Summary of hydrologic investigations by the United States Geological  
Survey at White Sands Missile Range, New Mexico

By

Leon V. Davis and Fred E. Busch

Introduction

The White Sands Missile Range (including the Range Extension) lies principally in the vast semiarid Tularosa Basin of south-central New Mexico but includes also the San Andres Mountains, along the western side of the missile range; the San Augustin Mountains, at the southwestern corner; the Sierra Oscura, in the north-central part; and the Los Pinos Mountains, in the northwestern part of the North Extension of the range.

The U.S. Geological Survey for many years has, at the request of the U.S. Army, made investigations to determine the availability and quality of water that might be utilized by military installations in and near the Missile Range. The studies involved geologic mapping, well inventory, drilling, testing by pumping of exploratory test wells, obtaining quality of water data, rendering technical assistance during the drilling and completion of supply wells, and monitoring water levels, chiefly in the Headquarters area. The results of the various studies are summarized in this report.

Explanatory text is at a minimum; maps, charts, and tables present the data in graphical form. The reader is referred to the list of references for the individual reports from which most of these data were taken. The summary was prepared at the request of the U.S. Army Post Engineer, White Sands Missile Range. The location of the Missile Range is shown in figure 1.

---

Figure 1 (caption on next page) belongs near here.

---

Figure 1.--Index map showing White Sands Missile Range. Large circled numbers indicate areas of separate sheets of figures 4 and 5; hachured areas are overlap between sheets. Small circled numbers refer to areas mentioned in text and listed at upper right of this map.

This summary report contains maps showing the areas of investigation; the outcrops of consolidated sedimentary and igneous rocks, and alluvium (bolson fill); contours on the water table in alluvium; water-level changes; quality of water data; areas where potable water<sup>1/</sup> is known to be or probably is present; areas where inferior water is known to be or probably is present, and areas where non-potable water probably is present. The general occurrence of water at the White Sands Missile Range and the hydrologic and geologic conditions at the Headquarters area, within the range, are shown on maps and cross sections. Records of wells and detailed chemical analyses of water are given in tables. Most electrical and other types of geophysical logs of many wells in the White Sands Missile Range and adjoining areas are on file at the U.S. Geological Survey, Geology Building, University of New Mexico, Albuquerque, N. Mex., and at Headquarters, White Sands Missile Range.

---

<sup>1/</sup> In this region, sulfate and chloride are the principal mineral constituents that render much of the water unfit for human consumption. Generally, if neither of these constituents is present in objectionable quantities, the water does not contain other dissolved minerals in objectionable quantities. In this report, the term "potable" describes water in which neither the sulfate nor the chloride is present in excess of 250 ppm (parts per million), as recommended in the U.S. Public Health Service standards. Water containing between 250 and 500 ppm of either sulfate or chloride and less than 750 ppm of the two together is called "inferior" or "near potable". Water containing more than 500 ppm of sulfate or chloride or more than 750 ppm of both is called "nonpotable". Water containing more than 1,000 ppm of dissolved water commonly is called "saline water."

### Well-numbering system

The system of numbering wells and springs used in this report is that used by the Geological Survey in New Mexico and is based on the common subdivisions in sectionized land. The number, in addition to designating the well or spring, locates its position to the nearest 10-acre tract in the land net. The number is divided by periods into four segments. The first segment denotes the township south or north of the New Mexico base line; the second denotes the range east or west of the New Mexico principal meridian; and the third denotes the section. Most of the area discussed in this report is south of the base line, and most of it is east of the principal meridian. The letter N has been placed after the first segment of the number if the well or spring is north of the base line.

The fourth segment of the number, which consists of three digits, denotes the particular 10-acre tract in which the well or spring is situated. For this purpose, the section is divided into four quarters, numbered 1, 2, 3, and 4, in the normal reading order, for the northwest, northeast, southwest, and southeast quarters, respectively. The first digit of the fourth segment gives the quarter section, which is a tract of 160 acres. The quarter section is divided into four 40-acre tracts numbered in the same manner, and the second digit denotes the 40-acre tract. Finally, the 40-acre tract is divided into four 10-acre tracts, and the third digit denotes the 10-acre tract. Thus, well 17.9.12.422 is in the  $NE\frac{1}{4}NE\frac{1}{4}SE\frac{1}{4}$  sec. 12, T. 17 S., R. 9 E., as shown in figure 2.

---

Figure 2 (caption on next page) belongs near here.

---

If a well or spring cannot be located accurately within a 160-acre tract, zeros are used for the appropriate digits of the final segment. If the well or spring cannot be located more closely than the section, the fourth segment of the well number is omitted. Letters a, b, c...are added to the last segment to designate the second, third, fourth, and succeeding wells or springs listed in the same 10-acre tract. An S in front of the number indicates a spring.

Some wells and test wells are listed by the White Sands Missile Range Post Engineer numbers as well as the numbers in the general well-numbering system.

Figure 2.--System of numbering wells and springs in New Mexico

(S in front of number indicates a spring).

## Definitions of terms used in the summary

Aquifer - A geologic formation, a part of a formation, or a group of formations that is water bearing.

Field coefficient of permeability - the number of gallons of water that can pass in 1 day through a 1-square-foot cross section of the aquifer at right angles to the direction of flow under hydraulic gradient of unity at the prevailing temperature.

Coefficient of transmissibility - the coefficient of transmissibility, in gallons per day, is equal to the field coefficient of permeability multiplied by the thickness of the saturated aquifer, in feet.

Coefficient of storage - the volume of water an aquifer releases or takes into storage per unit surface area of the aquifer per unit change in the component of head normal to that surface.

Specific yield - the ratio of the volume of water a saturated rock will yield by gravity to its own volume.

Specific capacity - yield in gallons per minute per foot of drawdown.

Abbreviations used in the summary

acre-ft = water discharge, or volume, in acre-ft

(the volume of water required to cover 1 acre to a depth of 1 foot).

Equal to 43,560 cubic feet, or 325,850 gallons.

gpm = gallons per minute

gpd = gallons per day

ppm = parts per million

T = coefficient of transmissibility

S = coefficient of storage

P = coefficient of permeability

t = time, in any specified unit

s = drawdown, in feet

Q = discharge, in gallons per minute

MP = measuring point

## General occurrence and quality of water

Supplies of potable ground water are relatively sparse at the White Sands Missile Range in south-central New Mexico. Potable water generally is confined to permeable zones in the fanslope debris along the flanks of the mountains that bound the Tularosa basin. The few streams containing potable water in White Sands Missile Range and adjoining areas are fully appropriated and other than the Rio Grande are restricted to the mountains along the east side of the basin.

Although supplies of potable water are sparse, abundant supplies of water of inferior or nonpotable quality are available in the lower fanslopes and in the basin proper (fig. 3).

---

Figure 3 (caption on next page) belongs near here.

---

Figure 3.--Diagrammatic section showing general occurrence of ground water along the flanks of the uplifts in Tularosa Basin.

Because of the wide range in climate from lowest to highest elevations and because rocks in the region differ greatly in hydraulic characteristics, the occurrence of both surface water and ground water vary greatly at different places.

The only economically important bodies of surface water near the Missile Range, aside from infrequent flood flows, are the Rio Grande and the perennial streams in the Sacramento Mountains and Sierra Blanca, which are Rio Tularosa northeast of the town of Tularosa, Rio Bonito, Eagle Creek, and the upper parts of the Three Rivers drainage system, in Three Rivers Canyon and Indian Creek. Malpais Spring, in the floor of Tularosa Basin, discharges about 1,500 gpm (gallons per minute) of saline water to Salt Creek. Lake Lucero, in the west central part of Tularosa Basin, is a large wet-weather lake. The water is highly saline.

The quantity and quality of ground water varies widely. The potential yield, or amount in storage, of water of different quality is given in table 1; the general water-bearing characteristics of the various water-bearing beds are given in table 2; well data are given in table 3; and quality-of-water data for wells are given in table 4; spring data are given in table 5; and quality-of-water data for springs are given in table 6.

Table 1.--Potential perennial yield or amount in storage of water of different quality in Tularosa Basin and adjoining areas.

Area	Potable water (potential perennial yield, in acre-feet per year, except where noted otherwise)	Inferior water (potential perennial yield, in acre-feet per year, except where noted otherwise)	Nonpotable water (acre-feet in storage)	Typical yield of wells Range (gpm)
Northern Jornada del Muerto	30	200	11,000,000	25-1,000
Rio Grande valley at Bosque del Apache	30,000	-	-	20-1,800
Northern Tularosa Basin	30	200	6,000,000	15- 225
Carrizozo area	-	20,000	1,500,000	
Three Rivers area	1,000	1,000	200,000	10- 225
Tularosa-Alamogordo	a/ 1,000	500	8,000,000	100-1,076
Area southeast of Valmont	1,000	1,000	1,000,000	---
Upper Sacramento River canyon	800	-	-	50- 100
Hueco Plateau	b/ 250,000	b/ 1,000,000	7,000,000	---
Southern Tularosa Basin-Hueco Bolson	15,000	5,000	65,000,000	25- 450
White Sands Missile Range Headquarters area	2,000	-	3,000,000	35- 800
West-central Tularosa Basin	30	60	50,000,000	25- 280
Southern Jornada del Muerto	b/ 1,500,000	b/ 6,000,000	3,000,000	25-1,000

a/ Temporary yield, for at least several years; quality likely to worsen if rate of withdrawal continues or is appreciably increased.

b/ Acre-feet in storage.

The largest supplies of potable ground water are in the Rio Grande valley in the vicinities of Bosque del Apache Wildlife Refuge and Las Cruces, and in the southwestern part of Tularosa Basin and the northwestern part of Hueco Bolson between White Sands Missile Range and El Paso, Texas. Potable ground water also underlies parts of southern Jornada del Muerto, relatively small areas at the sides of Tularosa Basin, and extremely small areas in the rest of the region.

Twelve large-capacity wells have been constructed west of the Rio Grande in the Bosque del Apache wildlife Refuge by the U.S. Fish and Wildlife Service; one reportedly was tested at 1,500 gpm and the other at more than 2,000 gpm. A test well to determine the availability of ground water on the east side of the river in the Bosque del Apache Wildlife Refuge as a source of supply for Stallion Range Camp yielded 150 gpm and had 37 feet of drawdown. This area is within the Rio Grande Underground Water Basin, closed by the State Engineer to additional appropriation of water except for domestic use. Under the regulations, additional large wells can be developed only if appropriations of surface water or ground water equalling in quantity the amount to be pumped from the new wells are retired from use.

A zone of potable ground water extends from the Headquarters area of White Sands Missile Range along the east side of the Organ and Franklin Mountains to the El Paso area. The Hueco Bolson probably has as much as 6.2 million acre-feet of potable ground water in storage in New Mexico and 7.4 million acre-feet in Texas. Proper well-field planning would permit recovery of at least half this amount before that remaining became critically contaminated by underlying highly-mineralized water. However, this area has not been adequately evaluated by drilling and testing. Pumpage in the El Paso area was about 69,000 acre-feet in 1962 (Marvin E. Davis, written communication, 1964).

Other occurrences of potable ground water, important because of location, are as follows: In the northern part of Jornada del Muerto, the Fite PW well in the SW $\frac{1}{4}$  sec. 4, T. 6 S., R. 2 E., the Hardin Ranch well in the NE $\frac{1}{4}$  sec. 27, T. 12 S., R. 2 E., and the Trail Canyon well in the SW $\frac{1}{4}$  sec. 36, T. 6 S., R. 5 E. yield small quantities. In the northern part of Tularosa Basin, the Baca well in the NE $\frac{1}{4}$  sec. 34, T. 6 S., R. 6 E. and the Mockingbird Gap well in the NW $\frac{1}{4}$  sec. 15, T. 9 S., R. 5 E. yield small quantities. In the west-central part of Tularosa Basin, the MAR wells in the SW $\frac{1}{4}$  sec. 17, T. 19 S., R. 5 E. yield potable water, and the Bairds Ranch well in the SE $\frac{1}{4}$  sec. 23, T. 17 S., R. 4 E. yields near-potable water.

The Murray well in the SE $\frac{1}{4}$  sec. 32, T. 8 S., R. 5 E., during a test, yielded 100 gpm of water that contained about 300 ppm sulfate and less than 700 ppm dissolved solids. The well is one of the few sources of usable water in that area.

Most recharge to the aquifers in and near the White Sands Missile Range is in the areas adjacent to the mountain masses and in the Rio Grande Valley. Precipitation that falls in the recharge areas is partly absorbed by porous fan materials and percolates downward to the water table. Part of the runoff in arroyos heading in the mountains also infiltrates and recharges the aquifers. In the Rio Grande Valley water infiltrates directly from the river and from irrigated fields.

Recharge in the region is small and most ground-water bodies have attained their present storage only through many hundreds, perhaps thousands, of years of accretion from recharge. Although recharge is expressed as a certain figure annually, there may be no recharge during some years.

The potable ground-water supplies can be recharged to some extent by artificial recharge through wells or ponds.

Additional ground-water supplies may be developed in untested areas in which hydrologic investigations indicate possible sources of potable water. Most of these areas will be along the flanks of the mountains bounding Tularosa Basin. It is possible that potable water will be found in the alluvial fans on the sides of the San Andres Mountains throughout its extent in the missile range. Figure 4 (in

---

Figure 4 (caption on next page) belongs near here.

---

pocket) shows well locations, probable quality of ground water, and possible occurrence of water in the White Sands Missile Range. Figure 5

---

Figure 5 (caption on next page) belongs near here.

---

(in pocket) shows locations of wells, outcrop of consolidated sedimentary rocks, igneous rocks, and contours on the water table in the Bolson fill. Test wells should be located in geologically favorable areas because of the inhomogeneity of the fan material. Alluvial fan sediments may be too poorly sorted to yield much water, even in areas geologically favorable for potable water.

Figure 4.--Map showing locations of wells; chemical quality of water, and areas of possible occurrence of potable, inferior, and non-potable water in the White Sands Missile Range and adjacent areas.

5.--Map showing location of wells, well data, extent of bolson fill, and contours on the water table in the bolson fill in the White Sands Missile Range and adjacent areas.

### Headquarters area

(References: Herrick, 1960, 1961; Hood, 1963)

The headquarters of White Sands Missile Range is principally in sec. 24, T. 22 S., R. 4 E., in eastern Dona Ana County, about 25 miles east of Las Cruces, N. Mex., and about 40 miles north of El Paso, Tex. The headquarters area lies within a reentrant in the mountains bordering Tularosa Basin on the west (figs. 4 and 5). The wells supplying water to the Missile Range headquarters are in sec. 13 and the northern part of sec. 24, T. 22 S., R. 4 E., at the mouth of the reentrant.

The configuration of the bedrock in the reentrant is presented on two maps (figs. 6 and 7), one showing the thickness of the bolson

---

.Figure 6 (caption on next page) belongs near here.

7 (caption on next page) belongs near here.

---

deposits, the other showing altitude of the bedrock surface above sea level.

Figure 6.--Approximate thickness, in feet, of the bolson deposits  
in the Headquarters area, White Sands Missile Range,  
based on earth resistivity data.

7.--Approximate altitude, in feet, of the bedrock surface in  
the Headquarters area, White Sands Missile Range, based  
on earth resistivity data.

The direction of slope and the gradient of the water table within the reentrant in 1954 and 1964 are shown by means of contour lines on figures 8 and 9. The contour lines indicate that within that part of

---

Figure 8 (caption on next page) belongs near here.

---

9 (caption on next page) belongs near here.

---

the reentrant between Antelope Hill and the central part of the Organ Mountains the ground water moves eastward through the bolson deposits. The depression contour in the east half of section 13 on the 1964 map shows that pumpage has reversed the water-table gradient in that area.

The depth to water within the reentrant in 1954, as shown in figure 10, ranged from a few feet near the mountains to about 400 feet

---

Figure 10 (caption on next page) belongs near here.

---

in the vicinity of test well T-1 (22.4.1.444). By 1964 the water level had declined below the bottom of T-1 at 412 feet below land surface and was about 410 feet below land surface at well 15 (22.4.13.424) in the Headquarters well field (fig. 11). The decline of the water

---

Figure 11 (caption on next page) belongs near here.

---

level from 1954 to 1964 is shown in figure 12. The decline of the

---

Figure 12 (caption on next page) belongs near here.

---

level in the Main Gate well for the period 1961-63 is shown in figure 13.

---

Figure 13 (caption on next page) belongs near here.

Figure 8.--Approximate configuration of the water table in the Headquarters area, 1954.

9.--Approximate configuration of the water table in the Headquarters area, January 1964.

10.--Approximate depth to water in feet below land surface in the Headquarters area, 1954.

11.--Approximate depth to water below land surface in the Headquarters area, January 1964.

12.--Map showing approximate water-level decline 1954-64 in Headquarters area well field.

13.--Hydrograph of observation well (Main Gate well) equipped with continuous water-stage recorder, White Sands Missile Range Headquarters area. Daily hydrograph for 1961-63.

The total volume of saturated materials underlying that part of the reentrant west of the access highway is about 4 million acre-feet. If an average porosity of 25 percent is assumed, the total quantity of ground water within the reentrant area is approximately 1 million acre-feet. A large part of this water is not available to wells, of course. The ground water in the bolson deposits east of the access highway is highly saline, and overpumping of wells could induce migration of the saline water toward the wells.

The section in figure 14 shows the general relation between land

---

Figure 14 (caption on next page) belongs near here.

---

surface, water table, and bedrock within the reentrant at the Headquarters area in 1963.

Logs of wells and construction data for wells in the Headquarters area are given in tables 7, 8, and 9.

27 of 48

Material	Thickness (feet)	Depth (feet)
Sand, fine to very coarse, and bit-cut fragments of larger rocks	10	125
Sand, fine to very coarse	15	140
Sand, fine to very coarse, and bit-cut fragments of larger rocks	10	150
Sand, fine to very coarse	5	155
Sand, fine to very coarse, and small bit-cut flakes of larger rocks	10	165
Sand, fine to very coarse	5	170
Sand, fine to very coarse and bit-cut fragments of larger rocks. Grain size mainly coarse	5	175
Sand, coarse, with small amounts of fine- to very coarse sand	15	190
Sand, mainly coarse, and bit-cut fragments of larger rocks	10	200
Sand, fine to very coarse, and bit-cut fragments of larger rocks	5	205
Sand, fine to very coarse, some small pebbles and bit-cut fragments of larger rocks	25	230
Sand, fine to very coarse, and bit-cut fragments of larger rocks	5	235
Sand, medium to coarse	5	240
Sand, very fine to coarse	35	275
Sand, very fine to coarse and some bit-cut fragments of larger rocks	5	280

Table 7.--Logs of wells in the Headquarters area - continued

Test well T-6 (22.4.14.133) - continued

28 of 48

Material	Thickness (feet)	Depth (feet)
Sand, very fine to very coarse	5	285
Sand, very fine to very coarse, and some bit-cut fragments of larger rocks	5	290
Sand, very fine to coarse	10	300
Sand, very fine to coarse, and some bit-cut fragments of larger rocks	5	305
Sand, very fine to coarse, bit-cut fragments of larger rocks, and small bits of steel from drill bit	5	310
Sand, fine to medium, and bits of steel	5	315
Sand, fine to medium, small pebble, and bits of steel	5	320
Sand, fine to coarse, and bits of steel	5	325
Sand, fine to coarse, and bit-cut fragments of larger rocks	10	335
Sand, fine to coarse, bit-cut fragments of larger rocks, and bits of steel	5	340
Sand, fine to coarse, bit-cut fragments of larger rocks, and a little brown clay	5	345
Sand, fine to coarse, and bits of steel	5	350
Sand, fine to coarse, bit-cut fragments of larger rocks, and bits of steel	10	360
Sand, fine to coarse, much bit-cut rock, and bits of steel	5	365
Sand, fine to coarse, bit-cut rock, and bits of steel	5	370
Sand, fine to coarse, much bit-cut rock, and bits of steel	10	380
Sand, mainly very coarse, and much bit-cut fragments of of larger rocks	35	415

Table 7.--Logs of wells in the Headquarters area - continued

Test well T-6 (22.4.14.133) - concluded

Material	29 of 48	
	Thickness (feet)	Depth (feet)
Sand, medium, and much bit-cut rock	5	420
Sand, mainly very coarse, and much bit-cut rock	25	445
Sand, mainly very coarse, and much bit-cut rock.		
Samples have a uniform dark gray-brown color. Many		
large bit-cut chips from 490 to 500 feet	55	500
Igneous rock, mainly bit-cut chips of brown, fine;		
many chips have distinct conchoidal fracture	15	515
	Total depth	

Note: During course of drilling it was observed that much very fine sand and apparently some clay was carried away in the drilling mud. Almost all sand grains are angular to subangular because the parent rock is nearby. Grain sizes from 325 to 372 probably were reduced from original size by slow grinding from a worn and broken bit. Rock chips, noted as "bit-cut" are the result of the reduction of boulders and other large particles in the fan debris; these larger particles increased in number with depth to the vicinity of the bedrock top at about 490 feet, thus the increase in the amount of bit-cut material. A part of the erosional debris apparently was partly cemented, as shown by the relatively clean hole prior to setting casing.

## Recharge

The source of all the ground water in the Headquarters area is precipitation within the reentrant and in the nearby mountains, an area of about 40 square miles. The average annual precipitation in the entire area of the reentrant west of the access highway probably is about 15 inches. According to Herrick (1960) the average annual natural recharge to the bolson deposits within the Headquarters reentrant probably is in the order of 2,000 acre-feet.

## Discharge

Within the Headquarters area the only appreciable discharge of ground water from the bolson deposits is by transpiration and, artificially, by pumping. Most of the ground water is discharged outside the area.

The total amount of ground water pumped in the Headquarters area in 1954 was about 300 million gallons, or about 1,000 acre-feet, equal to approximately 50 percent of the estimated average recharge of 2,000 acre-feet. However, water levels in the area are declining and will continue to decline (see figs. 10, 11, and 12). The pumpage from the Headquarters well field is shown by the graph on figure 15.

---

Figure 15 (caption on next page) belongs near here.

---

Figure 15.--Pumpage in the Headquarters area well field, million  
of gallons, 1953-63.

## Quality of water

All the wells supplying water to the housing and cantonment areas of the Headquarters area produce water of exceptionally good chemical quality. (See table 4 and figure 3.) The wells within the reentrant produce water containing an average concentration of about 240 ppm of dissolved solids. Although the deeper water obtained from wells 14 and 15 during drilling contained more dissolved solids than the shallow water, the deeper water is of a chemical quality well within potable limits.

Eastward from the cantonment area the ground water contains increasing amounts of dissolved solids, the deeper water having the higher concentrations. In June 1953 shallow water from test well T-4, 2 miles east of the access highway, contained only 329 ppm of dissolved solids, but a water sample obtained from a depth between 956 and 1,003 feet in the same well contained 7,480 ppm of dissolved solids, mostly sodium chloride. The electric log of test well T-4 indicates that the ground water at that site is saline below a depth of approximately 760 feet. The shallow water farther east in the central part of Tularosa Basin is highly saline, unfit for watering stock, and probably similar in quality to water from the Gregg site wells.

East of the headquarters area the fresh water mixes with saline water moving to the south and southwest through the main part of Tularosa Basin. Immediately east of the reentrant the fresh water apparently overrides the saline water (fig. 14).

The data indicate that south and north of the Headquarters area fresh water probably is confined to a relatively narrow belt close to the base of the mountains.

## Possibilities of encroachment of saline water

The bolson deposits in the vicinity of the wells consist of clay, silt, sand, and some gravel. In general, the deposits in that part of the re-entrant are fairly well stratified. The vertical movement of ground water within the zone of saturation is considerably more restricted than lateral movement. The interface between fresh and saline ground water is sharply defined in the places where data were obtained, indicating that vertical mixing is slight under natural conditions.

Saline ground water may not extend beneath the wells north of the cantonment area. Saline water has not been sampled from wells west of the access highway, but samples of water from wells 15 and 16 should be analyzed chemically at about 6-month intervals as a precautionary measure. Even if saline water should eventually reach the wells, it would be in small quantities compared to the amount of fresh water with which it would be diluted during pumping. The dissolved solids content of the water presently produced by the wells is so low that considerable saline contamination could be tolerated without the water becoming nonpotable.

A few miles east of the reentrant, near T-4, where the shallow ground water is reported to be highly saline, the water table is about the same level as the present lowest nonpumping water levels in wells in the eastern part of the well field (fig. 9). It is apparent from figure 9 that a low mound of water is present between T-4 and the well field and that the pumping levels in the well field must be lowered further before saline water will move toward the well field. Such movement would be slow, probably less than a few hundred feet per year. Water quality in test wells basinward of the pumped area is monitored by periodic sampling; precise rate of water movement is one of the objectives of the well field evaluation study now under way.

## Transmissibility of bolson deposits

The coefficient of transmissibility of the bolson deposits has been computed from data obtained from several pumping tests. Analysis of a pumping test of well 9 in the old well field indicated a coefficient of transmissibility of only 800 gpd per foot. This test was of short duration, and it was not possible to make other tests in that area. Examination of pump-test data and available drillers' logs of wells in that area indicates that the average transmissibility of the bolson deposits is much lower in the old well field than it is in the present well field north of the cantonment area. Coefficients of transmissibility obtained from pumping tests made in the present well field ranged from 2,500 at well 11 to 60,000 gpd per foot at well 10. The computed average coefficient of transmissibility in the vicinity of wells in the present well field is about 15,000 gpd per foot, although the average throughout the reentrant may be less than that.

## Effects of pumping

Declines of water levels have been as much as 89 feet from 1954 to 1964 (fig. 12). If pumping is distributed uniformly among the wells declines of the water levels will be spread throughout the well field and the danger of an excessive decline at any one well will be reduced to a minimum. An accurate record of water-level fluctuations in all the wells should be maintained and measurements should be made at least once every 2 months. This information is needed to accurately evaluate the effects of pumping and thereby plan most efficient use of the ground-water resources.

## Small Missile Range area

(Reference: Hood, 1963)

The principal work area in the Small Missile Range is sec. 15, T. 21 S., R. 5 E. The potable water supply for the area in 1961 came from a shallow well (21.5.11.411) that had been yielding water since 1952. The original yield of the well was 15 gpm. However, by 1961, the yield was only 10 gpm and was inadequate for the needs of the area. Attempts to rehabilitate the well were unsuccessful.

Well 21.5.15.411 is shallow and the water from it is potable. Reportedly the aquifer is fine sand. However, a deep well at this location probably would yield water inferior to that from the shallow zone. Investigations were made upslope towards the mountains to the west in sections 16 and 17, where the probability of obtaining potable water from coarse sand and gravel is greater. (See figs. 3 and 4.)

The locations for test drilling were about a mile east of a fault scarp that extends northeastward through the NE cor. sec. 21, T. 21 S., R. 5 E. West of the fault a pediment slope extends into a reentrant in the mountain front through which arroyos carry runoff to the flats. The pediment is cut on granite and is covered by only a few feet of overburden. East of the fault, which has a vertical displacement of more than 1,000 feet, the bolson fill is thick. Two wells, SMR 1 (21.5.17.244) and SMR 2 (21.5.17.424) were drilled. SMR 1 was completed as a production well. The well yields 75 to 100 gpm. However, this is not the maximum capacity of the well.

Drilling of well SMR-1 began June 3 and was completed June 25, 1960. The first water was found at 285-90 feet. The hole was drilled to 600 feet but was cased with 6-inch casing only to 473 feet below land surface. A total of one hundred twenty-eight feet of the casing was slotted opposite selected zones. The slots were cut approximately one-eighth inch wide and 4 inches long, staggered in rows, 12 slots per foot.

Well SMR-1 was equipped as a production well with a submersible pump in the Spring of 1962. Yield of the well ranges from 75 to 90 gpm.

Drilling of well SMR-2 began at the end of June 1960, and was finished at the end of September. The first water was found at 305 feet below land surface. Total depth was 765 feet.

The well was cased with 8-inch casing to about 608 feet below land surface and 6-inch casing from 598 to 747 feet. These casings were perforated from 295 to 588 feet, and from 608 to 715 feet.

The annular space between the 8-inch casing and the wall of the hole was filled with gravel by pouring the gravel into the space at the surface and then bailing the well to settle the gravel. The well initially required about 9 cubic yards of gravel.

The saturated bolson fill at the test sites is more than 450 feet thick. The top of the saturated zone is about 3,890 feet above mean sea level at test well SMR-1 and about 3,894 feet at SMR-2. The source of water in the Small Missile Range area is west of the well sites. Ground water moves east-southeastward from the well sites toward the flats of the Tularosa Basin and then moves southward. Recharge to the Small Missile Range area comes partly from absorption of precipitation and subsequent underground transmission from the reentrant above the test well area, and partly from absorption of precipitation and arroyo flow in the vicinity of the test wells.

The quantity of recharge can be estimated from the slope of the water surface, the coefficient of transmissibility of the bolson fill, and the width of the area concerned. The water levels in the area had not been disturbed prior to test drilling so the flow of water through the area should represent the amount of water entering the aquifer. The slope from SMR-1 to the production well at the Small Missile Range work area is 51 feet in 1.29 miles, or about 40 feet per mile. The coefficient of transmissibility was about 20,000 gpd per foot, as determined by the aquifer test at SMR-2. For a mile width of the aquifer the rate of flow =  $20,000 \times 40 = 800,000$  gallons per day per mile, or about 900 acre-feet per year per mile.

The coefficient of transmissibility at test well SMR-1 is about 7,900 gpd per foot for a saturated section approximately 200 feet thick. The coefficient of transmissibility at test well SMR-2 is about 20,000 gpd per foot for a saturated section about 450 feet thick. These figures are approximately comparable when related to thicknesses. The specific capacity for SMR-2 after pumping about 12 hours at 116 to 180 gpm was nearly 12 gpm per foot of drawdown. The specific capacity for SMR-1 was computed to be about 5.9 gpm per foot.

Well logs of SMR-1 and 2 are given in table 10.

Table 10.--Log of wells in the Small Missile Range.

Production well SMR-1 (21.5.17.244) - (formerly Test well SMR-1)

Material	Thickness (feet)	Depth (feet)
Soil, full of sand and gravel. Fragments are angular	5	5
Gravel, pebbles, and some very coarse sand	5	10
Sand, fine- to very coarse-grained, and gravel	5	15
Sand, coarse- to very coarse-grained, gravel and small pebbles	5	20

Clay, sandy brown, and very coarse-grained sand	5	760
Sandstone, well-cemented, arkosic. Driller called this bedrock because of the hardness of the rock and the slowness of drilling	5	765

The water obtained from wells SMR-1 and SMR-2 is very hard, but the concentration of dissolved solids is about 500 ppm and individual constituents are low in concentration.

## Hazardous Test Area

(Reference: Hood, 1963)

In July 1960, the Geological Survey was requested to investigate the possibility of obtaining 10 to 15 gpm of water in the northern part of the Hazardous Test Area. The water was intended to supply domestic needs for a planned small installation in the NW $\frac{1}{4}$ SW $\frac{1}{4}$ NW $\frac{1}{4}$  sec. 24, T. 21 S., R. 4 E. Only the area north and northwest of the point of use was studied, because of its favorable topographic position..

During July and August 1960, brief reconnaissance in the Hazardous Test Area revealed only two wells that might supply the required amount of water. Other wells and the springs in the area were inoperative, dry, or yielded less than the required amount of water. Several old mine shafts in the area which might supply the required amount of water were not investigated because the water from mines generally is polluted.

## Ground water in the area

The few control points indicate that the overburden in the area does not contain water. Water in wells and other excavations is from igneous rock. The water table in the Hazardous Test Area slopes steeply southeastward in the same direction as the land surface. Although the depth to water is not uniform throughout the area, no well has a water level greater than about 120 feet below land surface. Most, if not all, of the water is stored in the near-surface zones of shattered and weathered rock. The amount of water stored in the area probably is small, because the granite contains water only in joints and other fractures. The overburden and the fractures in the granite have a large intake capacity, and water, when available, enters the system readily. Maximum yield of wells probably would not exceed 25 gpm. The yields of heavily-pumped wells in the Hazardous Test Area probably would diminish substantially during drought, a time when water generally is most needed, because the storage capacity of the aquifer is low and the recharge is irregular.

## Wells investigated

Construction data were collected and performance tests made on wells 21.-.11.311 and 21.4.22.222. Both wells are used from time to time to supply water for wildlife in the area; both wells are equipped with windmills. Supplementary data from Alamo Springs (S21.5.7.431), obtained during a visit prior to the Hazardous Test Area study, also was used in evaluating the water resources of the area.

Well 21.4.11.311, on the east side of the Drop Test Tower site, was equipped both with a windmill and a gasoline engine. The well had 6-inch casing and was 198 feet deep. Depths to water in the well were as follows:

Date	Depths to water below land surface (feet)
2-12-53	110.9
7-12-60	70.6
7-14-60	70.7

The well was tested July 14, 1960 by pumping approximately 3 hours, at the end of which time the water level had declined to the bottom of the pump intake. Pumping for 3 hours at 3 gpm produced 68 feet of drawdown or about 0.04 gpm per foot of drawdown. The well was not considered further because the yield was inadequate for the intended purpose.

Well 21.4.22.222 is west of the test houses in the Nike Warhead Test Area and near the north end of Mineral Hill. In August 1961, the well was equipped only with a windmill. The well contained about 10 feet of 8-inch surface casing; below the pipe to a depth of 80 feet the granite in the wall of the well was stable and required no support.

The well was test pumped at a rate of 3 gpm for  $5\frac{1}{2}$  hours August 5, 1960, and the drawdown was 2.4 feet (fig. 16). The results of the test indicated

---

Figure 16 (caption on next page) belongs near here.

---

that the well might meet the requirements of 10-15 gpm, and further work was planned. In addition to a longer, better-controlled pumping test, it was proposed that the well be deepened, because more of the fracture system in the granite might be penetrated and the yield of the well increased.

Prior to deepening, the well was tested by bailing at a rate of about 32 gpm and measuring the rate of recovery. Figure 17 shows

---

Figure 17 (caption on next page) belongs near here.

---

recovery measurements after the bailing test. The residual drawdown was 0.45 foot 20 minutes after the very short period of bailing.

The deepening of well 21.4.22.222 began October 8, 1960, and ended October 12. The log of the well (table 11) indicated the rock penetrated was granite from 80 to 125 feet and a dark, fine-grained, igneous rock from 125 to 130 feet. The deepening of the well caused no change in the water level in the well.

Figure 16.--Preformance test of well 21.4.22.222, Hazardous Test

Area, White Sands Missile Range, N. Mex., Aug. 5, 1960.

17.--Recovery of water level after bailing well 21.4.22.222,

Hazardous Test Area, White Sands Missile Range, N. Mex.,

Oct. 6, 1960.

Table 11.--Log of well 21.4.22.222, Hazardous Test Area

(Stock well deepened from 80 to 130 feet, October 1960)

Material	Thickness (feet)	Depth (feet)	Drilling time (minutes)
Bottom of existing well	-	80	-
"Granite", mainly quartz and feldspar with a low percentage of ferromagnesian minerals	10	90	210
"Granite", as above. Drill cuttings finer	5	95	95
"Granite", quartz and feldspar, with increased ferromagnesian mineral content. Cuttings coarser	15	110	300
"Granite", as from 95 to 110 feet. Cuttings very fine- grained	5	115	120
"Granite", as from 110 to 115	10	125	110
Igneous rock, dark gray. Texture very fine-grained but rock is holocrystalline. Approximately 50% ferromagnesian minerals	5	130	50

The well was test pumped for 12 hours October 13, 1960.

Measurements during the test are shown in figure 18. The depths to

---

Figure 18 (caption on next page) belongs near here.

---

water shown in the figure have been corrected so as to be comparable with depths to water shown in figures 16 and 17.

Data in figure 18 show that well 21.4.22.222 can produce approximately 10 gpm for periods of at least 12 hours, or about 7,200 gallons, without a large drawdown. The well, however, cannot yield much more than 10 gpm without large drawdown and probable temporary exhaustion of the supply after a few hours of pumping. Twelve hours pumping at an average rate of about 12 gpm produced a drawdown of 12.2 feet, a specific capacity of 0.9 gpm per foot of drawdown. This figure for specific capacity is comparable with that obtained from the test on August 5, 1960 and shows that deepening the well did not increase the productive capacity of the well.

Figure 18.--Water levels during drawdown and recovery and rate of discharge during performance test of well 21.4.22.222, Hazardous Test Area, White Sands Missile Range, N. Mex., Oct. 13-14, 1960.

The residual drawdown, approximately 17 hours after pumping stopped, was about 1.6 feet, a significant part of the total drawdown. The residual drawdown still was relatively large several days after the test. The storage area contributing water to the well is limited, and continuous day-to-day pumping of well 21.4.22.222 might seriously deplete the water in storage during dry periods.

### Chemical quality of water

Two samples of water were obtained from well 21.4.22.222, one sample before and one after deepening the well. The analyses of water from well 21.4.22.222 show that deepening the well did not change significantly the chemical character of the water. The water is chemically suitable for drinking but contains about 5 ppm fluoride and about 20 ppm nitrate. The water should not be consumed by persons whose teeth still are developing. The waters probably should be examined for bacteriological purity because the nitrate content is so high.

## Gregg site

(Reference: Hood, 1963)

The Gregg site optical laboratory is in the NW $\frac{1}{4}$ SE $\frac{1}{4}$  sec. 8,  
T. 22 S., R. 6E.

Two wells were drilled at Gregg site, a test well and later a production well. The test well was drilled during August 9-12, 1961, to a depth of 1,010 feet. The well log is given in table 12. A water sample was obtained through the drill stem from the interval 281-300 feet. The test well was cased with 8-inch casing to a depth of 500 feet and performance tested. The specific capacity was about 11.5 gpm per foot of drawdown and the pumping rate was about 175 gpm. A water sample was collected at the end of the pumping period.

A production well was drilled about 4 feet south of the test well and was completed to a depth of 478 feet. The hole was 27-3/4 inches in diameter and was cased with 14-inch casing perforated in the same zones as used in the test well. The annular space between the casing and the wall of the hole was gravel-packed.

Table 12.--Log of Gregg test well (22.6.8.414)

Materials	Thickness (feet)	Depth (feet)
Samples missing	130	130
Sand, tan, silty, very fine to coarse, and some caliche	10	140
Sand, tan, silty, very fine	10	150

Clay, red, compact, with greenish reduction spots. Some clays are almost dry in appearance	60	1,010
		Total depth

The static water level in the Gregg test well was about 213 feet below land surface. The water-surface altitude was 3,807 feet. The water surface at Gregg Site is lower than at test well T-5 (22.5.20.111), altitude 3,880 feet, and test well T-4 (22.5.16.111), altitude 3,828 feet, which are to the west between the Headquarters area and Gregg Site. The difference between the altitude of the water at Gregg Site and at test wells T-4 and T-5 establishes a continuous slope of the water table from the Headquarters well field to the main part of the Tularosa Basin near Gregg Site. No reliable data are available east of Gregg Site, but the water table in the vicinity of Gregg Site probably is the lowest in the basin at the latitude of the White Sands Headquarters.

A performance test was made on the production well at Gregg Site October 30 from 9:50 a.m. to 8:50 p.m. The results of the several measurements are shown in figures 19, 20, and 21.

Figure 19.--Drawdown and residual drawdown in Gregg well (22.6.8.414), White Sands Missile Range, N. Mex., during performance test on Oct. 30, 1961.

20.--Rate of discharge and sand content of water pumped from Gregg well (22.6.8.414), White Sands Missile Range, N. Mex., during performance test on Oct. 30, 1961.

21.--Coefficient of transmissibility of the bolson fill in the vicinity of Gregg well, White Sands Missile Range, N. Mex. using residual drawdown after pumping test on Oct. 30, 1961.

The specific capacity of the production well was 12.4 gpm per foot at the end of the pumping period, while the well was being pumped at a rate of about 740 gpm. The coefficient of transmissibility (fig. 21) is 19,600 gpd (gallons per day) per foot. These data indicate that the well can sustain pumping rates of several hundred gallons per minute for prolonged periods of time. The figure for transmissibility shows that the formation can transmit large amounts of water to the well when the water level is lowered by pumping. At a pumping rate of 600 gpm, the well could be pumped for prolonged periods with a pump setting of about 300 feet.

The well produced sand throughout the performance test. The amount produced was generally less than 5 ml per liter. Even in these quantities, however, it would be best to pump the well to waste for a short period each time the pump is started, to avoid filling the storage reservoir or plugging the distribution system.

Ground water from the Gregg Site area is unsuitable for most uses. The analyses of samples of water from the test well and the production well show that water as shallow as 300 feet, or about 90 feet below the water table, contains about 8,900 ppm of dissolved solids and that water from below 500 feet contains about 15,000 ppm of dissolved solids.

Rhodes Canyon Range Camp (pole 1788) area

(Reference: Hood, 1963)

Ground water at Rhodes Canyon Range Camp (pole 1788) is nonpotable.

The water in the fill for several miles east and south of the camp probably is saline, as evidenced by the saline residue in the low areas. Potable water probably is present to the west and northwest of the camp.

A well about 4 miles south of the camp and shown on the Black Top Mountain topographic map as the G Henderson well (14.5.8.321), yields water containing about 6,000 ppm of dissolved solids of which about 2,400 ppm is chloride. The depth to water is reported to be 54 feet below land surface.

The McDonald South well (13.5.29.341) has a reported water level of 100 feet below land surface. Soldiers from Rhodes Canyon Camp reportedly used water from the well before potable water was trucked to the camp. The inferred potable water at well 13.5.29.341 and the runoff from the mountains indicate the large composite fans reaching from Rhodes Canyon northward to the base of Salinas Peak may contain coarse-grained debris that will yield an appreciable quantity of potable water.

## Rhodes Canyon Wells

Two test wells (RC-1, 12.5.31.433 and RC-2, 12.5.28.432) were drilled in the Rhodes Canyon-Salinas Peak area in 1964. Well 12.5.28.432 was drilled with a rotary drill to a depth of 358 feet and a water sample collected. The water was saline and the well was abandoned. Well 12.5.31.433 was drilled by cable tool to a depth of 942 feet. A seep of water was obtained when the well was about 530 feet deep and the water rose to about 484 feet below land surface. Although the water obtained was potable, the well would yield only about 2 gallons per minute or less, and the yield did not increase as the well was deepened.

The test wells in the Rhodes Canyon-Salinas area did not obtain an adequate supply of water. However, the water obtained from well 12.5.31.433 was potable and a well drilled farther up the fan slope might obtain a larger yield.

## Salinas Peak area

(Reference: Hood, 1963)

Data relating directly to the occurrence of ground water in the Salinas Peak area was obtained for 11 wells and 2 springs. All these sources are on the backslope of the mountains. Water sources on the east face of the mountains were not visited because they are relatively inaccessible.

The potential yield of the formations to wells cannot be estimated accurately. The only wells in the area are stock wells that are pumped at rates of only 1 to 5 gpm.

The only potable ground water sampled in the Salinas Peak area was that from Grapevine Spring (SL2.4.2.141). Wells and springs elsewhere in the area yield water containing from 1,500 to more than 2,000 ppm of dissolved solids, of which the sulfate content amounts to 500 ppm or more. All the water is very hard and the overall chemical quality of water deteriorates from the crest of the mountain to the northwest, toward the Jornada del Muerto.

The ground water sampled, with the exception of that from Grapevine Spring, is not suitable for human consumption, owing to the sulfate content of the water.

Water suitable for use by military personnel probably is not present in the Salinas Peak area in quantities adequate for the needs of Salinas Peak Site and Salinas Camp.

## Exploration for ground-water supplies

The immediate area of Salinas Camp ( $NW\frac{1}{4}SE\frac{1}{4}SE\frac{1}{4}$  sec. 36, T. 11 S., R. 4 E. does not seem promising; however, a test well there would determine the aquifer possibilities, and if water were obtained, the supply would be at the point of use. A test well 500 feet deep probably would be adequate.

One test well farther down Grapevine Canyon in the  $SW\frac{1}{4}NE\frac{1}{4}SW\frac{1}{4}$  sec. 35, T. 11 S., R. 4 E. would determine aquifer possibilities in the general area. The site is on the access road at its intersection with the side canyon that contains Grapevine Spring, offers adequate room off the road for drilling, and is on or adjacent to one of the major transverse faults that cross the mountain range. A test well of 500 feet probably would be adequate.

### Mockingbird Gap area

(References: Herrick and others, 1960; Weir, 1964)

The Mockingbird Gap well (9.5.15.143), derives potable water containing less than 100 ppm of sulfate from a fracture zone in the Bursum Formation and yields approximately 30 gpm with a drawdown of 5 to 9 feet in about 8-hours time. The water level continues to decline if the well is pumped continuously during the periods of no rainfall, and the pumping water level is lowered to the pump intake, about 135 feet below the land surface. The nonpumping water level in the Mockingbird Gap well has been as high as 25 feet below the land surface after heavy rains in the area, and reportedly this well occasionally has flowed. When the water level is 25 feet or less below the land surface, about 3 million gallons (about 9 acre-feet) of water can be pumped from storage above the level of the pump setting.

The water level in Mockingbird Gap well rises within a few days after water flows in the arroyo near the well. The fracture-aquifer is recharged in the immediate vicinity of the well, probably in an area less than 100 yards upstream. Longer periods of storm flow in the arroyo cause far more effective recharge to the aquifer than do brief freshets. Impounding runoff with check dams along the arroyo upstream from Mockingbird Gap well would increase the amount of recharge from rainwater that normally runs off quickly.

In the area around Mockingbird Gap Hills and Oscura Gap, ground water in usable quantity and quality has been obtained from only one source; the Murray well (8.5.32.431). Several holes have been drilled between Mockingbird Gap Hills and the northern end of the San Andres Mountains, including one dry 400-foot test hole drilled 0.5 mile south of George MacDonald's Murray well. The Murray well is completed in a fault zone. Pumping tests of the well indicate a specific capacity of about 5 gpm per foot of drawdown at a pumping rate of 100 gpm. The static water level in the Murray well is 192 feet below land surface. Water from the well contains 298 ppm of sulfate and 684 ppm of dissolved solids.

Water from the Murray well has been used to supply water for domestic use to areas in the northern and central range since 1956. The Murray well obtains water from a small reservoir in consolidated rocks. The reservoir can be depleted quickly by pumping.

## Malpais area

(References: Herrick and others, 1960; Weir, 1964)

The alluvium is the principal aquifer in the Malpais area. The Yeso Formation of Permian age also might yield water to deep wells in the central basin, but no wells are known to penetrate the Yeso there.

Water of reasonably good chemical quality is known to occur in only a very few, relatively small localities within the northern part of the Malpais area. Most of these are along the east side of the area. In a small area north and east of the village of Oscura relatively shallow wells yield as much as 50 gpm of water containing less than 300 ppm of sulfate. Deep wells in the Carrizozo area reportedly yield as much as 50 gpm of water similar in chemical quality to water from wells at Oscura. Aquifers containing saline water in the central part of the Malpais basin are capable of yielding 500 to 1,000 gpm or more.

Malpais Spring (12.7.8.422), at the south end of the malpais, has a low flow of more than 1,000 gpm of water containing, according to one analysis, 5,100 ppm of dissolved solids, including 1,910 ppm of sulfate and 1,200 ppm of chloride. A well at Oscura Range Camp will yield 500 gpm of water containing about 4,000 ppm of dissolved solids, including 1,900 ppm of sulfate and 640 ppm of chloride. Most of the stock-watering wells in the basin yield less than 10 gpm.

## Chupadera Mesa-Transmalpais Hills area

(References: Herrick and others, 1960; Weir, 1964)

The Transmalpais Hills, an outlier of Chupadera Mesa, lie adjacent to and west of the malpais, and are geologically and hydrologically similar to Chupadera Mesa. Here the San Andres is dry and water occurs in the Yeso Formation at depths of 200 to about 700 feet, depending on the topography. All water analyzed from the Yeso Formation in this area contained 3,000 ppm or more of dissolved solids, including 2,000 ppm or more of sulfate. A 700-foot well near Red Canyon Range Camp yields 100 gpm per foot of drawdown from solution channels in the Yeso Formation. Most of the wells in the area supply water for livestock and yield less than 20 gpm; however, near the north end of the Transmalpais Hills, one irrigation well (5.9.25.333) approximately 90 feet deep yields enough water for irrigating about 100 acres of forage crops. The well reportedly yielded 2,000 gpm originally, but soon after it was put into use the yield declined to about 300 gpm.

Steven Tank well (7.8.29.144) on Chupadera Mesa yields water of fair quality (678 ppm of sulfate). No data are available as to the capacity of the well, but it probably will yield about 10 gpm.

## Sierra Oscura backslope area

(References: Herrick and others, 1960; Weir, 1964)

The backslope of Sierra Oscura is here considered to include the area from the crest of the range eastward to Red Canyon.

Almost all the ground water in the rocks of Pennsylvanian age occurs in fractures in the limestone and appears in springs, shallow wells, and collection galleries on the backslope. These sources yield only very small quantities of water, but the water is potable.

Known sources of water from rocks of Permian age in the Sierra backslope area yield small quantities of water that is generally poor in quality. The Bursum Formation, the oldest Permian formation in the area, yields potable water at two localities, Brush Tank Canyon and near R. C. Withers Tank in sec. 18, T. 7 S., R. 7 E. A well at each of these places yields less than 5 gpm of potable water; however, an upper water-bearing zone in the Brush Tank Canyon area yields 7 to 15 gpm. Analyses of water from two wells indicate the water in this upper zone contains more than 100 ppm of nitrate, but is otherwise of good quality. The single well near R. C. Withers Tank reportedly is very weak, but the water from the well is of good quality, containing only 205 ppm of sulfate. The yield of this well might be increased by treatment with acid

Red Canyon Spring (S7.7.15.421) yields about 3 gpm of water containing 1,880 ppm of sulfate. The spring water issues from cracks in the Abo Sandstone of Permian age.

Atlas Project area, Holloman Air Force Base

(References: Hood, 1960; Rapp, 1957)

Test drilling for process water for the Atlas Project at Holloman Air Force Base consisted of drilling, developing, and test pumping three test wells: T-1, T-2, and T-4. The work extended over a period of about 4 months; drilling of test well T-1 began on April 19, and the final measurements of the water level in test well T-4 were made on August 24, 1956. The logs of the wells are given in table 13.

### Atlas test well T-1

Drilling of test well T-1 (16.8.13.400) at the planned site of the Atlas Project commenced on April 19, 1956 and was completed on May 6, 1956.

The water from Atlas test well T-1 is very saline, containing about 1,800 ppm dissolved solids.

As the final yield of test well T-1 was only 50 gpm, which was below the minimum requirement of 75 gpm, the casing was removed and the well was plugged and abandoned. On the basis of this performance of test well T-1 and of several wells in the vicinity, 50 gpm is generally about the maximum yield that can be expected from wells in the area from test well T-1 westward to the eastern margin of the White Sands dunes area.

### Atlas test well T-2

After test well T-1 had been abandoned test well T-2 (16.9.4.441) was drilled. Several rather distinct beds of sand and gravel were penetrated (table 13). The more permeable beds are thin and scattered through the clay and silt that make up most of the section drilled.

On July 5 the test well was pumped for 4 hours at a rate of 60 gpm with a drawdown of about 40 feet. The pumping rate was then increased to 90 gpm for 45 minutes, at the end of which time some air was being pumped with the water. The discharge rate was then decreased to 75 gpm and pumping was continued for a period of 7 hours and 15 minutes. The specific capacity for the test well was a little less than 0.5 gpm per foot of drawdown.

The water from test well T-2 is quite hard and fairly saline, containing about 1,110 ppm dissolved solids, but it is of much better quality than water from test well T-1.

#### Atlas test well T-4

Drilling of test well T-4 (16.9.8.100) began on August 3, 1956, and was completed at a depth of 403 feet August 7, 1956. Most of the material penetrated was silt and clay. Only two zones, between depths of 67 and 77 feet and 90 and 99 feet, appeared to be somewhat permeable. The well was cased with about 400 feet of 8-inch casing, of which more than 250 feet was perforated with 1/8 by 4-inch slots. Perforated sections of casing were set at the following depths: 44 to 142 feet, 170 to 250 feet, and 270 to 350 feet. Static water level in the well on August 21, 1956 was 50.6 feet below land surface. The log is given in table 13.

Table 13.—Logs of wells in the Atlas Project areaAtlas test well T-1 (16.8.13.442)

Material	Thickness (feet)	Depth (feet)
Silt, buff to white gypsiferous, and caliche -----	5	5

## Tularosa-Alamogordo area

(References: Herrick and others, 1960; Meinzer, 1915)

The Tularosa-Alamogordo area extends west from the foothills of the Sacramento Mountains for about 12 miles, north from Tularosa about 10 miles, and south from Alamogordo about 7 miles.

In the Tularosa-Alamogordo area the valley fill can be divided into two parts, a thick section of older alluvium and an overlying, relatively thin section of younger alluvium.

Ground water in moderate to large quantities is available in much of the area, but water of good quality is scarce. Most of the ground water is highly saline, containing particularly calcium, sodium, chloride, and sulfate. Sulfate in the ground water is sufficient to render the water unfit for domestic or livestock use.

The quality of ground water in the vicinity of the Boles well field differs vertically as well as laterally. Two distinct water-bearing zones in the younger alluvium can be differentiated -- a deep, thick zone containing potable water and a shallow, thin zone containing water of inferior quality.

Water from the deeper part of the older alluvium is probably of poor quality. Meinzer (1915, p. 133) stated that water from a depth of 890-1,200 feet in a deep well near Dog Canyon (south of the Boles well field) was reported to be salty. Presumably this well tapped the lower part of older alluvial fill, but did not penetrate to the bedrock.

Water from the bedrock underlying the valley fill is generally saline. A sample of water from well 18.8.5.431, about 6 miles southwest of Holloman Air Force Base, which probably taps the Yeso Formation, contained about 8,400 ppm of dissolved solids, including about 3,000 ppm of sulfate, and about 2,500 of chloride, and it had a hardness of about 2,600 ppm.

## Carrizozo area

(References: Herrick and others, 1960)

The Carrizozo area extends from the vicinity of Carrizozo southeast to Nogal and southwest to Oscura. This area of about 150 square miles is a part of the Tularosa Basin and lies between the Sierra Blanca on the east and the malpais (lava flow) on the west. (See fig. 22, in pocket).

---

Figure 22 (caption on next page) belongs near here.

---

Large quantities of ground water are available from the alluvium in a part of the area. Generally the water is very hard and high in dissolved solids, a large part of which is sulfate. A considerable quantity of ground water containing about 600 ppm or less of sulfate could be obtained from the alluvium near Carrizozo.

No quantitative data are available on the hydrologic characteristics of the valley fill. Information is needed on the trend of nonpumping and pumping water levels, specific capacities of wells, transmissibility of the aquifers, and interference between pumped wells.

Evidence indicates that the thickest sections of alluvium in the area are a few miles south and southwest of Carrizozo. Near the center of the plain a few miles east and southeast of Carrizozo the alluvium generally is slightly more than 100 feet thick; however, it is not improbable that the alluvium is thicker at some places in that general area. The remainder of the area is not considered favorable for the occurrence of saturated alluvium that would yield large quantities of water to wells.

### Three Rivers area

(References: Hood and Herrick, 1962)

The Three Rivers area includes about 150 square miles between the west slope of Sierra Blanca and U.S. Highway 54, at the boundary between Otero and Lincoln Counties about 20 miles north of Tularosa, New Mexico (fig. 23, in pocket). The area is drained by Three Rivers

---

Figure 23 (caption on next page) belongs near here.

---

and its tributaries. Two of the tributaries, Three Rivers Canyon and Indian Creek, have perennial flows in their upper reaches at the west side of Sierra Blanca.

The depth to water in Three Rivers area ranges from less than a foot in parts of the creek beds to as much as 150 feet. In the lower parts of the reentrant, in the northwestern part of T. 11 S., R. 10 E., and the southwestern part of T. 10 S., R. 10 E., the range in depth to water is between about 20 and 50 feet.

As indicated by the water-table contours on figure 23, the ground water moves southwestward from the reentrant area toward the main part of Tularosa Basin. Several small springs issue where eastward-dipping impermeable beds force the ground water to the surface.

Figure 23.--Map of the Three Rivers area, Otero and Lincoln Counties,  
N. Mex., showing well and spring data and contours on  
the water table, 1957.

The water resources of the Three Rivers area can be most fully and most economically developed by mixing waters of inferior chemical quality with potable water to yield a product of potable or near-potable quality to the pipeline. This may be accomplished in several ways. For example, data indicate that wells producing at least 100 and possibly as much as 200 gpm can be developed in the vicinity of test well 11.10.7.232. Although the ground water in that area may be expected to contain from 300 to 500 ppm of sulfate, by mixing this water with less saline surface and ground water, the final product would be of reasonably good quality. The base flows of Three Rivers and Indian Creek probably have an average sulfate content of about 100 ppm. Such water mixed in equal proportion with ground water containing an average of as much as 400 ppm of sulfate would produce water containing about 250 ppm of sulfate for delivery to the pipeline.

A dependable supply of at least 1,000 acre-feet per year of water containing an average of not more than 250 ppm of sulfate can be developed in the Three Rivers area, if both surface-water and ground-water sources are utilized. This estimate includes diversions on both Three Rivers and Indian Creek and approximately six wells. More than 1,000 acre-feet per year can be developed if more wells are drilled or a somewhat inferior water is permitted.

Area southeast of Valmont and north of Orogrande pipeline :

(References: Herrick and others, 1960)

An area about 12 miles south of the Boles well field and along the east side of Tularosa Basin, southeast of Valmont and north of the Orogrande pipeline, has been suggested as a possible source of potable ground water. The area includes about 150 square miles adjacent to the Sacramento Mountains and northeast of the Jarilla Mountains, in the central part of Otero County, N. Mex. (See fig. 24 in pocket.)

---

Figure 24 (caption on next page) belongs near here.

---

Figure 24.--Map of an area southeast of Valmont and north of Orogrande pipeline, Otero County, N. Mex., showing contours on the water table, depth to water, and sulfate content of ground water, 1956.

Ground water in the bolson fill moves southwestward and westward from the mountains toward the lower part of the basin, as indicated by the water-table contours on figure 24. The water-table gradient ranges from about 25 feet per mile in the southeastern part of T. 19 S., R. 9 E., to about 50 feet per mile in the southwestern part of T. 18 S., R. 10 E. Data are not available with which to determine the configuration of the water table in the southern part of T. 19 S., R. 10 E., and T. 20 S., R. 10 E. The ground water in these areas is moving westward at gradients of 25 to 30 feet per mile. The depth to water in the bolson fill in the area shown on figure 24 ranges from less than 30 feet in the northwestern part of the area, the vicinity of Valmont, to at least 200 feet in the southern part of T. 19 S. and the northern part of T. 20 S., Rs. 9 and 10 E.

## Boles well field area

(Reference: Hood, 1959)

The Boles well field is on bolson fill of which the most permeable zones are the first 200 to 300 feet below the land surface. Production wells drilled in the area need not be more than 300 feet deep. Wells drilled within about one-half mile of the mountains possibly can be drilled to somewhat greater depths because the coarse-grained bolson fill is thicker closer to the mountains but not necessarily more productive. The permeability of the aquifer in the Boles well field, and consequently the yields of wells, increases from east to west, as a result of the better sorting of the fill at increasing distance from the mountains.

At the 1955 rate of production from the existing production wells, it is estimated that the water level in the center of the well field will decline in the order of 30 feet in 5 years, 40 feet in 10 years, and 50 feet in 20 years. To minimize lowering of water levels in the well field, and thus reduce the possibility of migration of saline water from the west, it is suggested that future wells be considered in the eastern three-fourths of sec. 19, the northern half of sec. 30, excepting the northwest 40 acres, and possibly the southwest part of sec. 20, T. 17 S., R. 10 E. Generally a well spacing of 1,000 feet seems adequate. The optimum distribution of wells in this new area seems to be a straight line extending southward from Boles well 5.

Logs of wells drilled in the Boles well field area are given in table 14.

Test well 11 (17.9.25.444)			18 of 54
Material	Thickness (ft)	Depth (ft)	
Clay, firm, tan, becoming softer toward bottom -----	20	20	
Clay, soft, silty, tan, with minor amount of gravel --	10	30	
Clay, firm, tan, with some silt or sand near top -----	10	40	
Clay, slightly sandy, tan -----	10	50	
Clay, sandy, tan, intercalated with thin strata of very fine-grained sand. Partial loss of circulation when 60 feet reached -----	10	60	
Clay, slightly silty, tan, containing yellow-brown spots	20	80	
Clay, slightly gritty, red-brown -----	35	115	
Clay, red-brown, with some caliche -----	5	120	
Clay, soft, tan to brown, with some caliche -----	10	130	
Clay, soft, silty, brown, and caliche -----	22	152	
Clay, silty and silt -----	8	160	
Clay, silty, and caliche; clay became red at about 260 feet -----	147	307	

Table 14.--Logs of wells and test wells drilled in 1954 and 1955 in  
vicinity of Boles well field - Continued

Test well 4 (17.9.26.431)			19 of 54
Material	Thickness (ft)	Depth (ft)	
Soil, tan -----	3	3	
Clay with large amount of caliche -----	7	10	
Clay, red; sandy near top and becoming full of caliche at about 15 feet -----	13	23	
Caliche, gray clay, and crystalline gypsum -----	5	28	
Clay, red and gray -----	2	30	
Sand, very fine-grained -----	2	32	
Clay, red, becoming very sandy at 39 feet -----	8	40	
Clay and sand -----	1	41	
Sand, very fine-grained, and minor amount of caliche --	2	43	
Sand, very fine- to fine-grained, becoming clayey toward bottom -----	7	50	
Sand, with minor amount of clay -----	1	51	
Clay, soft, red-brown and white; very sandy at top and grading downward to a gritty clay at bottom ----	9	60	
Clay, sandy, with large amount of very fine-grained sand	5	65	
Clay, gritty, red, containing grains of caliche or very small gravel, and becoming redder and more compact toward bottom -----	12	77	
Clay, sandy, tan -----	4	81	
Clay, red, intercalated with strata of very hard sandy caliche -----	5	86	

Table 14.--Logs of wells and test wells drilled in 1954 and 1955 in  
vicinity of Boles well field - Continued

Test well 4 (17.9.26.431) - Concluded			20 of 54
Material	Thickness (ft)	Depth (ft)	
Sand, clayey, and caliche, with a hard stratum at			
89 feet -----	5	91	
Clay, soft, sandy, and very small gravel -----	3	94	
Clay, compact, gritty, red -----	1	95	
Clay, soft, sandy -----	3	98	
Clay, soft, gritty, red -----	12	110	
Clay, sandy, and sand -----	10	120	
Clay, sandy, white -----	10	130	
Clay, sandy, white, grading downward into very sandy, red-brown clay -----	10	140	
Clay, firm, red -----	2	142	
Clay, soft, slightly gritty, brown, becoming very gritty toward bottom -----	8	150	
Clay, soft, brown, with very small gravel, fine-grained sand and a few thin strata of caliche-cemented sand -----	9	159	
Clay, soft, gritty, brown -----	4	163	
Clay, soft, gritty, red and white -----	2	165	
Clay, firm, brown, with much small gravel -----	2	167	
Clay, soft, gritty, brown, becoming very gritty and sticky from 170 to 180 feet and very soft from 185 to 187 feet -	23	190	
Clay, soft, gritty, brown and white -----	10	200	
Clay, moderately firm, red-brown -----	9	209

Test well 20 (17.9.36.414)		
Material	Thickness (ft)	Depth (ft)
Soil, silty, clayey -----	5	5
Clay, red -----	22	27
Clay, silty, brown -----	3	30
Clay, silty, brown, and caliche, with white clay near bottom -----	10	40
Clay, white, and caliche -----	6	46
Caliche, hard -----	1	47
Clay, white, and caliche -----	3	50
Sand, and sandy red and white clay -----	6	56
Clay, firm, red -----	4	60
Clay, sandy, red -----	5	65
Clay, sandy, red, and caliche -----	35	100
Clay, sandy, red, and caliche; sandier near bottom; with some very small black gravel -----	10	110
Sand, sandy white clay, very small, black gravel and minor amount of caliche -----	10	120
Clay, sandy, red, with some black gravel and minor amount of caliche -----	10	130
Clay, red; caliche; minor amount of gravel; and some thin strata of sand -----	20	150
Clay, sandy, red; some thin strata of sand; and minor amount of caliche -----	10	160

Table 14.--Logs of wells and test wells drilled in 1954 and 1955 invicinity of Boles well field - Continued

Test well 20 (17.9.36.414)- Concluded

22 of 54

Material	Thickness (ft)	Depth (ft)
Clay, red, very sandy in some zones, with thin, hard strata of caliche at 166 and 168 feet -----	10	170
Clay, red, 50 percent; and caliche, 50 percent -----	10	180
Clay, silty, brown, and caliche, becoming somewhat sandy toward bottom -----	30	210
Clay, sandy, red, intercalated with thin strata of medium- to coarse-grained sand and caliche, with minor amount of gravel near bottom -----	20	230
Clay, red-brown, and caliche with thin stratum of caliche at 243 feet -----	60	290
Clay, red-brown -----	10	300
Clay, red-brown, with caliche and minor amount of black gravel -----	12	312

## Jornada del Muerto Apollo site

(Reference: Doty, 1963)

### Geology and ground water occurrence

The Jornada del Muerto is a topographic basin whose southern extremity, in which the Apollo PSD facility lies, is between the Dona Ana and San Andres Mountains. The rocks exposed in these mountains on either side of the basin have been eroded, filling the basin to an unknown depth with bolson fill.

The bolson deposits consist of irregular beds and lenses of unconsolidated to semi-consolidated clay, silt, sand, and gravel, and mixtures of these particle sizes. Wells in the Jornada del muerto obtain water, which is unconfined or semiconfined, from permeable beds of sand and gravel in the bolson deposits. The bolson deposits and the saturated zone within the deposits thin toward the mountains: thus the probability of obtaining an adequate supply of water decreases with nearness to the mountains. Apollo Site wells C, D, G, and H apparently did not penetrate a sufficient thickness of saturated bolson deposits to yield the required quantity of water. Wells I and J penetrated 682 and 602 feet of saturated bolson deposits, respectively, and when cased as water wells, each had 400 feet of slotted casing open to the saturated sections. (See table 15.)

Table 15.--Records of wells drilled at Apollo PSD

facility

Well C

Location: NW 1/4 sec. 4, T. 21 S., R. 3 E., Dona Ana County, N. Mex.

Altitude: Land-surface altitude 4,590 feet :

interpolated from USGS topographic maps.

Depth: 1,011 feet below land surface datum.

Date completed: April 22, 1963 (Plugged and abandoned).

Drilling contractor: Layne-Texas Co., El Paso, Tex.

Drilling method: Hydraulic rotary

Casing and well record: 8-inch test well drilled to 1,011 feet December 6-18, 1962. Well reamed to 16-inch and cased full depth with 12 3/4-inch casing March 27 to April 15, 1963. Casing perforated with 3/16 x 2-inch mill-cut slots, 12 slots around, staggered rows, from 350-460, 590-650, 690-720, and 800-1,000 feet. 24-inch surface casing cemented to 30 feet.

Well completion record: 12 3/4-inch casing pulled and well plugged with heavy mud and abandoned April 22, 1963. Steel cap welded on surface casing.

Table 15.--Records of wells drilled at Apollo PSD

facility - continued

Well C - concluded

Geologic source:

Probably bolson deposits, from 360 to 450 feet. Water level was lowered from 362 to 752 feet by bailing at a rate of about 38 gpm with 90-gallon bailer indicating that the well was incapable of producing the desired yield.

Summary of material penetrated:

Material	Thickness (ft.)	Depth (ft.)
Bolson deposits -----	453	453
Igneous rock (weathered) -----	50	503
Igneous rock (unweathered) -----	508	1,011

**Well J**

Location: NW $\frac{1}{4}$ SE $\frac{1}{4}$ NW $\frac{1}{4}$  sec. 31, T. 20 S., R. 3 E., Dona Ana County, N. Mex.

Altitude: Land surface altitude 4,410 feet

interpolated from USGS topographic map.

Depth: 850 feet below land surface

Date completed: May 31, 1963

Drilling contractor: Layne-Texas Co., El Paso, Texas

Drilling method: Hydraulic rotary

Casing and well record: 10-inch test well drilled to 939 feet. 30 feet of 18-inch surface casing cemented in and well reamed to 16-inch to 850 feet. 12 3/4-inch casing installed to full depth. Casing perforations: mill-cut 3/16 x 2-inch slots. 12 slots around, staggered rows. Perforated intervals: 400-700, 740-840

Well completed record: Fitted with temporary steel cap.

Geologic source: Bolson deposits. Water level lowered from 337 to 388 feet by pumping at rate of 1,000 gpm for 24 hours.

Summary of material penetrated:

939 feet of bolson deposits.

---

### Aquifer test

Wells I and J were test pumped at approximately 1,000 gpm for 24 hours. A semi-log plot of water-level recovery versus time indicates the coefficient of transmissibility is about 48,000 gpd per ft for well I and about 80,000 gpd per ft for well J. The coefficient of transmissibility are on the order of those expected from bolson deposits, and the relatively small drawdown of water levels indicates that the wells are in good hydraulic connection with the aquifer.

### Chemical quality of water

The sulfate content of water from all the wells except C was more than the U.S. Public Health Service recommended limit of 250 ppm. The water from wells I and J contains about 300 ppm sulfate. The water is extremely hard; the hardness as  $\text{CaCO}_3$  of water from wells I and J is 378 and 418 ppm, respectively. Water of appreciably better quality probably cannot be obtained within about 10 miles of the facility.

## Bosque del Apache Wildlife Refuge

(Reference: Weir, 1964)

This area includes a strip along the Rio Grande through a 10-mile reach south of San Antonio, N. Mex. (fig. 1). In this area the Recent flood-plain deposits constitute the major aquifer.

Generally water from wells east of the Rio Grande in the Bosque del Apache is inferior to impotable owing mainly to the movement of mineralized ground water into this area from the northern Jornada del Muerto. This water of poor quality comes from wells tapping the flood-plain deposits as well as older unconsolidated basin fill although wells tapping the flood-plain deposits at the edge of the river yield somewhat better water, apparently owing to dilution by the river water in the shallowest part of the aquifer.

Except for a small grassy marsh area along U.S. Highway 85 from 1 to 3 miles south of the northern boundary of the wildlife refuge in the Bosque del Apache Grant (west of map area), wells west of the river yield potable water from both the flood-plain deposits and the Santa Fe Group. Shallow wells in the grassy marsh area yield inferior water because of a concentration of salts in the marsh area by evapotranspiration. This inferior water may exist only in the shallowest part of the aquifer.

## Stallion Range Center

(Reference: Weir, 1964)

Stallion Range Center is a small administrative and service installation in the northern part of the Jornada del Muerto. Water levels in wells in the Stallion Range Center area range from 150 to 450 feet below the land surface, from east to west and the depth to water is 327 feet in well 6.3.5.232 at Stallion Range Center (see table 16 for log). Well 6.3.5.232 supplies nonpotable water to the Range Center. The water is too saline for domestic use; calcium, magnesium, and sulfate are the principal chemical contaminants.

The results of the chemical analyses of water from wells drilled in 1956 indicate that the western and northern flanks of the Cerro Colorado volcanic mass are underlain by water of potable and near-potable quality. The sulfate content in the ground water underlying this part of the area ranges from about 220 to about 900 ppm. Yields from three test wells drilled in secs. 1, 4, and 10, T. 6 S., R. 2 E, range from 2 to 40 gpm.

Table 16.--Log of well 6.3.5.232, Stallion Range Center

Material	Thickness (feet)	Depth (feet)
Samples missing	20	20
Sand, very fine to medium, and small gravel of volcanic rocks	20	20
Sand, very fine to medium, small gravel of volcanic rocks, and some clay	10	50
Sand, fine to very coarse, and small gravel of volcanic rocks	40	90

Material	Thickness (feet)	Depth (feet)
Sand, very coarse, very small gravel, and tan silt	10	260
Clay, red, very coarse sand, very small gravel and tan silt	10	270
Clay, white, very coarse sand, very small gravel, and tan silt	5	275
Clay, tan and white, silty	5	280
Clay, tan silty, and a small amount of very coarse sand	14	294
Silt, tan to cream	6	300
Clay, tan silty	20	320
Silt, brown, and very fine sand. Some very coarse sand	18	338
Silt, brown, very fine sand, some very coarse sand, and small volcanic gravel	9	347
Clay, tan, very silty	5	353
Clay, tan very silty, very coarse sand and small gravel	22	375
Silt, very fine sand, and very silty tan clay	5	380
Sand, very fine to very coarse, and small gravel	20	400
Sand, very fine to very coarse, small gravel, and brown silt. Some clay 430-435.	50	450
Samples missing	58	508
Sand, medium to very coarse, and small gravel	4	512
Sand, medium- to very coarse-grained, small gravel and small pebbles	11	523
Sand, very coarse and gravel	5	528
Sand, fine to coarse	5	532

Table 16.--Log of well 6-3.5.232, Stallion Range Center - concluded

Material	Thickness (feet)	Depth (feet)
Sand, medium to coarse, and brown clay	7	539
Sand, fine to very coarse	5	544
Sand, fine to very coarse and small gravel	31	575
Clay, brown, fine to very coarse sand and small gravel	5	580
Silt, brown and very fine to coarse sand	30	610
Sand, very coarse, and small gravel	5	615
Sand, very coarse, small gravel, and brown silt	5	620
Sand, very coarse, gravel and small pebbles	15	635
Sand, fine to very coarse, and brown clay	30	665
Sand, very coarse, small gravel and brown silt. Some clay from 693-to 700, and a large pebble 705-10	45	710
Sand, very coarse, gravel and small pebbles. General grain sizes somewhat smaller 725-30, and one large pebble 735-740	30	740
Sand, medium to very coarse and gravel	10	750

Notes: All clays were calcareous. Clay, silt, and sand below 400 feet are uniformly coffee-brown in color. All gravel and pebbles observed are detritus of "volcanics"; some are holocrystalline but very fine-grained, and some are glassy with very small phenocrysts. The general appearance of the volcanics is red-brown when wet, but a dusty lavender when dry.

Red Canyon Range Camp

(Reference: Weir, 1964)

Well 7.8.8.322, the second of two wells drilled at Red Canyon Range Camp to supply nonpotable water to the camp, was test pumped for 48 hours in November 1956.

Red Canyon well 2 (7.8.8.322) was pumped at approximately 200 gpm and the water level decline was observed in the pumped well and in Red Canyon well 1 (7.8.8.412), 1,000 feet east of the pumped well, where the water level declined 1.25 feet during the test. The decline in the pumped well was 2.12 feet during the pumping period. The specific capacity of the pumped well is approximately 100 gpm per foot of drawdown. Transmissibility is about 45,000 gpd per ft.

## MAR facility water supply

(References: Doty, 1964, 1964a)

Three test wells (19.5.17.333, 19.5.28.443, and 19.5.21.111) were drilled near Lucero Ranch in 1963 to find potable water for the MAR facility. All three wells produced potable water but only test well 1 (19.5.17.333) produced an adequate quantity of water for the facility. Two production wells (19.5.17.331 and 19.5.17.334) were drilled late in 1963 and put in service in the Spring of 1964.

MAR 1 test well was drilled to 1,000 feet and plugged back to 650 feet because water quality depreciates below that depth. The test well was pumped for 12 hours at 165 gpm with a drawdown of about 40 feet below the nonpumping depth to water at 225 feet. The pumped water had a specific conductance of 809 micromhos and contained 42 ppm chloride and 162 ppm sulfate.

MAR 1 (19.5.17.331) and MAR 2 (19.5.17.334) production wells were completed at 550 and 650 feet respectively. The wells drilled were of 20-inch diameter, cased with 10-inch pipe mill-slotted,  $1/8 \times 2\frac{1}{4}$  inch slots, 9 slots around, below the water level, and gravel packed. The wells are designed to pump about 100 gpm. The quality of water obtained from the wells is similar to that from the test well.

The log of MAR test well 1 (19.5.17.333) is given in table 17. This log is representative of other wells drilled in the MAR facility area.

Table 17.--Log of MAR-1 test well

## Upper Sacramento River canyon

(Reference: Mourant, 1959)

The Sacramento River originates in the Sacramento Mountains in central Otero County, N. Mex., about 10 miles southeast of Alamogordo. The upper part of the Sacramento River flows southeastward through canyons several hundred feet deep. The valley floor is extremely narrow except in the cienega (marshy) areas, where it is several hundred feet wide. The river has a perennial flow only in cienega areas. The Southern Pacific Co. was diverting about 250 gpm of water from two of the cienega areas in December 1956 which was transported by pipeline to Orogrande, about 35 miles southwest.

Ground water in the Sacramento River canyon area occurs mainly in the upper part of the Yeso Formation. The depth to water in two wells in sec. 34, T. 17. S., R. 11 E., which furnish water to the installation at Sacramento Peak, is about 200 feet. In many places in the Sacramento River canyon in T. 18 S., Rs. 11 and 12 E., the ground water discharges through springs (fig. 25). The depth to

Figure 25 (caption on next page) belongs near here.

---

water in well 19.12.15.144 at the Circle Cross Ranch, is about 170 feet. The wells in sec. 34, T. 17 S., R. 11 E., are reported to yield 50 gpm. each. Well 19.12.15.144 is not equipped with a pump, and the yield of the well is not known. The Yeso Formation probably contains one or more zones of saturation throughout this part of the Sacramento Mountains, and wells drilled in most of the upper part of the Sacramento River canyon will yield at least 50 gpm and possibly as much as 100 gpm. The development of wells a short distance upstream from the spring area probably would cause the yields of the springs to decline rapidly.

pipeline.

## The Hueco Bolson

(Reference: Knowles and Kennedy, 1958)

The Hueco Bolson is in the extreme western part of Texas and south-central New Mexico, covering parts of El Paso County, Tex., and Dona Ana and Otero Counties, N. Mex. (See fig. 1.) Wells tapping the bolson deposits furnish the major part of the water supply for the city of El Paso, Ciudad Juarez, Fort Bliss, Biggs Air Force Base, and private industries in the area. The progressively-increasing demand for water made it obvious that a comprehensive investigation of the quantity and quality of water in storage in the entire Hueco Bolson would be essential for the proper planning of future water supplies. A test-drilling program was started in 1953, jointly sponsored by the city of El Paso, the United States Army, the United States Air Force, and the Texas Board of Water Engineers. The drilling was supervised by the United States Geological Survey.

Thirty-three deep test wells were drilled, comprising a total footage of 32,456 feet. Water samples for chemical analysis were obtained by means of drill-stem tests at most of the wells. An electric log was made after each test well was completed, water-level measurements were made in each well, and pumping tests were made at several selected wells. In addition to the test-drilling program, all available information was collected for existing wells in the area, and chemical analyses were made of water samples collected from many of the wells. Records of the wells and explanatory text and illustrations are contained in U.S. Geological Survey Water-Supply Paper 1426 (Knowles and Kennedy, 1958). The data from Water-Supply Paper 1426 are not included in this report, but illustrations showing the altitude of water levels and saturated thickness of fresh-water-bearing material (Knowles and Kennedy, 1958, pls. 2 and 10 are included herein as figures 26 and 27 (pls. 2 and 10 of Water-Supply Paper 1426)

Figure 26.--Map showing water-level contours in the Hueco Bolson area,  
Texas and New Mexico, January 1954.

27.--Map showing saturated thickness of fresh-water-bearing  
deposits (chloride content less than 250 parts per million)  
in the Hueco Bolson area, Texas and New Mexico.

The Hueco Bolson is an intermontane lowland sparsely covered with low vegetation. The bolson is traversed by the Rio Grande Valley (figs. 26 and 27), the portion of which south of El Paso, known locally as the Lower Valley, is reached by an abrupt drop of 200 to 300 feet from the bolson surface, which is known locally as the Mesa. No well-developed drainage channels are on the Mesa, and the precipitation on it either infiltrates or is lost by evapotranspiration.

The bedrock that underlies the bolson deposits and makes up the surrounding mountains is relatively impermeable and will not supply large quantities of water to wells. The Franklin and Organ Mountains, which form part of the western boundary of the Hueco Bolson (figs. 26 and 27), consist largely of granitic and porphyritic rocks that were the source beds for much of the bolson deposits. The latter consist of lenticular layers of clay, sand, and gravel, which cannot be correlated for long distances. The sands and gravels are thickest and coarsest near the Franklin and Organ Mountains and become progressively thinner and finer grained toward the east. The maximum known thickness of the bolson deposits is 4,920 feet. Caliche lying nearly everywhere beneath the surface of the bolson affords a rather effective barrier to recharge from above. The caliche beds are partly or completely missing beneath depressions in the bolson, however, and recharge takes place when water collects in the depressions during periods of heavy rainfall.

Contours of water levels in the Hueco Bolson (fig. 26) show that the principal area of recharge is along the east edge of the Franklin and Organ Mountains, where the runoff from the mountains infiltrates into the coarse gravel of alluvial fans. The water in the bolson deposits in the Mesa is unconfined and almost everywhere is of good quality. The bolson deposits in El Paso Valley contain fresh water but are overlain and underlain by alluvial deposits containing mineralized water. The lowering of the artesian head in the bolson deposits in places has permitted the infiltration of salt water into the fresh-water-bearing beds. Two large cones of depression, one in El Paso Valley and one in the Mesa, have been formed by large withdrawals of ground water.

Pumpage from deep wells in the El Paso area has increased steadily since 1906. The average withdrawal in 1953 was 27.9 mgd (million gallons per day), of which 13.1 mgd was pumped from wells in the Mesa and 14.7 mgd was pumped from wells in the El Paso Valley.

The fresh water--defined as that containing less than 250 ppm (parts per million) of chloride--in the Hueco Bolson is in a trough of irregular width and depth roughly parallel to the Franklin and Organ Mountains (fig. 27). Salt water--defined as that containing more than 750 ppm of chloride--is present in the bolson sediments that lie beneath and east of the fresh-water-bearing beds and in the younger alluvium in the El Paso Valley. A body of inferior water is present between the fresh and salt water and differs in thickness from place to place.

Pumping tests at wells in the Hueco Bolson showed that the coefficient of transmissibility ranged from 38,000 to 164,000 gpd (gallons per day) per foot. Because of the shortness of the tests, the coefficient of storage of the bolson deposits could not be determined accurately.

The volume of the saturated bolson deposits in Texas is at least 31.6 million acre-feet and in New Mexico at least 24.8 million acre-feet. Of this, about 7.4 million acre-feet in Texas and 6.2 million acre-feet in New Mexico is available for recovery by wells. On the basis of about 50-percent recovery of the available water, 30 mgd could be withdrawn from storage for a period of 110 years. Artificial recharge would extend this period. Suggested methods of artificial recharge are by means of wells on the Mesa and a system of ditches and detention dams in the arroyos along the mountain fronts.

Although a large quantity of water is available in the bolson deposits, detailed planning and proper development will be necessary to secure maximum recovery from the reservoir without serious salt-water encroachment.

## Conclusions and suggestions

The data and maps in this report show that potable water underlies narrow belts of land at the foot of the Franklin and Organ Mountains and the southern part of the San Andres Mountains in the western part of the area and the Sacramento Mountains in the eastern part. The belt of potable water is bounded basinward by a narrow belt of inferior water. The major part of the Tularosa Basin and Hueco Bolson contain non-potable water. Removal of large quantities of potable water locally from ground storage causes water levels in wells to decline, and at places the water-table gradient has been reversed from the normal basinward slope. Eventually, the removal of large quantities of potable water from storage will induce movement of inferior and non-potable water into the areas now containing potable water.

Figure 4 shows areas of potable water having little development both north and south of the headquarters area. Unfortunately, these areas have not been adequately explored to define accurately the amount of potable water in storage.

The expected long-term need for increasingly larger supplies of potable water in the White Sands Missile Range and adjacent areas can be met only by additional evaluation and development. The following program of evaluation is suggested:

1. Continue the present program of monitoring pumpage, water levels in wells, and quality of water in production and observation wells. Extend the monitoring to keep pace with new development of water supplies.

2. Drill additional test and observation wells in the potable water areas to determine more accurately what is happening in heavily-pumped centers and the quantity of potable water in storage.
  - a. At least three more observation wells are needed northwest, west, and southwest of the headquarters well field.
  - b. Additional wells northward from the headquarters to a few miles north of the MAR wells in the potable water belt would be desirable. Larger yields from a thicker zone of fresh water might be possible between the MAR wells and the mountain front.
  - c. Several wells should be drilled in the potable water belt southward from the headquarters area several miles into the Fort Bliss Military Reservation.
  - d. At least one deep test well (to bedrock at a depth of 1,000 to 5,000 feet) should be drilled 6 to 10 miles east of the headquarters to evaluate differences in pressure head and chemical quality of water. We know that the water increases in salinity with depth to the depths tested, but we do not know that the salinity continues to increase to bedrock. In some similar basins of New Mexico, water of good quality has been found below zones of saline water.
  - e. One or two additional test wells should be drilled northwest of Rhodes Canyon to further explore for potable water.

- f. Drill test wells to locate new sources of potable water near areas of need. Small areas of potable water surely must exist at some unexplored places. Our increasing knowledge of the geology and hydrology of the missile range increases the chances of finding additional supplies of potable water.
3. A geophysical survey should be made in each area before the test drilling is started. The geophysical work should be a combination of surveying, for accurate control, and gravity survey, for economical coverage of large areas.
4. Investigate the quantity of surface water available for artificial ground-water recharge in the potable water areas. Also, evaluate the efficiency and cost of collecting water for direct use or artificial recharge from areas coated with asphalt. A small coated watershed (9 acres) is currently being studied. Gaging stations to measure the natural runoff from three watersheds near the headquarters are being planned. Construction of artificial recharge facilities may be feasible in the future, especially in the headquarters area.

5. Ground-water recharge with treated sewage effluent up-gradient from the headquarters well field would be a safe, sanitary method of supplementing the supply of potable water in the well field. This recharge could be accomplished with properly constructed infiltration pits. Movement of this water vertically through a hundred feet or more of the zone of aeration and a mile or more horizontally in the zone of saturation after treatment would assure its safety and even its esthetic value.
6. A large saline-water conversion plant may become feasible in the future. A very large volume of saline ground water is stored in the Tularosa basin. Conversion of this saline water to fresh water could supply the missile range indefinitely, even after large increases in water demand.
