the greater part of the section being limestone. The sandstones from which flowing wells are obtained apparently have found in the limestone cover as complete a check to the escape of water as would have been made by shale. The district to the west and north of the Coal Measures area is fully as productive in artesian flows as that within the limits of this formation.

The border line between the Lower Magnesian and Potsdam strata has not been satisfactorily determined. Professor Udden has found

CHAPTER X.

AN ACCOUNT OF THE PALEOZOIC ROCKS EXPLORED BY DEEP BORINGS AT ROCK ISLAND, ILL., AND VICINITY.

By J. A. Udden.

GENERAL STATEMENT.

Within a distance of 6 miles from the cities of Moline, Rock Island, and Davenport, 21 deep wells have been made, up to the present time (January, 1896), for the purpose of obtaining artesian water. The wells are scattered over an area extending 11 miles east and west and about 6 miles north and south. With the exception of the well in the

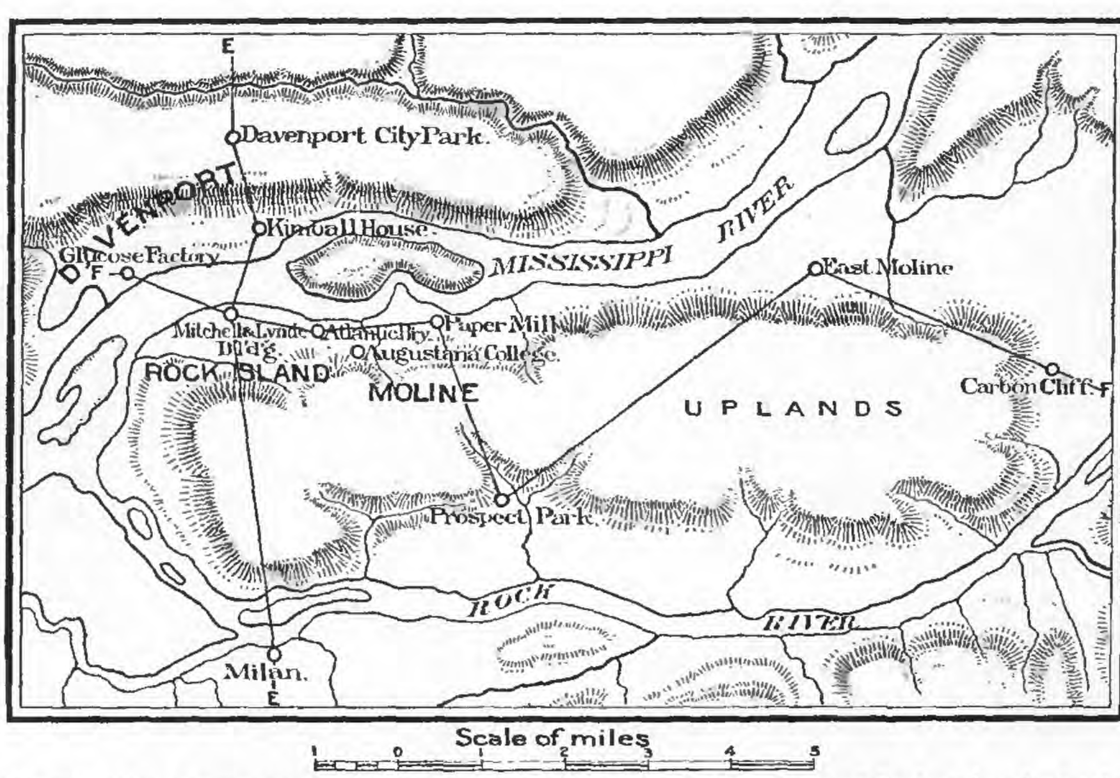

FIG. 71.—Map showing location of deep wells in Davenport, Moline, Rock Island, and suburbs, by J. A. Udden.

city park in Davenport, all are located on the bottom lands of the Mississippi and the Rock rivers, some of them just in the lower slope of the river bluffs. The well in the Davenport Park is the only one which has not furnished a flow of water.

Reports on the nature of the strata explored by these borings have been published in a few instances, but a comparative study of the obtainable data from this locality has not been made. At any rate, the results of such a study have not been placed on record.

The author has examined specimens of drillings from six wells, and

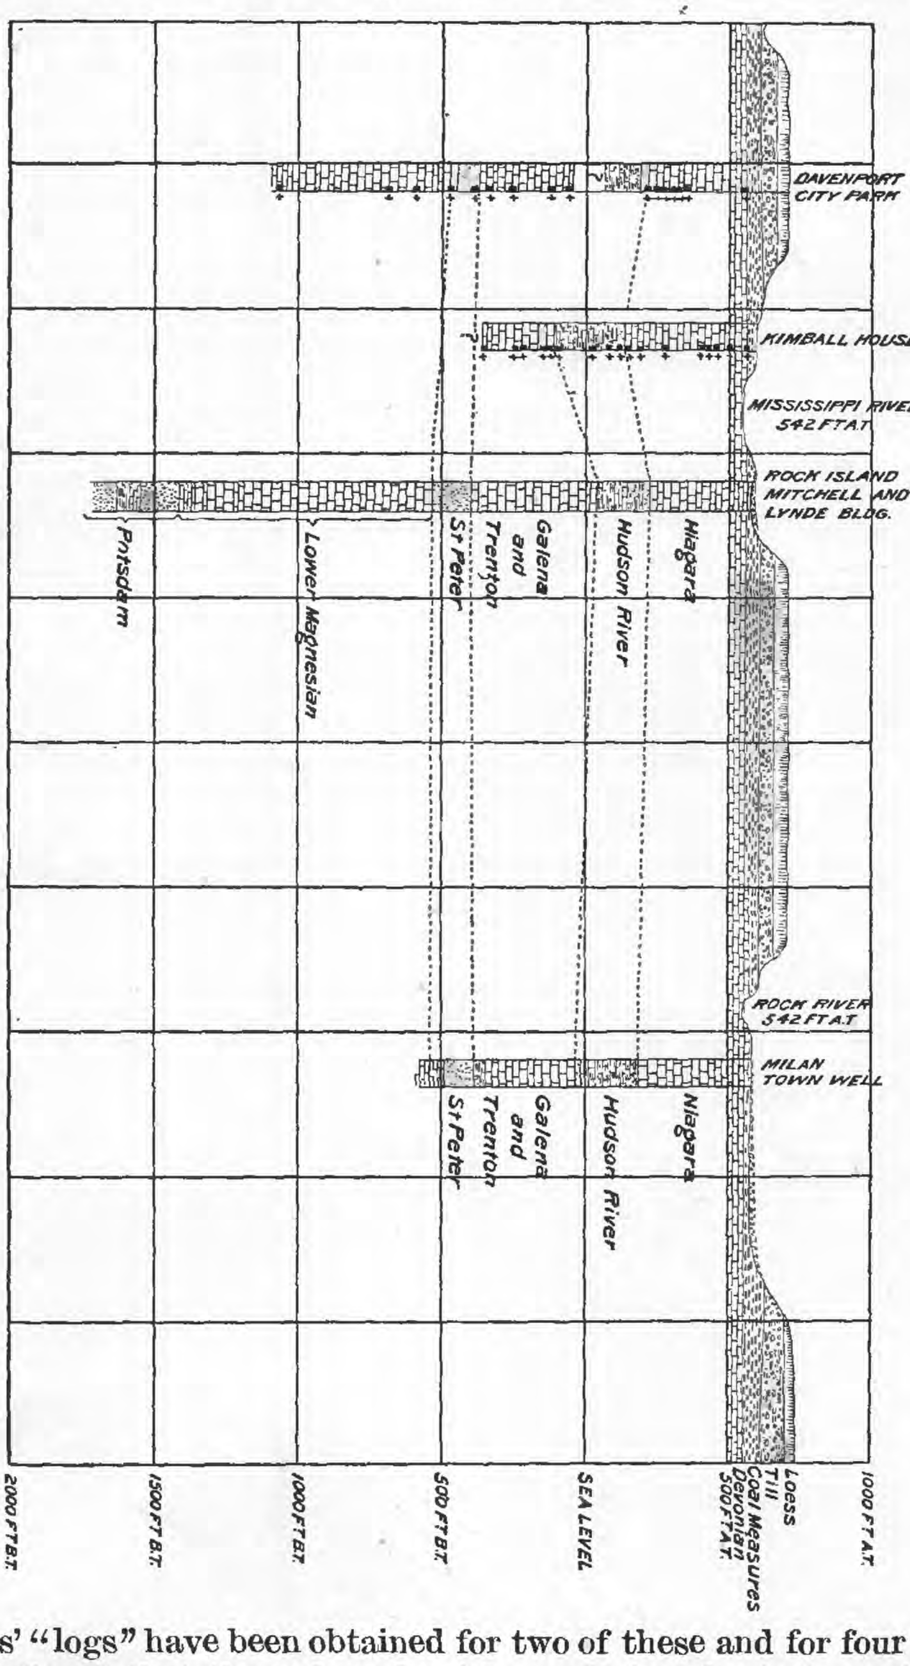

FIG. 72.—Geological section from Davenport, Iowa, to Milan, Ill.

drillers' "logs" have been obtained for two of these and for four others. It is believed that these data furnish a sufficient basis for estimating the thickness of the formations penetrated. They also throw considerable light on the lithological character of the rocks at different depths and on the geological structure of the area covered. (See figs. 72 and 73.)

The data which have been obtained may be found in condensed form at the close of this paper.

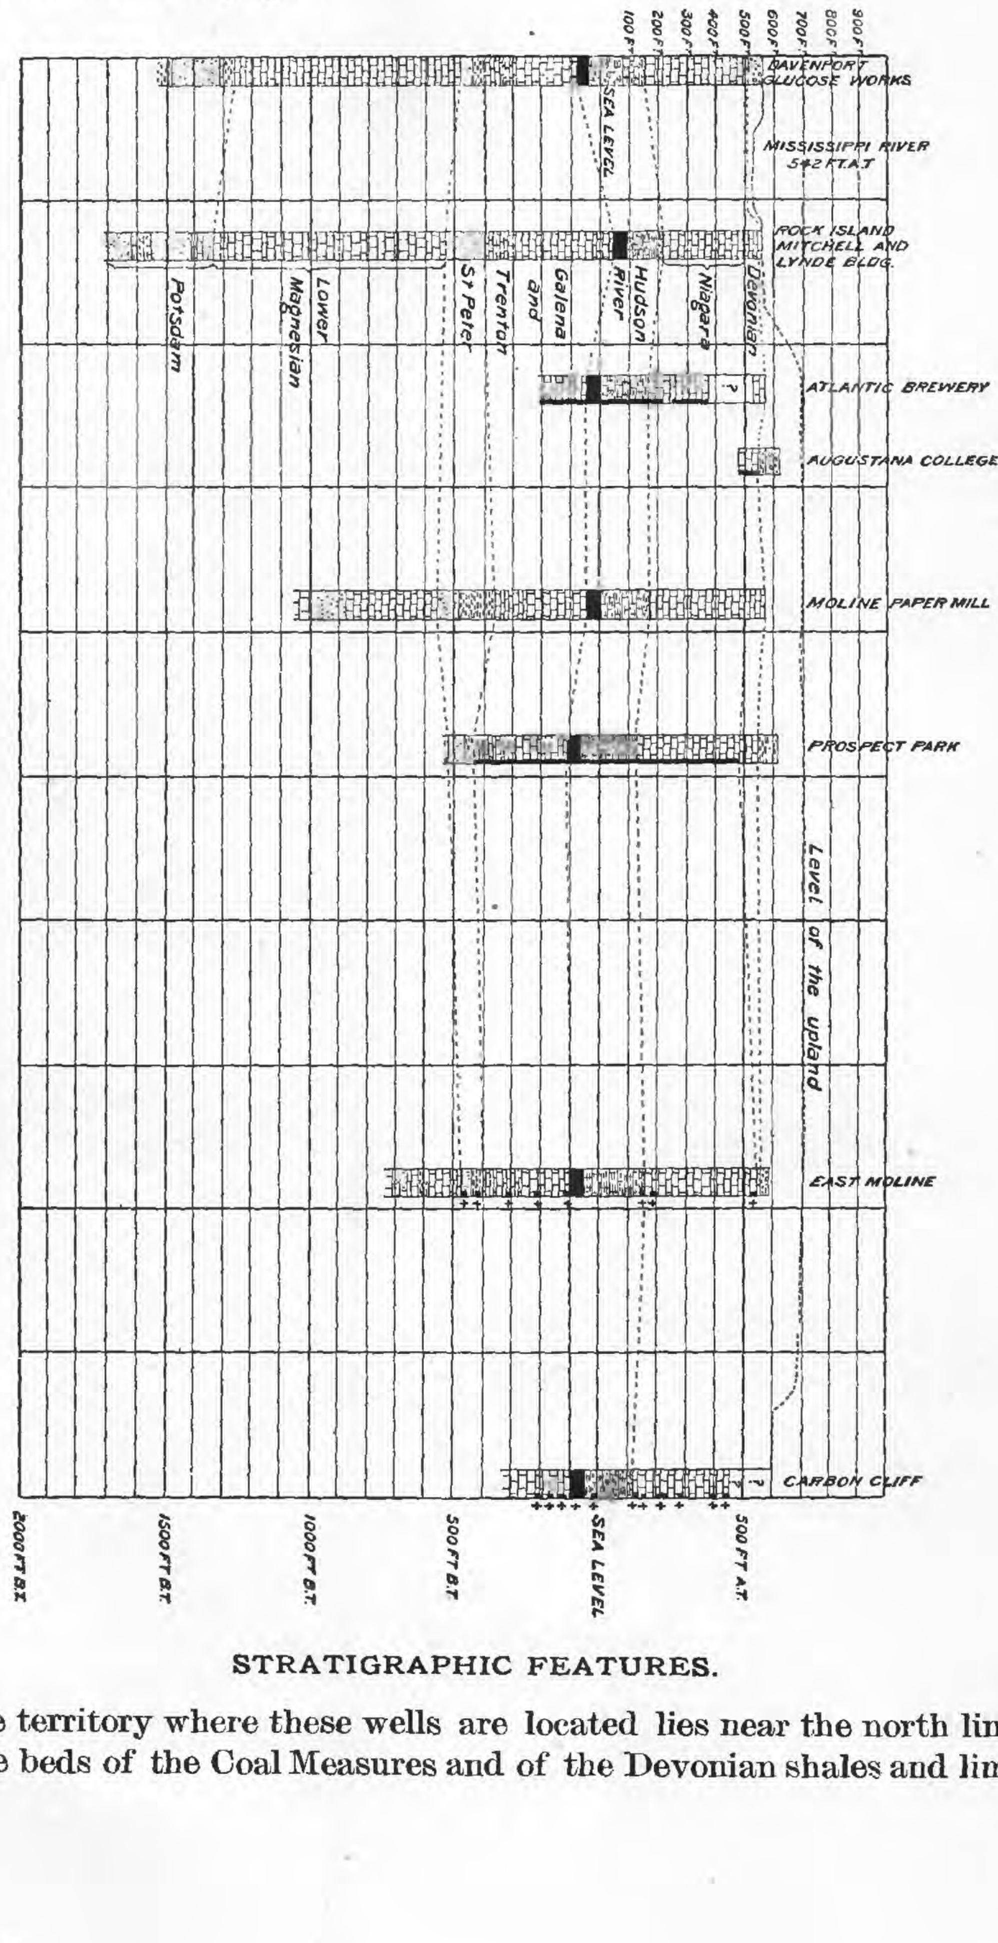

FIG. 73.—Geological section from Davenport, Iowa, to Carbon Cliff, Ill.

STRATIGRAPHIC FEATURES.

The territory where these wells are located lies near the north limit of the beds of the Coal Measures and of the Devonian shales and lime-

EXAMINATION OF WELL DRILLINGS.

DAVENPORT, IOWA; WELLS AT THE GLUCOSE FACTORY.

[Elevation of the curbs of the wells, 562 feet above tide.]

At the glucose factory in Davenport four wells have been drilled close together, no two wells being more than 250 feet apart. The logs

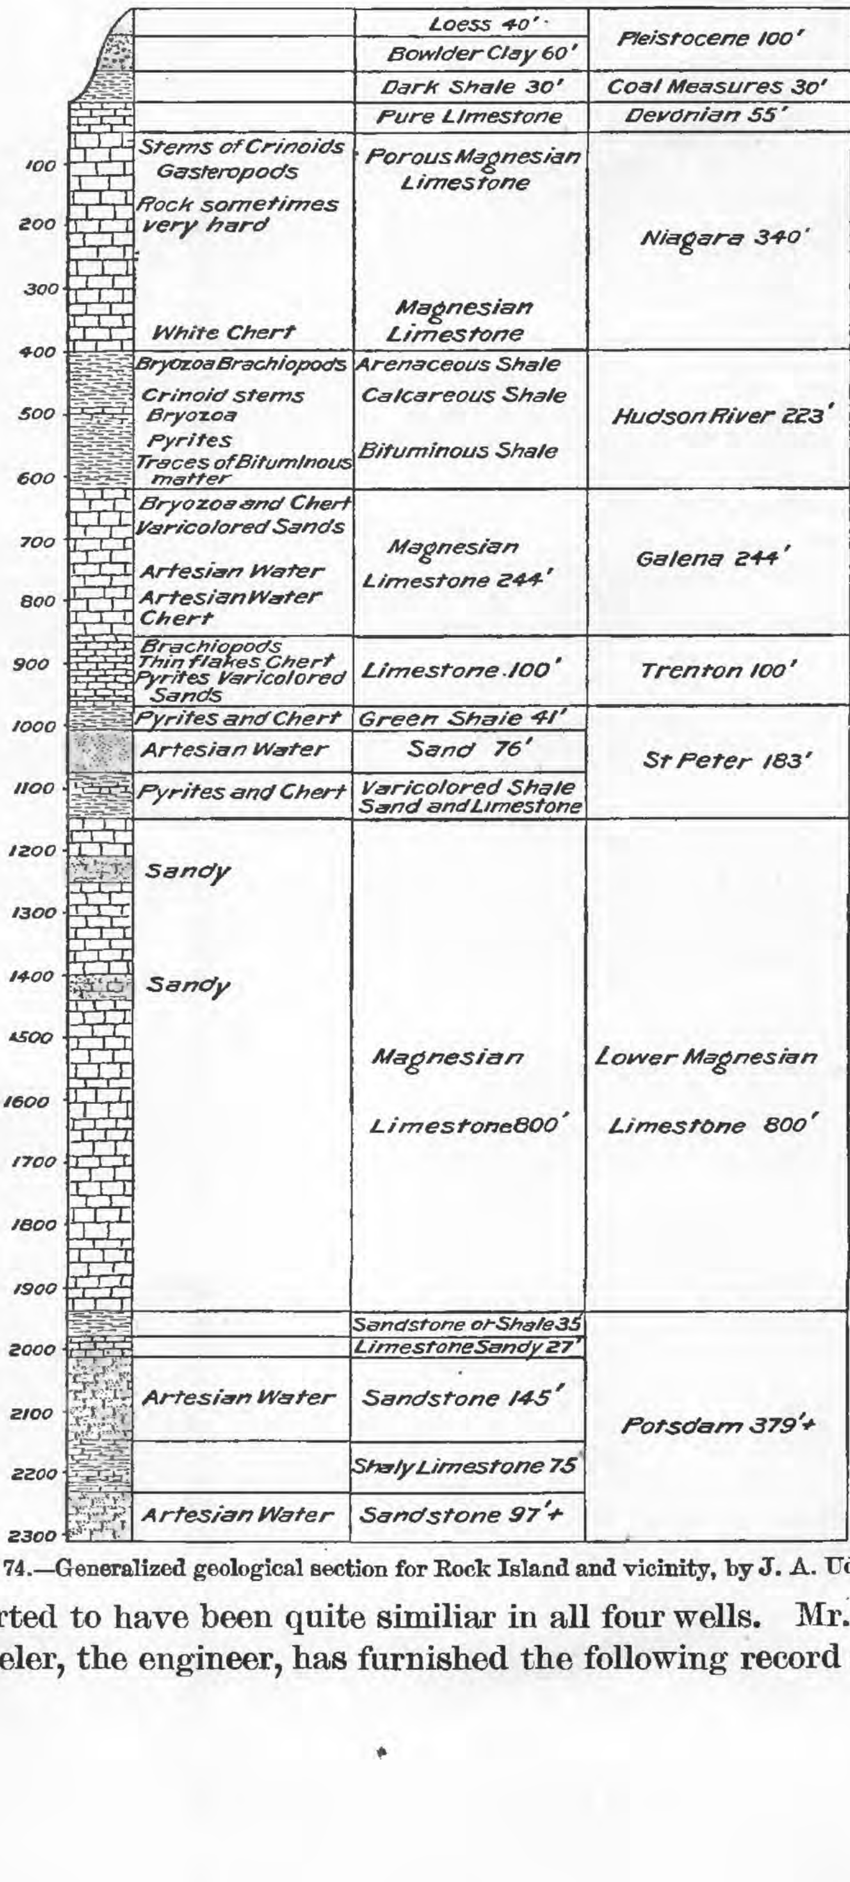

FIG. 74.—Generalized geological section for Rock Island and vicinity, by J. A. Udden.

are reported to have been quite similiar in all four wells. Mr. William Schoendeler, the engineer, has furnished the following record as repre-
