

DESCRIPTION OF MAP UNITS
Geologic units are identified according to morphologic, stratigraphic, and albedo characteristics following conventional techniques developed for planetary geology (Wilhelms, 1987; chapters 9, Tanaka and others, 1991). Many formal and informal geologic maps of the Olympus Mons region have been produced on a variety of map bases from other Mariner 9 or Viking images. Because of the great improvement in the quality and resolution of Viking images, we compare our map units only with those of Viking based studies.

The earliest formal, Viking based mapping was a 1:2,000,000 scale base flow map series of the Tharsis region (Scott and others, 1981). These maps were prepared before some of the photomosaic bases were compiled and before the Viking dataset was complete. However, the series contained the first detailed mapping that applied time-omnigraphic units. Next, Tanaka (1983) produced an informal map at 1:2,000,000 scale on a reduced version of the 1:2,000,000 scale map base used here and analyzed the geologic history of the region in detail. Finally, Scott and Tanaka (1986) mapped the entire western equatorial region of Mars and reanalyzed the stratigraphy of the units according to a new system based on crater densities; the system was further elaborated by Tanaka (1988). On Scott and Tanaka's map, the map units were organized in a hierarchical scheme and formal geologic names, such as the Olympus Mons Formation, were defined. We generally follow the conventions set forth on that map, except where modifications or added details are necessary. Our map unit symbols can be compared with those of the previous maps listed in table 1.

APRON MATERIALS
(Materials deposited in northern lowlands)

Aap **Ridged material**—Large, thin lobes with long, even, concentric ridges and troughs extending westward from scarp of Olympus Mons. Interpretation: Flattened distal debris flows originating from collapse and disintegration of scarp, perhaps accreted by melting of ground ice.

Aah **Hummocky material**—Bunch parts of lobate deposits extending westward from Olympus Mons scarp, includes irregular longitudinal ridges, grooves, pits, and hummocky terrain. Generally near head or center of lobate deposits. Interpretation: Proximal debris deposits made up of large blocks of scarp material.

Aab **Blocky material**—Large blocks or hummocky masses, some scarp have transverse ridges. Mapped along base of northwestern and northern parts of Olympus Mons scarp. Interpretation: Landslide debris blocks derived from scarp by rotational and translational movements.

Aaa **Smooth material**—Relatively smooth, lobate deposits with lineations parallel with flow margins. Occurs in high relief areas of Achernon Fossae north of lat 21°N. Interpretation: Product of superglacial mass wasting of ice-rich slope materials.

NORTHERN PLAINS ASSEMBLAGE
(Materials deposited in northern lowlands)

Medusae Fossae Formation—Consists of thick, extensive, relatively flat sheets, smooth to grooved and gently undulating; also moderate, sparsely cratered; south and west of Olympus Mons. Members distinguished by morphology:

Aan **Rolling plains member**—Forms broad, low hills and smooth rolling surfaces; outflow from flat topped, stepped mesas, some roughly circular with irregular central pits or depressions; sparsely cratered. Embay and overlies aureole materials; grades into and overlies striated member and is overlain by some landfills. Interpretation: Possibly eolian material, but irregularly shaped and elliptical craters several kilometers long may be source vents for some pyroclastic material. Surfaces both depositional and erosional.

Aam **Striated member**—Forms broad, rolling or level plains, characterized by sets of aligned, striated ridges and grooves; sparsely cratered. Basal parts of aureole of Olympus Mons. Interpretation: May be extensive pyroclastic deposits marked by ridges formed by eolian erosion along joints.

Aal **Pit member**—Characterized by crescent shaped pits; flatter part of lower aureole member of Olympus Mons Formation. Interpretation: Fracture eolian and perhaps pyroclastic material; pits may be eolian blowouts.

Aarc **Arcadia Formation**—Low lying plains material in Amazonis and Arcadia Planities west and north of Olympus Mons. Members distinguished on basis of morphology; members 2, 4, and 5 not mapped in this region.

Aa3 **Member 3**—Relatively flat, featureless surface; low lobate flow recognized in southern Amazonis Planitia; sparsely cratered; locally mantled. Interpretation: Lava flows interbedded with and locally overlain by eolian material.

Aa1 **Member 1**—Broad, rugged, incised lobate flows partly buried by mantle of smooth material. Interpretation: Relatively thick volcanic flows, possibly pyroclastic. Mantle probably eolian.

THARSIS ASSEMBLAGE
(Basis of Tharsis region, most interested to be volcanic)

Olympus Mons Formation—Consists of Olympus Mons caldera, plains, shield, aureole, and scarp members.

Caldera members 1-4—Floor materials of cooled collapse craters that make up composite summit caldera of Olympus Mons. Marked by grooves, pits, and volcanic ridges. Interpretation: Solidified lava flows associated with latest summit volcanism and magma-chamber collapse.

Plains member—Relatively smooth, lobate scarp and tongue-like flow features common in high resolution (<100 m/pixel) images. Overlays all adjacent units except perhaps some lower flank flows of Olympus Mons, sparsely cratered. Flows and narrow channels originate from fissures east of Olympus Mons between lat 14° and 17°N; circular rims and depressions occur along fissures. Flood eastern and southern periphery of Olympus Mons and smaller area on east edge of Achernon Fossae. Interpretation: Among youngest lava flows of Olympus Mons, extruded from fissures east of volcano.

Shield members—Series of four units exposed on shield of Olympus Mons. Equivalent to Olympus Mons shield materials Aom1, 2, 3, and Aom4 of Morris and others (1991).

Shield member 4—Lava flows, primitive, tongue-like flow having lobes and distinct margins and terminations; sparsely distributed over northwestern part of shield. Interpretation: Youngest lava flows on flanks of Olympus Mons.

Shield member 3—Lava flows, intermediate stage, hundreds of meters to several kilometers across and 10 to more than 100 km long. Relatively smooth radial ridges, as much as 10 m wide and 40 km long, occur in places. Sparsely cratered. Beginnings and terminations of most flows indistinct on flanks, but where flows have extended onto plains many flows terminate in lobate scarps. Flows form anastomosing networks and bury southwestern and northeastern parts of basal scarp. Interpretation: Lava flows of postcrater stage. Smooth ridges probably enclose lava tubes formed during prolonged eruptions, which served as discharge centers for many lower flank flows.

Shield member 2—Flows have rough hummocky surface and relatively low albedo (color enhancement, sheet 1). May be irregular with lobate channels. In broad sheets, are indistinct. Sparsely cratered. Member covers most of upper flank of shield. Interpretation: Lava flows whose dark color may be due to composition, weathering, or lack of eolian cover.

Shield member 1—Flows have indistinct boundaries or vague, tongue-like outlines. Surface rough to smooth, hummocky. Many irregular to round pit craters (<100 m to 1 km in diameter). Outflow and channels. Dark and light streaks and patches. Moderately cratered. Forms summit of Olympus Mons and some terraces nearby; cut by eolian vents. Interpretation: Oldest undisturbed lava flows on Olympus Mons. Dark and light streaks may be due to thin covering of eolian material.

Aureole members—Sequence of broad, overlapping lobes, corrugated sheets surrounding Olympus Mons. Origin controversial (see text).

Upper aureole member—Characterized by series of ridges and grooves that roughly parallel outflow channels. Individual ridge segments are 10 to 50 km long, estimated to be as much as 1 km high. Shows interesting patterns that differ in length and width over different parts of deposit. Ridge patterns interrupted by several sets of intersecting ridges or sinuous grooves, which may be grooves or crosscut valleys, and long, linear fractures with little displacement. Overlies middle aureole members a, b, and lower aureole member.

Middle aureole member a—Ridges more degraded and have different orientations than adjacent ones in upper aureole member. South half of unit partly buried by Medusae Fossae Formation, but terminus of deposit extends out to desert. North half of unit partly buried by upper aureole member, but terminus can be seen where upper member apparently has been eroded away. Overlies lower aureole member c, and partly buried by upper aureole member; embayed by plains member of formation.

Middle aureole member b—North of Olympus Mons; rests on middle member b; shows lower aureole member, whose ridges overlap and truncate ridges of member c.

Middle aureole member d—Overlies lower aureole member north of Olympus Mons, surrounded by flows of plains member.

Middle aureole member e—Overlies lower aureole member east of Olympus Mons; surrounded by flows of plains member.

Lower aureole member—Ridges and knobs generally smaller than those in overlying members; trends of some hills and knobs concentric with or perpendicular to outer edge of deposit. Where well exposed, ridges are closely spaced (30 to 40 ridges per 100 km). High resolution images of ridges show aerodynamic shapes similar in form to terrestrial sanddunes. Degradation most intense southwest of Olympus Mons. Most extensive aureole deposit; virtually surrounds Olympus Mons. Large areas buried under mantle of plains member south of Olympus Mons.

Scarp members—Form basal pedestal of Olympus Mons and covered by shield members; origin controversial (see text).

Western scarp member—Capped by bright, smooth material that is scarpal areas has been stripped off to reveal a layer with corrugated surface similar to that of aureole material but at much smaller scale. At top of scarp, material is exposed at several places dipping toward center of Olympus Mons. In places buried by shield member 3 or degraded as apron material.

Eastern scarp member—Consists of rugged blocks bounded by cliffs and ledges. Surface locally planar and cut by grabens. Mapped as fractured plains material (unit HHI) by Morris and others (1991).

Tharsis Montes Formation—Narrow to broad lobate flows, moderately cratered. Interpretation: Lava flows extruded from Aom4-Mom4 (Fig. 1) or local fissures.

Younger member—Flows southeast of Olympus Mons, cut by low grabens and faults. Overlies fractured plains material, embay lower aureole member, and is partly buried by Medusae Fossae Formation.

Older member—Flows southwest of Olympus Mons partly buried by Medusae Fossae Formation.

Ceratus Fossae Formation—Long, lobate flows with levees that extend southwesterly from highly fractured and faulted region of Ceratus Fossae (Fig. 1). Found only near east border of map area. Unit overlies lower member of Alba Patera Formation and is partly buried by plains member of Olympus Mons Formation in map area. Interpretation: Lava flows extruded from fissures of Ceratus Fossae.

HIGHLAND MATERIALS
(Materials that are older than most of Mars)

Fractured plains material—Forms smooth plains cut by closely spaced fractures and grabens trending mainly northwest-southwest; low flow fronts moderately well cratered. Occurs southeast of Olympus Mons, overlain by lower aureole and plains members of Olympus Mons Formation and Tharsis Montes Fossae. Interpretation: Forms older lava plains of Tharsis region.

Achernon Fossae assemblage—Materials of and encircled by arcuate, heavily fractured mountain chain north of Olympus Mons.

Plains unit—Smooth, rolling plains material marked by subdued crater rims and wide ridges, well cratered. Recognized within basin surrounded by Achernon Fossae. Overlies lower aureole and plains members of Olympus Mons Formation. Interpretation: Eolian or pyroclastic material may be in part extruded from volcanoes of mountain unit.

Mountain unit—Three types: (1) irregular small mesas and domes commonly with summit craters along northern and western margins of Achernon Fossae; (2) long, north-south-trending ridge with central rift in western Achernon Fossae; and (3) hills overlain by structurally complex terrain (for example, at lat 30°N, long 31°W). Later types overlies fractured unit of assemblage. Interpretation: Volcanoes formed during fracturing of Achernon Fossae or eroded remains of thick mantle.

Fractured unit—Blocky, mountainous, highly cratered material broken by low, narrow grabens commonly in parallel belts. Most craters superposed on fractures. Small channels cut crater walls, basins of ridges, and rough, hummocky areas. Forms annular mountain range more than 700 km long north of Olympus Mons that encloses basin covered by plains unit of assemblage; also embayed by lower aureole member of Olympus Mons Formation. Interpretation: Ancient volcanic rocks intensely deformed and fractured by local volcanotectonic activity.

Alba Patera Formation—Extensive flows in northeastern part of map area; upper member not present in map area. Interpretation: Lava flows from Alba Patera (Fig. 1).

Middle member—Found near northeast corner of map area as distal parts of a few narrow, elongate flows, commonly with lobate channels, that extend nearly 200 km from west flank of Alba Patera. Overlies lower member of formation; cut by low grabens of Alba Fossae (Fig. 1); moderate crater density.

Lower member—Extensive field of lobate flows; moderately cratered. Some flows extend nearly 1,000 km from Alba Patera. Cut by several grabens of Alba Fossae. Embay Halea Fossae and Achernon Fossae assemblages.

Halea Fossae assemblage—Materials of slightly elevated area cut by arcuate faults of Halea Fossae, northeast of Olympus Mons.

Plains unit—Relatively smooth, moderately cratered plains material. Tongue-like flows extend radially from center of Halea Fossae. Interpretation: Late stage lava flows of volcanic tectonic center.

Hilly unit—Low, cone-shaped hills a few kilometers across, some having annular pits. Interpretation: Volcanic cones or shields.

Fractured unit—Shield material cut by concentric grabens; moderate relief. Interpretation: Part of old, broad, deformed volcanic shield.

Crater materials—Craters having rims larger than 10 km in diameter are mapped and classified on the basis of their morphologic characteristics. More highly degraded craters are excluded or are either old or formed in more erodible material than less degraded craters. Crater materials are interpreted to have formed by impacts or secondary ray craters (not mapped) except at least one crater diameter from center of crater. Central peak conspicuous in low and bowl shaped in craters less than 30 km. Floor lower than adjacent terrain, rough in craters greater than 30 km and bowl shaped in craters less than 10 km. Conspicuous central peaks common.

Material of sharp-rimmed craters—Rims complete, raised, and clearly identifiable; hummocky ejecta or secondary ray craters (not mapped) extend at least one crater diameter from center of crater. Central peak conspicuous.

Material of rounded-rimmed craters—Rims complete, raised, and rough where diameter is greater than 30 km. Floor lower than adjacent terrain, rough in craters greater than 30 km and bowl shaped in craters less than 10 km. Conspicuous central peaks common.

Material of shallow craters—Rims similar to crater rims but generally have narrow, smooth walls. Floors smooth, flat, lower than adjacent terrain. Central peaks small or absent.

Material of highly degraded craters—Rims incomplete, largely lobate material. Floors like those of c₂ craters but about same elevation as adjacent terrain. Central peaks absent.

Crater—Dashed where approximately located.

Contour—Dotted where buried or inferred; bar and ball on mountain side. On narrow grabens, ball either centered between graben-bounding faults or on angle line representing closely spaced lava.

Fault on cross section (sheet 2)—Arrows show relative movement.

Thrust fault—Dotted where buried or inferred; southeast on upper plate.

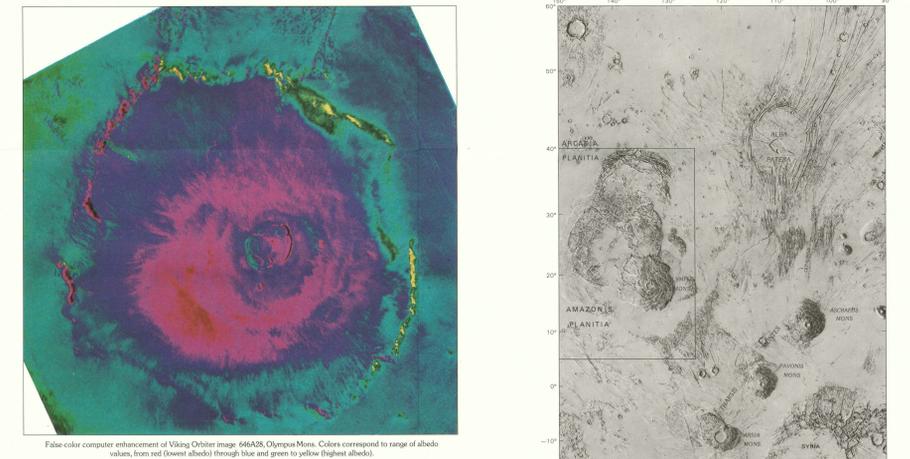

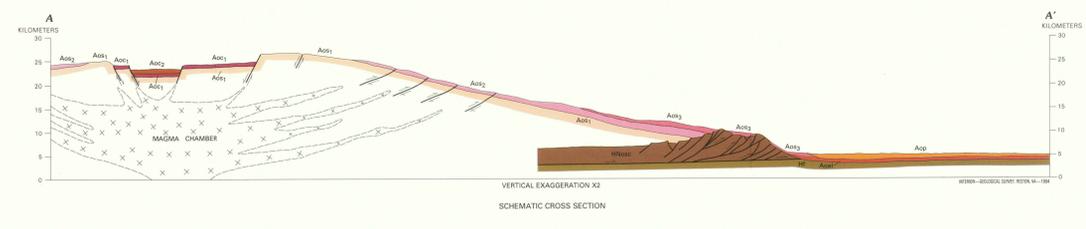

Scarp—Dashed where buried; line at top; bars show downslope.

Ridge—Line at crest.

Lava flow front—Hashes point away from flow.

Depression—Circle.

Intracater rim crest—Circle.

GEOLOGIC MAPS OF THE OLYMPUS MONS REGION OF MARS

By
Elliot C. Morris and Kenneth L. Tanaka
1994

Figure 1. Major features of Olympus Mons region; base from U.S. Geological Survey (1982). Box indicates approximate boundary of geologic map (sheet 1).
