Radioactive springs geochemical data related
to uranium exploration--Basic data and use of
multivariate factor scores

by Robert A. Cadigan and J. Karen Felmlee
U.S. Geological Survey, MS 916, Federal Center,
Box 25046, Denver, Colorado 80225

ABSTRACT

Radioactive springs and wells at 33 localities in the States of Colorado, Utah, Arizona, and New Mexico have been studied and sampled to obtain geochemical data to determine whether such data are useful in a uranium exploration program. Most samples were collected from mineral-rich springs probably related to hydrothermal systems of various ages.

Two sets of data were obtained, the first based on the chemical composition and physical and chemical properties of spring and ground water, and the second based on the chemical composition of mineral precipitates deposited by radioactive springs. Multivariate statistical analysis of the water data suggests four major geochemical factors affecting the 23 parameters measured. These factors were labeled as total dissolved solids, alkalinity, temperature, and Fe-U concentration. Multivariate statistical analysis of the precipitate data suggests five factors affecting the 32 element values measured. These factors were labeled as mineral contamination, Mn precipitation, Fe-As-Be precipitation, heavy metals precipitation, and Ba-Ra precipitation.

Relative intensities of the geochemical processes represented by the factors were computed using factor scores. Sample localities were ranked on

the basis of relative intensities, and the five localities with the highest intensities were selected as being the most favorable for more intensive exploration for uranium.

Immediate use of such selection would be experimental because of the lack of industry experience at this time in the exploration of active hydrothermal systems for uranium.

Introduction

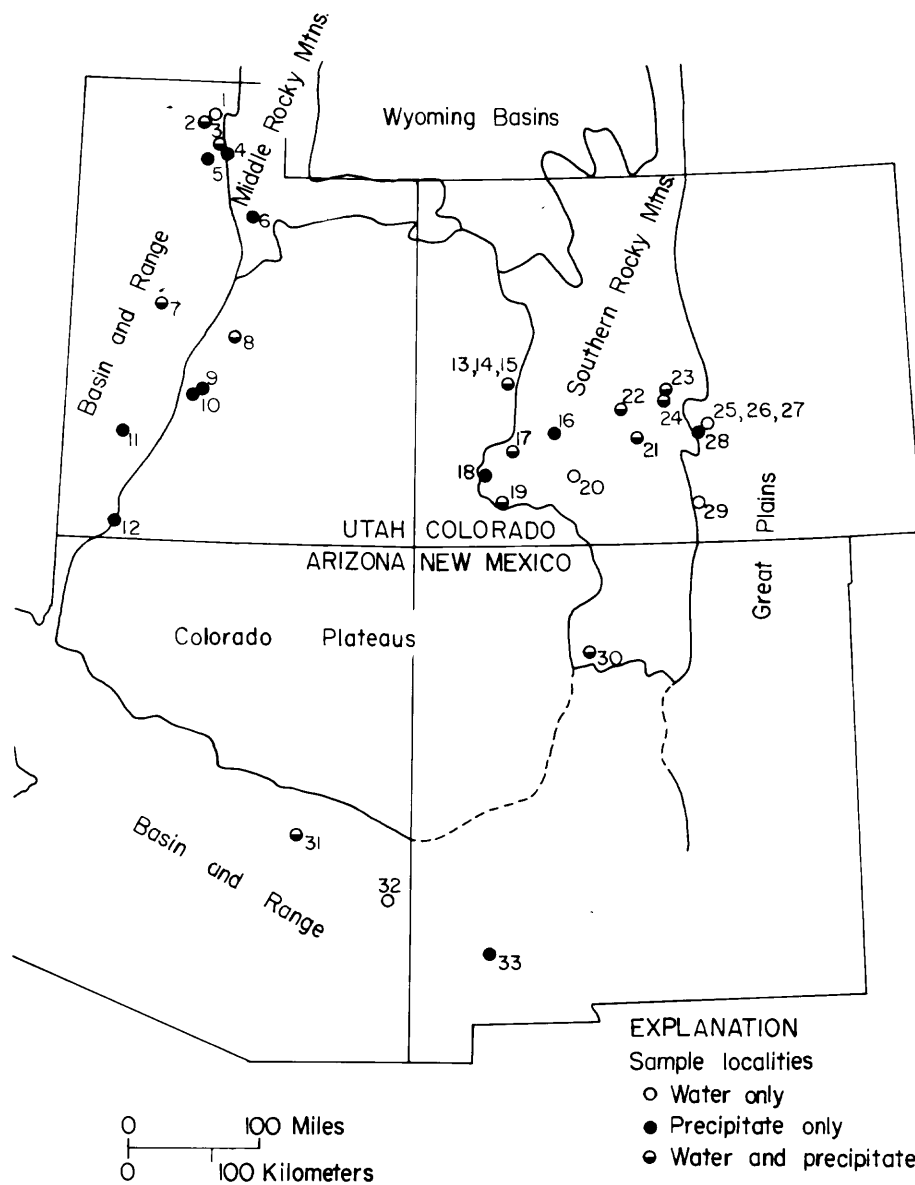

The purposes of this report are (1) to present the geochemical data which formed the basis for a previous report and (2) to illustrate the use of multivariate factor analysis for the purpose of evaluating relative favorability of areas containing uranium-bearing mineral springs. The previous report, entitled "Radioactive springs geochemical data related to uranium exploration," was presented at the 25th International Geological Congress in Sydney, Australia, in August 1976, and has since been published (Cadigan and Felmlee, 1977). The reader is referred to the 1977 report for discussions of previous work, sampling and analytical methods, sample bias, mineralogy of precipitates and other related information which for the sake of brevity will be omitted here.

Area of study

The 33 springs whose geochemical characteristics are described in this report are located in the Southern Rocky Mountains of Colorado and New Mexico and in the Basin and Range province of New Mexico, Arizona, and Utah. The Colorado Plateau occupies the center of this area but contains relatively few recognized mineral or thermal springs, and these are located near the margins of the Plateau. Sample localities and kinds of analytical data available from each site for this report are shown on figure 1. Table 1 lists the sample localities by county, State, and geographic longitude and latitude.

Figure 1.- Sample localities of selected springs and flowing or pumped wells. The symbols indicate the kind of samples for which data are available.

Data

Physical properties and geochemistry of the spring water and precipitate samples vary considerably. Table 2 shows the range of values and the median value for each measured parameter. The data used for statistical analysis in this report are given in tables 3 and 4. Data on water (table 3) were compiled from analyses of our samples and from analyses published in other reports since 1962 by the U.S. Geological Survey and by other organizations. Data on precipitates, table 4, are entirely from our own samples.

Mineralogy

The term "travertine" (properly a field term) has been used to describe the hard crystalline precipitates associated with many mineral springs. Travertine may consist of almost pure calcite or a mixture of minerals that can be differentiated by X-ray diffraction. Calcite most commonly composes 10 percent or more of each of the samples of precipitate that we collected. Other minerals present that compose 10 percent or more of at least one sample are barite, manganite, hematite, goethite, gypsum, fluorite, romanechite ($\text{BaMn}^{+2}\text{Mn}_8^{+4}\text{O}_{16}(\text{OH})_4$), and pyrolusite. Quartz, feldspar, dolomite, and mica are among the minerals identified that represent detrital grains and rock fragments in the samples. X-ray diffractometer traces do not account for the significant amounts of As or W known to be present, as shown in tables 2 and 4. This discrepancy suggests that these two metals are present in amorphous or noncrystalline forms. Some precipitates contain native sulfur in minor to major amounts. At some springs, deposits of Fe and Mn minerals as well as S have been mined as ores. Parts of the Stinking Hot Springs travertine deposit were found to be composed almost entirely of barite; part of it has been mined, first as a possible uranium ore (because of its high radioactivity), then later as a soil conditioner.

¹Only 16 samples.

²Only 17 of the most radioactive samples.

Table 3.--Analytical data for water samples from localities shown on Figure 1.

[Major ions were analyzed by wet chemical method; trace metals, by emission spectrography; radium by radiochemical method; and uranium, by extraction fluorometry. Data for locs. 20-24 and 29 are from Mallory and Barnett (1973) and V. J. Janzer (written commun., 1974); major ion data for location 7 are from Mundorff (1970), and radium and uranium values for loc. 19 are from Scott and Voegeli (1961) and for loc. 1 are from O'Connell and Kaufmann (1976).]

Factors controlling the geochemistry of waters and precipitates

Some of the geochemical factors that affect the measured parameters can be identified and their effects evaluated by using statistical multivariate factor analysis. Geochemical factor analysis is a matter of establishing, mathematically, cause and effect relationships in which the causes may be identified with geochemical factors or processes and the effects are the variations in parameter values. Three to six factors commonly account for more than 50 percent of the variation in a set of associated parameters. Conventionally the factors (causes) that can be identified are selected for interpretation, even though the number selected does not account for all the variation (effects). The first factor to come out of the analysis accounts for more variance than any subsequently derived factor, and for this reason it is identified as the most important factor affecting the parameters (variables). The second factor is second most important in its effects, and so forth.

For further discussions of factor analysis applied to data matrices, the reader should consult detailed papers by Imbrie (1963), Steiner (1965), Cadigan (1972), and a comprehensive text by Harman (1967).

Factor analysis of water sample data

The results of the R-mode factor analysis of the water sample data, table 3, are shown in table 5. Factor matrices for two to ten rotated varimax factors were studied, and the four-factor matrix was selected as most adequately establishing the order of importance and identifying the major causes of variation in the variables listed. The four factors account for 77 percent of the variance in the data for in the 27 water samples.

Note: Underlined factor loadings are those for variables most affected by the factor under which they are listed. If a variable is significantly affected by a second or third factor, its loading for that factor is shown in parentheses. Communalities are the sums of the squares of the factor loadings for each variable. They represent the proportion of variance in each variable accounted for by the four factors; thus, four factors account for 67% and 81%, respectively, of the variance in Ra and U concentrations in the waters.

We identified the four geochemical factors or processes as total dissolved solids (TDS), alkalinity, temperature, and Fe-U concentration. Table 5 variables and their numerical factor loadings, which represent the correlation between the variable and the respective factors, are divided into four blocks, representing factor groups. The upper block, for example, contains the variables most affected by increases and decreases in TDS. The second block contains variables most affected by variation in alkalinity; the third, variables most affected by variation in temperature; and the fourth block contains three interacting elements, Fe, U, and Ba.

With an increase or decrease of amounts of TDS in solution, most of the variables tend to increase or decrease in proportion to the squares of their factor loadings. Increases in alkalinity of the waters (factor 2) not only increase the concentrations of ions used as an indicator of alkalinity, $\text{HCO}_3 + \text{CO}_3$, but also increase pH. Decreases in alkalinity tend to be marked by increased values for Al, Mn, NO_3 , SO_4 , Fe, and Ca, and decreased values for $\text{HCO}_3 + \text{CO}_3$ and pH. Increases in temperature of the waters (factor 3) are marked by increased values for F, SiO_2 , SO_4 , and Mn; decreases in temperature tend to be marked by increased amounts of Ra. The effect of Fe-U concentration (factor 4) is more subtle. Increases in amounts of Fe and U in solution are marked by the presence of increased amounts of SO_4 , Mg, SiO_2 , and Ra. Decreased amounts of Fe and U in solution are marked by increased values for Ba, temperature, pH, and Mn. This complicated relationship occurs because Ba tends to remove SO_4 from solution and to precipitate as barite, which coprecipitates Ra. The loss of the SO_4 ion may cause an increase in pH, which brings about precipitation of Fe, U, Mg, SiO_2 , and Mn.

Factor analysis of precipitate sample data

Multivariate R-mode factor analysis was also done on data from 54 precipitate samples collected at 24 mineral spring localities (table 4).

We selected the first five factors as best identifying the major causes of variation in concentration of the elements listed. The five factors shown in table 6 account for 69 percent of the variance. The five major factors in order of importance are mineral contamination; Mn precipitation, Fe, As, and Be precipitation, heavy metals precipitation; and Ba precipitation. Table 6 variables and their loadings are divided into five blocks representing what might be called factor groups, as was done with the water data factor analysis.

The factor identified as mineral contamination is the most important single process affecting the variation of parameter values studied. Mineral contamination represents contributions of detrital grains, rock fragments, clay particles, and mineral dust transported by wind, water, or gravity from adjacent terrain, and soluble mineral salts from within the spring area deposited by transpiration and evaporation. This contamination process is negatively related to the precipitation of Ca mostly as CaCO_3 . The loadings suggest that precipitation of Ca and contamination represent opposing processes occurring at mineral spring sites. The second factor or process, the deposition of black and reddish-black Mn-rich precipitates, characteristically includes deposition of W, Mo, Sb, and Nb and to some extent Ga and Ba, and is inversely related to the deposition of Ca, Mg, and Na. The third factor, deposition of reddish-brown Fe-As-Be precipitates, characteristically includes deposition of Ge, Na, Y, and Ra(eU). Radium, represented by eU (total radiation count stated in terms of equivalent uranium), As, and related elements are coprecipitated by Fe(OH)_x . The fourth factor, precipitation of

Note: Underlined factor loadings are those for variables most affected by the factor under which they are listed. If a variable is significantly affected by a second or third factor, its loading for that factor is shown in parentheses. Communalities are the sums of the squares of the factor loadings for each variable. They represent the proportion of variance in each variable accounted for by the five factors; thus five factors account for 54% and 78%, respectively, of the variance in Ca and eU concentrations.

the heavy metals Co, Ni, U, Pb, Mo, Cu, Zr, and Cr, a classically hydrothermal suite of metals, is possibly related to igneous source rocks and TDS in the transporting solution. The fifth factor is precipitation of Ba as barite and coprecipitation of Ra and Sr.

Factor 5 confirms the strong association between Ba and Ra precipitation previously observed. The Mn and Fe-As-Be precipitation factors are also positively related to the occurrence of high eU (Ra). Spring localities where Mn- and Fe-rich precipitates are being deposited are typically, and in part conspicuously, radioactive. The factor groups are compatible with field observations and support the validity of our sampling procedures. In other words, the results of the statistical analysis of the sample data support what we think we see in the field.

Older precipitate deposits of extinct radioactive springs (or of springs which have migrated to new outlets) and the older parts of deposits of active springs lose most of their radioactivity in about 5,000 years. This loss of radioactivity is caused by radioactive decay of ^{226}Ra , which has a half life of 1,600 years. The phenomenon may be used as semiquantitative evidence to help estimate the cumulative period of activity of some modern springs and to identify older travertine deposits of active radioactive spring systems.

Factor scores for water samples

The intensity of the effects of the processes or factors determined in factor analysis can be measured by factor scores as computed by Steiner (1965). Algebraically the process of factor analysis can be visualized as a system of linear equations of the form:

$$Z_{ji} = a_{jk}f_k$$

in which i stands for the observations (samples) from 1 to N ; j , for the variables from 1 to n ; and k , for the factors from 1 to p . The problem is to

calculate the a's (factor loadings) and the f's (factor scores); Z_{ji} represents the Z scores (Dixon and Massey, 1951, p. 24) of each variable (j) for each sample (i). Tables 5 and 6 show the factor loadings for each variable.

The equation for computing factor scores is

$$f_{ki} = b_{kj}Z_{ji}.$$

b can be computed several ways, but the simplest way to obtain factor scores according to Steiner (1965), is to substitute factor loadings a for the b values. Thus the formula would be:

$$f_{ki} = a_{kj}Z_{ji}.$$

The factor scores are calculated by converting all data matrix natural log values to Z scores. Then a factor score is computed for each sample for each factor. For example, to compute a factor score for one sample for factor 1 in table 5, the standard score value for each variable is multiplied by the appropriate factor loading, and the results, added algebraically, yield a single score for the sample for factor 1. When this procedure is applied to all water samples for all factors the result is the factor score matrix of table 7. This matrix was computed from the data in table 3 and the factor loadings in table 5.

The scores are a quantitative measure of the intensity of the effects of the four factors. The high factor 1 scores for localities 1, 2, 3, 24, 30, and 31 suggest that the total dissolved solids effect is highest in samples collected from these locations (Crystal Hot Springs, Stinking Hot Springs, Utah Hot Springs, Taylor Soda Springs, Soda Dam Hot Springs, and Salt Banks Springs). Highest alkalinity effect (factor 2) is found in samples from a pumped well in Pueblo County (loc. 20) and from Poncha Hot Springs (loc. 22).

Table 7.--Computed factor scores (as defined by Steiner, 1965)
for water sample data (table 3)

Locality number	Sample number	Total dissolved solids	Alkalinity	Temperature	Fe-U concentration
		Factor 1	Factor 2	Factor 3	Factor 4
1	76MSW8	16.19	-4.34	1.04	3.15

20	MIN-1	-0.75	-.07	2.86	-.70
20	MIN-2	-.97	1.37	3.28	-.70
21	SAG-4	-5.05	2.24	1.40	-1.52
21	SAG-4	-5.43	2.31	1.31	-.159
22	CHA-7	-9.59	3.13	3.76	-3.10
22	CHA-6	-.930	2.89	3.48	-2.88
23	PAR-4	3.92	1.74	-1.31	+3.89
24	FRE-1	8.23	.87	-2.01	+5.31
25	75MSW10	1.83	.10	-.86	2.03
26	75MSW11	-19.59	6.75	-8.88	-3.52
27	75MSW13	-11.13	.70	-4.47	1.76
29	HUE-5	-13.45	2.57	-4.69	-3.31
29	HUE-4	-14.00	1.67	-4.72	-2.93
30	75MSW8	5.29	1.22	-3.79	-.55
31	76MSW1	13.86	-1.36	2.00	4.66
32	76MSW2	7.33	-.96	.58	-2.77

Highest temperature effect (factor 3) is found at Baker Hot Springs, Poncha Hot Springs, and Box Canyon (Ouray) Hot Springs. Highest Fe-U effect (factor 4) is found at Doughty Springs (Alum Spring), Taylor Soda Springs, and Salt Banks Springs.

In contrast, the samples showing lowest intensity effects of any factor are indicated by the large negative values for that factor. Thus, the sample with the least alkalinity effect is from Doughty Springs (Alum Spring). The sample with the lowest Fe-U effect is from the Col. Chinn well.

The four factors represent in a broad sense four new variables, and the scores are quantitative measures of the effects of these variables on the parameters measured.

Linear correlation coefficients (r) among the factors, using the scores in table 7, are calculated to be:

<u>Factors</u>	1	2	3	4
1 TDS.....	1.0			
2 Alkalinity.....	-.49	1.0		
3 Temperature.....	.42	-.32	1.0	
4 Fe-U concentration....	.53	-.61	.15	1.0

Coefficients of $r > \pm .38$ are significant at the 95-percent level, and those $> \pm .49$ are significant at the 99-percent level. All computed coefficients are significant except the ones between alkalinity and temperature and between Fe-U and temperature. Highest correlations are between alkalinity and Fe-U concentration (-.61), between TDS and Fe-U concentration (.53), and between TDS and alkalinity (-.49). The high correlations are interpreted to mean that Fe-U and TDS are generally both lower in waters of high alkalinity.

A scatter diagram of alkalinity factor scores and corresponding Fe-U factor scores (fig. 2) confirms the generally negative relationship between

Figure 2.--Scattergram of alkalinity factor scores plotted against iron-uranium concentration factor scores for 27 spring- and well-water samples.

the two. The extreme Fe-U high score is for a sample collected at Doughty Springs (Alum Spring), which has acidic water. On the other hand, the next highest Fe-U score is from Taylor Soda Springs, which has moderately alkaline waters. Of the springs studied, the higher Fe-U scores tend to occur in waters with alkalinity scores in the range of +1.0 to - 5.0. The lower Fe-U scores tend to occur in water with alkalinity scores in the range of +5.0 to -1.0.

Factor Scores for precipitate samples

Trace element data from table 4 and the factor loadings in table 6 were used to calculate factor scores for the 57 precipitate samples. The factor score matrix is shown in table 8.

As with the water samples, if the factors are considered to be geochemical processes, and the factor loadings an indication of the effects on the parameters measured, the factor scores are measures of intensity of the total effect of each process on each sample. Negative scores indicate low intensities, high positive scores indicate relatively high intensities.

Computed linear correlation coefficients (r) of the factor scores using all possible pairs are shown below:

	<u>Factors</u>	1	2	3	4	5
1	Mineral contamination.....	1.0				
2	Mn precipitation.....	.21	1.0			
3	Fe-As-Be precipitation.....	.71	.45	1.0		
4	Heavy metals precipitation...	.84	.33	.71	1.0	
5	Ba-Ra precipitation.....	.19	.43	.35	.07	1.0

Coefficient values of .27 or greater are significant at the 95-percent level, values of .35 or greater are significant at the 99-percent level.

Table 8.--Computed factor scores (as defined by Steiner, 1965)
for precipitate sample data (table 4)

Levels of Fe-As-Be and heavy metals precipitation correlate highly with mineral contamination, and levels of Fe-As-Be and Ba-Ra precipitation correlate highly with Mn precipitation. Thus there appear to be two groups of significantly intercorrelating factors: 1, 3, and 4; and 2, 3, and 5. The first group seems related to mineral contamination and heavy metals deposition. The second group seems related to Ra deposition. Factor 3 is included in both groups. The intercorrelations emphasize the fact that the effects of some of the geochemical processes tend to overlap to a highly significant degree. Thus, for example, the factor identified by us as mineral contamination is affected by the factors identified as Fe-As-Be precipitation and heavy metals precipitation, and the latter two factors are similarly related. Calcium precipitation (a factor?) may be a process competitive with the first four factors. Magnesium may occur both in mineral contaminants and in precipitates. Note its apparent negative relationship with Ca in factor 1 and its positive relationship with Ca in factor 2 in table 6.

Ranking of localities

Factor scores were used to rank the various sample localities in terms of the intensity with which each of the identified geochemical processes operated. This was done by using the highest sample score at each locality. For example, ranking of the water-sample localities in terms of scores for factor 4, the Fe-U concentration factor, produced the following six highest ranking localities and scores:

1. Doughty Springs	5.85
2. Taylor Soda Springs	5.31
3. Salt Bank Springs	4.61
4. Guffey Soda Springs	3.89
5. Crystal Hot Spring	3.15

6. Bakers Bridge Hot Springs 2.99

The six highest ranking localities for precipitate samples in terms of scores for factor 5, the Ba-Ra precipitation factor, are:

- | | |
|---------------------------|------|
| 1. Doughty Springs | 5.13 |
| 2. Poncha Hot Springs | 4.14 |
| 3. Stinking Hot Springs | 3.40 |
| 4. Soda Dam Hot Spring | 3.00 |
| 5. Box Canyon Hot Springs | 2.78 |
| 6. Red Hill Hot Springs | 1.98 |

The five highest ranking localities based on a composite of the scores of the four factors for water samples and the five factors for precipitate samples are shown in the following list and in figure 3:

1. Poncha Hot Springs
2. Salt Banks Hot Springs
3. Taylor Soda Springs
4. Crystal Hot Springs
5. Box Canyon Hot Springs

Based on the higher intensity of geochemical processes involving radioactive elements, these localities are considered to be the ones most likely to be associated with uranium mineralization.

Conclusions

The data presented in this report indicate that samples of water and precipitates from radioactive mineral springs and wells can supply a considerable amount of geochemical information of value in a uranium exploration program.

Multivariate statistical analysis and the computation of factor scores yield reproducible evidence regarding the relative intensities of geochemical

processes operating at the sampled localities. Based on the relative intensities of geochemical processes involving uranium and radium as measured by factor scores, localities may be selected as sites for further exploration for uranium deposits associated with active hydrothermal systems.

The immediate value of using radioactive mineral spring data for uranium exploration purposes cannot be demonstrated. Little exploration for uranium in hydrothermal systems has been attempted, owing to unevaluated risks related to depths of ore and a lack of knowledge concerning possible ore grades and size of deposits. Further geochemical study of the radioactive springs may provide additional information needed to decrease the risks involved in exploratory drilling of the uranium-rich hydrothermal systems.
