ABSTRACT

A technique is presented for estimating the magnitude and frequency of floods on streams in Massachusetts with drainage areas between 0.25 and 497 square miles. Multiple regression techniques are used to define the relation between flood peaks, collected at a network of gaging stations maintained by the U.S. Geological Survey, and a set of basin characteristics. Results indicate that flood peaks may be estimated from knowledge of the drainage area, main channel slope, and mean annual precipitation of the basin. The relations are presented graphically for user convenience.
INTRODUCTION

The purpose of this investigation is to develop a useful technique for estimating the magnitude and frequency of floods on streams where flood flows are virtually natural. Flood magnitude is expressed in terms of a volume rate of flow (discharge) and in units of cubic feet per second (ft³/s). Flood frequency is expressed in terms of recurrence interval, which is the average interval of time, in years, within which the given flood magnitude will be exceeded once. The relationship between flood recurrence interval and chance that the flood will be exceeded in a given period of years is discussed in Supplemental Data, p. 41.

This is the second status report on the study of flood frequency of small Massachusetts watersheds. An earlier report, "Flood magnitude and frequency of small Massachusetts streams, preliminary estimating relations" by Carl G. Johnson and G. Alan Laraway, was dated September 16, 1971. The investigation has been in progress since 1962 in cooperation with the Massachusetts Department of Public Works and the Federal Highway Administration.

Previous reports, Benson (1962), Green (1964), Knox and Johnson (1965), and Johnson (1970), have presented methods for estimating flood magnitude for various recurrence intervals. However, each of these methods was developed from data collected on large streams and is applicable only to streams draining more than 10 square miles (mi²). The estimating relations in this report were developed from data collected on small streams (drainage area less than 10 square miles) over the past 10 years in addition to data collected on larger streams. Therefore, the relations presented herein apply to all streams in Massachusetts, except as noted in the section on ACCURACY AND LIMITATIONS.
ESTIMATING PROCEDURE

In general, the most reliable estimates of future flood flow magnitudes are obtained by frequency analysis of gaging records. Locations of gaging sites where flood records are of adequate length for frequency analysis are identified in table 3, p. 27; and the 2-, 5-, 10-, and 25-year flow magnitudes, as defined for each site, are shown in table 2, p. 26.

For ungaged sites, peak discharges $P_2$, $P_5$, $P_{10}$, $P_{25}$, $P_{50}$, and $P_{100}$ for recurrence intervals of 2, 5, 10, 25, 50, and 100, respectively, can be estimated by the following equations:

\[
\begin{align*}
  P_2 &= 0.0645A^{0.816}S^{0.091}P^{4.59} \\
  P_5 &= 0.0795A^{0.831}S^{0.116}P^{4.67} \\
  P_{10} &= 0.102A^{0.852}S^{0.132}P^{4.60} \\
  P_{25} &= 0.144A^{0.885}S^{0.155}P^{4.43} \\
  P_{50} &= 0.193A^{0.911}S^{0.171}P^{4.27} \\
  P_{100} &= 0.260A^{0.940}S^{0.187}P^{4.08}
\end{align*}
\]

in which,

- $A$ is drainage area, in square miles,
- $P$ is mean annual precipitation, in feet of water, and
- $S$ is main channel slope, in feet per mile.

Detailed explanation of how these characteristics are evaluated is given in table 5, p. 37-38.
These estimating relations can also be presented graphically. The 2-, 5-, 10-, 25-, 50-, and 100-year peak discharges can be estimated from the nomographs, or alignment charts, shown in figures 1 through 6, respectively. The procedure for estimating peaks from nomographs is as follows:

1. Locate the value of the appropriate basin characteristic on scales (a), (b), and (d). For a detailed explanation of how these characteristics are determined, see table 5, p. 37.

2. Draw a straight line between the values on scales (a) and (b).

3. From the intersection of this line (step 2) with scale (c), draw a straight line to the value of the basin characteristic on scale (d).

4. The estimated peak discharge is determined at the point of intersection of this line (step 3) with scale (e).
FIGURE 1. -- NOMOGRAPH FOR ESTIMATING P

EQUATION OF GRAPH: \( P_2 = 0.0645A^{0.816}S^{0.0912}4.59 \)

EXAMPLE: For a stream with drainage area of 10 mi², main channel slope of 10 ft/mi, and mean annual precipitation of 4.5 ft (54 in); the estimated 2-year peak discharge is 520 ft³/s.
FIGURE 2. -- NOMOGRAPH FOR ESTIMATING \( P \)

\[ P_5 = 0.0795A^{0.8315}S^{0.116}P^{4.67} \]

**EXAMPLE:** For a stream with drainage area of 10 sq mi, main channel slope of 10 ft/mi, and mean annual precipitation of 4.5 ft (54 in), the estimated 5-year peak discharge is 790 ft³/s.
FIGURE 3. -- NOMOGRAPH FOR ESTIMATING $P_{10}$
EQUATION OF GRAPH: \[ P_{25} = 0.144A^{0.885}S^{0.155} \]

EXAMPLE: For a stream with drainage area of 10 sq mi, main channel slope of 10 ft/mi, and mean annual precipitation of 4.3 ft (54 in), the estimated 25-year peak discharge is 1,200 ft³/s.

FIGURE 4. -- NOMOGRAPH FOR ESTIMATING \( P_{25} \)
I.

EQUATION OF GRAPH: \( P_{50} = 0.193 A^{0.911} S^{0.171} P^{4.27} \)

EXAMPLE: For a stream with drainage area of 10 sq mi, main channel slope of 10 ft/mi, and mean annual precipitation of 4.5 ft (54 in), the estimated 50-year peak discharge is 1,400 ft\(^3\)/s.

FIGURE 5. -- NOMOGRAPH FOR ESTIMATING \( P_{50} \)
EQUATION OF GRAPH: $P_{100} = 0.260A^{0.940}S^{0.187}P^{4.08}$

EXAMPLE: For a stream with drainage area of 10 mi², main channel slope of 10 ft/mi, and mean annual precipitation of 4.5 ft (54 in), the estimated 100-year peak discharge is 1,600 ft³/s.

**FIGURE 6. -- NOMOGRAPH FOR ESTIMATING $P_{100}$**
ACCURACY AND LIMITATIONS

Standard error of estimate (table 1) is a measure of how well the flood peaks experienced agree with those computed by the estimating relations. Approximately two out of three sites with flood records had estimated peak discharge values within one standard error of estimate of the observed value, and approximately 19 out of 20 had values within two standard errors of estimate. Peak discharges determined from the frequency curves at each site for the 50- and 100-year recurrence intervals plotted against those determined from the estimating relations are shown in figures 7 and 8, respectively.

Figure 7. -- Graph of observed and estimated 50-year peak discharges
Figure 8. -- Graph of observed and estimated 100-year peak discharges.
Applicability of empirical relations of this type to a site is dependent on similarity of the basin characteristics above the site to those of the basins on which the relations are based. Consequently, the relationships developed apply only to those largely rural, unregulated streams in Massachusetts whose basin characteristics fall within the range of values given in table 2. (The highest and lowest values of each basin characteristic in table 2 are underscored.) For example, the relationships do not apply to streams with drainage areas less than 0.25 mi² or more than 500 mi².

In addition, the estimating relations do not apply to streams on Cape Cod or in the eastern part of Plymouth County. Because the relatively high infiltration and storage capacities of these basins are not adequately represented in the data collection network, it is expected that the estimating relations would significantly over estimate the peak discharges in that area.

ANALYTICAL TECHNIQUE

Data-collection Network

Annual maximum discharges determined for at least 7 consecutive years at 92 stations in Massachusetts and in Vermont and Rhode Island near the Massachusetts border were used in this analysis (figure 9 and table 3). The drainage area above 60 of these stations is less than 10 square miles. The remaining 32 stations were selected from the network of gaging stations maintained by the U.S. Geological Survey in Massachusetts. Only those stations where the effect of regulation on the annual peak was considered to be minimal (Johnson, 1970, p. A2-A6) were selected for this analysis.
Determination of Flood Frequency at Data-collection Stations

A flood-frequency curve for each gaging station was prepared using methods recommended by the Hydrology Committee, Water Resources Council (1967). A sample curve is shown in figure 10. From these curves, peak discharges $P_2$, $P_5$, $P_{10}$, $P_{25}$, $P_{50}$, and $P_{100}$ were determined for recurrence intervals of 2, 5, 10, 25, 50, and 100 years, respectively.

Determination of Basin Characteristics

Multiple regression techniques were used to develop estimating relations by relating each peak discharge ($P_2$, $P_5$, $P_{10}$, $P_{25}$, $P_{50}$, and $P_{100}$) to a set of physical and meteorological characteristics of the stream's drainage basin. Twelve basin characteristics which logically could have at least an indirect effect on peak discharges were selected for use as independent variables. The basin characteristics selected were:

- $A$, drainage area, in square miles,
- $S$, slope of stream, in feet per mile,
- $L$, length of stream, in miles,
- $St$, area of lakes and ponds, in percent of drainage area,
- $E$, mean basin elevation, in thousands of feet above mean sea level,
- $F$, forested area, in percent of drainage area,
- $P$, mean annual precipitation, in feet of water,
- $I_{24,2}$, precipitation intensity for 24 hours at 2-year recurrence interval in inches,
- $T$, mean minimum January temperature, in °F,
- $Sn$, mean annual snowfall, in inches,
- $Si$, soils index, in inches,
- and $Sh$, shape factor, ratio of average basin width to length.

For a more detailed explanation of how these characteristics are determined, see table 6, p. 40.
Determination of Estimating Relations

The relation between each peak discharge (dependent variable) and the set of basin characteristics (independent variables) was developed by step-forward multiple-regression techniques. In step-forward multiple regression, a sequence of multiple linear regression equations are computed by adding one independent variable at each step. The variable added is the one which makes the greatest reduction in standard error of estimate of the regression equation. Objective statistical tests in the regression techniques are helpful in determining which basin characteristics should be retained in the final estimating relations and provide insight as to their relative importance to the relations.

These multiple-regression techniques require linearity between the dependent and independent variables. Previous studies relating flood peaks to basin characteristics, Benson (1962), Knox and Johnson (1965), Thomas and Benson (1970), and Johnson (1970), have shown that the logarithms of flood peaks are linearly related to the logarithms of basin characteristics. Therefore, all data were transformed into logarithms to satisfy the requisite of linearity before the regression analysis was performed.
The results of this type analysis are summarized by the following equations, in which the basin characteristics listed are the only ones that were shown to be statistically significant.

\[
P_2 = 0.197A^{0.831}S_t^{0.198}p^{4.71}S_i^{0.642} \\
P_5 = 0.290A^{0.857}S_t^{0.098}S_{st}^{0.134}p^{4.37}S_i^{0.577} \\
P_{10} = 0.102A^{0.852}S_t^{0.132}p^{4.60} \\
P_{25} = 0.144A^{0.855}S_t^{0.155}p^{4.43} \\
P_{50} = 0.193A^{0.911}S_t^{0.171}p^{4.27} \\
P_{100} = 0.260A^{0.940}S_t^{0.187}p^{4.08}
\]

For the final estimating relations, the regressions for \(P_2\) and \(P_5\) were re-run with only independent variables \(A, S, \) and \(p\) so that all equations would contain common variables. In these regressions, all three independent variables were found to be statistically significant at greater than the 95 percent level. The resulting equations (page 3) show a slightly higher standard error of estimate (45 percent and 47 percent, respectively) than that computed using all of the independent variables. However, the added convenience for the user of the relations was judged to outweigh the slight increase in error.
DISCUSSION

The period of record of annual peaks on most of the small streams necessarily is relatively short (about 10 years). Therefore, it contains time sampling errors, or errors that result from estimating future events (especially the less frequently occurring flood peaks, $P_{25}$, $P_{50}$, and $P_{100}$) from a past record that is not representative of future occurrences. Some errors of this type are preserved in the estimating relations and, in general, mask the underlying relation between flood peaks and basin characteristics. Consequently, improvement in the estimating relations would be expected by obtaining a more representative sample.

One means of obtaining a more representative sample is by relating rainfall, for which there is a longer period of record, to flood peaks by a watershed model incorporating the physics of the process by which rainfall and floods are related. Another means is to observe annual peaks for an additional period of time.

Convert temperature in degrees Fahrenheit (°F) to degrees Celsius (°C) by the following equation:

$$°C = \left(\frac{5}{9}\right) \times (°F - 32).$$
Table 5.--Method of computing independent variables used in estimating relations

Basin characteristics drainage area, main channel slope, and mean annual precipitation should be determined by the following methods or by methods of equivalent accuracy.

1) **Drainage area.** Trace drainage area boundary lines on topographic maps along divides indicated by contour elevations, starting at the point on the stream for which the drainage area is desired. Interpolation between contours may be indicated by reference to trails, old roads, or firebreaks in forested areas, all of which frequently follow drainage divides. Also, detailed information may be obtained from highway or street profiles, from examination of aerial photographs, and from ground reconnaissance. Trace drainage area boundaries on uncontoured maps midway between streams only when more accurate indications of correct boundaries cannot be obtained practically. Planimeter the outlined drainage area to obtain the drainage area in square miles.

2) **Main channel slope.** Outline the main channel on a map of the basin. Upstream from each stream junction point, choose the main channel as the stream that drains the most area. Continue the main channel to the ridge beyond the upstream end of the stream line on the map by drawing flow lines indicated by contours. Measure the total length by a map measurer or set of dividers set to one-tenth of a mile, locate the points 85 and 10 percent of the total length above the point of interest on the stream, and determine the altitude of these points. The main channel slope is computed as the difference in altitude in feet divided by the length in miles between the two points.
(3) **Mean annual precipitation.** Locate the basin of interest on the map given in figure 11. By interpolation determine the mean annual precipitation for the basin to the nearest inch. Convert mean annual precipitation in inches to feet.
Table 6.--List of independent variables used in regression analysis

a. Drainage area (A), in square miles, as taken from the latest Geological Survey streamflow reports.

b. Main-channel length (L), in miles, from the gaging station to the basin divide, as measured with dividers set to 0.1 mile or with a map measurer.

c. Main-channel slope (S), in feet per mile, determined from elevations at points 10 percent and 85 percent of the distance along the channel from the gaging station to the divide. This index was described and used by Benson (1962, 1964).

d. Mean basin elevation (E), in thousands of feet above mean sea level, measured on topographic maps by laying a grid over the map, determining the elevation at each grid intersection, and averaging those elevations. The grid spacing was selected to give at least 25 intersections within the basin boundary.

e. Forest cover (F), in a decimal fraction of the drainage area covered by forests as shown on the topographic map, determined by the grid method, and increased by 0.01.

f. Mean annual precipitation (p), in inches, determined from an isohyetal map (Knox and Nordenson, 1955).

g. Area of lakes and ponds (St), expressed as percentage of the drainage area, determined by the grid method, and increased by 0.5 percent.

h. The maximum 24-hour rainfall having a recurrence interval of 2 years \( (1_{24}^2) \), expressed in inches. This characteristic was determined from U.S. Weather Bureau Technical Paper No. 29.

i. Minimum January temperature (T), in degree Fahrenheit, was determined from the U.S. Weather Bureau publication series "Climates of the States" and increased by 1 degree.

j. Snowfall (Sn), in inches, is the average total seasonal snowfall and was determined from an isohyetal map provided by the U.S. Weather Bureau.

k. Soils index represents values of potential maximum infiltration, in inches, during an annual flood, under average soil moisture conditions (Si). This characteristic was provided by the Soil Conservation Service.

l. Shape factor was determined by dividing A by L².
Relationship between recurrence interval and chance that a flood will be exceeded at least once in a given period of years

Some important problems in hydrology are concerned with the chance that a flood of certain size will be exceeded within a given period. Let \( p \) equal the probability of exceeding an annual flood of given magnitude. Assume the magnitude-frequency relationship is known without error and that annual peaks are randomly distributed in time. Then recurrence interval, \( R_l \), is equal to \( 1/p \). The probability of not exceeding the discharge for a given recurrence interval is \( 1 - p \), and the probability that it will not be exceeded in the next \( n \) years is:

\[
(1 - p)^n.
\]

Therefore, the probability that the flood will be exceeded at least once in the next \( n \) years is:

\[
1 - (1 - p)^n.
\]

This relationship is summarized in table 5. For example, the chance that a 50-year flood will be exceeded in any 20-year period is 33 percent.

Table 7.--Chance, in percent, that a flood of indicated recurrence interval, \( R_l \), will be exceeded at least once in any \( n \) year period.
