### CONVERSION FACTORS AND DEFINITION

The following factors can be used to convert inch-pound units in this report to the International System of units (SI).

Multiply inch-pound unit	By	To obtain SI unit
<pre>cubic foot per second (ft<sup>3</sup>/s) foot (ft) inch (in.) mile (mi) square mile (mi<sup>2</sup>)</pre>	0.02832 0.3048 25.40 1.609 2.590	cubic meter per second meter millimeter kilometer square kilometer

National Geodetic Vertical Datum of 1929 (NGVD of 1929): A geodetic datum derived from a general adjustment of the first-order level nets of both the United States and Canada, formerly called mean sea level. NGVD of 1929 is referred to as sea level in this report.

By Charles Parrett and J. A. Hull

### ABSTRACT

Once-monthly streamflow measurements were used to estimate long-term mean annual flow, mean monthly flow, and various points on the flow-duration curve for 72 sites in the mountainous areas of western Montana. The estimated flow characteristics at 56 measurement sites, together with data from 22 gaging stations, were used to develop maps showing the variability of mean annual runoff in inches for three areas.

Data from all measurement sites plus data from 34 gaging stations were used to develop regression equations relating mean annual flow to drainage area and precipitation, and equations relating flows of 10, 20, 30, 40, 50, 60, 70, 80, and 90 percent exceedance probability to mean annual flow. The study area was divided into two regions with a different set of estimating equations applicable to each region. The estimating equations for mean annual flow had coefficients of determination ( $R^2$ ) of 0.944 and 0.971 in the two regions, with corresponding standard errors of estimate of 33 and 17 percent. The coefficients of determination for the estimating equations for flows of various exceedance percentages ranged from 0.849 to 0.981 in one region and from 0.889 to 0.971 in the other.

Average errors of prediction were also calculated using data withheld from the regression analyses. The estimated average error for predicting mean annual flow was -16 percent in one region and -23 percent in the other. The estimated average prediction errors for flows of various exceedance percentages ranged from +2 percent to -38 percent in one region and from +18 to -15 percent in the other.

### INTRODUCTION

Recent energy shortages, coupled with the soaring costs of conventional energy sources, have spurred interest in alternative and renewable forms of energy. In the mountainous regions of Montana this interest has focused on the development of small-scale hydroelectric power. Almost 50 applications for preliminary permits under the Federal Energy Regulatory Commission licensing procedures were granted or pending as of November 1983 in western Montana.

The feasibility of small hydropower development is dependent upon the amounts of streamflow available for diversion. Unfortunately, few continuous-record streamflow-gaging stations have been established on small (drainage areas less than about  $100~\rm{mi}^2$ ) mountain streams in Montana. This paucity of data has made it difficult to adequately assess the potential for small hydropower development in Montana.

Previous studies by Boner and Buswell (1970), Farnes (1978), and Potts (1983) provided techniques for estimating mean annual streamflow at ungaged sites in the mountainous areas of Montana. A recent study by Cunningham and Peterson (1983) also provided a procedure for estimating flow-duration curves at potential hydropower sites in Montana. In each instance, however, the estimating techniques were

based on existing streamflow-gaging data, and thus might not be reliable when applied to ungaged small mountain streams.

Accordingly, the present study was undertaken in cooperation with the Montana Department of Natural Resources and Conservation. The purpose of the study was to expand the small, mountain streamflow data base and to refine previously developed estimation techniques.

The purpose of this report is to present the streamflow data and to describe the refined techniques for estimating streamflow characteristics developed from these data. Streamflow was measured once monthly at selected potential hydropower sites in western Montana. These data, together with miscellaneous streamflow data and gaging-station data previously collected on mountain streams, were then used to estimate long-term flow characteristics at each site. The streamflow data and estimating techniques described herein will be useful to hydropower developers, land-use managers, water-rights administrators, and others who need to estimate streamflow characteristics in the mountains of western Montana.

In addition to streamflow data collected by the U.S. Geological Survey, flow data were furnished by Bill Schultz of the Montana Division of Forestry, Wally Page of the Flathead National Forest, and Larry Meshew of the Kootenai National Forest. The assistance and cooperation of these individuals are greatly appreciated.

### DESCRIPTION OF THE AREA

The study area includes that part of Montana within the upper Columbia River basin as shown in figure 1. This area, generally referred to as western Montana, is composed largely of north— to northwest—trending mountain ranges separated by long, straight valleys. Except for the valley floor areas, the study area is generally rugged and densely forested. Almost all potential, small hydropower sites are located in the rugged mountains of the study area.

Annual precipitation varies greatly in the study area, primarily because of the effects of the mountains. Annual precipitation thus tends to be greater in the mountains and generally greater on the western slopes than on the eastern slopes. Most precipitation occurs as snow, although significant amounts of rainfall commonly occur in May and June.

Annual runoff generally follows the precipitation pattern, with greater amounts occurring in higher-elevation areas. Streamflows vary greatly on a seasonal basis; snowmelt provides the bulk of annual runoff in May and June. The smallest streamflows generally occur during fall and winter when base flows are entirely the result of ground-water inflow.

Significant concentrations of small hydropower permit applications have occurred in the Yaak River drainage in the northwestern part of the study area and in the Swan River drainage in the east-central part. Both areas receive more than 40 in. of precipitation annually, are densely forested, and have numerous small streams with well-formed drainage patterns and steep channels. Although few small hydropower permit applications have been made in the Bitterroot River drainage, the west side of the Bitterroot River is similar in topography and climate to the Swan River drainage. This area also receives more than 40 in. of precipitation annually,

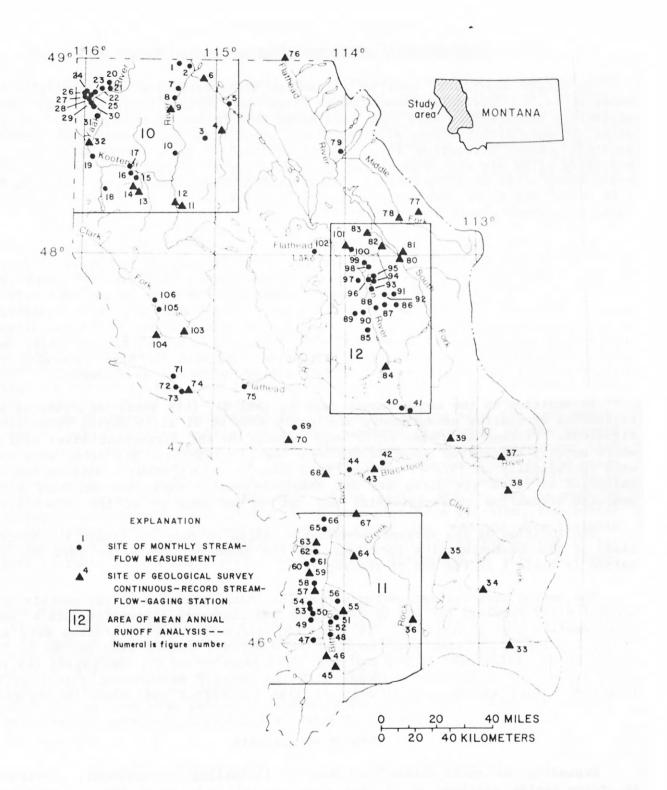

Figure 1.--Location of streamflow-measurement sites and gaging stations.

is extremely rugged and densely forested, and may thus have as much hydrologic potential for small hydropower development as the Swan River drainage.

### STREAMFLOW MEASURING SITES AND GAGING DATA

To obtain additional data on streamflow characteristics at potential hydropower sites, 51 streamflow-measurement sites were established, and once-monthly streamflow measurements were made from March 1982 through February 1983. Of these sites, 10 were either active or discontinued crest-stage gage sites where some data on stage versus streamflow were already available. Using crest-stage gages as measuring sites was also a means for minimizing travel costs. Also, four of the 51 measurement sites were located at discontinued streamflow-gaging stations on Fortine Creek, Big Creek near Rexford, the St. Regis River, and Bear Creek near Essex. These measurements were used for correlation purposes only.

Most of the streamflow-measurement sites were located in the Kootenai River basin and in the Swan River basin, the two areas of current hydropower interest. The sites were selected near main-traveled roads where possible to ensure year-round access. On several streams in each area, more than one measurement site was used to determine streamflow variability within the same drainage. Year-round access was not possible at most of the additional measuring sites on these streams. The rest of the 51 sites measured in 1982-83 were located on streams that, based upon a reconnaissance-level onsite inspection, appeared to have favorable flow characteristics and a sufficient fall (slope) for hydropower development.

In addition to the measurements made in 1982-83, this study incorporates miscellaneous streamflow measurements previously made at 21 sites during other investigations. Fifteen of these sites were located in the Bitterroot River drainage where monthly streamflow measurements were made in 1958-59. Six sites were measured sporadically in 1974-75 as part of a lake tributary study. Because the data collected at these six sites are not complete monthly data, the accuracy of the computed streamflow characteristics may not be as good as at the other sites.

The location of the streamflow-measuring sites is shown in figure 1. Descriptions of the measuring-site locations and the measured streamflow data are contained in table 1 at the end of the report.

The method used for estimating streamflow characteristics at the monthly measurement sites requires the use of concurrent and long-term streamflow data at nearby streamflow-gaging stations. In addition, streamflow-gaging station data from throughout the study area were required to develop a common base period of flow record at all sites used in the analysis. The location of all the gaging stations used, either for comparison purposes with the monthly measurement sites, or for long-term record extension purposes, is also identified and shown in figure 1.

## METHODS OF ANALYSIS

Expanding the small-stream data base by installing conventional, continuous-recording gaging stations would have been prohibitively expensive. In addition, any new stream-gaging station would have to be operated at least several years to obtain enough data to determine long-term streamflow characteristics. Accordingly, an alternative method based on once-monthly discharge measurements at selected sites was used.

# Estimating streamflow characteristics from discharge measurements

Riggs (1969) found that an annual mean discharge could be determined from once-monthly discharge measurements with an expected error of about ±10 percent. In New York, Hunt (1963) also found that miscellaneous streamflow measurements made during base-flow periods could be used to estimate flow-duration curves with about the same accuracy. In both instances, the streamflow measurement made at the ungaged site is compared with the daily mean discharge for the same day at a nearby gaging station. If the gaging station is in the same general hydrologic setting as the site in question, the relationship between the daily mean discharge and some streamflow characteristic at the gage can be assumed to be the same at the ungaged site. Thus, for example, if the daily mean discharge at the gaging station is one-half the monthly mean discharge, then the measured discharge at the ungaged site is also assumed to be one-half its monthly mean discharge. Likewise, if the daily mean discharge at the gaging station is equal to the 50-percent exceedance discharge on the flow-duration curve, the measured discharge at the ungaged site is also assumed to be equal to the 50-percent exceedance discharge.

To obtain an estimate for the annual mean discharge at an ungaged site, Riggs recommended that discharge measurements be made each month. The measurements are made near the middle of the month on the assumption that a measured discharge at that time is closer to the mean discharge for the month than a measurement made near the beginning or end of the month. The ratio of the monthly mean discharge to the daily mean discharge is determined for the nearby gaging site for each month. Each monthly ratio is then multiplied by the measured discharges at the ungaged site to estimate monthly mean discharge. The estimated monthly means are then averaged to obtain an estimate of the annual mean discharge for the year the measurements are made. In addition, a graphical plotting of each measured discharge versus the concurrent daily mean discharge at the gaging station can be made on log-log paper. In general, the closer the points plot to a 45°-line, the better is the relationship between the ungaged and the gaged site, and the more reliable are the estimates of monthly mean discharge. An application of the method is illustrated in table 2, and the plotting of concurrent discharges is shown in figure 2.

Concurrent discharges are also used to determine flow-duration curves for ungaged sites. From the period of record at the gaged site, the exceedance percentage is determined for each concurrent daily mean discharge. The same exceedance percentage is assumed applicable to the concurrent streamflow measurement at the ungaged site, and the points are plotted on log-probability paper. A smooth curve fitted through the points as shown in figure 3 determines the final estimated flow-duration curve for the same period of record as the gaged site. The flow-measurement data used to construct figure 3 are listed in table 3.

### Extending streamflow records to a common base period

The techniques just described will provide at an ungaged site an annual mean discharge for the year in which the miscellaneous measurements are made and a flow-duration curve for the period of record at the concurrent gaging station. Because the length of record at the gaging stations used for comparisons varied from 5 to 45 years, all records were extended to a common base period. This extension would hopefully eliminate any bias in the estimated flow characteristics due to short, perhaps unrepresentative, streamflow records.

Estimated annual mean discharge 23.0

The method chosen to extend streamflow records was a statistical regression procedure developed by the U.S. Army Corps of Engineers (1971). The regression procedure (HEC-4) uses monthly flow data from several streamflow gages in an area to estimate missing monthly flow values for each gage and for each year of record. The model also preserves the variance of the unadjusted short-term record by adding a random component to the estimated values. Starting with the first year of data, missing monthly streamflows are estimated at all stations for each month in sequence. Thus, whenever a missing flow is being estimated, there always exists a valid value for all stations already examined that month and for all remaining stations in either the current or preceding month. The equation for estimating missing flows has the following general form:

$$Q_{i,j} = B_1 Q_{i,1} + \dots + B_{j-1} Q_{i,j-1} + B_j Q_{i-1,j} + B_{j+1} Q_{i,j+1} + \dots + B_n Q_{i,n} + \sqrt{1 - R_{i,j}^2} \cdot (Z_{i,j})$$
(1)

where

 $Q_{i,j}$  is the monthly flow logarithm, expressed as a standard normal deviate, for month i and station j,

Data used to prepare figure 2.

- B<sub>j</sub> is the beta coefficient for station j computed from a correlation matrix of flows at all n stations,
- $R_{i,j}$  is the multiple correlation coefficient for month i, and station j, and  $Z_{i,j}$  is a random number generated from a standard normal population.

If any station being used to estimate a missing monthly flow is also missing a flow value for that particular month (i), then the flow for the preceding month (i-1) is used in the right side of equation 1. If, for example, the monthly flow at station 1 and month i were missing, the first term on the right side of equation 1 would be  $B_1Q_{i-1}.1$ .

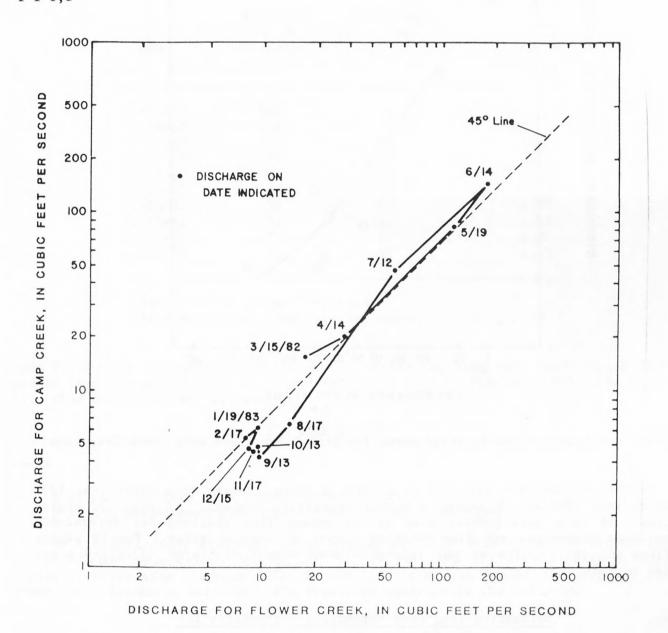

Figure 2. -- Concurrent discharges on Camp Creek and Flower Creek.

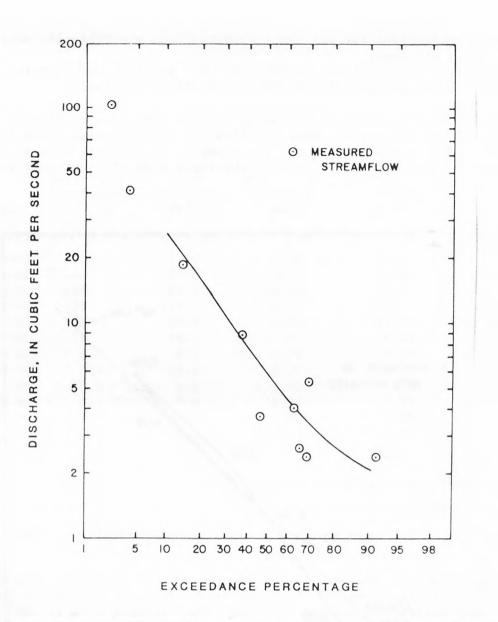

Figure 3.--Estimated flow-duration curve for Soup Creek above Soup Creek Campground.

The HEC-4 procedure was used to develop a common record from water year 1938 to water year 1982 at 38 gaging stations in western Montana. Of these 38 gaging stations, 19 were subsequently used as concurrent flow stations for determining annual mean discharges and flow-duration curves at ungaged sites. The 19 gaging stations and the results of the long-term mean annual discharge adjustments are listed in table 4.

# Estimating long-term streamflow characteristics

To obtain an estimate of the long-term mean annual discharge from an estimate of one annual mean, data from nearby gaging stations were used. In the northwestern part of the study area (Kootenai River drainage), five gaging stations with active record from March 1982 to February 1983 (sites 6, 14, 32, 103, and 104) were

Data used to prepare figure 3.

used to develop a regression equation for estimating long-term mean annual discharge from the annual mean discharge for March 1982 to February 1983. The equation thus derived is as follows:

$$Y = 0.88 \ X \ 1.00$$
 (2)

where

Y is the long-term mean annual discharge, and

X is the annual mean discharge for March 1982 to February 1983.

In the Bitterroot drainage, seven gaging stations with active record during the 1958 water year (sites 36, 46, 55, 57, 59, 64, and 67) were used to develop a similar regression equation relating the long-term mean annual discharge to the annual mean discharge for 1958. The resulting equation is the following:

$$Y = 1.11 \times 0.99 \tag{3}$$

where

Y is the long-term mean annual discharge, and

X is annual mean discharge for the 1958 water year.

<sup>&</sup>lt;sup>2</sup>From Swan River flow-duration curve.

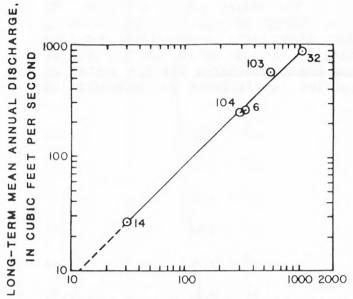

For the rest of the study area (Clark Fork drainage), four gaging stations with active record during March 1982 to February 1983 (sites 39, 43, 70, and 84) were used to develop the following regression equation:

$$Y = 0.77 \times 1.00$$
 (4)

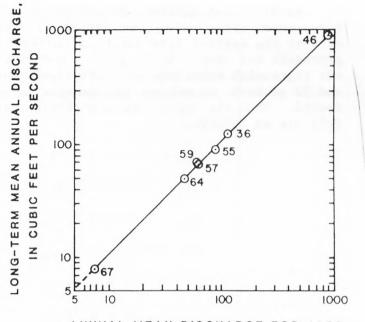

where the terms are the same as previously defined for equation 2. Plots of the three regression equations thus developed are shown in figure 4. The regression equations were used to calculate a long-term mean annual discharge at each flow measurement site where the annual mean discharge for the measurement year had previously been estimated.

Figure 4.--Regression equations relating long-term mean annual discharge to one annual mean discharge.

As discussed earlier, flow-duration curves were prepared for the ungaged flow measurement sites using the period of record at the nearby gaging stations. To convert the derived flow-duration curves to the 1938-82 base period, the following procedure was used. At 26 gaging stations with essentially natural flow, six linear regression equations were developed relating daily flows of 10, 20, 30, 50, 70, and 90 percent exceedance percentages to mean annual discharge for the period of record. The six equations and their respective coefficients of determination  $(r^2)$  are as follows:

$$Q_{10} = -21.66 + 3.01 Q_{2}$$
  $r^{2} = 1.00$  (5)

$$Q_{20} = -24.46 + 1.49 Q_A$$
  $r^2 = 1.00$  (6)

$$Q_{30} = 1.29 + 0.72 Q_A \qquad r^2 = 0.98 \tag{7}$$

$$Q_{50} = 8.37 + 0.35 Q_a$$
  $r^2 = 0.96$  (8)

$$Q_{70} = 7.76 + 0.24 Q_{A} \qquad r^{2} = 0.95 \tag{9}$$

$$Q_{90} = 6.94 + 0.17 Q_A \qquad r^2 = 0.94 \tag{10}$$

where

 $Q_i$  is the daily flow with an exceedance percentage of i, which ranges from 10 to 90, and

 $Q_{\Delta}$  is the mean annual discharge for the period of record.

To obtain the regression coefficient (the number multiplied by  $\mathcal{Q}_A$ ) for any exceedance percentage, a smooth curve relating the coefficient to exceedance percentage was drawn as shown in figure 5. To compute a point on the long-term (1938-82 base period) flow-duration curve for an ungaged site, the difference between the long-term mean annual discharge and the mean annual discharge for the period of record is calculated for the nearby gaging station used to estimate the flow-duration curve. This difference is multiplied by the appropriate regression coefficient in figure 5 and algebraically added to the flow value determined from the estimated flow-duration curve.

To illustrate, assume the flow-duration curve was estimated for an ungaged site using the methods previously described. Further assume the flow-duration curve shows that the 10-percent exceedance discharge is 210 ft $^3$ /s. At the nearby gaging station, the mean annual discharge for the period of record is assumed to be 30 ft $^3$ /s, and the long-term mean annual discharge is assumed to be 40 ft $^3$ /s. The adjusted long-term daily discharge with an exceedance percentage of 10 is computed for the ungaged site as follows:

$$Q'_{10} = 3.01 (Q_A' - Q_A) + Q_{10}$$
  
= 3.01 (40-30) + 210  
= 240 ft<sup>3</sup>/s

where the terms with primes are long-term values.

To compute long-term mean monthly discharges at the ungaged measurement sites, several techniques were tried. The first was to adjust the monthly mean values

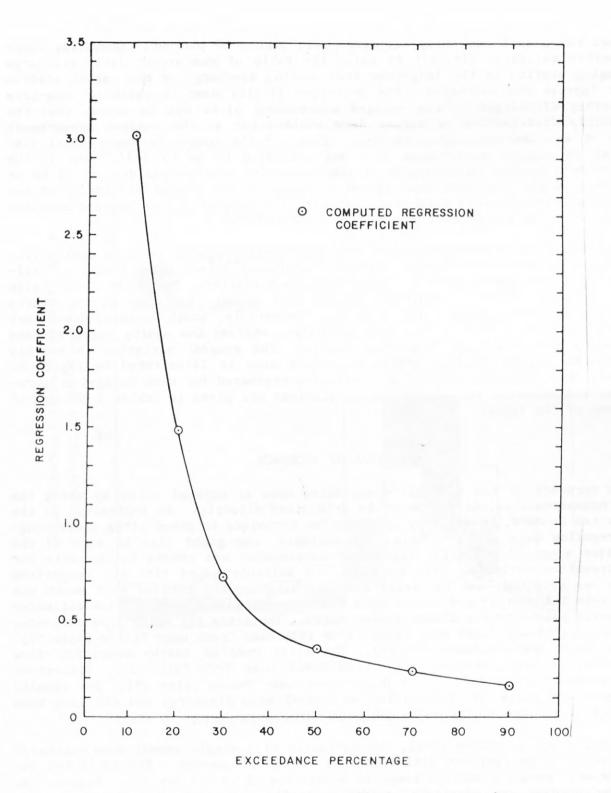

Figure 5.--Relationship of regression coefficient to exceedance percentage:

already computed as a part of the annual mean flow determination procedure. This technique was discarded, however, because the error associated with an individual monthly mean estimate was too large. Tests with gaging station data showed that individual monthly mean estimates could be in error by as much as 40-50 percent

even when the annual mean flow estimates were within 10 percent. Computing long-term monthly estimates directly by using the ratio of concurrent daily discharge at a gaging station to the long-term mean monthly discharge at the gaging station did not improve the estimates. The technique finally used to estimate long-term mean monthly discharges at the ungaged measurement sites was to assume that the same monthly distribution of annual flow would occur at the ungaged measurement site as at some nearby gaging station. Thus, if the long-term mean annual discharge at an ungaged measurement site was estimated to be 23 ft $^3$ /s, and if the long-term mean October discharge at a similar gaging station was determined to be 4.1 percent of the long-term mean annual discharge at the gaging station, then the best estimate for the long-term mean discharge for October at the ungaged measurement site would be 4.1 percent of 23 ft $^3$ /s or 0.9 ft $^3$ /s.

Adjustments to the computed long-term mean monthly discharges were subjectively made when it was known that the ungaged measurement site-streams functioned differently from the gaging stations considered most similar. Parmenter Creek (site 15), for example, becomes completely dry in late summer, but none of the nearby streams monitored by gaging stations do so. Conversely, South Woodward Creek near its mouth (site 90) has a fairly even discharge, whereas the nearby gaged streams show a large seasonal variation in discharge. The general variation in monthly streamflow at gaging stations within the study area is illustrated in figure 6. The final, long-term streamflow characteristics estimated for each ungaged measurement site and selected streamflow gaging stations are given in tables 5 through 10 at the end of the report.

### APPRAISAL OF ACCURACY

The accuracy of the streamflow estimates made at ungaged sites by using the monthly measurement technique cannot be determined directly. An indication of the accuracy can be made, however, by applying the technique to gaged sites where long-term streamflow data are available. Accordingly, one gaged site in each of the three major areas of potential hydropower development was chosen as the site for which streamflow estimates were required. A suitable gaged site for comparison purposes was selected, and the daily mean discharge on the 15th of each month was used to make the monthly and annual mean discharge estimates and the flow estimates for selected points on the flow-duration curve. The sites for which flow estimates were made were Flower Creek near Libby (site 14), Bear Creek near Victor (site 59), and Swan River near Condon (site 84). The sites used as nearby concurrent-flow gaging stations were, respectively, Yaak River near Troy (site 32), Bitterroot River near Darby (site 46), and Monture Creek near Ovando (site 39). The results of the accuracy tests for determining an annual mean discharge and the long-term mean annual discharge are given in tables 11-13.

As indicated by tables 11-13, the estimates of a single annual mean discharge have an error range (percent difference) of -3 to -11 percent. The estimates for long-term mean annual discharge range in error from -2 to -15 percent. Because the three test streams are considered to be generally representative of the streams actually measured, it is concluded that the estimates of long-term mean annual discharge have an average error of about +10 percent.

The estimated flow-duration curves for the three test streams are plotted in figures 7-9. The plotted points are taken from tables 11-13, and final values from the smoothed curves and the associated errors are listed in tables 14-16. The

average error for the estimated flow-duration curves ranged from 6 percent to 17 percent. The duration curves estimated for the ungaged flow measurement sites are thus believed to have a comparable average error of 10-15 percent.

The estimated long-term mean monthly discharges and the associated errors for the three test sites are given in tables 17-19. As indicated by the tables, the errors associated with the estimates of mean monthly discharge are much more variable and generally larger than the errors for estimating the mean annual discharge or the flow-duration curve. For each of the three test streams, at least one mean monthly discharge estimate was in error by more than 40 percent. On two of the test streams, the largest error for a monthly mean estimate exceeded 50 percent. The mean monthly discharge estimates made for the measurement sites are believed to have comparably large errors. The accuracy of the mean monthly flow estimates could be significantly improved only if more than one flow measurement per month were used or if the once-monthly flow-measurement program were continued for several years.

#### VARIATIONS IN MEAN ANNUAL RUNOFF

To more fully explore the variations in mean annual runoff throughout the study area, the three areas with the greatest concentrations of streamflow gages and flow-measurement sites are shown in detail in figures 10-12. Each figure shows the site number and location of each streamflow measurement site and streamflow-gaging station in the area. Also shown beneath each site number is the long-term mean annual runoff expressed in inches.

The first area is in the northwestern part of the study area and includes most of the Kootenai River drainage in Montana (fig. 10). As shown by the lines on the map, mean annual runoff generally increases from east to west in the Kootenai River area. The greatest annual runoff occurs in the mountainous regions southwest of Libby and west of the Yaak River. The streams in the Yaak River drainage having multiple-measuring sites indicate that annual runoff generally increases with elevation. Lines of equal mean annual runoff were drawn in figure 10 by assuming that the computed values of mean annual runoff were effectively located at the centroids of the individual drainage basins. Elevation and maps showing average annual precipitation (U.S. Soil Conservation Service, 1977) were used as a guide in drawing lines where no runoff data were available. The lines of equal mean annual runoff can be used to estimate mean annual runoff at any ungaged site in the area. needs to be emphasized, however, that mean annual runoff is determined at the centroid of the drainage area upstream from the site and not at the site itself. Also, the locations of the lines are based on a limited number of flow-measurement sites and considerable variation between the lines is possible.

The second area is composed largely of the Bitterroot River drainage (fig. 11). In this area, mean annual runoff varies markedly from the east side of the Bitterroot River, where computed values range from 4 to 14 in., to the west side of the Bitterroot River, where mean annual runoff ranges from 26 to 43 in. On the west side, the computed values of mean annual runoff are consistent from south to north, except for the two northernmost streams, Bass Creek and Sweeney Creek (sites 65 and 66). Although multiple measuring sites were not used on streams in the Bitterroot area, mean annual runoff was assumed to increase with elevation, and the lines of equal mean annual runoff were drawn accordingly. A previous study by McMurtrey and others (1972) indicated that streams on the west side of the Bitterroot River generally lose a substantial amount of their flow when they leave the mountain canyons and flow over the porous alluvium of the valley floor. Consequently, the lines of equal mean annual flow shown in figure 11 will not provide accurate estimates of mean annual flow at locations on the valley floor.

The third area is drained by the Swan River and the South Fork Flathead River (fig. 12). Mean annual runoff tends to be greater on the east side of the Swan River than on the west side, although the east-west variation is not as pronounced as in the Bitterroot area. Mean annual runoff also generally increases from south to north on the east side of the Swan River. The multiple measuring sites in the Swan River area indicate a large increase in mean annual runoff from the valley floor to the mountains. As in the Bitterroot area, substantial streamflow losses evidently occur as the mountain streams enter the alluvium of the valley floor. Consequently, the lines of equal mean annual runoff will not provide accurate estimates of mean annual flow in the valley-floor area.

Several anomalies in the general pattern of mean annual runoff variation also occur in the Swan River area. Porcupine Creek (site 97) and Johnson Creek (site

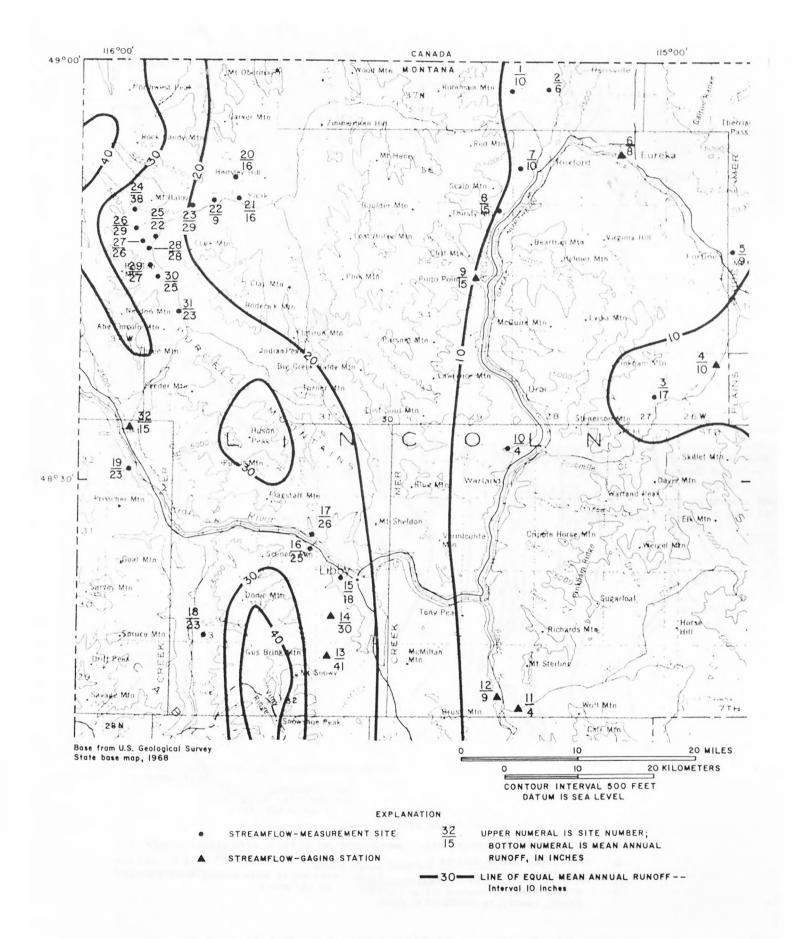

Figure 10.--Mean annual runoff in the Kootenai River area.

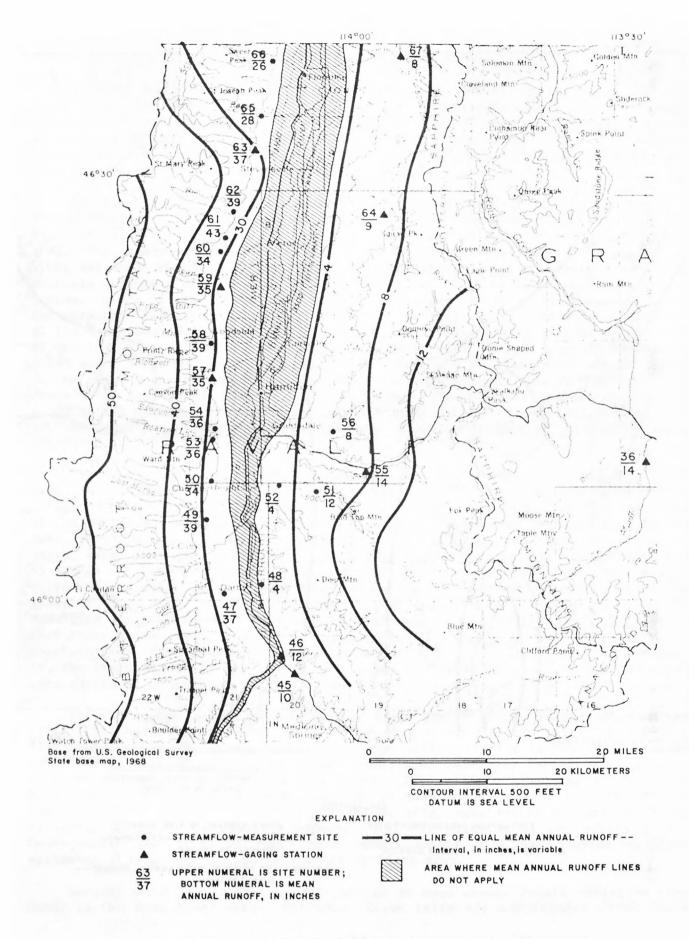

Figure 11.--Mean annual runoff in the Bitterroot River area.

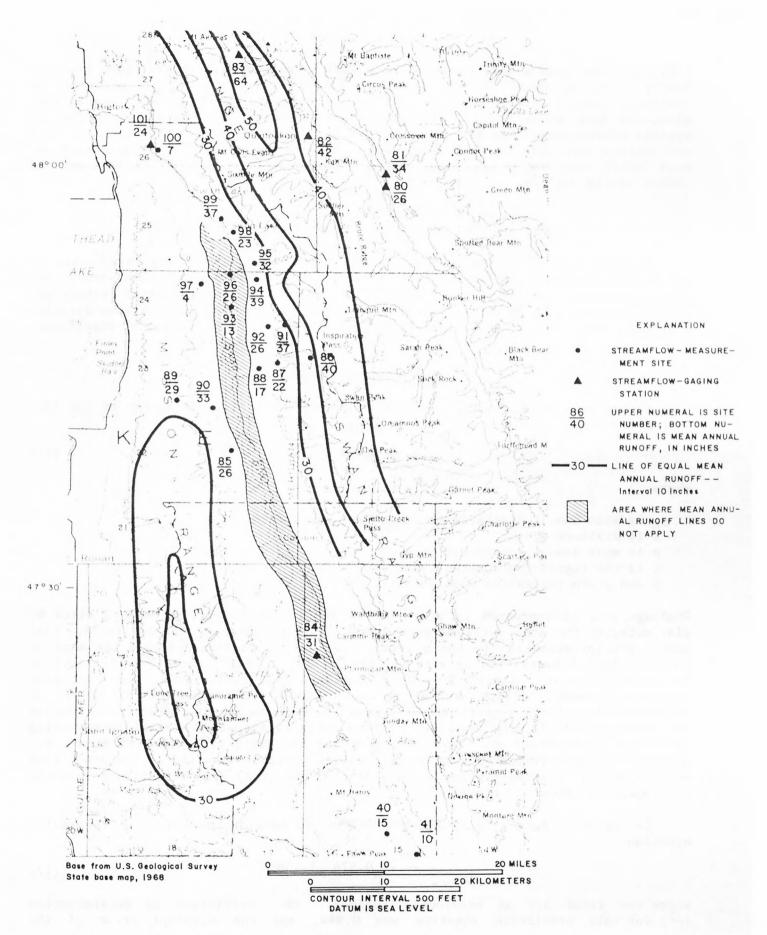

Figure 12.--Mean annual runoff in the Swan River area.

100) both have mean annual runoff values substantially smaller than those from any nearby measuring site. These streams may traverse sections of very permeable or fractured bedrock that intercept a large percentage of the annual streamflow. Also, the mean annual runoff of South Woodward Creek is evidently increased by springs between measuring sites 89 and 90. These anomalies serve to emphasize that generalized maps such as figures 10-12 can be used to accurately estimate mean annual runoff only where local geology and ground-water/surface-water interactions remain fairly uniform.

### EQUATIONS FOR ESTIMATING STREAMFLOW CHARACTERISTICS

Because maps of mean annual runoff could be developed for only three parts of the western Montana study area, prediction equations for estimating mean annual discharge anywhere in the study area were derived using multiple regression techniques. Prediction equations relating streamflows for various points on the flow-duration curves to mean annual discharge were also developed using multiple regression.

# Mean annual discharge

To estimate mean annual discharge, a multiple-regression equation of the following log-linear form was derived:

$$Q_A = aA^b p^C \tag{11}$$

where

 $\mathcal{Q}_{A}$  is mean annual discharge in cubic feet per second,

A is drainage area,

P is mean annual precipitation,

a is the regression constant, and

b and c are regression coefficients.

Drainage area is expressed in square miles and is determined for ungaged sites by planimetering the area outlined on the best-scale topographic map available. Mean annual precipitation is the basin average, in inches, determined from the maps of the U.S. Soil Conservation Service (1977). No other basin characteristics such as basin elevation or channel slope were considered for inclusion in the regression equations because previous studies by Potts (1983) and Farnes (1978) showed no other variables to be significant in estimating mean annual discharge. An equation for the entire study area was first derived using data from 92 streamflow-measuring sites and gaging stations. Examination of the residuals from the preliminary regression equation indicated that better results would be obtained if the study area were separated into two regions. Consequently, the study area was divided into the two regions as shown in figure 13.

In Region 1, data from 47 sites were used to develop the following regression equation:

$$Q_{A} = 0.0165 A^{0.974} P^{1.159}$$
 (12)

where the terms are as previously defined. The coefficient of determination  $(R^2)$  for this prediction equation was 0.944, and the standard error of the

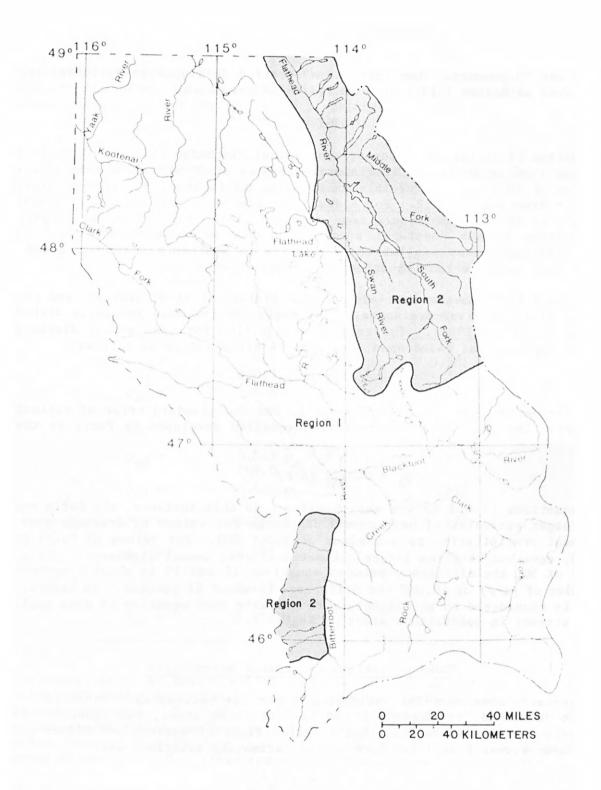

Figure 13.--Region boundaries.

estimate was 33 percent. The prediction equation developed by Potts for the same general area as Region 1 (Region 3 in the Potts report) is similar:

$$Q_A = 0.0292 \ (A \cdot P)^{1.003} \tag{13}$$

Equation 13 yields estimates of mean annual discharge that are slightly larger than those from equation 12. For a drainage area of 10 mi $^2$  and a mean annual precipitation of 10 in., the result from equation 13 is about 32 percent larger than the result from equation 12. For a drainage area of 10 mi $^2$  and a mean annual precipitation of 40 in., the result from equation 13 is about 7 percent larger. Because equation 12 was developed specifically for mountainous areas and smaller streams (drainage areas smaller than 100 mi $^2$ ) in western Montana, equation 12 is probably more reliable than equation 13 in those instances.

Region 2 includes the west side of the Bitterroot River drainage and the Swan River and Flathead River drainages. This region corresponds generally with Region 4 defined by Potts (1983). The regression equation for mean annual discharge derived for Region 2 was based upon data from 24 sites and is as follows:

$$Q_n = 0.0313 \ (A \cdot P)^{1.045} \tag{14}$$

The coefficient of determination was 0.971, and the standard error of estimate was 17 percent. The corresponding prediction equation developed by Potts is the following:

$$Q_{\Delta} = 0.0411 \ (A \cdot P)^{0.995} \tag{15}$$

Again, equations 14 and 15 are very similar. In this instance, the Potts equation yields larger estimates of mean annual discharge for values of drainage area times mean annual precipitation to a maximum of about 200. For values of  $(A \cdot P)$  greater than 200, equation 14 gives larger estimates of mean annual discharge. For a value of  $(A \cdot P)$  of 50, the difference between equations 14 and 15 is about 8 percent, and for a value of  $(A \cdot P)$  of 10,000 the difference is about 17 percent. As before, equation 14 is considered to be slightly more reliable than equation 15 when applied to smaller streams in mountainous areas of Region 2.

## Flows of various exceedance percentages

Regression equations for estimating flows for various exceedance percentages were also developed for Regions 1 and 2. For these areas, the equations derived were log-linear regression equations relating flows of various exceedance percentages to mean annual flow. The form of the estimating equations was:

$$Q_{p} = a Q_{A}^{b} \tag{16}$$

where

 $\mathcal{Q}_n$  is the daily discharge in cubic feet per second for exceedance percentage of n,

a is the regression constant,

b is the regression coefficient, and

QA is the mean annual discharge in cubic feet per second.

The equations developed in Region 1 and their corresponding coefficients of determination are listed in table 20. Similarly, the estimating equations for flows of various exceedance percentages in Region 2 are given in table 21.

Table 20.--Estimating equations for flow-duration curve streamflows in Region 1

Discharge, in cubic feet per second, for indicated exceedance percentage	Equation	Coefficient of determination $(r^2)$
Q <sub>10</sub> =	2.866 Q <sub>A</sub> 0.995	0.981
Q <sub>20</sub> =	1.606 Q <sub>A</sub> 0.959	.962
Q <sub>30</sub> =	0.961 <sub>QA</sub> 0.941	.945
Q <sub>40</sub> =	0.603 <sub>QA</sub> 0.957	.937
Q <sub>50</sub> =	0.400 Q <sub>A</sub> 0.985	.932
Q <sub>60</sub> =	0.279 $Q_A$ 1.015	.922
Q <sub>70</sub> =	0.197 $Q_A$ 1.049	.905
Q <sub>80</sub> =	0.143 Q <sub>A</sub> 1.084	.875
Q <sub>90</sub> =	0.119 $Q_A$ 1.082	.849

The coefficients of determination in tables 20 and 21 are all close to 1.00, indicating very good correlation between mean annual discharge and flows of various exceedance percentages. In both regions, the coefficients of determination generally increase as the streamflows being estimated increase. Low flows (exceedance percentages greater than 50) are thus not as closely correlated with mean annual discharges as are the higher flows (exceedance percentages less than 50).

The equations for estimating discharges of various exceedance percentages can be compared to results obtained by Cunningham and Peterson (1983) by first dividing each equation by  $\varrho_{10}$ . Thus, in Region 1, the right side of each equation on table 20 must be divided by  $2.866~\varrho_A^{-0.995}$ , and in Region 2 the right side of each equation in table 21 must be divided by  $1.390~\varrho_A^{-1.170}$ . Solving the dimensionless equations for Region 1 for the smallest and largest values of  $\varrho_A$  (2.00 and 888 ft /s) produces two dimensionless flow-duration curves that are compared with the dimensionless flow-duration curves developed by Cunningham and Peterson (1983) in figure 14. Similarly, the dimensionless equations for Region 2 were solved for the smallest

Table 21.--Estimating equations for flow-duration curve streamflows in Region 2

and largest values of  $\mathcal{Q}_A$  in Region 2 (6.20 and 210 ft<sup>3</sup>/s), and the resulting flow-duration curves are compared with the Cunningham and Peterson curves in figure 15.

The two curves defined by Cunningham and Peterson were considered applicable in all mountainous regions of Montana and thus are the same curves in both figures 14 and 15. The upper curve, defined by Cunningham and Peterson, represents the expected flow response of mountain streams having the most stable streamflows. According to Cunningham and Peterson, such streams are generally located in densely forested areas with deep soil cover and have relatively flat slopes. The lower curve defined by Cunningham and Peterson is representative of mountain streams having the greatest variation in streamflow. Such sites, according to Cunningham and Peterson, are generally characterized by steep, rocky terrain with thin soil cover.

In Region 1, the dimensionless flow-duration curve for the smallest mean annual discharge lies totally within the band of curves defined by Cunningham and Peterson (fig. 14). The curve for the largest mean annual discharge falls well within the band of curves for smaller exceedance percentages, but lies slightly

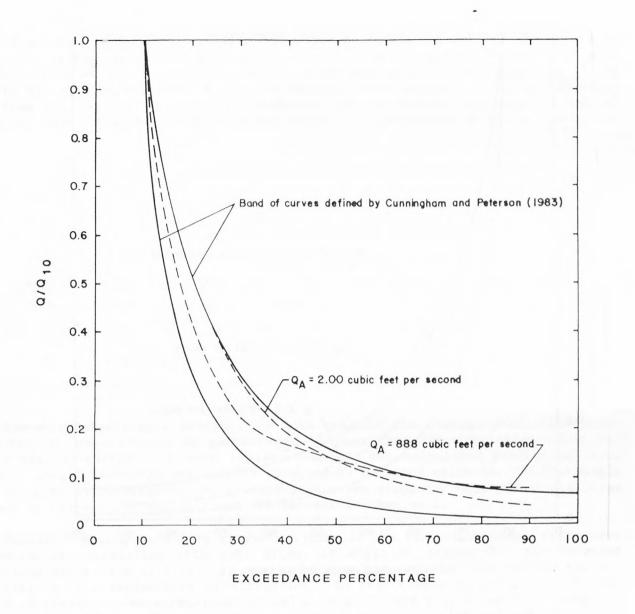

Figure 14.--Dimensionless flow-duration curves for Region 1.

above the band for exceedance percentages greater than 70. The pronounced flattening of the curve indicates that base flows on streams with large mean annual discharges generally tend to be more constant than these on streams with small mean annual flows.

In Region 2, the curve for the largest mean annual discharge lies totally within the band defined by Cunningham and Peterson, but the curve for the smallest mean annual discharge lies above the band for exceedance percentages between 20 and 80 (fig. 15). In this region, streamflows evidently fluctuate more on streams with large mean annual discharges than on streams with small mean annual discharges. This result may reflect the fact that many of the measuring sites on small streams (those with small mean annual discharges) in this region were located at higher elevations, where snowmelt is more gradual and takes place over a longer period of time than at lower elevations.

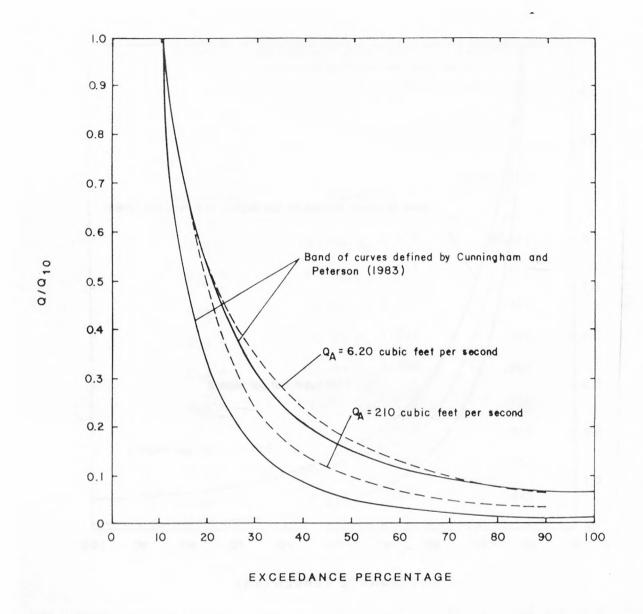

Figure 15.--Dimensionless flow-duration curves for Region 2.

Because the curves developed in this study plot fairly closely to the band of curves defined by Cunningham and Peterson, the results obtained from either method probably will not be significantly different in most instances. The equations in tables 20 and 21 are considered to be more reliable for the study area than the dimensionless curves developed by Cunningham and Peterson, primarily because of the additional small-stream data used.

## Prediction accuracy and limitations

Using the equations in tables 20 and 21 to estimate flow for any exceedance percentage requires an estimate for mean annual discharge. The error associated with an estimate for a flow of any exceedance percentage is thus composed of the error associated with making the mean annual discharge estimate as well as the

error associated with the estimating equations in tables 20 and 21. To obtain an indication of the prediction accuracy of the equations in tables 20 and 21 as well as the prediction accuracy of the equations for mean annual flow (equations 13 and 15), 10 sites in Region 1 and 5 sites in Region 2 were randomly selected and withheld from the regression analysis. Applying the estimating equations to the 15 sites not used, results in the average errors of prediction given in table 22.

Table 22. -- Average prediction error for regression equations

		A	_	error flow cl	-			-	nt,	
Region	$Q_A$	Q <sub>10</sub>	Q <sub>20</sub>	Q 30	Q40	Q50	Q60	Q70	Q80	Q90
1	-16	+2	-8	-9	-6	-6	-14	-19	-29	-38
2	-23	-15	-2	+2	+5	+5	+8	+12	+15	+18

Somewhat surprisingly perhaps, in both regions the average prediction error for flows of most exceedance percentages is less than the prediction error for mean annual discharge. In each region, however, the calculated prediction error for mean annual discharge was largely affected by one poor estimate. If the single poor estimate is eliminated, the average prediction error for mean annual discharge becomes -6 percent for Region 1 and -11 percent for Region 2.

Because the long-term flow characteristics at the flow-measurement sites were determined by correlation with gage sites, it might be argued that the computed prediction errors are artificially small, because the correlations reduced the actual site-to-site variability of streamflow. To test this assumption, the average errors of prediction were recalculated using only the six gage sites from among the 15 sites withheld from the regression analyses. This operation reduced the number of sites for calculating average prediction error to five in Region 1 and to only one in Region 2. The average prediction errors calculated using only the six gage sites are given in table 23.

Because the prediction errors calculated from the gage data only are generally less than the prediction errors calculated from all 15 randomly selected sites, the results in table 22 are considered to approximate the average error that can be expected from an estimate of streamflow at an ungaged site. As with any regression analysis, however, it needs to be emphasized that the equations are valid only within the range of values of the variables used to derive the equations and only for locations within the study region. For this study, the range of values of the independent variables is listed in table 24. Extrapolation beyond the range of values listed or application to sites outside the study area may give unrealistic estimates of streamflow.

The regression equations are also not applicable to mountain streams that are spring-fed or that periodically go dry because of very permeable streambeds or

2	2.88 - /1.3	47 - 72		

other unique localized geologic features. The equations thus are not applicable to the valley-floor areas of the Bitterroot or Swan River drainages. The equations also may not be applicable for sites where upstream storage in lakes and ponds is significant, or for sites that have upstream diversions. Some knowledge of the local hydrology and geology is a necessary prerequisite to the successful application of the regression equations. In some instances, a program of monthly streamflow measurements may be required to ascertain whether flow conditions in an area are unique. When very accurate flow estimates are required, the prediction equations can be supplemented and verified by miscellaneous streamflow measurements.

## SUMMARY

Miscellaneous measurements were used to estimate streamflow characteristics at 72 sites in the mountainous areas of western Montana. The characteristics included mean annual discharge, mean monthly discharge, and points on the flow-duration curve. A streamflow-correlation program permitted synthesizing the missing record at 38 gaging stations in the study area to develop a common 1938-82 period of record at all streamflow-measurement sites. Tests of the accuracy of using miscellaneous measurements to estimate long-term streamflow characteristics indicated that mean annual flow can be estimated at a measurement site with an expected error of about + 10 percent. The flow-duration curve can be estimated at a streamflow measurement site with an expected error of about 10-15 percent. Estimates of long-term mean monthly flow have the poorest accuracy, with expected errors of as much as 60 percent.

The estimates of long-term mean annual flow were used, together with applicable gaging data, to prepare maps showing the areal variability of mean annual runoff. The maps were prepared for the three areas in western Montana with the greatest concentration of flow measurement and streamflow-gaging sites.

Streamflow characteristics determined for the streamflow-measurement sites and gaging stations were also used to develop regression equations for estimating mean annual flow and flows of various exceedance percentages anywhere within western Montana. The best results were obtained when the study area was divided into two regions, with separate equations developed for each region. The regression equations for mean annual discharge used drainage area and mean annual precipitation as independent variables and had determination coefficients of 0.944 and 0.971 in the two regions, with corresponding standard errors of estimate of 33 and 17 percent. The mean annual flow equations were compared to similar equations developed in a previous study and found to give differences of 7 to 32 percent.

The regression equations for flows of various exceedance percentages used mean annual discharge as the only dependent variable and had coefficients of determination ranging from 0.849 to 0.981. The equations were converted to a dimensionless form and compared graphically with results from a previous study. Data from sites not used in the regression analyses were used to develop estimates of expected average errors of prediction when applying the equations to ungaged sites. The estimated average error for mean annual discharge was -16 percent in one region and -23 percent in the other, but would have been reduced to -6 percent and -11 percent had one poor estimate been excluded. The estimated errors for flows of various exceedance percentages ranged from +2 to -38 percent in one region and from +18 to -15 percent in the other.
