

A. RESOURCE APPRAISAL MAP FOR MESOTHERMAL VEINS BASED ON LITHOLOGY, STRUCTURE, AND KNOWN MINERAL OCCURRENCES

Note: The generalized and simplified geologic map was prepared as an underlay for various geophysical and geochemical data collected in the Wallace 1° x 2° quadrangle. A fuller treatment of geologic units and structure can be found on map I-1509-A in the Wallace CUSMAP folio.

CORRELATION OF MAP UNITS

OTv	Quaternary and Tertiary
Tv	Tertiary
Tk1, Tk2	Tertiary and Cretaceous
Ca	Cambrian
Zy1, Zy2	Late and Middle Proterozoic
Yp	Early Proterozoic

DESCRIPTION OF GEOLOGIC MAP UNITS

OTv: QUATERNARY AND TERTIARY VALLEY FILL DEPOSITS (QUATERNARY AND TERTIARY)—Alluvium, glacial deposits, and semiconsolidated to consolidated conglomerates interbedded in places with shale, coal, and volcanic ash, shown only in major valleys and basins or along main stream courses.

Tv: TERTIARY—Largely andesitic to dacitic welded tuff.

Tk1, Tk2: GRANITIC INTRUSIVE ROCKS (TERTIARY AND CRETACEOUS) DIORITIC INTRUSIVE ROCKS (TERTIARY AND CRETACEOUS) SEDIMENTARY ROCKS (CAMBRIAN)—Includes Red Lion Formation, Hamark Dolomite, Silver Hill Formation, Flathead Quartzite, and equivalent rocks.

Zy1, Zy2: MIDDLE PROTEROZOIC DIORITIC TO GABBROIC SILLS AND DIKES (LATE AND MIDDLE PROTEROZOIC) MISSISSIPPIAN GROUP (MIDDLE PROTEROZOIC)—Includes Picher, Libby, Garnet Range, and McNamara Formations, Bonner Quartzite, and Striped Peak, Mount Shields, Shepard, and Snowplow Formations.

Yp: EARLY PROTEROZOIC

WALLACE AND HELENA FORMATIONS (MIDDLE PROTEROZOIC)

Yah: WALLACE FORMATION (MIDDLE PROTEROZOIC)—Includes Empire, St. Regis, Spokane, Revett, and Burke Formations.

Yag: PRICHARD FORMATION (MIDDLE PROTEROZOIC)

Yaj: ANORTHOSITE, SCHIST, AND GNEISS (EARLY PROTEROZOIC)

CONTACT

THRUST FAULT—Dotted where concealed. Sawtooth on upper plate.

INTRODUCTION

Appraisal for mesothermal veins in the Wallace 1° x 2° quadrangle involves a complex procedure. Four maps and tests are used to show the data and the assessments: a single map, as used for other types of deposits in the quadrangle, would be extremely complex and essentially unworkable.

The group of four maps includes a map (A) showing analysis of three factors (lithology, structure, and known mineral occurrences) where sum total favorability scores are shown from high to low by colors that range from hot (red to blue), a map (B) showing analysis of two additional factors (geochemistry and geophysical) where a similar hot to cold system of nine colors is used, and a third map (C) that combines maps A and B to show resource assessment based on all the factors where the seven standard colors used for all resource probabilities (1 to 7) are shown. A fourth map (D) was prepared to test the credibility of the occurrence model and the complex appraisal procedure, as well as to show, insofar as possible, what the resource appraisal would have been if few or no mines or prospects were known in the quadrangle (map C minus the factor for known mineral occurrences, but assuming that some observations on the occurrence of veins in rocks would have been made by field geologists who mapped the area). The point scores for map D also use a hot to cold system of nine colors.

DERIVATION OF FAVORABILITY SCORES FROM LITHOLOGY, STRUCTURE, AND KNOWN MINERAL OCCURRENCES

LITHOLOGIC CHARACTERISTICS

Our mesothermal vein occurrence model (see map C) requires fractures to act as conduits for ore-bearing fluids. In order for a given lithologic unit to retain through-going fractures, the unit may be characterized by brittleness based on metamorphic grade or by an abundance of quartzite. In addition, favorability for fractures may be based on general observations regarding the rocks that commonly host veins in the quadrangle.

Boundaries of lithologic units on the map are more precise than lines bounding any other characteristic used to evaluate favorable ground for mesothermal veins. Within these lithologic boundaries, however, judgment has been used to classify areas. The favorability scores that result from these judgments range from +4 to -3 and are shown in figure 1.

STRUCTURAL CHARACTERISTICS

The structural factor for the occurrence of mesothermal veins involves recognition of both the type and amount of fracturing in various areas of the quadrangle. High-angle dip-slip faults and related fractures that tend to open the ground are more favorable than high-angle reverse or strike-slip faults, which tend to be less permeable because of the gouge formed along them. Exceptions to this tendency are common, however, because cross faults in high-angle reverse or strike-slip fault zones may have produced relatively open ground. Intensive fracture cleavage also tends to produce openings.

Estimates were made of the relative occurrence of fractures that tend to open the ground to mineralizing solutions in larger areas of the quadrangle. The boundaries between areas are not precise, but they separate general substance that exhibit different amounts of fracturing. The favorability score for the structure factor is given below:

- +4 Intensely fractured ground in a major zone of faulting, accompanied by light to overthrust folds and intense cleavage
- +3 Intensely fractured ground in a major zone of faulting, accompanied by upright open folds and minor cleavage
- +2 Highly fractured ground, may include thrust faults as well as high-angle faults
- +1 Moderately fractured ground that contains mostly high-angle faults
- 0 Slightly fractured ground that contains any type of faulting
- 1 Unfractured ground
- 2 No data on fracturing because of uncertainty of projections of faults and fault zones into covered bedrock

KNOWN MINERAL OCCURRENCES

Extensive mining and prospecting of mesothermal veins that have been discovered in the quadrangle provide information about favorable ground at the point of the mine or prospect. These point scores were translated into favorability areas by establishing a grid and then counting and contrasting the known occurrences. A producer was given a score of three points, and a developed or undeveloped prospect was scored as one point. All occurrences within an area the size of a township (36 mi on a side or about one half of 1 percent of the total area of the quadrangle) were

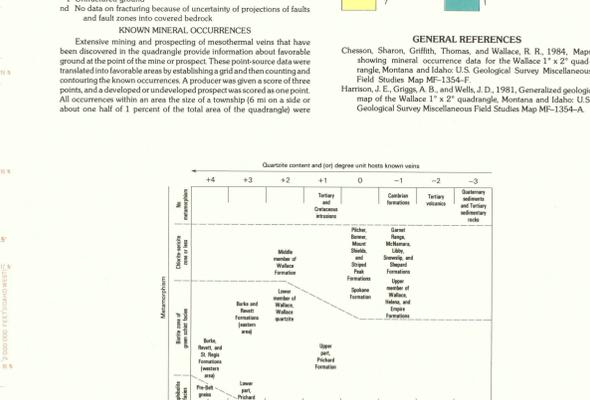

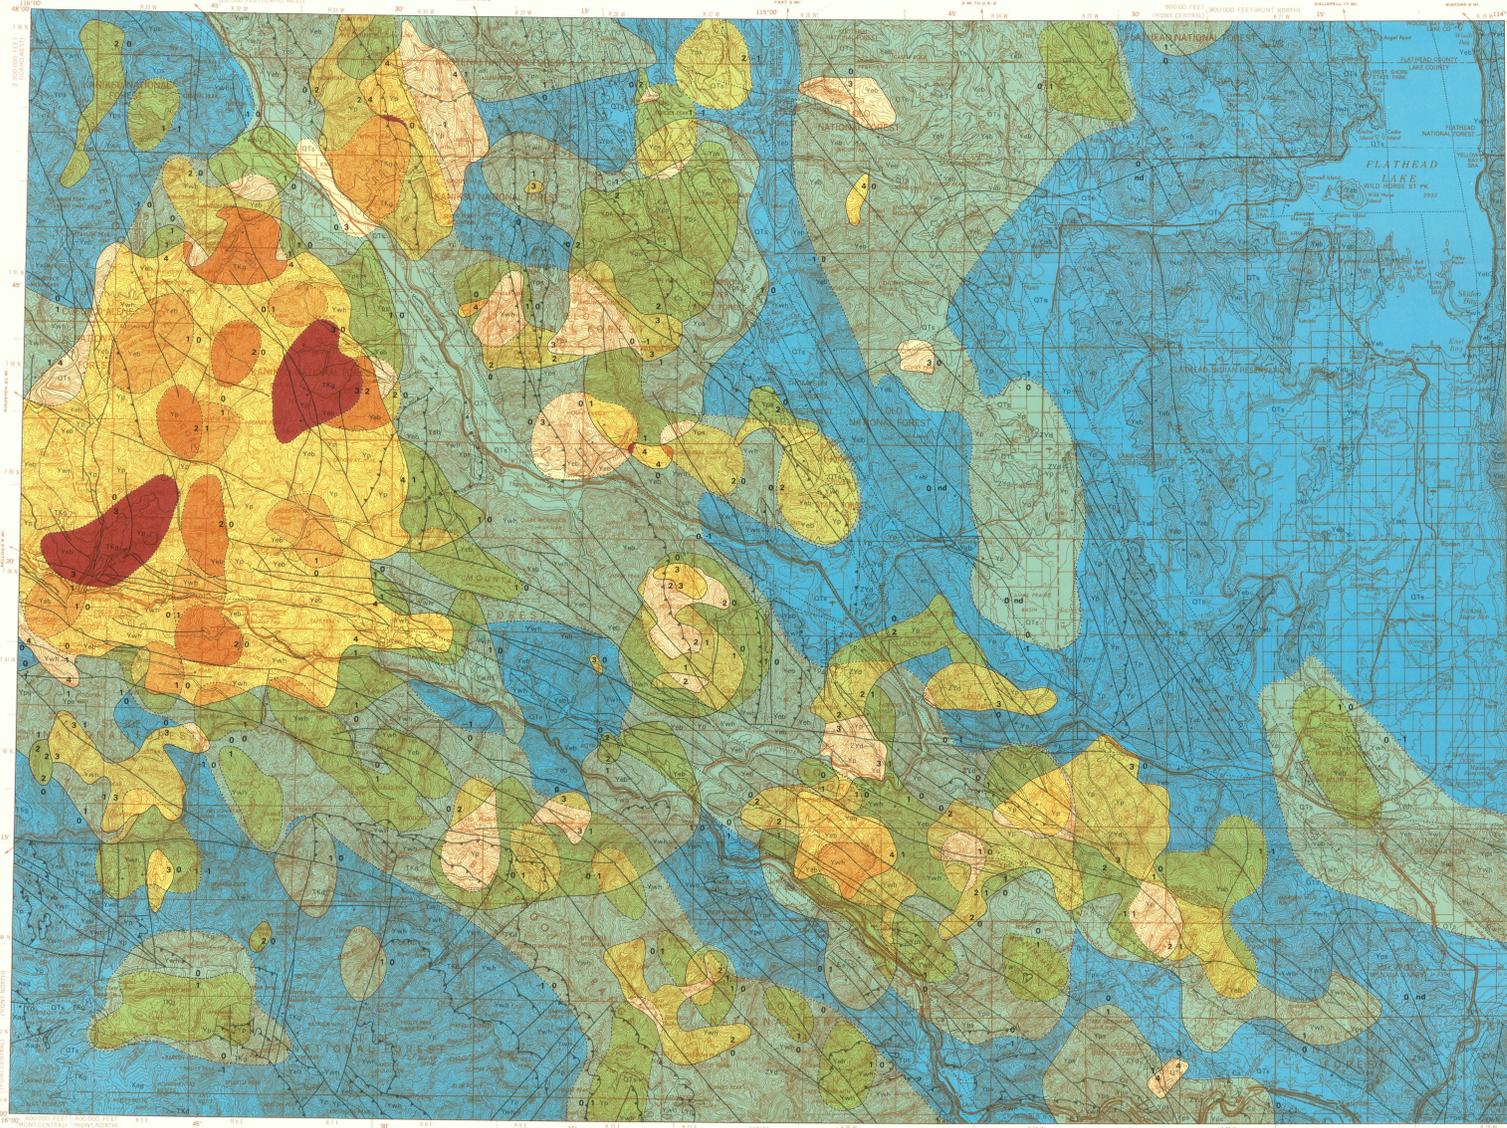

Figure 1.—DIAGRAM SHOWING DERIVATION OF FAVORABILITY SCORES FOR LITHOLOGY.

This map is part of a folio of maps of the Wallace 1° x 2° quadrangle, Montana-Idaho, prepared under the Continuum of U.S. Mineral Assessment Background Information about this folio is published in U.S. Geological Survey Circular 920.

B. RESOURCE APPRAISAL MAP FOR MESOTHERMAL VEINS BASED ON GEOCHEMICAL AND GEOPHYSICAL DATA

Note: The generalized and simplified geologic map was prepared as an underlay for various geophysical and geochemical data collected in the Wallace 1° x 2° quadrangle. A fuller treatment of geologic units and structure can be found on map I-1509-A in the Wallace CUSMAP folio.

DERIVATION OF FAVORABILITY SCORES FROM GEOCHEMICAL AND GEOPHYSICAL DATA

GEOCHEMICAL ANOMALIES

Mesothermal veins range in chemistry from simple to highly complex (see text accompanying map C). The veins of the Coeur d'Alene district yield a great range and variety of trace elements to stream-sediment samples from that district. But veins of the district, and mesothermal veins throughout the Wallace quadrangle, also can have a very simple chemistry, yielding stream sediments that show only anomalous amounts of lead, zinc, copper, or silver. This simple suite of anomalous elements may also be derived from other types of mineral occurrences, such as stratiform copper-silver occurrences (can have copper, silver, and lead) or stratiform Sullivan-type occurrences (can have lead, zinc, and silver). The probability is low, however, for any of the other occurrences to show all four elements contained.

In identifying favorable ground for mesothermal veins, we considered the total concentrations of lead, zinc, copper, and silver in samples of stream sediments. Cadmium, which is commonly present in anomalous concentrations in stream sediments near mesothermal veins, was not used as a signature element. Cadmium is closely related to zinc, commonly in sphalerite, that use of both zinc and cadmium would, in effect, give double weight to a single factor. Barium, also common to some mesothermal veins, was not used as a signature element either, because it has a high local variability in the quadrangle. Such erratic behavior limits its usefulness in defining regional geochemical trends. Some other potentially useful elements for trace-element signature in stream sediments, such as arsenic, molybdenum, and gold, also were not included in the generalized signature for mesothermal veins, because only a few samples contained amounts of those elements that were detectable by the analytical methods used.

Unique to mesothermal veins is the general presence of antimony. Antimony-bearing veins form a crude outer zone around the Coeur d'Alene district and occur at other places in what Frolking (1964) refers to as the "Greater Coeur d'Alene mineral belt"—essentially an extension of the Coeur d'Alene district along the Lewis and Clark line. In the Lewis and Clark partially extractable antimony is more closely related to mesothermal veins than is the total concentration of antimony in the same stream-sediment samples. The element is not part of the trace-element signature of any of the six other types of mineral occurrences identified in the Wallace quadrangle.

To help identify ground favorable for mesothermal veins, we also used a suite of elements that show anomalous concentrations in samples of nonmagnetic heavy-mineral concentrates. This suite consists of lead, zinc, silver, copper, antimony, and arsenic.

The identification of favorable ground by use of geochemical data includes three successive steps. In the first, all 1,229 samples of stream sediments were ranked according to their individual contents of lead, zinc, copper, and silver. For example, the sample having the greatest concentration of lead, according to atomic-absorption analysis, was assigned a rank of 1,229; the sample having the second greatest concentration was assigned a rank of 1,228, etc. Where samples had the same concentration, they were given the same rank. This ranking procedure was completed for all four elements, and then each sample was assigned a number that represented the sum of the ranks for lead plus zinc plus copper plus silver, and another number was assigned for just lead plus zinc. Each sum gave an estimate of the relative enrichment of the four-element suite and of the two-element suite. The sum of the ranks was used to give equal weight to each element. For example, actual values for silver rarely exceed a few parts per million, whereas values for lead are commonly in the hundreds of parts per million. If we used total metal content (sum of the actual values) then lead would be weighted unintentionally by tens of times more than silver, whereas the sum of the ranks gave lead the same weight as silver for significance in the geochemical signature. The numbers representing the sum of the ranks were divided into seven percentile classes that had upper limits of 100, 90, 80, 70, 60, 50, and 40. Geomorphic groups of samples that could be characterized as being in the 85th percentile or higher for lead plus zinc plus copper plus silver were identified and assigned a favorability of high, medium, or low, as outlined in the criteria described below. This same procedure was applied to the numbers for the sum of the ranks for just lead plus zinc, which identified additional groups that possibly represented lead-zinc veins containing little or no silver or copper. With the exception of the Sullivan-type occurrence model, samples assigned to other models were excluded from consideration in assigning favorability to mesothermal veins. In addition, isolated single-sample sites were not included, unless they fell within the top 5 percent of the rankings. The boundaries for the areas that contain groups of sample sites in the higher percentiles were generalized and drawn around drainages that contain those favorable samples.

In the second step, the data for nonmagnetic heavy-mineral concentrates were examined for the presence of anomalous concentrations of lead, zinc, silver, antimony, and arsenic. Groups of sample sites showing various combinations of these signature elements were classified into categories of high, medium, and low favorability. Many of these sites correspond in location and level of favorability with the areas outlined in step one. Where they do not, commonly around the edges of the first-step boundaries, the boundaries were expanded to include favorable areas indicated by the trace from nonmagnetic heavy-mineral concentrates. Finally, in the third step, the areas identified in the quadrangle that show an enrichment of partially extractable antimony in stream sediments were examined. The enriched areas were found by computer contouring of weighted averages at the corners of a square grid that enclosed 10.4 mi²; the weighted average was determined by an unpublished computer program that gives decreasing weight to values based on the distance away from the contouring point. We then identified areas where the weighted values exceed the geometric mean for all data (1.2 parts per million for antimony). These relatively high areas for antimony are believed to show another indication of favorable ground. Most areas of antimony enrichment correspond with areas already identified as favorable in steps one or two or serve to expand the favorable areas slightly. On map B we show the highest level of favorability found for an area in any step of our three-step procedure.

Favorability scores that range from +4 to 0 were assigned to the areas showing various levels of potential for mesothermal veins interpreted from the geochemical data. The scores and criteria for them are listed below:

- +4 Stream-sediment samples predominantly in the 90-95th percentile for summed signature elements; at least one-third are in the 95+ percentile. Nonmagnetic heavy-mineral concentrates in the 90+ percentile. Antimony or arsenic in a single site that contains antimony plus at least one other signature element.
- +3 Stream-sediment samples predominantly in the 85-90th percentile for summed signature elements; at least one-half are in the 85+ percentile. Nonmagnetic heavy-mineral concentrates from groups of sites have anomalous amounts of three or more signature elements, and antimony is present; also, a single site that shows four signature elements without antimony.
- +2 Stream-sediment samples predominantly in the 80-85th percentile for summed signature elements; at least one-third are in the 80+ percentile. Nonmagnetic heavy-mineral concentrates from groups of sites have anomalous amounts of two or more signature elements without antimony or a single site that contains antimony plus at least one other signature element.
- +1 Stream-sediment samples predominantly in the 75-80th percentile for summed signature elements; at least one-third are in the 75+ percentile. Nonmagnetic heavy-mineral concentrates from groups of sites have anomalous amounts of one or more signature elements without antimony.
- 0 Broad zones of higher magnetic intensity that surround areas having point scores of +2, +3, or +4.
- 1 Other areas where the regional magnetic and gravity data show no anomalies judged to be related to plutons.

DISCUSSION

Geochemical and geophysical factors used to derive map B are independent of the lithology, structure, and mineral occurrence factors used to derive map A. The Coeur d'Alene district and an area to the north and northeast of it are clearly favorable ground on both maps. However, the Greater Coeur d'Alene mineral belt, which extends southeast from the Coeur d'Alene district, is highly discontinuous in map B.

Boundaries for both geochemical and geophysical data are generalized and should not be considered precise. Original data for both kinds of information are of a reconnaissance nature, and boundaries between areas of different favorability values commonly have a precision of about 2 km. The geochemical and geophysical boundaries were generated independently and then combined without modification. As a consequence, small areas of overlap (perhaps those of 4 mi² or less) that result in isolated spots of higher favorability scores may not be as significant as they might appear on the map.

EXPLANATION FOR RESOURCE APPRAISAL

4 BOUNDARY BETWEEN AREAS THAT ARE ASSIGNED DIFFERENT RESOURCE POTENTIAL BASED ON GEOCHEMICAL DATA—Numbers are favorability scores for areas (see Geochemical anomalies section in text for detailed explanation)

1 BOUNDARY BETWEEN AREAS THAT ARE ASSIGNED DIFFERENT RESOURCE POTENTIAL BASED ON GEOPHYSICAL DATA—Numbers are favorability scores for areas (see Geophysical data section in text for detailed explanation)

SUM OF FAVORABILITY SCORES FOR GEOCHEMICAL ANOMALIES AND GEOPHYSICAL DATA (SUM TOTALS NOT GIVEN ON MAP)

4	7	4	1
