Background

The Cambrian-Ordovician (C-O) aquifer system underlies an area with a population of about 26 million people in parts of seven states that include the metropolitan areas of Chicago, Illinois; Milwaukee, Wisconsin; and Minneapolis-St. Paul, Minnesota. The C-O aquifer system ranks 9th in the Nation as a source of groundwater for public supply and 11th for domestic supply, and about 631 million gallons per day are pumped for those uses (Arnold and others, 2017a). Land use overlying the aquifer system is mostly agricultural (about 73 percent), undeveloped (about 16 percent), and urban land (about 3 percent).

Rocks of the C-O aquifer system are mainly marine sandstones and carbonates that are present at the land surface or beneath glacial deposits in southeastern Minnesota, northeastern Iowa, Wisconsin, northern Illinois, and extreme northwestern Indiana (Young, 1992; Wilson, 2012). The rock layers dip and thicken to the south and east into structural basins in southwestern Iowa, central Illinois, and western Michigan. In eastern Wisconsin; most of Iowa, Illinois, and Indiana; and Missouri, rocks of the C-O aquifer system are buried by younger rocks. Where the aquifer is at or near land surface, modern recharge to the aquifer system occurs primarily through direct infiltration of precipitation or percolation through overlying glacial deposits. Groundwater in large parts of the buried system was likely recharged during the Pleistocene by glacial meltwater (Siegel and Mandle, 1984). Shallow groundwater flows along short flow paths to local streams, whereas deeper groundwater flows along longer flow paths towards major river valleys, Lake Michigan, or downdip structural basins (Wilson, 2012). Groundwater in large parts of the buried system, in far western Iowa, most of Missouri, south-central Illinois, and Indiana, is too saline for drinking-water use.

Groundwater quality in the C-O aquifer system was evaluated by sampling 60 spatially distributed public-supply wells. Public-supply wells in the C-O aquifer system typically consist of solid casing extending downward from the land surface with an open interval beneath. The length of the solid casing for wells sampled for this study ranged from about 40 to 2,250 feet, and the total well depths ranged from about 100 to 2,630 feet. Water-quality data from these wells were used to estimate the percentage of the study area with concentrations that are high, moderate, and low with respect to constituent benchmarks. The accuracy of the estimates depends upon the distribution and number of wells, not on the size of the area (Belitz and others, 2010). Samples were analyzed for a large number of water-quality constituents derived from natural and human sources.
Inorganic Constituents With Human-Health Benchmarks

Trace elements and major and minor ions are naturally present in the minerals of rocks, soils, and sediments, and in the water that comes into contact with those materials. Samples were analyzed for 34 trace elements and major and minor ions, of which 19 have human-health benchmarks. Constituents from this group were detected at high concentrations in about 12 percent of the study area (the depth zone used for public supply) and at moderate concentrations in about 22 percent. Strontium, arsenic, and fluoride were the only constituents in this group that were detected at high concentrations.

Radioactivity is the release of energy or energetic particles during spontaneous decay of unstable atoms. Humans are continuously exposed to small amounts of natural radioactivity. Most of the radioactivity in groundwater comes from the decay of isotopes of uranium and thorium that are naturally present in minerals in aquifer materials. Samples were analyzed for eight radioactive constituents, of which four have human-health benchmarks. One of the four benchmarks is for the combined concentration of radium-226 plus radium-228 isotopes (combined radium). Radioactive constituents were present at high levels in about 45 percent of the study area and at moderate levels in about 22 percent. Combined radium concentrations and gross-alpha and gross-beta activity were present at high concentrations.

Nutrients are naturally present at low concentrations in groundwater; high and moderate concentrations (relative to human-health benchmarks) generally result from human activities. Samples were analyzed for five nutrients, of which two have human-health benchmarks. Common sources of nutrients, aside from soils, include fertilizer applied to crops and landscaping, seepage from septic systems, and human and animal waste. No nutrients were detected at high concentrations in the study area. Nitrate was detected at moderate concentrations in about 2 percent of the study area.

Inorganic Constituents and Field Measurements With Non-Health Benchmarks

(Not included in water-quality overview charts shown on the front page)

Some constituents affect the aesthetic properties of water, such as taste, color, and odor, or can create nuisance problems, such as staining and scaling. The benchmarks used for these constituents were non-regulatory secondary maximum contaminant level (SMCL) benchmarks established for public drinking water. Some constituents, such as fluoride and manganese, have human-health benchmarks and SMCLs. Samples were analyzed for 11 constituents that have SMCLs. One or more of these were present at high concentrations or values relative to the SMCL in about 63 percent of the study area and at moderate concentrations in about 25 percent.

Total dissolved solids (TDS) concentration is a measure of the salinity of the groundwater, based primarily on the concentrations of ions, and all water naturally contains TDS as a result of the weathering and dissolution of minerals in rocks and sediments. Concentrations of TDS can be high because of natural factors or as a result of human activities, such as applications to the land surface of road salt, fertilizers, or other chemicals in urban or agricultural areas. Most of the study area had high (40 percent) or moderate (37 percent) concentrations of TDS. Sulfate and chloride were present at high concentrations in about 23 and 8 percent of the study area, respectively, and at moderate concentrations in 17 and 2 percent, respectively. Fluoride was present at high concentrations relative to the SMCL in about 15 percent of the study area and at moderate concentrations in 22 percent.

Anoxic conditions in groundwater (low amounts of dissolved oxygen) can result in the release of iron and manganese in minerals to the groundwater. Iron was present at high concentrations relative to the SMCL in about 40 percent of the study area and at moderate concentrations in about 17 percent. Manganese was present at high concentrations relative to the SMCL in about 12 percent of the study area and at moderate concentrations in about 16 percent.

In some areas, the pH of the groundwater was not in the SMCL range of 6.5 to 8.5. The pH did not meet the standard in about 2 percent of the study area because it was less than 6.5, which is acidic and potentially corrosive.
Volatile Organic Compounds With Human-Health Benchmarks

Volatile organic compounds (VOCs) are present in many household, commercial, industrial, and agricultural products and are characterized by their tendency to volatilize (evaporate). Samples were analyzed for 90 VOCs, of which 38 have human-health benchmarks. VOCs were not detected at high concentrations in the study area but were detected at moderate concentrations in about 2 percent.

Pesticides With Human-Health Benchmarks

Pesticides, including herbicides, insecticides, and fumigants, are applied to crops, gardens and lawns, around buildings, and along roads to help control unwanted vegetation (weeds), insects, fungi, and other pests. Samples were analyzed for 227 pesticide compounds (pesticides and their breakdown products), of which 119 have human-health benchmarks. Pesticides were not detected at high or moderate concentrations in the study area.

Benchmark Type and Value for Selected Constituents

This table presents benchmarks for those constituents detected at high concentrations in the C-O aquifer system. Benchmark types are regulatory U.S. Environmental Protection Agency maximum contaminant levels (MCLs), non-regulatory health-based screening levels (HBSLs), and non-regulatory secondary maximum contaminant levels (SMCLs).

[Abbreviations: ppb, part per billion or microgram per liter (μg/L); ppm, part per million or milligram per liter (mg/L); pCi/L, picocurie per liter; mrem yr⁻¹, millirem per year]
High Concentrations of Combined Radium Were Common

The U.S. Environmental Protection Agency MCL for radium is based on the summed concentration of radium-226 and radium-228 (combined radium) and is set at 5 picocuries per liter (pCi/L). Combined radium concentrations were present at high concentrations in about 42 percent of the study area; however, the proportion varied depending on whether the aquifer is buried by younger rocks or not. Combined radium concentrations were moderate or high in about 37 percent of the area not buried by younger rocks, whereas they were moderate or high in about 91 percent of the area that is buried by younger rocks. The difference in combined radium concentrations between these two areas has been previously noted (Wilson, 2012) and is attributed to differences in geochemical conditions within the aquifer system that favor the adsorption of radium on aquifer materials where the aquifer is not buried by younger rocks and the release of radium into solution where the aquifer is buried by younger rocks.

Principal Aquifer Studies

The USGS NAWQA Project has been assessing the quality of groundwater since 1991. The NAWQA studies include Land Use Studies (LUS), Major Aquifer Studies (MAS), and Principal Aquifer Studies (PAS). These three study types are based on sampling networks of wells distributed across an area of interest. The LUS networks typically consist of observation wells that are relatively shallow, MAS networks typically consist of domestic-supply wells that are intermediate in depth, and PAS networks typically consist of public-supply wells that are relatively deep. A national synthesis of shallow and intermediate depth groundwater quality was reported by DeSimone and others (2014), and a regional synthesis of shallow and intermediate depth groundwater quality from the C-O aquifer system was reported by Wilson (2012). This fact sheet provides a summary of PAS data for 60 public-supply wells sampled in 2014 in the C-O aquifer system (data available in Arnold and others, 2017b).

The PAS assessments like this one allow for the comparison of constituent concentrations in untreated groundwater with benchmarks established for the protection of human health and for aesthetic qualities of drinking water and also provide a basis for comparison of groundwater quality among the principal aquifers. The data collected by the NAWQA Project include chemical analyses generally not available as part of regulatory compliance monitoring, including measurements at concentrations much lower than the levels used as human-health benchmarks and measurements of constituents that can be used to trace the sources and movement of groundwater.
