EARTHQUAKE HAZARD STUDIES IN SOUTH AMERICA

by

Juan Carlos Castano
Instituto Nacional de Prevencion Sismica-INPRES
San Juan, Argentina

INTRODUCTION

About 15 percent of the world's total seismic energy release corresponds to South America, making this region the most seismically active of the earth. Although most of South America presents some degree of seismic activity, there is no doubt that the Andean region is the one where almost all the activity is concentrated, as can be seen from the map of Figure 1.

The second factor, severity of the ground shaking required for earthquake-induced landsliding, has been investigated using both empirical data from historical earthquakes (Keefer, 1984) and a numerical technique developed by Newmark (1965). The Newmark analysis allows for inputs of both the static slope stability and a seismic strong-motion record, thus linking slope stability and seismic ground-motion. The Newmark analysis computes the displacement of a rigid friction block which is used to represent a potential landslide on the slope under study. We have defined the "critical displacement" as that beyond which the slope can be considered to have produced a landslide. We have assigned values of 10 cm and 2 cm as the critical displacements for coherent and disrupted landslides respectively. The severity of seismic shaking required to cause coherent slides is thus defined as that which according to the Newmark Analysis, would produce a displacement > 10 cm on a slope with a given A_c, that is $(A_c)_{10}$.

Using both the theoretical and the historic/empirical studies, we have delineated three zones surrounding the seismic event: 1) a zone (within the 50% probability line) within which there is a high probability of failure of susceptible slopes ($A_c < 0.05$ g); 2) a zone with a less than even, but still finite probability of failure of susceptible slopes; and, 3) a zone, beyond the outer limit defined by data from worldwide historical events, which is so far from the seismic source that the probability of landslides is very small, even on susceptible slopes.

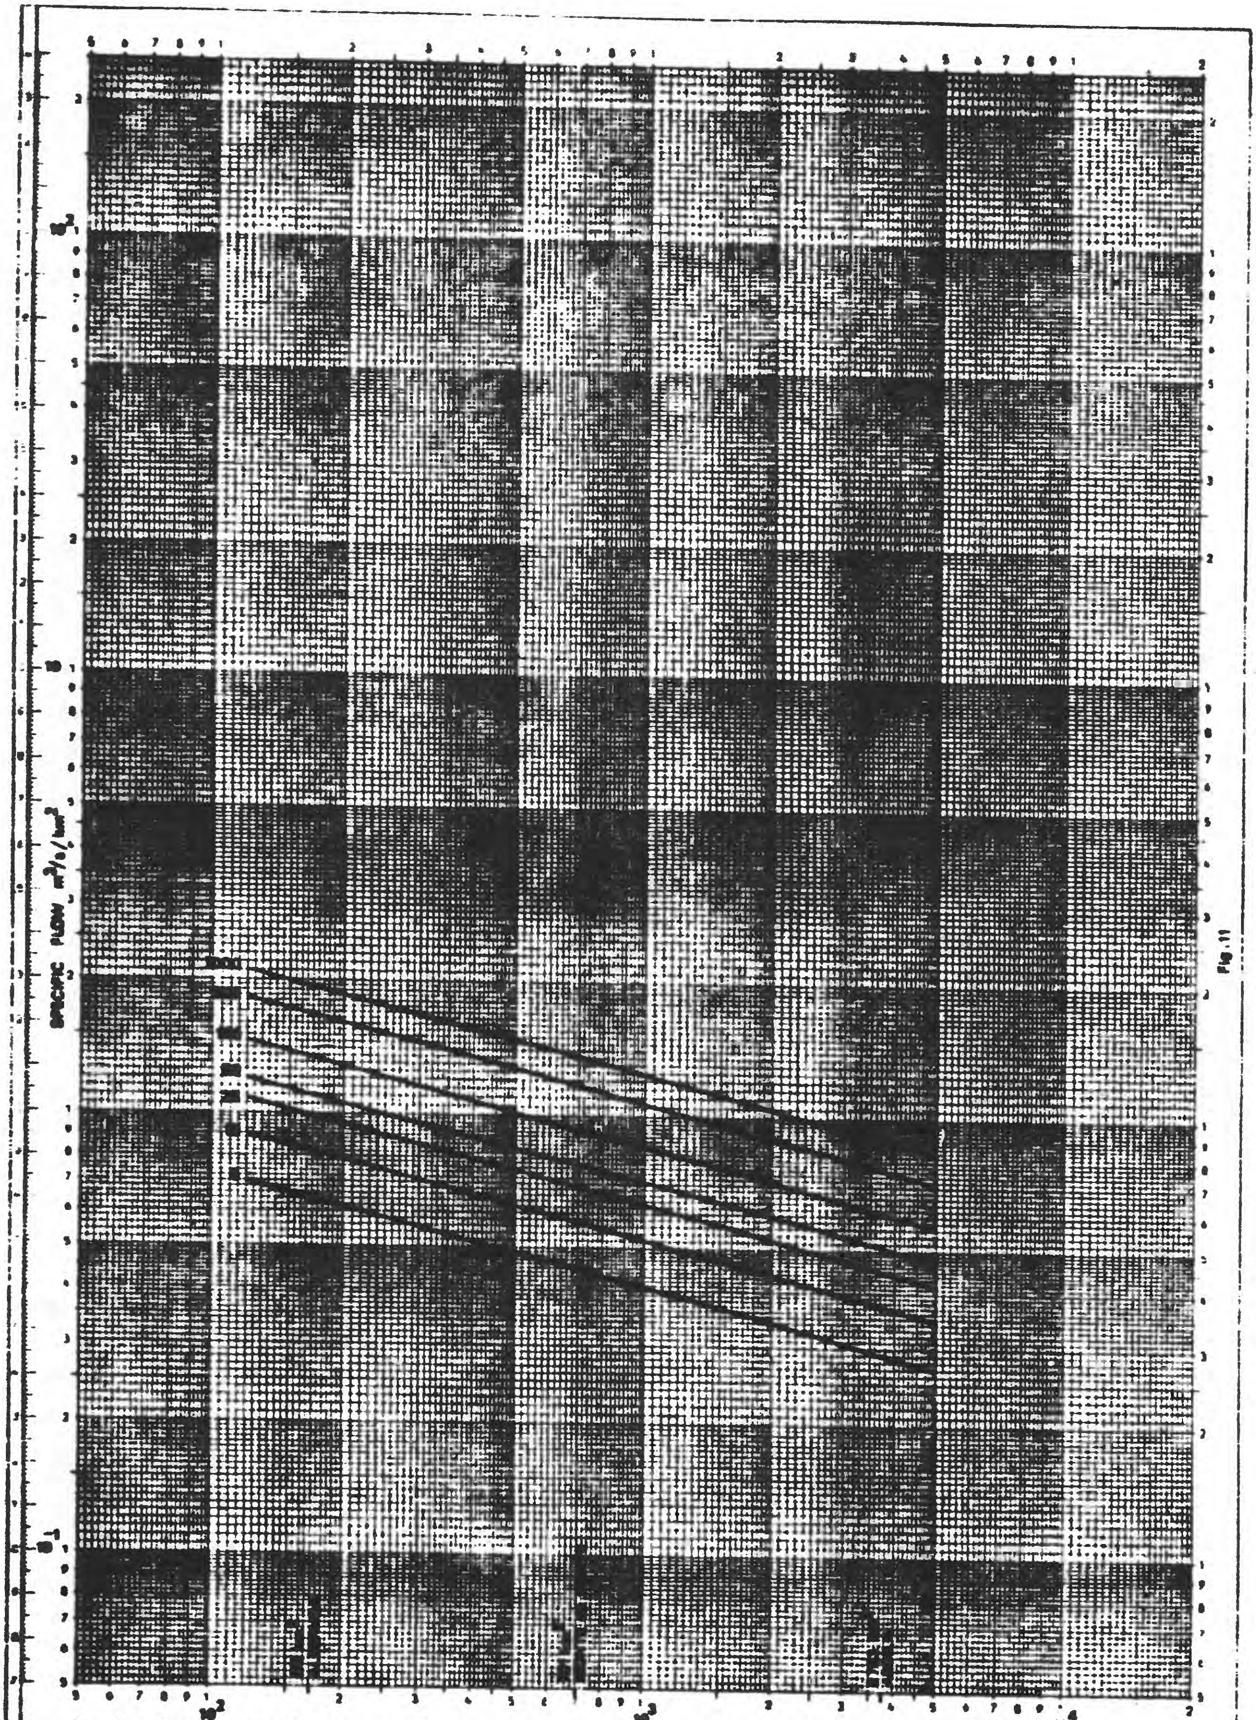

Figure 11

The Henrys Lake quadrangle is wholly within seismic risk zone 3, defined on the Seismic Map of the United States (Algermissen, 1969) as an area in which "major destructive earthquakes may occur."

If there were renewed movement along one of the active faults in the quadrangle, and an earthquake resulted, parts of the area would be more or less severely marred in one way or another. Manmade structures within these areas would be damaged to varying degrees. Some parts of the area would be inundated by oscillatory waves (seiches) set up in Henrys Lake and Hebgen Lake; ground breakage of varying degrees of intensity would occur in other parts of the area; and rockslides, rockfalls, and earthflows would be triggered locally. Two other maps, (1) Seiche, rockslide, rockfall, and earthflow hazards, Map I-781-C, and (2) Faults and ground-breakage hazards, Map I-781-D, depict the possible extent of these various geologic hazards. This map, derived from these other maps, divides the quadrangle into four zones of earthquake hazard. It shows those specific areas likely to be damaged by several of the geologic hazards listed above; in a sense it emphasizes the potential cumulative damage which may occur in any one locality.

Although some parts of the quadrangle may be unaffected during a major local earthquake, other parts may be severely marred as a result of the cumulative effects of several kinds of geologic events. Thus, in places the floor of the Henrys Lake basin may be practically undamaged, being broken here and there only by minor fractures. By contrast, some of the nearby mountainous parts of the area may be severely damaged by major ground breakage as well as by rockslides, rockfalls, and earthflows. Obviously, some parts of the area are much more hazardous than others. This map arbitrarily divides the quadrangle into four zones of earthquake hazard based in part on the kinds of geologic hazards likely to be triggered in any one area, and in part on the differing intensity or certainty of these events.

EARTHQUAKE HAZARD ZONE A – Double major hazard. Areas in which two kinds of major hazard are present. For example, includes areas most likely to undergo major ground breakage and inundation by a seiche.

EARTHQUAKE HAZARD ZONE B – Single major hazard. Areas in which two kinds of hazard are present, one of which is major. For example, includes areas in which rockslides, rockfalls, or earthflows are very likely but in which only minor ground breakage is likely.

EARTHQUAKE HAZARD ZONE C – Moderate hazard. Areas in which moderate or lesser hazards are likely to be present. For example, includes areas in which both moderate ground breakage and rockslides, rockfalls, or earthflows may occur.

EARTHQUAKE HAZARD ZONE D – Low hazard. Areas in which one or more lesser hazards are likely to be present. For example, includes areas in which only minor ground breakage is likely.

For most of the area the selected zones represent possible rather than certain damage. But, locally, a few areas are almost sure to be damaged; for example, the broad low flats which flank Henrys Lake. These lowlands are virtually certain to be repeatedly inundated by the back and forth sloshing of the lake that will occur during a major local earthquake. What is uncertain is the amount and degree of damage that will result from such oscillations.

VIBRATION DAMAGE – It has long been known that manmade structures built on unconsolidated or semiconsolidated materials are more likely to be damaged by the vibrations set up during an earthquake than comparable structures built on bedrock. Such damage can occur far from the epicenter[1]; what is important is the type of material on which the structures are built. Bedrock is preferable to unconsolidated detritus.

[1] An imaginary point on the earth's surface directly above the focus point (the position where the rocks first ruptured) of the earthquake.

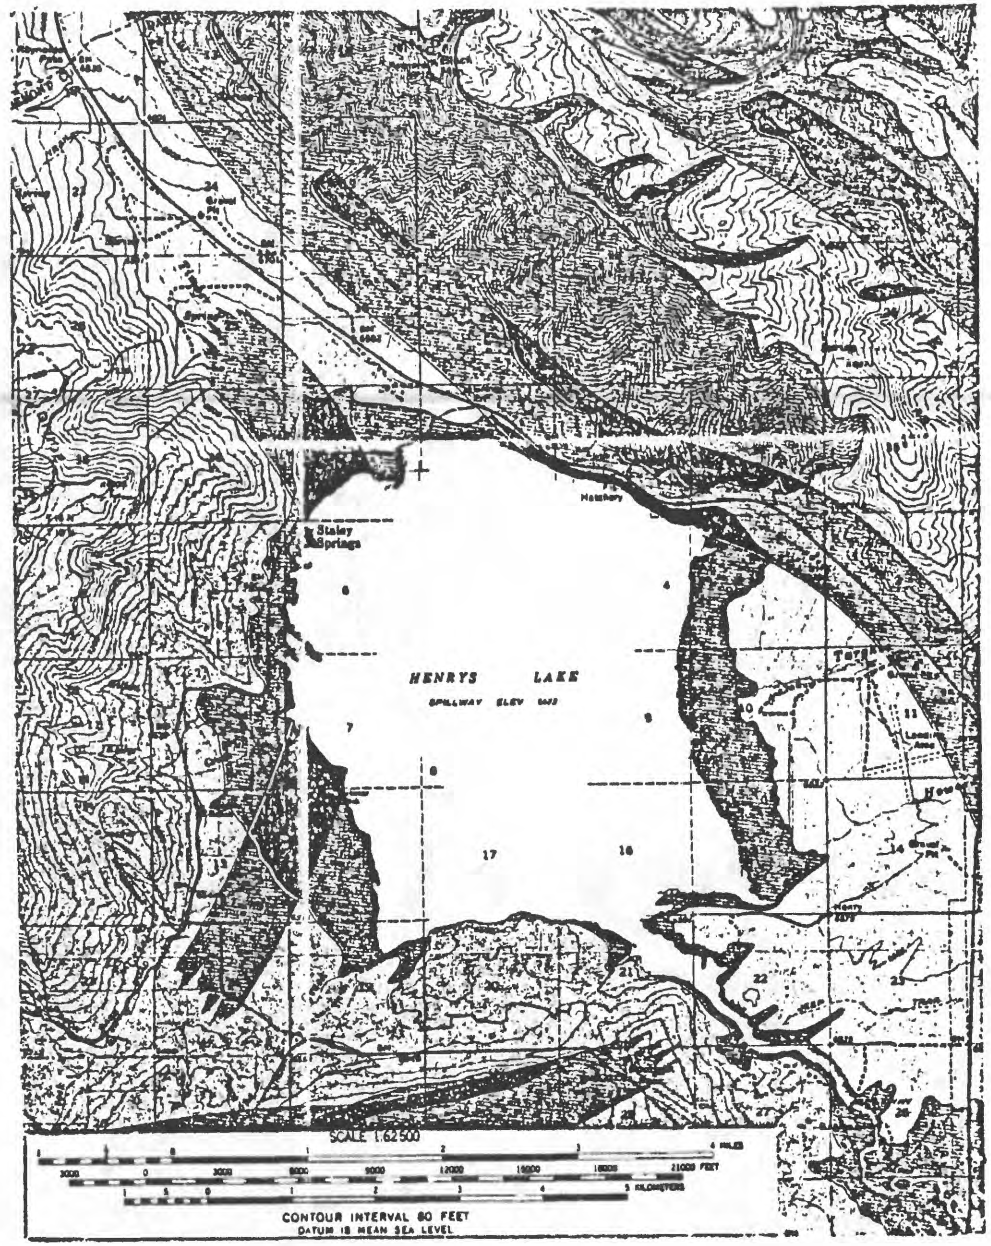

Figure 8. Earthquake hazard map of the Henrys Lake Quadrangle, Idaho and Montana (from Witkind, I. J., 1972).

PURPOSE

This map classifies part of west-central King County, Washington into areas of differing relative slope stability. Slope stability is a variable natural condition that may pose problems and should be evaluated before land use is changed. Knowledge of the distribution of areas of differing slope stability can help land planners and decision makers. Urbanization engulfs areas of different natural characteristics; failure to identify areas having potential problems can result in physical or financial difficulty.

This part of the Puget Sound lowland is separated into three classes of stability: terrain virtually free of stability problems (class 1), terrain almost certain to be susceptible to such problems (class 3), and terrain that is stable under natural conditions, but which may become unstable owing to man's activities, and which should be examined in detail before changes in land use are adopted (class 2).

The boundaries shown on the map are arbitrary lines based on available information. Areas of different classes too small to identify at this map scale, or changes in steepness of slope confined to the zone between contours so that these changes do not show on the map, are included within each classified area.

The map was compiled from data collected by others (see references). Their work and published descriptions of slope failures in the Seattle area has indicated that the presence or absence of tight silt or clay beds beneath sand beds is a principal geologic criterion for potential slope instability.

The selection of 15% slopes to separate classes 1 and 2 is also based on recorded experience of others.

The validity of this three-fold slope-stability classification has been checked briefly in the field.

DESCRIPTION OF SLOPE STABILITY CLASSES

In this report, slope stability refers to the resistance to gravitational forces of earth materials underlying an inclined surface; instability results in outward and downward movement of these underlying materials.

Class 1: characterized by slopes less than 15%, and by near-surface materials that probably do not include silty or clayey beds. Includes some hard glacial drift on gently rolling uplands. Slopes tend to be stable unless deeply excavated; subsequent instability generally is confined to excavation walls or embankments of artificial fill.

Class 2: characterized by slopes that are steeper than 15% and by absence of silty or clayey beds near the surface. Includes some hard glacial drift that generally forms steep slopes along bluffs and ravines, and caps small hills and ridges within the upland. Tends to be stable under natural conditions.

Class 3: characterized by slopes steeper than 15% and by silty or clayey beds near the surface, beneath sand. Includes glacial drift that generally forms steep slopes along bluffs and ravines. Although most slopes in class 3 are stable, all are believed to be potentially unstable and ready to slide from sufficient natural or man-made causes.

UNDERSTANDING SLOPE STABILITY

Stability of slopes is influenced by two general kinds of conditions: constant and changing. The constant factors, such as the general steepness of the land surface and the types and interrelation of geologic materials, tend to determine the location of slope instability. Changing factors, such as erosion, man's activities, and addition of moisture tend to determine the timing and frequency of landslides. Of these changing factors, the addition of excess moisture, most commonly by rainfall, is probably the most crucial in the Puget Sound region. As a result, most landslides occur during the rainy season.

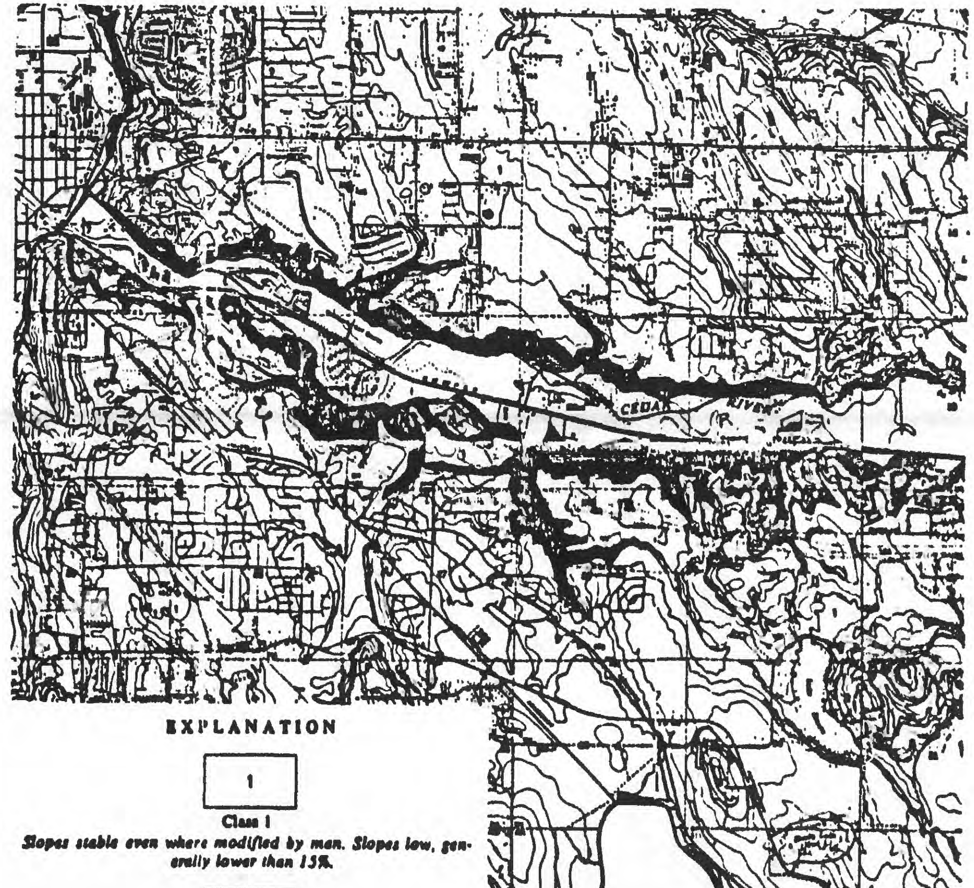
Geologic conditions may strongly influence relative stability on slopes of similar steepness. Most of the geologic materials in the map area are flat-lying and relatively weak glacial or alluvial deposits. The composition and physical characteristics of such deposits vary greatly, both laterally and vertically. Of particular importance is the occurrence of relatively impermeable materials, such as tight silt or clay, beneath or within more permeable materials, such as sand or gravel materials. Water moving through earth materials can saturate those which are permeable (sand or gravel) and is impeded by beds which are impermeable (silt or clay). The result may be to cause springs to flow from a hillside near the contact between the sand and clay, or to saturate the thin overlying soil materials that blanket the slopes, or to saturate the sand above the silt or clay; such saturation may cause the materials to lose cohesion and move downslope.

Other kinds of geologic materials also are important to the stability of a slope. Hard rock forms steep, normally stable slopes along some of the bluffs bounding mainland stream valleys; it also forms slopes of variable steepness in the mountains in the eastern part of the mapped area. In most places, slopes on hard rocks are stable. However, soil and slope debris overlying the rock may be unstable. Commonly, the thin soil and debris are highly permeable but the underlying rock is not. When saturated, the soil and debris move downward and the surface of the rock acts as a slip surface.

Two aspects of slope stability are not evaluated on this map. No attempt is made to determine or depict the effect of landslide debris encroaching upon flat, stable surfaces from unstable slopes uphill; sites along the base of class 3 slopes should be evaluated for this potential risk. Also, no assessment is made of the stability of man-made cuts and fills.

SCALE 1:48 000

1 MILES ½ 0 1



EXPLANATION

1 — Class 1
Slopes stable even where modified by man. Slopes low, generally lower than 15%.

2 — Class 2
Slopes normally stable, but may become unstable due to man's activities. Slopes moderate, generally steeper than 15%. Not underlain by clay beds, but may include ancient inactive landslides.

Class 3
Slopes readily become unstable due to natural events and to man's activities. Slopes moderate to steep, generally steeper than 15% and in places steeper than 40%. Probably underlain by tight silt or clay beds.

Modified land
Slopes not classified. Large excavations and fills made after the topographic map was prepared, so that map contours cannot be used to classify slope stability.

Old landslide deposits
A single deposit may include areas of different slope stability classes. Apparently stable now, but stability could change with changes in climate or slope.

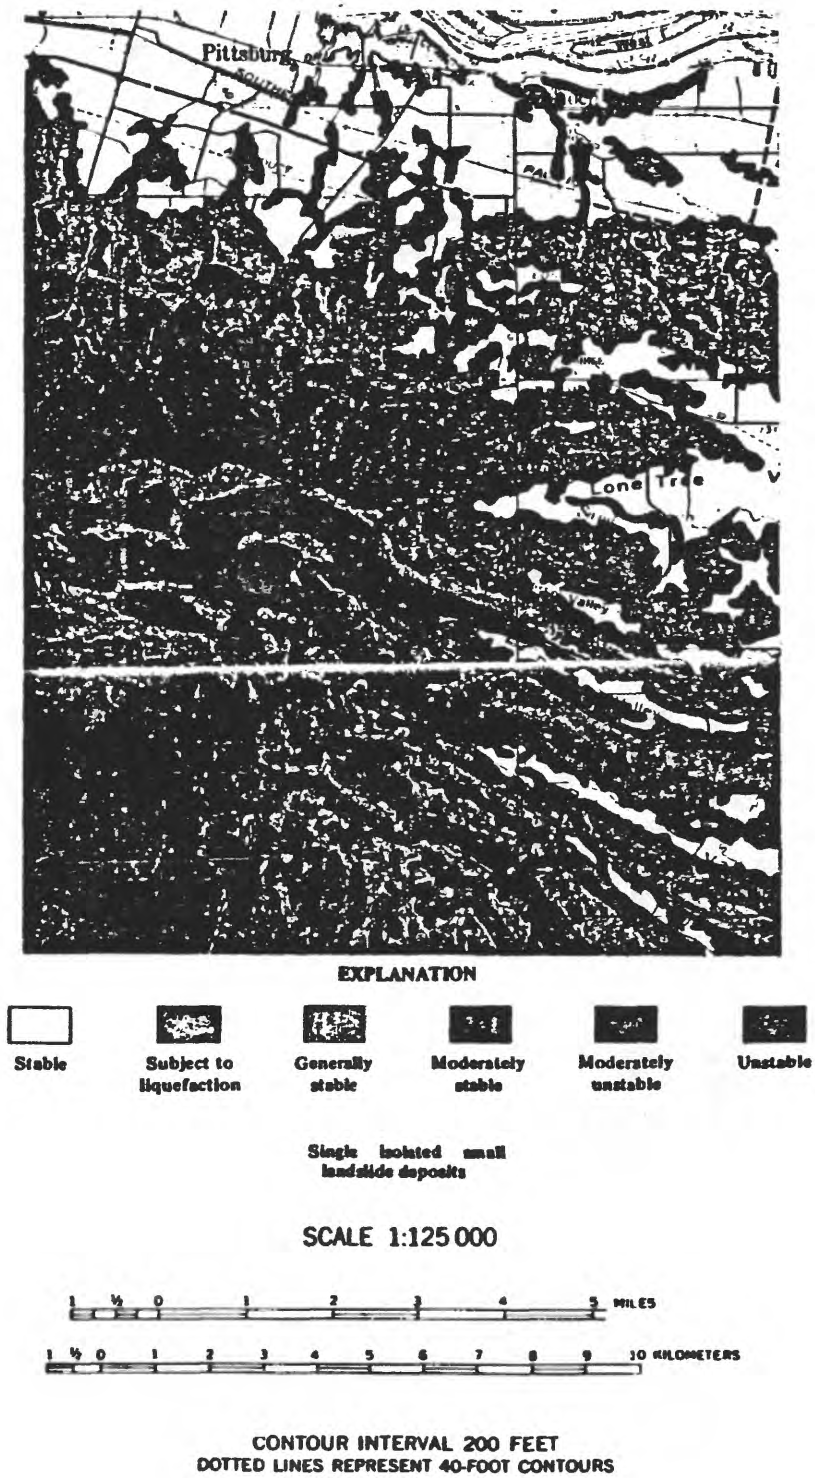

Figure 14. Relative slope stability map of part of northern Contra Costa and southern Solano Counties derived by combining the preliminary relaive slope stability map (figure 12) and map of bedrock and surficial geologic units considered to be especially susceptible to slope failures (figure 13).

The general procedure for producing composite maps by computer is illustrated in Fig. . In order to combine source maps with the computer, the mapped information must be converted to numerical form. Fast, economical computer processing is made possible when this information is stored in small subdivisions of the source map, called cells. In a process known as digitizing, a sampling grid is superimposed on the source map, and the latitude-longitude address and numerical code for the map unit are recorded for each cell. These data are put on punchcards for ease in updating and correcting and are stored on magnetic tape or disk for processing. The program user specifies, through a set of control cards, the way in which the digitized source maps are to be processed.

A composite map is prepared on a cell-by-cell basis by summing the numerical values that occur in each cell when several factors are combined. The resulting composite map, which represents the synthesis of all factors, is produced by a line printer. A detailed example of the compositing process is shown in Fig. , in which four single-factor maps are combined.

The source maps in Fig. a have been divided into cells, and the digitized version of each map is represented by Fig. b. Although letters are used here for clarity, a four-digit numerical code is actually recorded and stored wherever a factor is present in a cell of a source map being digitized. In the example (Fig.), the mapping program user considers it desirable to distinguish, on the composite map, each of the factors that contributes to every combination. In general, the number of possible composite map units, including each of the factors occurring alone, is given by the expression $2^n - 1$, where n is the number of factors. For a composite map of four factors, therefore, 15 map units are possible from the factors and their combinations. The expression may be simplified to 2^n if the null set (no factors occurring in a cell) is added to the total. By designating importance values 1, 2, 4, and 8 for the factors in this example (Fig. a, a unique score from 0 through 15 is calculated by the computer for each combination of factors as shown in Fig. d. The computer prints a user-selected symbol for each score level to produce the composite map. These symbols may be alphabetical, including special symbols; numerical; or combinations produced by overprinting as in the symbol for score 10, which is formed by combinig "T" and "V" (Fig. e).

The method of compositing that produces a unique score for every combination is very useful in understanding the interrelationships of large numbers of spatial factors. However, the method does have limitations. The 64 map units produced by compositing six factors may be fascinating to the program user but barely comprehensible to a subsequent user of the composite map. Several alternatives exist, all of which reduce the composite map complexity by sacrificing detail or the capability of identifying factors within combinations. The most straightforward technique for combining six or more factors is the assignment of equal importance values to all the factors. If six factors are combined, for example, and each factor is assigned the value one, the highest possible score is six, and the score indicates the number of factors that occur in each cell of the composite map. This method is particularly useful in analyses that involve a large number of factors of similar importance and type, where it is sufficient to show the occurrence, rather than the kinds, of factors in combination. If the factors do not have the same relative importance, a third technique may be used. Each of the factors is assigned a value that reflects its importance in the analysis, and the resulting scores are grouped by the program user. Each group consists of a range of scores the magnitudes of which will have similar meaning when the results of the composite map are used in making a decision. Although similar to the "unique combinations" method (Fig.), which provides for the assignment of different importances, this grouping of scores allows the program user to combine more factors in a composite map that is easier for users to read and understand.

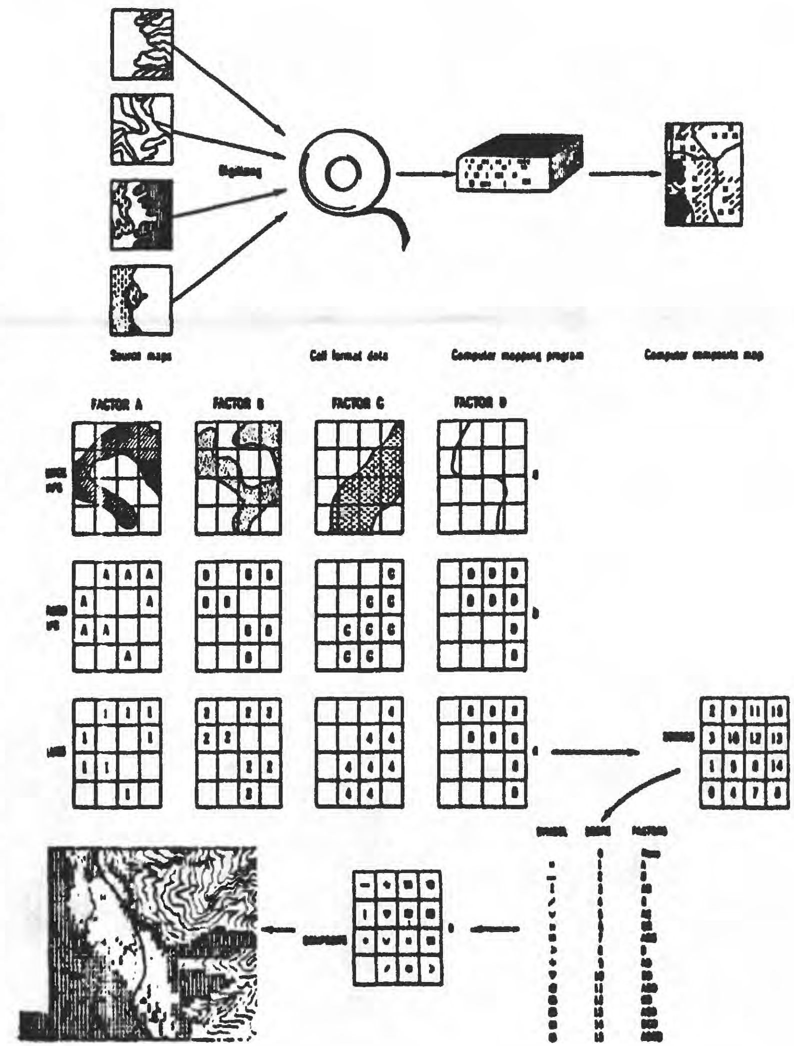

Figure 15. Example of computer-composite mapping a) source maps; b) digitized version of each source map; c) importance values of each factor; d) computer-scores for each combination F factors; e) symbols used in map construction (from Van Driel, 1980).

Land cover class, dominant vegetation, and map surface area in acres, hectares, and percent

The total surface area shown is 1,640,627 acres (2,563 sq. mi.), or 663,952 hectares (6,640 sq. km.).

I Water.—Ocean surfaces, and lake and river surfaces larger than 1 acre. (Area measurement excludes water surface outside seaward limit of study area.) .... 101,355 a (41,018 ha) (6.2 pct).

II Pond/Sedge Tundra Complex; Aquatic Tundra; or shallow water.—Very wet tundra areas with ponds and/or emergent communities of *Carex* spp. or *Arctophila*; and up to 50% moist or wet tundra...16,964 a (6,865 ha) (1.0 pct).

III Wet Sedge Tundra.—Wet tundra with little standing water or with up to half of surface area water-covered or emergent vegetation, or coastal areas periodically covered with salt water ..... 260,057 a (105,244 ha) (15.8 pct).

IV Moist/Wet Sedge Tundra Complex; or Dry Prostrate Shrub, Forb Tundra (*Dryas* river Terraces).—Moist sedge tundra with up to 40% wet sedge tundra; or dense prostrate mat of *Dryas* on river terraces .... 270,565 a (109,496 ha) (16.5 pct).

V Moist Sedge, Prostrate Shrub Tundra; or Moist Sedge/Barren Tundra Complex (frost-scar tundra).—Better-drained areas on rolling terrain sometimes with tussocks; or sparsely vegetated frost-scar tundra .... 434,512 a (175,845 ha) (26.5 pct).

VI Moist Sedge Tussock, Dwarf Shrub Tundra.—Well-drained upland tussock tundra in foothills with high percentage of cottongrass tussocks and dwarf or prostrate shrubs .... 414,550 a (167,766 ha) (25.3 pct).

VII Moist Dwarf Shrub, Sedge Tussock Tundra; or Moist Sedge Tussock, Dwarf Shrub/Wet Dwarf Shrub Complex (water track complex).—Upland tundra with shrubs to 50 cm high; or upland tussock tundra with shrubs in water tracks... 51,148 a (20,699 ha) (3.2 pct).

VIII Shrub-Tundra.—South-facing slopes in foothills or subalpine, with willow, birch, alder to 2m; or dense shrubs in water tracks .... 3,142 a (1,272 ha) (0.2 pct).

IX Partially vegetated areas.—Diverse habitats including river bars, alpine tundra and moss mats with barren rock and talus, lichen-covered, sorted stone-nets and beach or mud flats .... 27,678 a (11,201 ha) (1.7 pct).

X Barren gravel or rock.—Bare light-colored river gravel, gravel and sand spits, alpine barrens (especially dolomite), and cultural barrens (road or runway), often with rich but sparse flora ..... 27,642 a (11,186 ha) (1.7 pct).

XI Wet gravel or mud.—Extensive barren mud in river deltas and wet or dark-colored gravel on beaches or river beds, or dark-colored barren rock in mountains .... 28,402 a (11,494 ha) (1.7 pct).

XII Ice.—River icings in the braided stream channels of most larger streams .... 4,612 a (1,866 ha) (0.3 pct).

Introduction

This map is produced in conjunction with an environmental impact statement assembled by the U.S. Fish and Wildlife Service (USFWS) in anticipation of oil exploration on the Arctic National Wildlife Refuge coastal plain. Classification of vegetation and land cover is derived from digital multispectral data comprising Landsat scenes indexed in the margin. For location control and area measurement, land cover data are assigned to 50 x 50 m cells in UTM Zones 6 and 7, then merged into Zone 6 (extended) for map printing.

Vegetation classification and field review are by William Acevedo (Technicolor Graphic Services) and Donald Walker (Institute of Arctic and Alpine Research). Design of map and statistical products is by Leonard Gaydos and James R. Wray (USGS). Color separation and screening for four-color process printing are done on a large-format laser plotter using dot screens and angles developed on that equipment and plotted directly onto the separations as data are read from the digital file. The resulting colors replicate those otherwise achieved at USGS using open-window plate negatives, conventional mechanical screens, and the same process ink colors.

Area scales 1:250,000
