
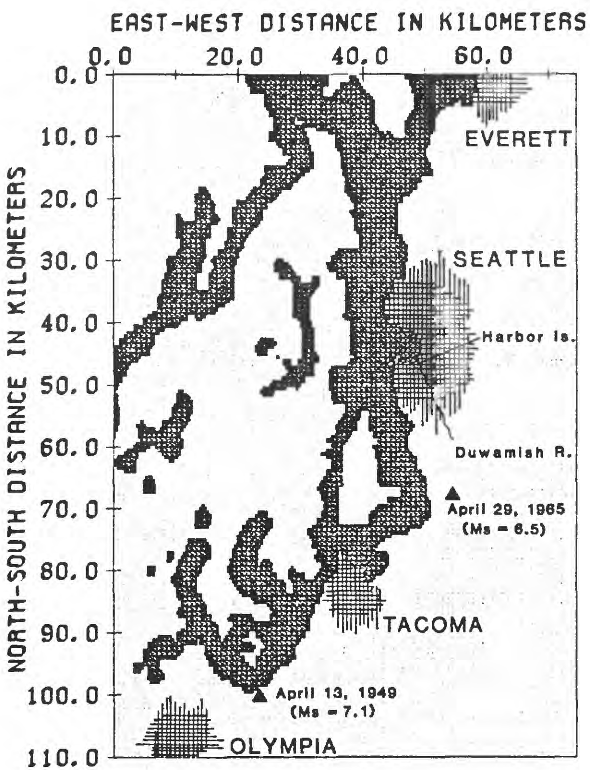

Figure 1. Reference map of study area. Origin of coordinates at NW corner is located at 48N latitude, 123W longitude. Epicenters of 1965 and 1949 earthquakes are shown by triangles.

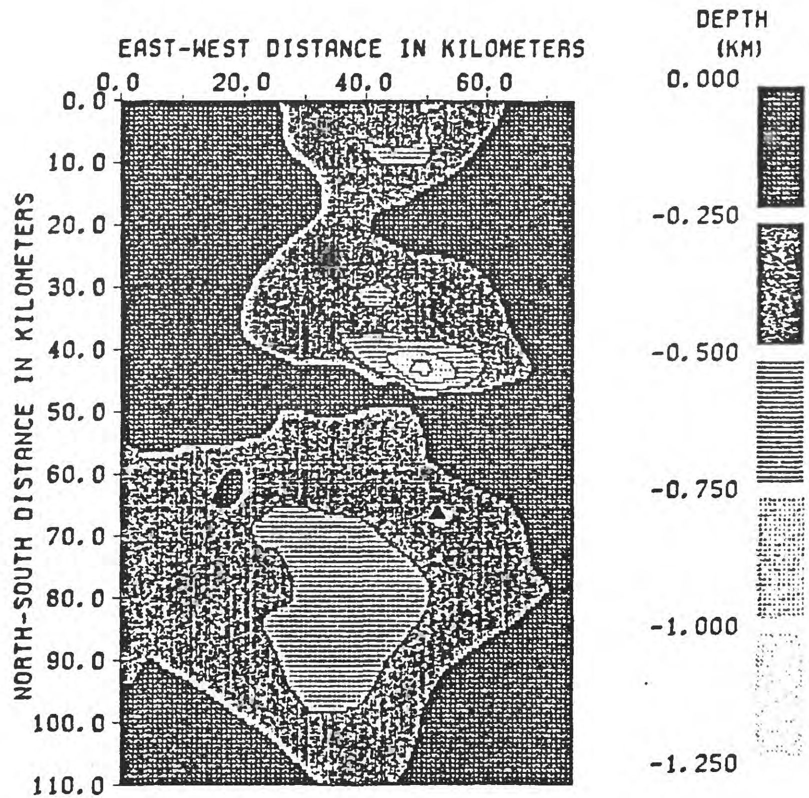

Figure 2. Contoured depth of sediments (Layer 2). Triangle is epicenter of 1965 event.

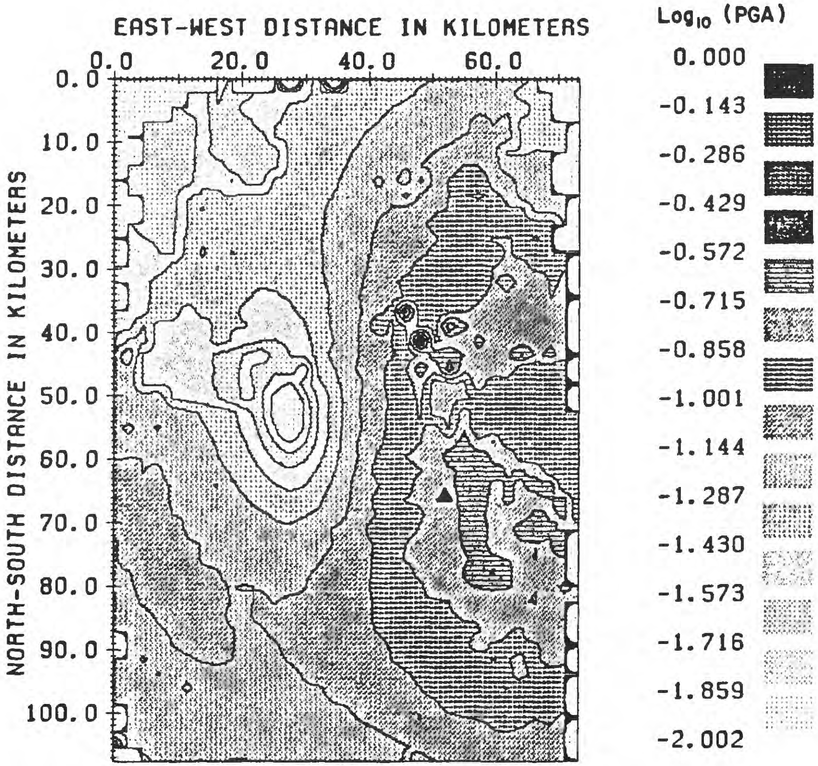

Figure 3. Contoured peak horizontal accelerations, 1965 earthquake, ISC epicenter. Note that the quantity contoured is the base ten log of acceleration, expressed as a fraction of g. Every change of 0.33 units is crudely equivalent to one seismic intensity unit. Low values of acceleration within 2-4 km of the edge of the model are artifacts of the modeling procedure and should be ignored. Triangle is epicenter of 1965 earthquake.

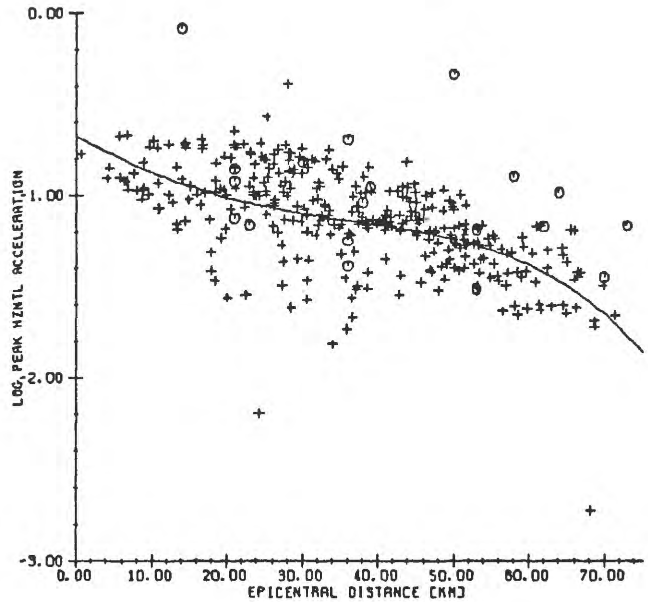

Figure 4. Plot of logarithm of peak ground acceleration (as fraction of g) vs. epicentral distance. Pluses (+) are predicted values from raytrace simulation of 1965 event. Circles are data from comparable Japanese earthquakes.

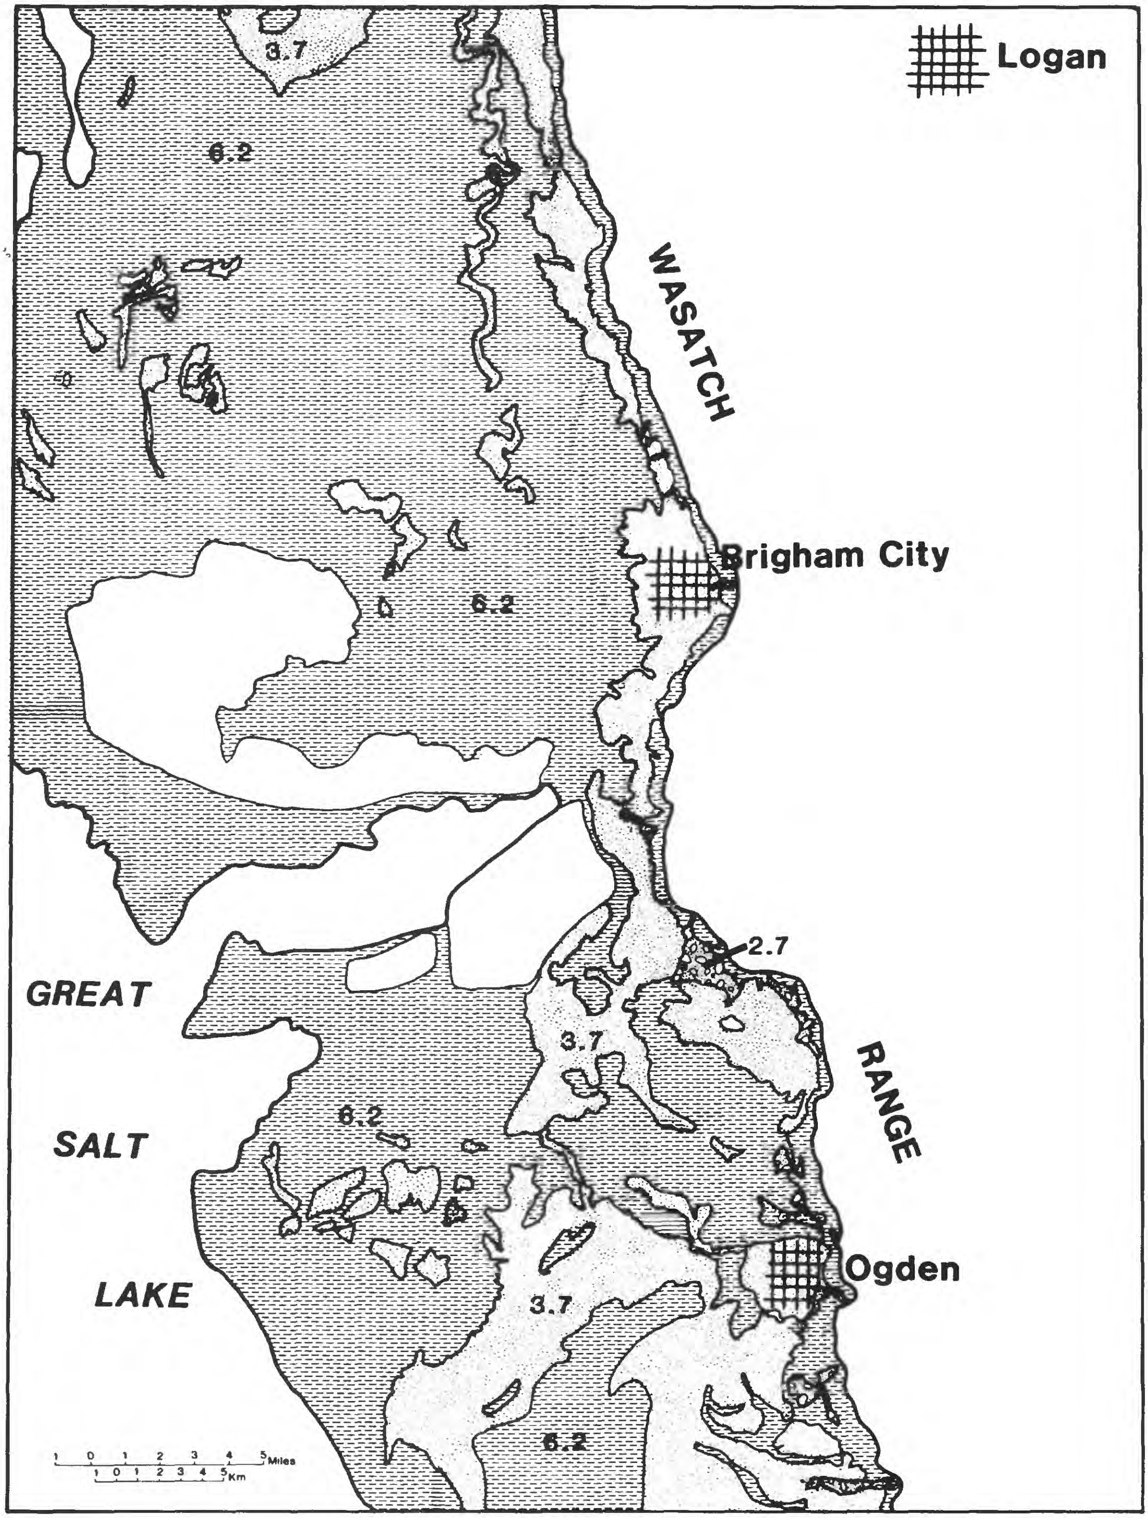

Figure 2.--Map of expected relative ground-shaking response in the north part of the Wasatch Front urban area. Numbers indicate mean ground response relative to bedrock locations.

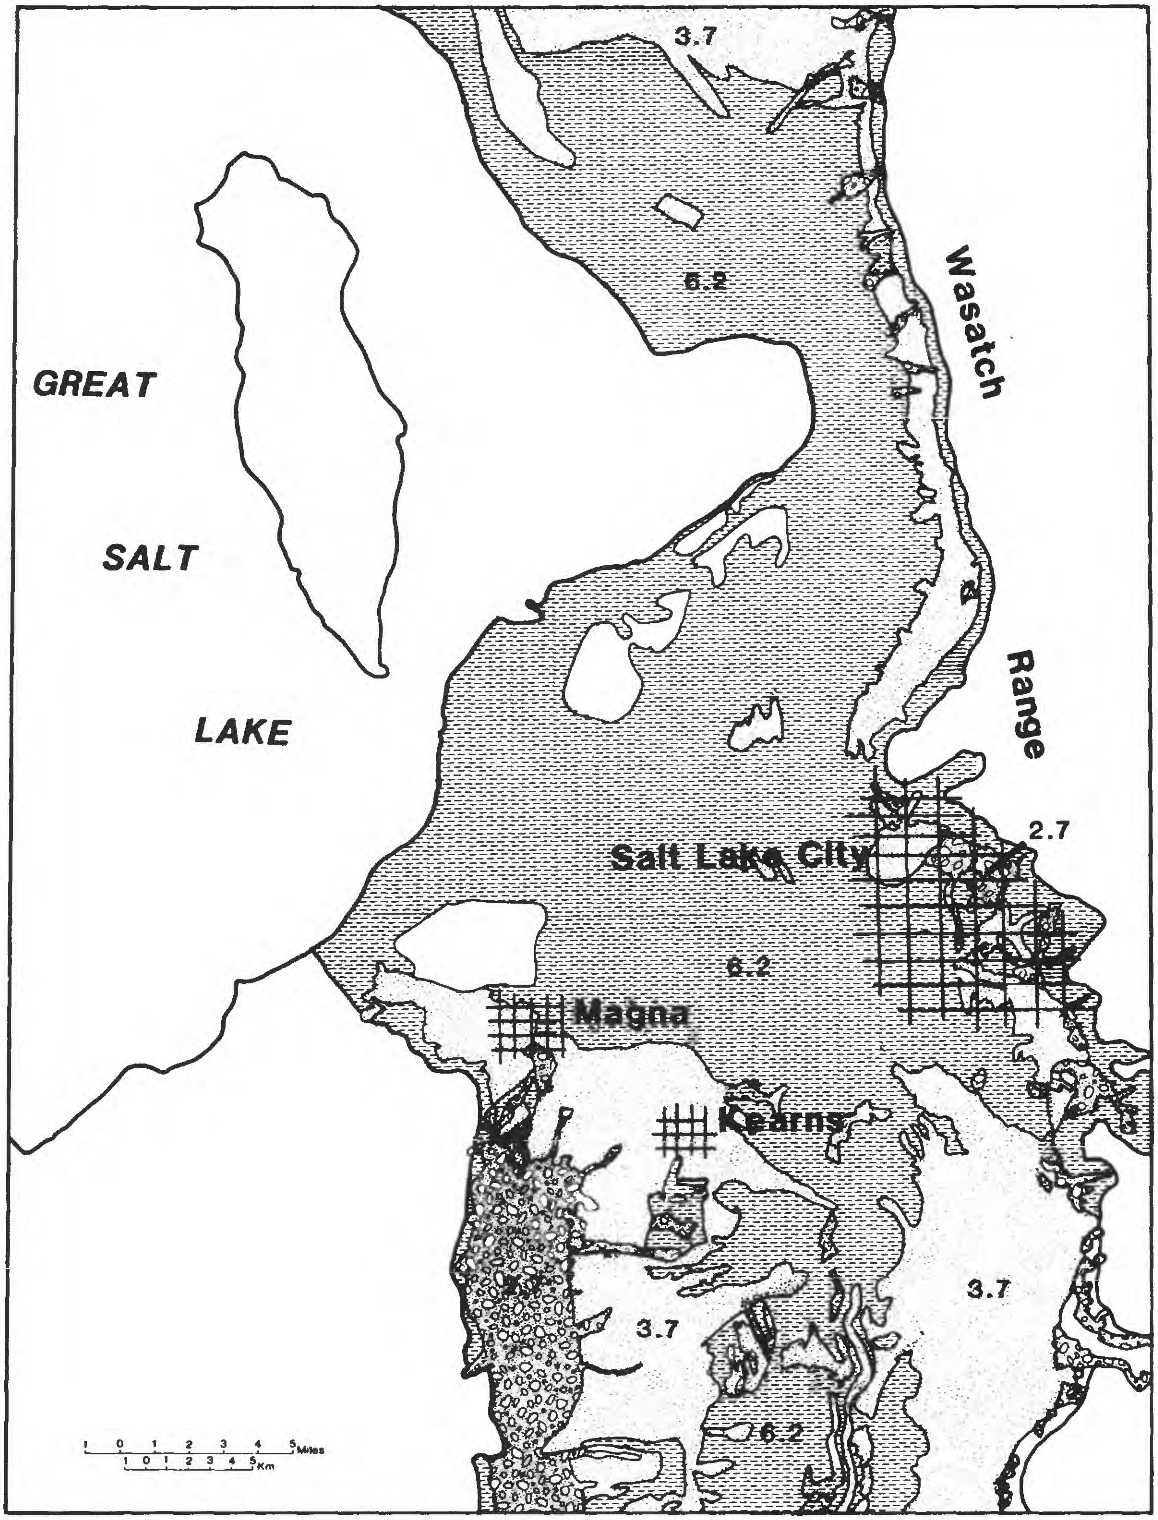

Figure 3.--Map of expected relative ground-shaking response in the central part of the Wasatch Front urban area. Numbers indicate mean ground response relative to bedrock locations.

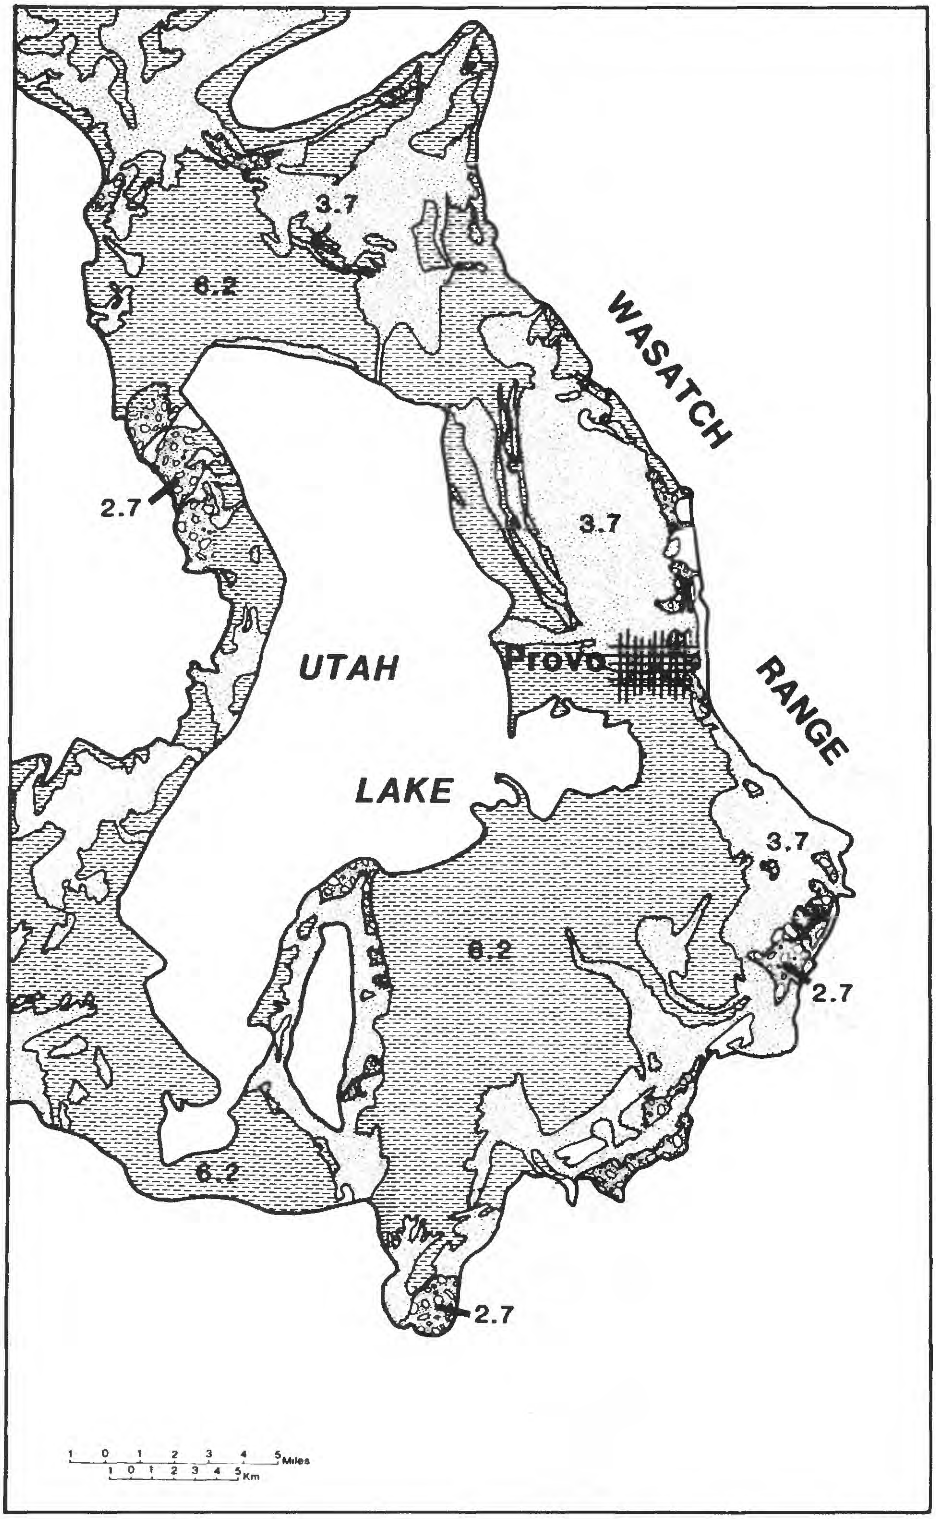

Figure 4.--Map of expected relative ground-shaking response in the south part of the Wasatch Front area. Numbers indicate mean ground response relative to bedrock locations.

Strong Ground Motion Prediction in Realistic Earth Structures

Investigations

1. Analysis of the strong motion records from the 1984 Morgan Hill earthquake.

2. Improvement of the isochron method for calculating high frequency synthetic seismograms for extended earthquake sources.

3. Preliminary design of a short-baseline two-dimensional accelerometer array for installation at Parkfield, California, for the observation of earthquake rupture dynamics.

Results

1. In collaboration with Greg Beroza of MIT, we are using the isochron method to model the ground accelerations caused by the 1984 Morgan Hill earthquake. Preliminary analysis of the data indicates that little energy was liberated while the rupture progressed from the hypocenter to Anderson Lake. Strong shaking at Coyote Creek initiated with a stopping phase (sic) generated near Anderson Lake. The strong shaking following the stopping phase may be caused by the subsequent propagation of the rupture past the barrier (?) that impeded its progress at Anderson Lake.

2. In collaboration with Greg Beroza, we have made further improvements to the speed and generality of the isochron method. Ability to handle wave attenuation was aided by the use of a Futterman Q operator, and the method was improved to remove the restriction that the slip time-funtion be position independent. The method can now accomodate completely arbitrary and general rupture behavior.

3. In collaboration with David Oppenheimer, we have initiated design of a two-dimensional array of accelerometers to be installed at Parkfield, California. We hope to use this array to record the next Parkfield earthquake. The array will consist of about 25 digital, 3-component accelerometers, located within a 2 km^2 area. The array design is being optimized to observe the rupture front in two dimensions as it propagates down the fault, although it will also be of use for studies of transient soil strain during the earthquake. To design the array, we are synthesizing ground motions at each proposed array element site, using the method discussed in investigation 2, above. The motions are analyzed by a moving window frequency-wavenumber analysis method. We break the ground motion into short time slices (1-2 seconds), and do f-k analysis
