Ground-Water Data for the Riley and Andrews Resource Areas, Southeastern Oregon

By Paul M. Townley, Constance M. Soja, and W. C. Sidle

INTRODUCTION

Appraisals of the resources of selected management areas in eastern Oregon are being made by the U.S. Bureau of Land Management. To provide needed hydrologic information, the Bureau of Land Management requested the U.S. Geological Survey to inventory ground-water data for the Riley and Andrews Resource Areas. The inventory included field location of selected wells and springs; measurement of ground-water levels, temperatures, specific conductance, and pH; and the collection of ground-water samples from selected sources to determine dissolved chemical constituents.

Included in this report are well data, drillers' lithologic logs, hydrographs of observation wells, a summary of observation-well data, and chemical analyses of ground water.

Previous Investigations

The ground-water resources in parts of the study area have been discussed in previous reports, the oldest being Waring's (1909), which covers most of the area. The report by Piper and others (1939) covers the eastern half of the area southward to Frenchglen. Leonard's report (1970) describes the occurrence, distribution, availability, and chemical quality of ground water in Harney Valley. The Harney Valley report (Leonard, 1970) could serve as a basis for interpretation and evaluation of data for similar playa areas. The report by Hubbard (1975) describes surface-water inflows to Malheur Lake and includes a detailed water budget.

Geologic information for the resource areas is included in the reports by Waring (1909), Piper and others (1939), and Leonard (1970). Available geologic maps at scales of 1:250,000 and 1:500,000 include "Geologic Map of the Burns Quadrangle, Oregon" (Greene and others, 1972); "Reconnaissance Geologic Map of the Adel Quadrangle, Lake, Harney, and Malheur Counties, Oregon" (Walker and Repenning, 1965); and "Geologic Map of Oregon East of the 121st Meridian" (Walker, 1977). Williams and Compton (1953) describe the geology and mineral deposits in the Pueblo Mountains and southern part of Steens Mountain. Several agencies have ongoing studies of the geothermal resources of Harney County, and results of those studies provide additional data, such as the chemical analyses of hot springs included in table 4.

Water levels in representative observations wells in Oregon are measured periodically by the Oregon Water Resources Department (formerly the Oregon State Engineer), and water-level reports are published by that agency (Bartholomew and others, 1973).

Location and Description of the Area

The Riley and Andrews Resource Areas include most of Harney County in eastern Oregon (fig. 1). Small segments extend into Lake and Malheur Counties and into Humboldt County, Nev. Boundaries of the resource areas were established by the Bureau of Land Management to define land units that are managed by the Bureau's Burns District. Land in the Riley and Andrews Resource Areas is in both private and public ownership, but the major part is held in public trust by the Bureau of Land Management. The total area included in the two resource areas exceeds 6,100 mi².

The only incorporated cities in the study area are Burns and Hines, Oreg., near the northeastern edge of the Riley Resource Area. The estimated combined population of the two cities was 5,170 in 1976 (Oregon Secretary of State, 1977). The population density of the two resource areas is greatest in the Harney Valley near Burns and Hines; elsewhere it is extremely light. Small unincorporated settlements include Riley, Wagonfire, Frenchglen, Andrews, and Fields, all in Oregon. Denio is adjacent to the State boundary in Nevada.

Good highways cross part of the study area, but much of the area is accessible only during summer and fall by using four-wheel-drive vehicles.

The Riley Resource Area includes the western two-thirds of Harney Basin, the closed basin that drains toward Malheur and Harney Lakes. That basin includes the flat, featureless plain of Harney Valley; a similar small plain around Harney Lake; and uplands that border those valleys. Harney Valley slopes from about 4,150 ft near Burns to 4,090 ft at Malheur Lake, and the plain around Harney Lake is a few feet lower. The Andrews Resource Area includes Steens Mountain, which attains an altitude of more than 9,000 ft and is the highest of the uplands. Also included are Catlow and Alvord Valleys, and parts of the Pueblo and Trout Creek Mountains. The lowest part of the Catlow Valley closed basin is about 4,500 ft, and the lowest part of Alvord Valley is about 4,000 ft.

Harney Basin and Catlow and Alvord Valleys are closed basins with only internal drainage. The principal streams in the Harney Basin are the Silvies River and Silver Creek, which flow southward and drain the upland in the northern part of the Riley Resource Area, and the Donner und Blitzen River which drains the western ramplike slope of Steens Mountain and flows northward into Malheur Lake. The largest stream in the Andrews Resource Area is Trout Creek, which flows north through Pueblo Valley into Alvord Lake, an alkali lake in Alvord Valley. In addition, numerous small streams flow off the east flank of Steens Mountain into Alvord Valley, and a few small streams flow into Catlow Valley.

General Geology

The uplands along the borders of Harney Basin are formed by volcanic and pyroclastic rocks and nonmarine sediments derived from volcanic rocks. Lava flows of varying composition include basalt, andesite, rhyolite, and dacite. The rhyolite and rhyodacite commonly are porphyritic or contain spherulites and opaline lithophysae. Obsidian occurs locally. The pyroclastics include tuff, breccia, welded tuff, pumice, cinders, and lapilli. Silt and clay predominate among the sediments, but sandstone, conglomerate, fanglomerate, diatomite, and unconsolidated sand and gravel occur locally. In many places, the sediments are interbedded with lava flows or pyroclastics.

The uplands are cut by numerous faults, and the rock strata slope gently toward Harney Valley, which is both an erosional and a structural basin (Leonard, 1970, p 11).

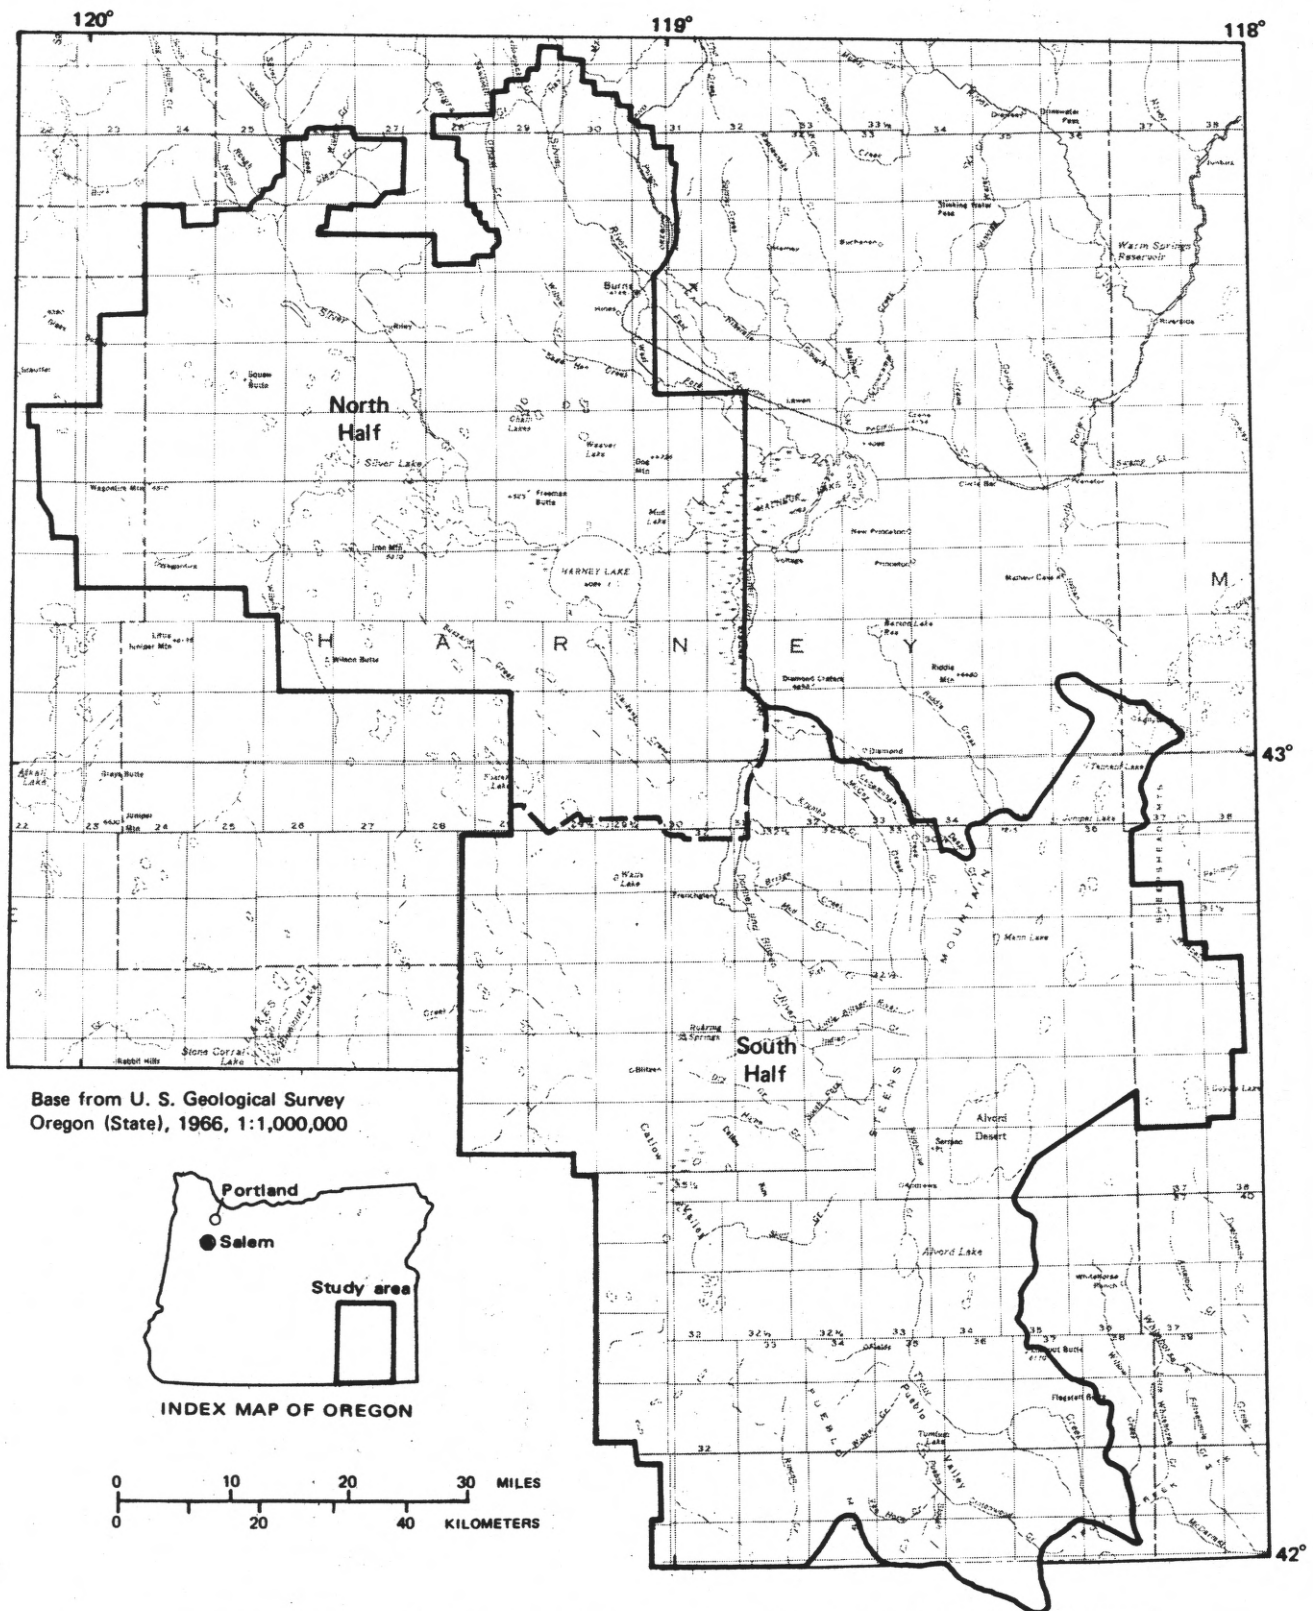

Figure 1.—Map showing the location and general features of the Riley and Andrews Resource Areas.

Unconsolidated valley-fill deposits underlie the Harney Valley floor to a maximum of about 250 ft (Leonard, 1970; Piper and others, 1939). The valley-fill deposits consist chiefly of silt and clay, but contain lenticular deposits of sand and gravel in alluvial fans and also along buried stream courses. Beneath the valley-fill deposits is a large but unknown thickness of consolidated rocks similar in composition to those exposed in the bordering uplands.

Farther south, faulting of the uplands has produced the Steens and Pueblo Mountains. These volcanic rocks have been tilted gently toward the west by a major set of faults (Williams and Compton, 1963, p. 32; Lund and Bentley, 1976, p. 51-53); consequently, most of the upland drains westward to the Donner and Blitzen River or into Catlow Valley. Catlow, Alvord, and Pueblo Valleys are underlain by an undetermined thickness of valley-fill deposits derived from these uplands.

Occurrence of Ground Water

Large quantities of ground water are withdrawn by numerous wells from sand and gravel and from consolidated rock aquifers near Burns, in Silver Creek and Catlow Valleys, and along the western margins of Alvord and Pueblo Valleys. Many wells produce as much as several hundred gallons of water per minute, and the water is used chiefly for irrigation. The distribution of the consolidated rock aquifers beneath the valley-fill deposits is generally poorly known, especially in Catlow and Alvord Valleys. Ground water in Harney Valley is generally confined beneath beds of clay or other rocks of low hydraulic conductivity (Piper and others, 1939). Locally, ground water in shallow sand and gravel aquifers is unconfined.

A large part of the study area is upland in which ground-water recharge is chiefly by direct infiltration of precipitation, and by local infiltration along streams during periods of high runoff. Each spring, snowmelt runoff from upland streams floods large areas of the Harney Valley floor and recharges the shallow section of the valley fill (Leonard, 1970). Upward movement of ground water from the underlying consolidated rocks also provides small quantities of recharge to the valley-fill deposits (Piper and others, 1939, p. 70). Similarly, Catlow, Alvord, and Pueblo Valleys receive the runoff from the Steens, Pueblo, and Trout Creek Mountains.

The general direction of movement of ground water in the Riley and Andrews Resource Areas is from upland recharge areas toward valley areas where the ground water is discharged from springs, by diffuse seepage to streams, by evapotranspiration, or by wells. In Harney Basin, ground water in the valley-fill deposits is moving toward Malheur and Harney Lakes. In Catlow, Pueblo, and Alvord Valleys, ground-water discharge from springs is common along the bases of alluvial fans. Evapotranspiration of shallow ground water probably is the cause of large areas of alkali soils in the valleys (U. S. Salinity Laboratory Staff, 1954).

Locally in these valleys, wells and springs yield warm, geothermally heated ground water; many of these sources are described by Piper, Robinson, and Park (1939) and Waring (1965). Chemical analyses of water from geothermal springs have been reported by Mariner and others (1975). Data for a few selected hot springs are listed in the accompanying tables; other data are available from files of the U.S. Geological Survey and Oregon Department of Geology and Mineral Industries.

EXPLANATION OF DATA

Well- and Spring-Numbering System

Wells and springs are assigned a number based on their location according to the rectangular system for subdivision of public lands. In successive order, the numerals represent the township, range, and section. Thus, well 36S/33E-16dcb is in township 36 south, range 33 east, section 16. A graphic illustration of this method of well location is shown in figure 2. The letters following the section number show the location in the section, the first letter designating the quarter section (160 acres), the second letter the quarter-quarter section (40 acres), and the third letter the quarter-quarter-quarter section (10 acres). Where two or more wells are in the same 10-acre subdivision, serial numbers are added after the third letter. For a spring, a lower case "s" follows the third letter.

Records of Wells and Springs

Records of wells and springs in the Riley and Andrews Resource Areas are listed in table 1, following the text. Some well records have been published for the Harney Valley area (Leonard, 1970; Gonthier and others, 1977). The wells in table 1, many of which have drillers' logs available, have been field located, and their locations are shown on plate 1. Well and spring locations were plotted on 1:63,360-scale Bureau of Land Management planimetric maps and Geological Survey 1:24,000 topographic maps. Table 1 also includes some data on selected springs, including an estimate of the discharge of the spring at the time of the visit. Little or no data were available, however, for estimating fluctuations in the discharge of those springs.

Figure 2.—Well and spring numbering system.

Drillers' Logs of Wells

Drillers' logs of wells are obtained from reports that have been submitted by drillers to the Oregon Water Resources Department since 1956, from Geological Survey files, and from records supplied by the Bureau of Land Management. Drillers' terminology for the materials penetrated, which varies from driller to driller, is used in table 2. The logs have been edited so that lithology is given first.

Hydrographs of Observation Wells

Date for observation wells in the study area are summarized in table 3, and are shown in figure 3 hydrographs of ground-water levels in 10 representative observation wells of 22S/31E-34ccb and 23S/31E-16dbb. Records for most of the wells started between 1962 and 1969, but measurements started in 1930. Ground-water levels generally rise each year when the ground-water reservoir is recharged and storage increases. If, over a period of time, ground-water discharge exceeds the rate of recharge, water levels gradually decline, and the hydrographs show a declining trend. Conversely, a rising trend occurs when ground-water recharge exceeds ground-water discharge. Seasonal variations range from less than a foot in well 25S/31E-29acb to more than 10 ft for several wells. In most of the study area, neither rising nor declining long-term trends are apparent, and the ground-water levels are more or less stable.

Chemical Quality of Ground Water

Ground-water samples from 25 wells and springs in the Riley and Andrews Resources Areas of Harney County were collected by the Geological Survey in 1979 for chemical analysis (table 4). In addition where possible, the specific conductance of water was measured, for each well and spring visited in 1979 and those measurements are reported in table 1. Table 4 also includes several analyses of water samples analyzed earlier from Harney Valley and several analyses of thermal springs from the Survey's geothermal file.

Analyses of samples from four wells (23S/23E-27acb, 26S/31E-33ccc, 29S/37E-17cca, 40S/36E-19ddd) and two springs (32S/36E-29daas and 37S/32½E-7dads) were made by the plasma-scan method. Determinations by that method are less precise than analyses by more "standard" methods; therefore, most of the constituents are reported to only one significant figure in table 4. In addition to the constituents reported in table 4, the plasma-scan analyses included a semiquantitative determination of more than 20 metals and trace elements which are tabulated in table 5.

The specific conductance of a water sample measures the ability of water to conduct an electrical current and is related to the concentration of the ionized dissolved constituents. Specific-conductance values in table 4 range from 56 to 4,590 micromhos per centimeter at 25°C, sulfate from 2.1 to 328 mg/L, fluoride from 0.1 to 19.0 mg/L, and arsenic from less than the detection limit to 1.0 mg/L. The highest measured values for all chemical constituents were in water from thermal springs. The source and significance of the chemical constituents and physical properties are summarized in table 6.

Figure 3.—Hydrographs of selected observation wells.

Thermal water has been defined as being at least 15°F (9°C) above the mean annual air temperature at the site (Waring, 1965), therefore 65°F or higher for the study area. Thermal water occurs in wells and springs in several parts of the Riley and Andrews Resource Areas, notably near Hines, around Harney Lake, and in Alvord Valley.

Temperatures above 100°F (38°C) were noted for five springs and one well reported in table 1. These waters have many similarities, including the concentrations of dissolved solids, silica, sodium, chloride, fluoride, and boron (table 4).

Table 1.--Records of selected wells and springs

Well or spring number: See page for description of well- and spring-numbering system.

Depth of casing: Depth of casing indicates total length of casing.

Finish: P, perforated; X, open hole; O, open end.

Character of material: Character of material refers to water-bearing formations as reported by driller.

Altitude: Altitude of land surface at well, in feet above mean sea level, interpolated from topographic maps.

Water level: Depths to water below land surface given in feet and decimals were measured by personnel of the Geological Survey; those given in whole feet

were reported by well driller or owner. F, flowing well whose static water level is not known.

Use: H, domestic; I, irrigation; P, public supply; S, stock; U, unused.

Remarks: Ca, chemical analysis reported in table ; L, driller's log in table ; B, bailed, P, pumped for indicated time to determine yield under "Well performance." Obs, observation well whose water level is measured periodically. Well and spring numbers are Burns District, Bureau of Land Management, identification numbers.

37S/32½E-7dads	< 10	< 10	< 50	< 10	70	< 50	7	10	70	< 5
40S/36E-19ddd	10	< 10	< 50	< 10	100	100	< 5	30	10	< 5

^{1/} These analyses were made using a direct-reading emission-spectrometric procedure utilizing an induction-coupled argon plasma excitation source. The results are considered to be semiquantitative, accurate only to one significant figure, and to have a confidence level of 68 percent. Where values are reported as < some numerical value, that number represents the lowest level of detection for that metal. For instance, "< 50" given for chromium indicates dissolved chromium in the water sample was less than the detection level of 50 ug/L.

Table 6.—Source and significance of chemical and physical characteristics of water

Constituent	Potential source(s)	Significance or definition
Silica (SiO ₂)	Silicate minerals in rocks.	Forms hard scale in high-pressure boilers.
Iron (Fe)	Iron-bearing minerals, well casings, and pipes.	In concentrations greater than 0.3 mg/L, may stain laundry and porcelain plumbing fixtures (National Academy of Sciences, 1974). Larger concentrations may impart objectionable taste to water.
Manganese (Mn)	Manganese-bearing minerals, decomposition of plant tissue.	In concentrations greater than 0.05 mg/L may cause brown to black stain in laundry and porcelain plumbing fixtures (National Academy of Sciences, 1974). Generally has same objectionable features as iron.
Calcium (Ca)	Rocks, soils, and "hardpan" deposits rich in calcium carbonate minerals and from fertilizers.	A constituent of scale deposits in water pipes, boilers, and cookware. Principal cause of water hardness.
Magnesium (Mg)	Ferromagnesium minerals in rocks.	A constituent of scale deposits in water pipes, boilers, and cookware. Second principal cause of water hardness.
Sodium (Na)	Sodium-bearing minerals in rocks; industrial wastes.	Large concentrations in combination with chloride give water salty taste. Large concentrations in irrigation water may reduce soil permeability.
Potassium (K)	Potassium-bearing minerals in rocks; present in plant tissue, sewage, industrial wastes, and fertilizers.	Essential plant nutrient.
Bicarbonate (HCO ₃) and carbonate (CO ₃)	Carbon dioxide in air and soil atmosphere, "hardpan" deposits, or cementing material in sediments; also decomposition of organic matter in soil.	In combination with calcium and magnesium, cause carbonate hardness. Carbonates of calcium and magnesium form scale in steam boilers and hot-water facilities and release corrosive carbon dioxide gas.
Sulfate (SO ₄)	Sulfide minerals in rocks, gypsum, precipitation, fertilizers, and sewage.	Sulfates of calcium and magnesium form hard scale. In concentrations greater than about 250 mg/L may have unpleasant taste and be cathartic to some individuals (National Academy of Sciences, 1974).
Chloride (Cl)	Soils and rocks, evaporite minerals, precipitation, animal wastes, and sewage.	Makes water corrosive; more than 250 mg/L may impart salty taste to water (National Academy of Sciences, 1974).
Fluoride (F)	Fluoride-bearing minerals which occur in trace amounts in most rocks.	Optimum concentrations tend to reduce decay of children's teeth; larger concentrations cause mottling of enamel of teeth. Concentration of fluoride in drinking water should not exceed 2 mg/L (U.S. Environmental Protection Agency, 1975).
Nitrate (NO ₃) as N	Bacterial action in soil and plants; concentrated in plant and animal wastes, sewage, and fertilizers.	Essential plant nutrient. In surface water excessive nitrate and phosphates in combination cause algal blooms which may result in organic enrichment of water and depletion of dissolved oxygen. Consumption of water with more than about 10 mg/L of nitrate as N may cause methemoglobinemia in infants (U.S. Environmental Protection Agency, 1975). In excess of average concentrations may indicate pollution by organic wastes.
Phosphorus (P or phosphate (PO ₄))	Phosphorus-bearing minerals present in most rocks in trace amounts. Component of sewage, animal wastes, fertilizers, and some detergents.	Essential plant nutrient. See nitrate.
Boron (B)	Boron-bearing minerals, volcanic gases, thermal springs, and sewage.	Essential in trace amounts to plant nutrition. In concentrations greater than about 2 mg/L, may be toxic even to tolerant crops (National Academy of Sciences, 1974).
Arsenic (As)	Dissolved from arsenic-bearing minerals. Ingredient of many herbicides and insecticides.	Prolonged consumption of water containing more than about 0.05 mg/L of arsenic may lead to chronic poisoning (U.S. Environmental Protection Agency, 1975).
Dissolved solids (residue on evaporation or calculated)		Measure of the concentration of dissolved solids in water.
Specific conductance		Indicator of the ability of a solute to conduct an electrical current. Gives indication of the concentration of dissolved solids in water.
Hardness as (CaCO ₃)	Mainly dissolved calcium and magnesium in water.	Property of water related to the formation of an insoluble curd with soap and the formation of scale in pipes, boilers, and cooking utensils.
pH (hydrogen ion activity)	Hydrogen ions in solution.	Hydrogen ion activity expressed in negative logarithmic units. A measure of the dissociation of water molecules. A neutral solution has a pH of 7.0.
Temperature	Determined by local environment.	Important physical characteristic that affects taste, efficiency of waste-treatment processes, cooling, suitability of habitat for aquatic life, and suitability for irrigation.
SAR (sodium-adsorption-ratio)	Calculated from the following equation: $SAR = \frac{(Na^+)}{\sqrt{\frac{(Ca^{+2}) + (Mg^{+2})}{2}}}$ where: Na ⁺ , Ca ⁺² , Mg ⁺² are in milliequivalents per liter.	Equation predicts the degree to which irrigation water tends to enter into cation-exchange reactions in soil. High SAR values imply a hazard of sodium replacing adsorbed calcium and magnesium; this replacement is damaging to soil structure.
