# Metal Uptake by Young Conifer Trees

By Harley D. King, Gary C. Curtin, and Hansford T. Shacklette

## Abstract

Nursery-grown seedlings of lodgepole pine, engelmann spruce, and douglas-fir were planted in clay pots in soil obtained from a coniferous forest, to which we added unweathered minerals representing four types of ore deposits. The four types of ore deposits and added minerals were: (1) Carlin-Cortez—arsenopyrite, cervantite, scheelite, metallic gold, and tetrahedrite; (2) high temperature—molybdenite, bismuthite, cassiterite, and scheelite; (3) low to moderate temperature—argentite, tetrahedrite, cerussite, anglesite, azurite, hydrozincite, metallic gold, and metallic mercury; and (4) gold deposits—metallic gold. Pots of seedlings in four experimental groups (each representative of one of the four types of ore deposits and minerals) and one control group were buried to the tops of the pot rims in a ponderosa pine and douglas-fir forest at 2,134 m (7,000 ft) elevation in the Central Rocky Mountains of Colorado. The trees grew here for 7 years with no artificial watering or fertilizing. At the end of this period, the trees were removed from the pots and divided into leaf, stem, and root fractions, which were each analyzed for their element content.

All trees survived the experiment and grew at a normal rate with no indications of metal toxicity. Analyses showed an increase of most added metals in the leaves, stems, and roots of trees of each experimental group.

These experiments demonstrated that the elements in unweathered minerals that were added to natural soils became soluble by natural processes and were taken up by tree roots, and then translocated to stems and leaves in a period of 7 years under normal environmental conditions of the Central Rocky Mountain region.

## INTRODUCTION

The biogeochemical method of prospecting for mineral deposits depends on the ability of plants to take up elements in amounts that reflect their concentrations in supporting substrates, which in turn have been influenced by nearby mineral deposits. An element, to be taken up by plant roots, must occur in the substrate in a form that

is available, and this form is extremely variable (Brooks, 1972, p. 95). Only a small amount of the total element content of soil is in a form that is soluble and that can be absorbed by roots and translocated throughout the plant. The chemical stability of the ore minerals in the soil zone of weathering varies greatly and ranges, for example, from very stable gold, to barite and cassiterite, which are stable, to the fairly stable minerals scheelite and wolframite, to the unstable minerals arsenopyrite and molybdenite (Andrews-Jones, 1968).

The nature of the biosphere strongly affects mineral weathering because many organisms, particularly bacteria and filamentous fungi, increase the solubility of minerals (Pauli, 1968). The higher order plants produce carbon dioxide and organic acids that are secreted at the soil/root interface, and these compounds may attack the minerals. Some plants also excrete hydrocyanic acid, which, in the root zone, has been shown to solubilize metallic gold (Shacklette and others, 1970). Mycorrhiza, a symbiotic association of filamentous fungi and plant roots, is suspected of producing hydrocyanic acid (Shacklette, 1974, p. 41), and this association is particularly common on roots of coniferous trees. Certain millipedes and larvae of moths that inhabit soil are known to produce hydrocyanic acid (Lakin and others, 1974). Baker (1978) reported that humic acid can dissolve, complex, and transport gold.

In experiments cited by Harley and Smith (1983, p. 225), three shrub species were grown in sand culture; one group of three species was inoculated with mycorrhizal fungi, another group of three species was not. Plants in the group that was not inoculated, therefore, had no mycorrhiza on their roots, did not grow well, and many died after various concentrations of zinc sulfate and copper sulfate in solution were added to the sand. The inoculated plants, which developed mycorrhiza on their roots, grew well in the same concentrations of the two metallic compounds previously mentioned. The stems and leaves of the plants without mycorrhiza contained higher concentrations of zinc and copper than did those of the plants with mycorrhiza because the two metals in the latter were

held in the mycorrhizal growth on the roots, and therefore could not pass up the stems and into the leaves. Read (1983) suggested that heavy metals become bound to the carboxyl groups in the pectic interfacial matrix between fungus and host roots, and therefore do not pass into the root cells. The ability of plants with root mycorrhiza to colonize mine spoil heaps and other areas contaminated with heavy metals, and their ability to grow better in various habitats with high concentrations of potentially toxic ions than do plants without mycorrhiza have been reported by many investigators (Harley and Smith, 1983).

The physical factors active in the weathering process are well known and include the action of water as a solvent and in the freeze/thaw cycle, the ion exchange properties of clay minerals, and other factors.

The experiments reported herein were designed to provide some measure of the effects of weathering on ore minerals and their uptake by trees under natural conditions in the Central Rocky Mountain region. The minerals selected commonly occur in four different types of ore deposits. For measuring the uptake of metals in these minerals, we chose young coniferous trees that were native to this region which, by analysis of their tissues, might indicate a time frame for mobility of metals in minerals that were added to the soil of the trees. Measurements are in metric system; both meters and feet are given for altitudes shown in feet on a topographic map; measurements cited from other sources are given in their system of units. A conversion table follows the table of contents.

We thank chemists E. F. Cooley for analyzing the samples by emission spectroscopy, and T. F. Harms for determining the mercury concentrations. Special gratitude

is extended to R. E. Van Loenen, who provided a plot for growing the trees on his mountain property and protected the plot from disturbances during the 7 years of the study.

## ORGANIZATION OF THE EXPERIMENTS

The experiments were organized to test the response of conifer species to the addition to the soil of certain metals in their mineral compound or elemental form. The trees were grown in an environment that closely resembles the natural conditions of tree growth on forested land in the Central Rocky Mountain region, except for the confinement of the tree roots in pots and the abnormal concentration of metals in soils of the experimental groups of trees.

### Trees Used, and Experimental Treatments

Twenty seedling trees each of lodgepole pine (*Pinus contorta* Dougl. var. *latifolia* Engelm.), engelmann spruce (*Picea engelmannii* (Parry) Engelm.), and douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) were obtained from the Colorado State Nursery in January 1972. These trees were rooted in soil enclosed in cardboard tubes. One seedling of each species was divided into leaf (needle), stem, and root sections, which were saved for analysis at the conclusion of the study. Four seedlings of each species were assigned to each of four experimental groups (I, II, III, and IV), and three seedlings of each species formed the control group (V). We removed the cardboard tubes from the seedlings and planted each tree in a clay pot 8 in. in diameter at the top, using the soil mixtures described herein. Each pot had a drainage hole in the bottom. The soil was then saturated with tap water; we did not water the trees again during the 7 years of the experiment.

We planted the trees in a plot in the edge of a douglas-fir and ponderosa pine forest at about 2,134 m (7,000 ft) altitude in the upper drainage basin of Turkey Creek, Jefferson County, Colo. The plot was in a slight drainage depression that was filled with snow to a depth of about 80 cm when the pots were taken to the site on January 18, 1972. The snow was removed, holes were dug for the pots in the partly frozen soil, and the pots were placed in the holes so that their tops were about even with the soil surface (fig. 1). The snow was shoveled back onto the plot, and an exclusion wire fence was erected around the plot. The arrangement of the experimental groups within the plot is shown in figure 2. The trees received no further attention during the 7 years of the experiment, except annual inspections during spring

or summer to remove fallen tree limbs and other debris from the plot, and to stake some trees that had been bent down by snow.

At the conclusion of the experiment in September 1978, the pots were lifted from the plot and brought back to the laboratory in Denver, Colo., where the trees were removed from the pots, the soil carefully removed from the tree roots, and each tree separated into leaves, stems, and roots. All trees survived the experiment, and the roots of most trees were confined to the soil within the pots.

## Soils and Minerals Used, and Preparation of Potting Mixtures

The soil used in the experiment was obtained from a coniferous forest on Squaw Pass, in the Colorado Front Range, about 40 km west of Denver, Colo., at an elevation of 2,984 m (9,790 ft). Soil at the collection site is developing from colluvium composed primarily of weathered biotite gneiss, and is classified as an inceptisol (Soil Survey Staff, 1975) because it is poorly developed and lacks a well-defined illuvial, clay-rich horizon. The soil was sieved with a stainless-steel screen having 6-mm average diameter openings, and the minus-6-mm fraction was used in the experiment. Fifty-seven splits of the soil, each weighing 3,000 g, were used for potting the seedlings. Another split of the soil was saved for analysis.

The ore minerals used in the experiment were commercially obtained, and, with the exception of gold and mercury, were in the form in which they occurred naturally. Information on the exact composition of the miner-

als (other than for gold and mercury) was not obtained. Some of the minerals may contain various elemental impurities or admixtures, or may vary in composition as discussed in standard mineralogy texts. For example, in tetrahedrite,  $(\text{Cu,Fe,Zn,Ag})_{12}\text{Sb}_4\text{S}_{13}$ , copper is always predominant; however, considerable substitution takes place that results in variable concentrations of iron, zinc, silver, lead, and mercury. The antimony in tetrahedrite may be replaced by arsenic in various proportions.

Some of the minerals were obtained as crystals, whereas others were in a granular or powdery form. Crystals were crushed in a chipmunk jaw crusher and sieved to minus 0.2 mm. The amounts added to each pot are shown in table 1. The minerals for each group were combined and mixed well.

**Table 1.** The mineral groups and amounts of minerals added to each pot

Experimental group	Amount per pot (in grams)
Group I. Minerals representing Carlin-Cortez-type deposits	
Arsenopyrite, $\text{FeAsS}$ -----	26.2
Cervantite, $\text{Sb}_2\text{O}_4$ -----	21.4
Scheelite, $\text{CaWO}_4$ -----	7.0
Tetrahedrite, $(\text{Cu,Fe,Zn,Ag})_{12}\text{Sb}_4\text{S}_{13}$	20.3
Gold, Au, metallic-----	.03
Total-----	74.93
Group II. Minerals representing high-temperature deposits	
Molybdenite, $\text{MoS}_2$ -----	18.1
Bismuthite, $(\text{BiO})_2\text{CO}_3$ -----	27.5
Cassiterite, $\text{SnO}_2$ -----	22.3
Scheelite, $\text{CaWO}_4$ -----	7.1
Total-----	75.0
Group III. Minerals representing low- to moderate-temperature deposits	
Argentite, $\text{Ag}_2\text{S}$ -----	12.8
Tetrahedrite, $(\text{Cu,Fe,Zn,Ag})_{12}\text{Sb}_4\text{S}_{13}$	15.6
Cerussite, $\text{PbCO}_3$ -----	18.3
Anglesite, $\text{PbSO}_4$ -----	18.3
Azurite, $\text{Cu}_3(\text{CO}_3)_2 \cdot (\text{OH})_2$ -----	18.2
Hydrozincite, $\text{Zn}_5(\text{OH})_6(\text{CO}_3)_2$ -----	6.7
Gold, Au, metallic-----	.03
Mercury, Hg, metallic-----	.09
Total-----	90.02
Group IV. Gold deposits	
Gold, Au, metallic-----	0.03

**Figure 2.** Arrangement of the groups of trees in the plot. The control group, V, of nine trees is in the background. The four experimental groups are (left to right and front to rear) III, IV, I, and II. Within each of the four groups, the rows are (left to right) lodgepole pine, engelmann spruce, and douglas-fir. Photographed at the conclusion of the experiment. The pots, whose tops are 8 in. in diameter, indicate scale.

The gold was obtained as sheets 0.0007 in. thick, 30 mm by 75 mm, and weighing 0.75 g. The sheets were cut into small squares about 1 to 2 mm on a side, and the amount added to each pot was approximately 0.03 g. The surface area of sheet gold added to the pots was approximately 2 cm<sup>2</sup>.

Mixtures of the ore minerals and soils were prepared individually for each pot by combining the splits of ore minerals with 3,000 g of soil and mixing well in polyethylene buckets. These mixtures were used as the soil medium in planting the seedlings of the experimental groups. Soil with no added minerals was used in the nine control seedling pots.

Minerals that contain antimony, arsenic, gold, and tungsten were used for Group I because these elements are found in anomalous amounts in Carlin-Cortez disseminated gold deposits, Nevada (Erickson and others, 1964; Erickson and others, 1966; Wells and others 1969). Minerals containing these elements at Carlin are arsenopyrite, realgar, orpiment, stibnite, scheelite, and gold (Radtke and others, 1972; Harris and Radtke, 1976). Warren and Hajek (1973, p. 124) summarized this type of deposit as follows: "A Carlin-Cortez type of gold deposit may be considered as an epithermal type of mineralization where vein development is relatively unimportant and finely disseminated gold occurs in replacement bodies predominantly in sedimentary rocks containing significant amounts of calcium and accompanied with anomalous amounts of barium, strontium, arsenic, antimony, mercury and copper." The minerals used for Group I include arsenopyrite (FeAsS) for arsenic; cervantite (Sb<sub>2</sub>O<sub>4</sub>), a secondary mineral formed by the oxidation of stibnite, and tetrahedrite ((Cu,Fe,Zn,Ag)<sub>12</sub>Sb<sub>4</sub>S<sub>13</sub>) for antimony; scheelite (CaWO<sub>4</sub>) for tungsten; and metallic gold for gold.

Minerals used for Group II are found in high-temperature deposits and include molybdenite (MoS<sub>2</sub>); bismuthite ((BiO)<sub>2</sub>CO<sub>3</sub>)—a secondary mineral formed by the alteration of bismuthinite, native bismuth, and other primary bismuth minerals; cassiterite (SnO<sub>2</sub>); and scheelite (CaWO<sub>4</sub>). Elements of interest in this group are bismuth, molybdenum, tin, and tungsten. Minerals used for Group III, which represent low- to moderate-temperature deposits, include argentite (Ag<sub>2</sub>S); tetrahedrite ((Cu,Fe,Zn,Ag)<sub>12</sub>Sb<sub>4</sub>S<sub>13</sub>); cerussite (PbCO<sub>3</sub>), a supergene lead mineral formed by the action of carbonated waters on galena; anglesite (PbSO<sub>4</sub>), a secondary mineral usually formed by the oxidation of galena; azurite (Cu<sub>3</sub>(CO<sub>3</sub>)<sub>2</sub>·(OH)<sub>2</sub>), a secondary mineral chiefly formed by the action of carbonated waters on other copper minerals; hydrozincite (Zn<sub>5</sub>(OH)<sub>6</sub>(CO<sub>3</sub>)<sub>2</sub>), a secondary mineral formed by the alteration of sphalerite; metallic gold (Au); and metallic mercury (Hg). Elements of interest in this group include copper, gold, mercury, lead, silver, and zinc.

## LABORATORY PROCEDURES AND ANALYTICAL METHODS

### Plants

Roots were washed to remove remnants of the soil mixture by shaking them in beakers filled with tap water and placing them in an ultrasonic-cleaner (generator output frequency, 25 KHZ) water bath for about 4 minutes each. Root samples to which soil still adhered were washed additionally by repeating the same technique. Although the samples were washed until all visible soil was removed, in many of the samples concealed particles of soil could still have been present beneath the thin, loosely attached, and often cracked outer layer of the roots, thus contaminating the samples. All samples were dried in an oven at 35°C.

Stems and roots were cut into small pieces with pruning shears, and were ground in a Wiley mill.<sup>1</sup> Splits of leaves, stems, and roots were ashed in a muffle furnace during a 24-hour period, while the temperature increased slowly at a rate of about 50°C per hour to a maximum of 550°C, and stayed at that temperature for most of the remaining time.

Ash samples of roots were sieved with a screen having 0.119-mm average diameter openings, and some small amount of plus-0.119-mm-diameter sand was removed from most samples. Ash samples of leaves, stems, and roots were pulverized and homogenized by shaking vigorously for 2 minutes in 1-oz plastic containers to which two 6-mm-diameter glass balls had been added.

The ash samples were analyzed for 32 elements by a semiquantitative emission spectrographic method described by Mosier (1972) and modified by Curry and others (1975). Plant analyses for mercury were made using the Hatch and Ott (1968) method, with modifications by T. F. Harms (U.S. Geological Survey, unpub. data). The limit of determination for each element using these methods is given in table 2.

### Soils

Soils were sieved, and the minus-80-mesh fraction was pulverized to minus 100 mesh and analyzed for 31 elements by a semiquantitative emission spectrographic method outlined by Grimes and Marranzino (1968). Soils analyzed include the natural potting soil and soil from three of the control pots after 7 years of tree growth. Results are given in table 3.

## RESULTS

### Growth and Condition of the Trees

The three tree species used in this study naturally grow slowly when young. The average height of the tallest 25 percent of douglas-fir seedlings at a forest site in Colorado was reported by Fowells (1965, p. 549) as 32.6 in. at 7 years of age. He also stated that roots of lodgepole pine seedlings grow slowly (p. 376), and that both root growth and shoot growth of engelmann spruce were slow. Five-year-old seedlings averaged less than 1 in. in height when grown under natural conditions (p. 302). Judging from these findings, the growth rates of the trees in our experiments seem not to have been reduced by the minerals added to the soils or by confinement of the roots in pots. At the conclusion of our study, the approximate heights of the tallest trees of each species were as follows: lodgepole pine, 65 cm; douglas-fir, 60 cm; and engelmann spruce, 52 cm. Variation occurred in the growth rate of trees within a species, regardless of which experimental procedure was used, and the variation in growth of the control group of trees fell within this range of variation (fig. 3).

The amount of soil used per pot seemed adequate for the root growth for 7 years; no trees were potbound (pots tightly packed with roots), and only a few pine trees

had produced root growth extending a few centimeters through the pot holes (fig. 4). Pine trees (and probably also spruce and douglas-fir) have a short root-hair zone (Bold, 1967, p. 518) which limits the absorption of elements from the soil solution that surrounds their roots. Mycorrhizal fungi, however, invade the root cells and form a symbiotic association, termed a mycorrhiza, that increases the absorptive ability of the root system. When the soil was removed from the pots, abundant mycorrhizae were observed at the pot/soil interface (figs. 4 and 5) in some pots.

### Analysis of Seedlings as Received from the Nursery

One seedling tree of each of the three conifer species was divided into leaf, stem, and root samples at

the beginning of the study, and these samples were held, without further preparation, in plastic bags at room temperature until the conclusion of the experiments and then randomly interspersed with the experimental samples when submitted to the laboratory for analysis. The analyses are given in table 4. The seedling analyses can be compared to analyses of the control group of trees (table 5), which had grown 7 years longer than the seedlings, to provide a measure of changes in element concentrations that may have occurred with age. The number of samples in both groups is too small for conclusive comparisons to be made; however, some of the stronger differences or similarities between the groups may indicate tendencies for element absorption that either change or remain nearly constant with the age of the trees.

### Uptake of Metals by the Trees

The uptake of metals is demonstrated by comparisons of the elements in samples of experimental trees with those of the control trees that grew in soils to which no minerals were added. The possibility of contamination of the root samples of Groups I-IV by the minerals added to the soils greatly reduced the usefulness of some root samples for measuring element absorption from the soil solution. Contamination by adhering soil is suspected, but not proven, of the samples of experimental trees if concentrations of the added elements in root samples greatly exceed concentrations found in root samples of the control trees. If the root-sample analyses within a group of four replicates range widely, the highest value probably repre-

**Figure 3.** Trees at the conclusion of the study. The three rows of trees selected to show height are (left to right) lodgepole pine, engelmann spruce, and douglas-fir. The pots, whose tops are 8 in. in diameter, indicate scale.

**Figure 4.** Soil (inverted) from the pot in which a lodgepole pine tree grew. The dark lines on the soil surface are rootlets; the irregular white lines at the soil summit are the mycelium of a mycorrhizal fungus. Several roots are shown that grew through the drainage hole in the pot. The pots, whose tops are 8 in. in diameter, indicate scale.

sents contamination of a single sample, and the lower values may more nearly represent concentrations taken up by the roots. If values for leaves, stems, and roots in a set of replicates are all high compared to those of the corresponding control samples, little or no root contamination is suggested. The greatest reliance was placed on analyses of the stem and leaf samples, because their contamination by minerals added to the soils is unlikely.

**Figure 5.** Rootlets of lodgepole pine with mycorrhizae. The hyphae (filamentous strands of the fungus), although too small to be seen in this photograph, are indicated by the masses of fine soil particles that have adhered to the rootlets. Where no mycorrhizal fungi occur on the rootlets, no soil adheres.

Analyses of leaves, stems, and roots of the three conifer species in the control group and the experimental groups are given in tables 5–9. Discussions of species characteristics in respect to uptake of elements of greatest interest in mineral exploration follow.

## Antimony

Antimony was added as cervantite and tetrahydrite to Group I soils and as tetrahydrite to Group III soils. This element was not detected in the natural potting soil (table 3), in soil removed from pots of the control group of trees (table 3), or in any tissues of trees that grew in soil to which no antimony had been added. It was, however, found in leaves of seedling trees as received from the nursery (table 4) and in roots of Group II trees (table 7).

Analyses of Group I (table 6) showed no antimony in the conifer leaves, some in stems of spruce (50–700 ppm) and douglas-fir (200 ppm), and some (50 ppm) in one sample of pine stems. Roots of pine and douglas-fir contained high (2,000–>5,000 ppm) antimony concentrations. One spruce-root sample contained a high amount of antimony (5,000 ppm), whereas low values (200–700 ppm) were obtained for the other three samples. For one spruce tree a value of 700 ppm was obtained for both stems and roots, suggesting negligible root contamination for that sample.

Analyses of Group III (table 8) showed antimony in two samples of douglas-fir leaves (50 ppm), and in stems of pine (50–150 ppm) and douglas-fir (50 ppm), but not in stems of spruce. Generally, root-sample values were lower for this group than for Group I. The higher values for both groups are probably influenced by contamination.

**Table 4.** Element concentrations and percent ash of seedling trees as received from the nursery

[One tree of each species was analyzed. Concentrations expressed as parts per million in ash, except where percent is indicated. Leaders (--), element was not detected in the sample]

## Arsenic

Arsenic was added as arsenopyrite to Group I soils. No arsenic was found in the natural potting soil (table 3), in soil removed from pots of the control group of trees (table 3), or in tissues of the seedling trees as received from the nursery and the control group of trees (tables 4 and 5).

Analyses of Group I (table 6) showed arsenic in leaves of only one sample of pine (1,000 ppm) and in stems of one sample of spruce (<200 ppm), but in roots of all samples of all species (1,000–>5,000 ppm). All samples of douglas-fir in Group I contained 5,000 ppm or greater concentrations of arsenic. These results demonstrate the remarkable ability of douglas-fir to accumulate arsenic, as was pointed out by Warren and others (1968), and indicate the practical use of douglas-fir as a biogeochemical indicator for arsenic, a pathfinder element in prospecting for gold. Roots, but not stems or leaves, of engelmann spruce and lodgepole pine possibly could be used as arsenic indicators. Soil contamination of root samples may not be an important factor in the high arsenic levels in roots of these conifers (1,000–>5,000 ppm), as both the leaves and stems of douglas-fir contained as much arsenic as was found in the root samples or more.

## Bismuth

Bismuth was added as bismuthite to Group II soils. This element was not found in the natural potting soil or in the soil removed from control pots (table 2). Bismuth concentrations of >500 ppm were found in leaves of seedling trees as received from the nursery (table 4), but much less was found in their stems and roots (<50 to 100 ppm). In trees of the control group (table 5), bismuth generally was more concentrated in leaves and stems than in roots. The results for bismuth show abnormally high values for nearly all samples of all organs for all groups, including the control group. Bismuth values for leaves and stems of these species of conifer trees rarely exceed 1 ppm (G. C. Curtin and H. D. King, unpub. data). A possible explanation for the high values of bismuth in most samples is that the bismuth mineral added to Group II soil was solubilized and dispersed into the soils of other groups in the growing plot.

Analyses of Group II (table 7) showed high levels of bismuth (>500 ppm) in samples of all roots. Stem samples of these trees contained more bismuth (200–>500 ppm) than was found in corresponding leaf samples (70–200 ppm), and the bismuth levels in both generally were higher than in leaves and stems from soils having no added bismuth (<1–200 ppm).

## Copper

Copper was added as tetrahydroite to Group I soils, and as tetrahydroite and azurite to Group III soils. Copper was found in the natural potting soil and soils of the control plants in amounts ranging from 50 to 70 ppm (table 3). Copper in the seedling trees ranged from 70 to 200 ppm (table 4), the lower concentrations being in the roots. Trees of the control group (table 5) generally contained copper concentrations in leaves, stems, and roots that were somewhat higher than those found in the seedling trees.

Analyses of Groups I and III (tables 6 and 8, respectively) did not show an increase in copper levels in stems and leaves above concentrations found in the control trees (table 5), but much higher levels accumulated in the roots (5,000 ppm and greater). This high concentration of copper in the root samples probably represents the effects of soil contamination.

## Gold

Gold was added as gold leaf to soils of Groups I, III, and IV. Gold was not detected in the natural potting soil or in the control group soils (table 3). It also was not detected in the seedling trees (table 4) or in the control group of trees (table 5).

Analyses of Group I (table 6) showed gold in one stem sample each of pine, spruce, and douglas-fir (2, 3, and 15 ppm, respectively); in one leaf sample of spruce (5 ppm); and in all but one root sample (5–200 ppm). Gold was not found in leaves, stems, or roots of the Group II trees (table 7) to which no gold was added.

Analyses of Group III trees (table 8) showed gold in only one sample of spruce stems (10 ppm) and two samples of douglas-fir stems (2 and 5 ppm), but in roots of six samples (7–100 ppm). In the analyses of Group IV trees (table 9), only five samples of stems contained gold (<2–15 ppm), whereas all but one root sample contained gold (2–200 ppm).

In a study of gold in 2-year-old stems of pine (*Pinus radiata* Don.) that grew around old mine workings in Tasmania, Australia, Baker (1981, p. 8) reported gold values as much as 4.8 ppm, whereas trees outside the area of mine workings averaged 0.05 ppm. Baker's values for gold in trees at the mine workings correspond to our three values of 2, 3, and 5 ppm for gold in pine stems from soils to which gold leaf had been added.

In summary, these experiments demonstrate that metallic gold can be solubilized in favorable soil environments and can be translocated from roots to stems. The mechanisms regulating the absorption of gold by the conifer species are still imperfectly understood, but are discussed below.

The soil of Groups I, III, and IV was carefully broken up and searched for remnants of added gold leaf. Several pieces of gold leaf were recovered; some had edges that appeared to have been eroded during the 7 years that the trees grew in the pots. Analyses of stems and roots of some trees that grew in this soil (tables 6, 8, and 9) clearly demonstrate that gold was absorbed by the tree roots. Gold must be in a soluble form to enter plant tissues—particulate gold, even as a colloidal suspension, is not taken up by plants (Shacklette and others, 1970). The possible methods by which gold enters biogeochemical cycling were discussed by Lakin and others (1974), and experiments on the absorption of gold by plants were described by Shacklette and others (1970). The active role of humic acids in dissolving, complexing, and transporting gold was discussed by Ong and Swanson (1969), Curtin and others (1970), and Baker (1978). The utilization of humus-rich forest soil in geochemical exploration for gold was described by Curtin and others (1968), and a review of the absorption of gold by plants was given by Girling and Peterson (1980). Kelly and Cloke (1961) proposed methods for the solubilization of gold in near-surface environments that were independent of biologic processes.

One method of gold solubilization that is likely to occur in the rooting zone of soils is the production by various plants and other organisms of cyanoglycosides and of enzymes that hydrolyze the glycosides to produce hydrogen cyanide. Although more than a thousand cyanogenic plants are known, none grew in or near the pots of conifers used in this study. Some soil fungi are cyanogenic, but mycorrhizae are not known to have this property, although Shacklette (1974, p. 41) reported some evidence of cyanogenic ability of mycorrhizae associated with an herbaceous plant species. The solubilization of gold in the present experiments may have been caused by cyanogenic fungi or other organisms in the soil, by the action of humic acids in the soil solution, or by other processes that are unknown.

## Lead

Lead was added as cerussite and anglesite to Group III soils. The tetrahedrite, added to Groups I and II, may contain lead. A lead concentration of 70 ppm was found in natural potting soil and in soil removed from pots of the control group at the end of the study (table 3). Lead concentration in the seedling trees (table 4) was lowest in root samples, ranging from 20 to 150 ppm; lead concentrations in leaves and stems ranged from 100 to 500 ppm. Lead concentrations in trees of the control group (table 5) were somewhat higher than those in seedling trees.

The lead content of Group III trees (table 8) was generally greater in stems, and notably greater in roots,

than in the same plant organs from the control group (table 5). The increased lead concentration in roots may have been caused by soil contamination of the root samples. The lead content of roots from Group I trees (table 6) and from Group II trees (table 7) to which no lead was added, except possibly in tetrahedrite as noted above, was much higher than in roots from the control group.

## Mercury

Mercury was added as metallic mercury to Group III soils. Neither soils nor seedling trees were analyzed for this element. Mercury was detected in all parts of all other trees sampled in this study. The mercury in leaves and stems of the control group trees (table 5) had ranges similar to those of all experimental groups to which no mercury had been added. But mercury levels in the stems and leaves of trees that grew in soil to which mercury had been added were as much as ten-fold higher than those of the control group. Mercury values in roots were an order of magnitude higher than leaf and stem values in all groups to which no mercury had been added. Levels of mercury in roots of the Group III trees were high (as much as 25 ppm); these high concentrations may be partly the result of soil contamination.

Metallic mercury, being insoluble in water, cannot enter tree roots; therefore, this element must have been converted to a soluble compound, most probably by soil microorganisms.

## Molybdenum

Molybdenum was added as molybdenite to Group II soils. It was not found in the natural potting soil, or in soil removed from pots of the control group (table 3). Molybdenum was detected in all samples of seedling trees and in all tree samples of the control group in concentrations ranging from 5 to 100 ppm (table 4).

Analyses of Group II trees (table 7) showed more molybdenum in all organs than was found in corresponding organs of the control group of trees. Root-sample values were all >500 ppm molybdenum and probably represent some contamination. Leaf samples generally had higher values than did stem samples. Trees in the other experimental groups (I, III, and IV) had molybdenum values similar to those of trees in the control group.

## Silver

Silver was added as tetrahedrite to Group I soils and as argentite and tetrahedrite to Group III soils. Silver was not detected in the natural potting soil or in soil removed from pots of the control group (table 3). All sam-

ples of the seedling trees (table 4) contained silver (1–5 ppm), with most of the highest concentrations in the leaves. All trees of the control group (table 5) had highest values (10–50 ppm) in the roots.

Analyses of Groups I and III (tables 6 and 8, respectively) showed silver in concentrations ranging from 0.3 to 200 ppm, with highest values (15–200 ppm) generally in the roots. Most root samples were probably somewhat contaminated, as reflected by the difference between silver values for roots of trees in the control group (table 5) and those from soil having added silver. The leaves of one spruce tree, however, contained as much silver (5 ppm) as was found in roots of the same tree (table 8), which indicated that the root sample had not been contaminated by soil. Judging from analyses of root samples of the control group of trees, roots of these conifers are expected to have higher silver values than are leaves and stems.

Other experimental groups to which various minerals, but no silver, had been added showed different trends in silver concentrations in the trees. Silver values of Group IV trees (table 9) were similar to those of trees in the control group. Silver values for stems and leaves of Group II trees (table 7) were generally lower than those of Group III trees (table 8), but root values of Group II trees tended to be higher.

## Tin

Tin was added as cassiterite to Group II soils. None was found in the natural potting soil or in soils removed from pots of the control group of trees (table 3). Tin was found in all samples of seedling trees (table 4) in concentrations ranging from 5 to 100 ppm, and in most tree samples of the control group (table 5) in concentrations ranging from 5 to 30 ppm.

Tin concentrations in Group II trees (table 7) tended to be somewhat higher in leaves and stems than in the same organs of trees in the control group; however, the roots contained so much more tin (>500 ppm) than was found in roots of the control group (5–30 ppm) that soil contamination of the root samples seems a certainty.

Tin in trees of Groups I, III, and IV (tables 6, 8, and 9, respectively) was found in concentrations similar to those of the control group of trees.

## Tungsten

Tungsten was added as scheelite to soils of Groups I and II. No tungsten was found in the natural potting soil or in soils removed from pots of the control group of trees (table 3). Tree seedlings (table 4), trees in the control group (table 5), and trees in Groups III and IV (tables 8 and 9, respectively) likewise contained no detec-

tible tungsten, with the exception of one sample of douglas-fir stem in the control group (100 ppm).

Group II trees (table 7) contained tungsten only in roots (200–1,000 ppm), and tungsten was detected below measurable concentrations (<50 ppm) in one sample of douglas-fir stems. Group I trees (table 5) contained tungsten in most root samples (50–1,000 ppm) and in stems of four tree samples (<50–50 ppm). Tungsten was not found in any leaf sample of this study.

The tungsten found in root samples may have resulted largely from soil contamination of the samples. The tungsten concentrations found in the few stem samples are noteworthy in that this element is seldom reported in analyses of any plant material.

## Zinc

Zinc was added as hydrozincite and as tetrahedrite to Group III soils and as tetrahedrite to Group I soils. Zinc was not found in the natural potting soil or in soils removed from pots of the control-group trees (table 3). This element was found in all samples of seedling trees, ranging from 0.2 to 0.5 percent (table 4), and in trees of the control group, ranging from 0.1 to 2 percent (table 5).

Group III trees (table 8) contained zinc concentrations of 0.2–>2 percent, with values for roots generally at or near the upper limit of this range. Soil contamination probably did not contribute greatly to these root values.

Zinc concentrations in trees of Groups I, II, and IV (tables 6, 7, and 9, respectively) were similar to those found in trees of the control group (table 5).

## Effects of Species Differences in Metal Uptake by Coniferous Trees

The small number of replicate samples used in this study was insufficient to evaluate metal uptake by different species with a high degree of confidence. Some apparent species differences, however, are so consistent in the experiments that they are worth mentioning.

The ability of douglas-fir stems and leaves to concentrate arsenic has been discussed. The contrasts in arsenic uptake between this species and lodgepole pine and engelmann spruce are striking, considering that the three species are in the same family (Pinaceae) and share many physiological properties. It is also noteworthy that in Groups II and III, to which various metals, but no arsenic, were added to the soils (table 7 and 8, respectively), only douglas-fir accumulated arsenic to measurable levels in some root and stem samples. Douglas-fir would be classified in the Kovalevskii system (1979) as a “nonbarrier species” to arsenic.

The apparent inability of lodgepole pine to accumulate high concentrations of barium is suggested by results of this study. Although barium was not added to soils of any experimental group, it was present in the natural potting soil and in soil removed from pots of the control group in concentrations ranging from 500 to 700 ppm (table 3). Lodgepole pine consistently contained low concentrations of this element, compared to higher concentrations found in engelmann spruce and douglas-fir. Using the terminology of Kovalevskii (1979), lodgepole pine would be classified as a "high barrier species" in respect to barium.

### **Differences in Element Concentrations among Leaves, Stems, and Roots**

The three conifer species tend to concentrate bismuth in decreasing amounts in leaves, stems, and roots (tables 4, 5, 6, and 9) if the soils contain low concentrations of bismuth. If the trees are grown in soil with added bismuth, the tendency is reversed (Group II, table 7). If grown in soils with various metals, but no bismuth added (Group III, table 8), the trees did not show a clear trend to concentrate bismuth in any organs.

Lead tends to be more concentrated in stems than in leaves of trees whether lead was added or not. Lead in the root samples was greatly increased in the trees growing on soils to which lead was added (Group III), but the increase may have been caused by soil contamination.

Zirconium commonly was more concentrated in stems than in leaves in the control group of trees as well as in all experimental groups. Many root samples had concentrations of this element that were as much as or greater than the concentrations found in the natural potting soils (table 3).

### **Differences in Element Uptake by 7-year-old Trees versus Seedlings**

Element contents of the seedling trees as received from the nursery (table 4) were compared with those of the control group of trees (table 5) and the experimental groups (tables 6–9), which had grown for 7 years.

Antimony was found in leaves of all seedling trees (50–100 ppm), but not in most leaves or other organs of older trees. Antimony was found in leaves of only two trees grown in soils to which antimony had been added (Group III, table 8).

Bismuth concentrations were much higher in seedling leaves than in the 7-year-old trees of all groups, including those that grew in soils to which bismuth had been added (Group II, table 7).

The silver values in leaves of lodgepole pine and engelmann spruce seedling trees were higher than those in the stems, whereas in the 7-year-old trees of the control group and in most samples of the experimental groups the stems contained more silver than the leaves. Douglas-fir contained more silver in leaves than in stems of most samples, regardless of the age of the trees.

Tin values were much higher (50–100 ppm) in samples of seedling tree leaves than in samples of all other leaves that were analyzed, except some leaf samples from trees (Group II, table 7) growing in soil to which tin had been added (50–70 ppm).

The zirconium levels in seedling tree roots were much higher (1,000 ppm) than in all other roots analyzed (20–500 ppm), except in two samples of roots (1,000 ppm each) in groups to which various elements (but no zirconium) had been added to the soil (Groups I and III, tables 6 and 8, respectively).

The causes of the higher concentrations of the above elements in certain organs of seedling trees are not known. It is unlikely that these elements occurred in appreciable quantities in insecticides, fungicides, or fertilizers that may have been used at the tree nursery, nor was contamination of the seedling trees with this group of elements probable in ordinary growing and other cultural practices.

## **CONCLUSIONS**

Seedling trees of ponderosa pine, engelmann spruce, and douglas-fir grew normally in soil having anomalous concentrations of metals that are characteristic of four types of mineral deposits. The general response of the trees was an increase in the metallic elements in leaves and stems, and in roots of some samples, as compared to control groups of trees grown in soils with no added metals. These results demonstrate that unweathered minerals added to soils released their metals in a soluble form available to the trees within a 7-year period, under normal weathering conditions of soil materials in the Central Rocky Mountain region of the United States.

In general, no great differences in uptake of metals were found among the three species of trees. Douglas-fir, however, showed a remarkable ability to concentrate arsenic in leaves and stems, and lodgepole pine was found to be greatly limited in the absorption of barium. Differences among the concentrations of metals in leaves compared to stems were indicated by higher barium and bismuth values in leaves, but differences in other element values were erratic. Although samples of roots commonly had high concentrations of most metals, the contamination of the root samples by ore minerals that were added to the soil obscured any evidence that the high values found were entirely of elements within the root tissues.

Higher concentrations of antimony, bismuth, silver, tin, and zirconium were found in the seedlings than in the 7-year-old trees. The reasons for these differences are not known.

Mercury in leaves and stems of trees grown in soil containing mercury (Group III) was as much as 10 times higher than in those grown in soil containing no mercury. The mercury level of the roots was increased a thousand fold, but a greater part of this increase may have been caused by contamination of the samples. The mercury most likely was converted to an organic compound by soil organisms before it was taken up by the roots.

Metallic gold added to the soil resulted in an increase of gold in only some organs of a few tree samples. No gold was detected in the seedlings, the control group, or in Group II trees.

The role of mycorrhizae in metal uptake may explain the survival of the trees that grew in above-normal concentrations of metals, and the high concentrations of these metals found in roots of these plants. Thus, the presence or absence of effective mycorrhizae may be one of perhaps many factors that determine whether a plant is a barrier or a nonbarrier species for particular elements in the substrate.

The results of this experiment may have a variety of applications in biogeochemical exploration for mineral deposits. The results provide some guidelines for interpreting metal concentrations that might be found in the various organs of similar species of conifer trees growing in soils over concealed or unknown mineral deposits of the types simulated in this experiment. The results also show that young conifer trees are capable of accumulating highly anomalous amounts of metals within short periods of time and may be useful as a sample medium in biogeochemical investigations.
