AREA SOUTHWEST OF ELSINORE

The Elsinore area is one of the most seismically active in Utah. Five earthquakes of magnitude 5 or greater are assigned to the area--two in 1910 and three in 1921 (Williams and Tapper, 1952, Arabasz and McKee, 1979). An intense cluster of microseisms ($M \leq 1.9$) was recorded in 1981 about 4 km southwest of Elsinore (Julander, 1983). The cluster is centered at the alluviated gap connecting Joseph Flats with the broad Sevier Valley. The envelope containing the densest part of the cluster dips steeply and has an east-west strike. Eight focal mechanisms, all indicate predominantly strike-slip faulting (Julander, 1983). As with the aftershocks northeast of Annabella, the focal mechanisms divide into two types with approximately interchangeable P and T axes, and are indicative of strong slip inhomogeneity and incompatibility.

North of the alluvial gap at Joseph Flat, at a locality marked X on figure 31, faulted and tilted Sevier River Formation is unconformably overlain by Quaternary alluvium. A fault at this locality with attitude 054°, 76° SE and an estimated displacement of 30 m contains striated clay suggesting a 34° rake to the southwest. The predominately strike-slip component is dextral. Although we have no direct evidence of the direction and sense of slip on the Dry Wash fault in the vicinity of the alluvial gap, elsewhere its strike-slip component is known to be sinistral. Therefore, the geologic record suggests incompatible strike slip on northeast-striking faults; this suggestion is geometrically and mechanically consistent with the microseismic data. As with the faults northeast of Annabella, our preference is to interpret such incompatible slip as an indication of lateral block motion.

A northwest-southeast gravity profile across Joseph Flat and the Dry Wash fault shows no significant anomaly at the fault (Halliday and Cook, 1978). Instead, a 10-mGal gravity low is located beneath Joseph Flat with its axis about 2 km northwest of the fault trace. These data are consistent with our interpretation that the Dry Wash is primarily a strike-slip fault and that the alluvial basin beneath Joseph Flat results mainly from the southerly projection of an open south-southwest-plunging syncline (fig. 3).

Steven (1979) mapped north- to northeast-striking faults whose traces are well marked by scarps in Quaternary alluvium on the north and south flanks of the alluviated gap separating Joseph Flat from Sevier Valley. A northeast-trending fault scarp about 3 m high is formed on a gently inclined river terrace (terrace 4, fig. 33), south of which are remnants of three additional geomorphic surfaces that show southward-increasing erosional dissection and southward-increasing eastward inclinations (fig. 34). The relationships suggest increasing eastward tilts on increasingly older Quaternary surfaces. The faulting, which appears to be mostly normal sense, and the tilting, which may be on the east flank of an anticline, paired with the syncline beneath Joseph Flat, seems to represent higher rates of Quaternary deformation than those seen along major structures extending away from the alluviated gap.

FIGURE 33 AND 34 FOLLOW TEXT

Witkind (1983) noted the colinearity of the Sanpete-Sevier Valley anticline and the Sevier fault and suggested a genetic relationship between the two. Within this same context we suggest an alternative interpretation for the concentration of seismicity and young deformtion. The concentration could be related to lateral movement of the relatively ductile rocks of the Arapien Formation. The southernmost exposures of the Arapien are directly northeast of the graben, and equivalent rocks could exist in the shallow subsurface beneath the graben. Perhaps Arapien rocks have flowed into the extensional regime of the northeasterly projection of the Sevier fault where, because of a reduction in confining pressure, they tend to spread laterally. As suggested by Witkind (1983) movement of the Arapien could be stimulated by displacements on buried faults. Arapien rocks could be supplied to the fault zone from beneath the Sevier Plateau. This is consistent with our observations in the vicinity of exposed Arapien rocks where there is an indication that these rocks have been drawn out from beneath the Sevier Plateau (fig. 22). Such flowage would tend to remove most or all surface and near-surface traces of the Sevier fault. Though this is an attractive alternative for explaining the thin-skinned extensional attenuation in rocks above the Arapien, it does not explain fault-slip and seismicity data that indicate that strike-slip motions are common on north and northeast-trending faults and that lateral motions have occurred parallel to the principal fault-fold trend. These factors introduce complexities that seem to require competing deformational processes.

FIGURE 6.--Photograph looking northwest from Dry Wash fault across Clear Creek in foreground to trace of sinistral strike-slip fault in middle distance (scar between arrow and heavy line, labeled FT). Fault parallels the Dry Wash fault and juxtaposes south-dipping rocks of the north flank of the Clear Creek downwarp beyond trace against north-dipping rocks of the south flank of the downwarp on camerman's side of trace. Tj, Joe Lott Tuff Member; Ts, Sevier River Formation; light-weight continuous lines are contacts, light-weight dashed lines accentuate bedding traces. Linear skyline elements and vegetation stripes below skyline show extent of south-dipping flank of downwarp. See figure 7 for closeup views of fault which is very well exposed in area of scar (labeled X).

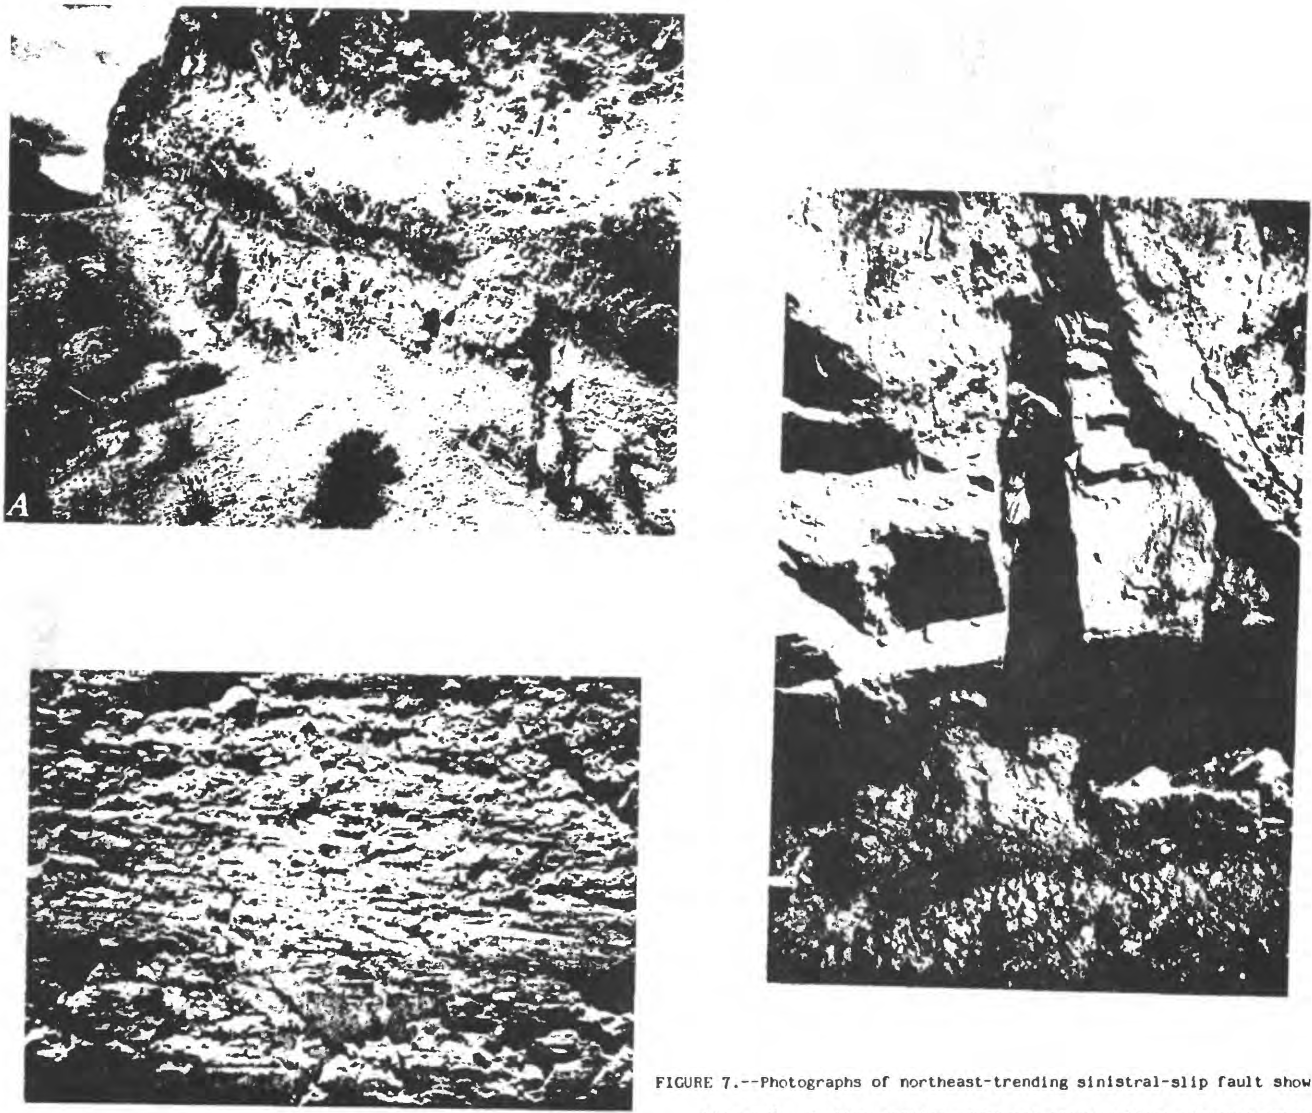

FIGURE 7.--Photographs of northeast-trending sinistral-slip fault shown in figure 6. A, View looking southwest showing large striated grooves on Joe Lott Tuff Member where coarse cemented gravels of the Sevier River Formation (visible in lower part of scarp) have spalled away from fault surface. B, Close-up view of striations on large groove shown in A. Arrow drawn on fault surface in center of view is 3 cm long and shows motion direction of block as required by streamlining of gouge deposits to right of small mechanically resistant lithic inclusions in tuff above arrow. C, View looking down at fault surface (in shade) separating clayey sands of the Sevier River Formation in foreground from Joe Lott Tuff Member. The mechanically weak clayey sands are squeezed like toothpaste into a conspicuous tension gash about 20 cm wide in the mechanically resistant Joe Lott Tuff. Though not visible, the shaded fault surface is conspicuously striated, showing that the Joe Lott block moved to the left (sinistral).

FIGURE 8.--Well-exposed large smooth striated surface of small sinistral-slip fault in Joe Lott Tuff Member. Rough surfaces (near top of photo) that extend out from and offset the large smooth surface also contain gently plunging striae (not obvious in photo). Displacement on the rough-surface fractures is dextral, showing that they are conjugate to the large smooth surface.

FIGURE 11.--Photograph looking northwest at excavated surface of steep planar fault that cuts transversely through northeast-tilted beds of the Sevier River Formation at locality A on figure 3. See figure 12 for stereographic plot of fault and other data. Cameraman is standing on clayey and sandy sediments (not visible) that are downthrown by oblique dextral slip against coarse clastic gravel and conglomerate across the fault.

FIGURE 13.--View looking north along well-exposed Joe Lott Tuff Member in footwall (left and center) of north-northwest-striking normal fault at locality B on figure 3. Hanging wall block (right edge of photo) consists of poorly exposed Sevier River Formation.

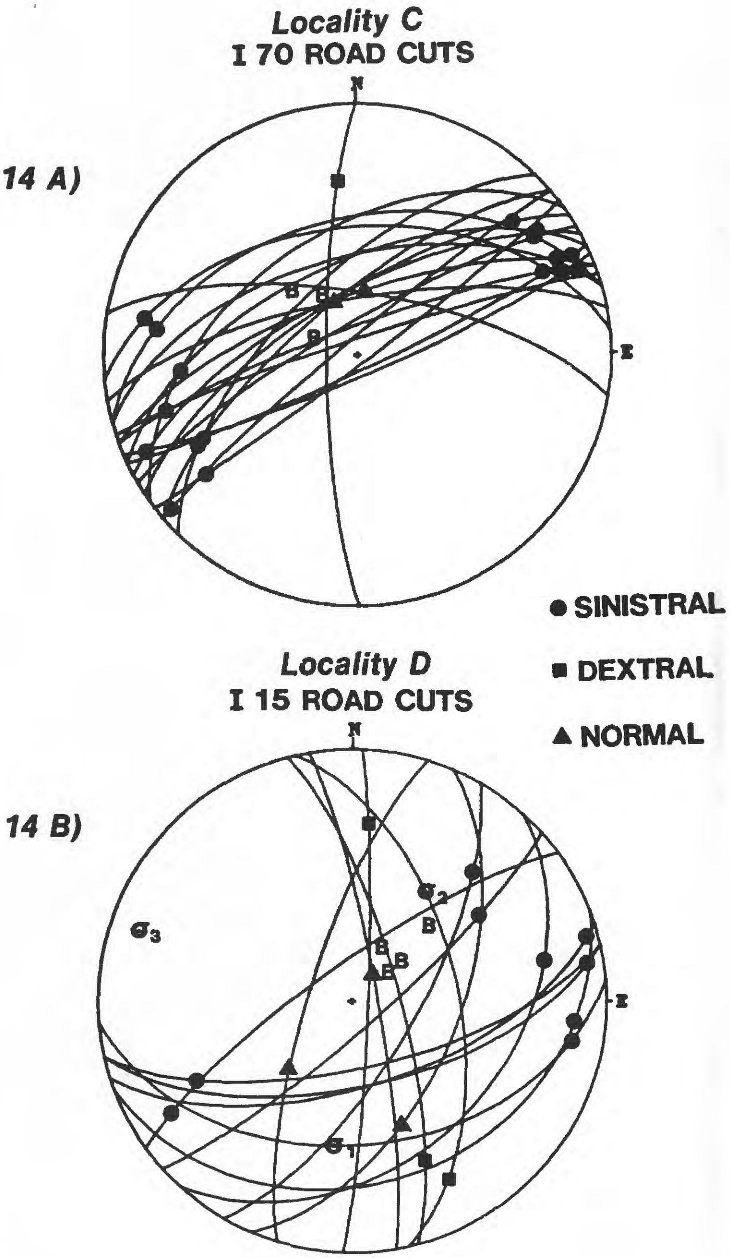

FIGURE 14.-- Lower-hemisphere plots of faults as great-circle arcs and striae in those faults as filled symbols distinguished according to type of slip. Poles to bedding are shown by the symbol B. A, Faults to locality C (I-70 roadcuts). Most are sinistral except for one north-trending dextral and two dip-slip faults. Note that the poles to bedding plot near the normal-faulting striae suggesting an association between the stratal tilting and the dip-slip components of faulting. B, Faults at locality D (I-15) roadcuts). Those that strike between 015° and 085° are all sinistral or normal sinistral. The remaining are dextral except for a normal fault with a steep rake. The faults do not appear to have any simple genetic relationship to stratal tilting. The computed stress axes are poorly constrained because of the small sample size and predominance of sinistral slip. Nevertheless, the position of σ_3' is reasonable when compared with other computed orientations reported herein (table 1). The moderate inclination of σ_1' could result from late-stage rotation of the faults and bedding.

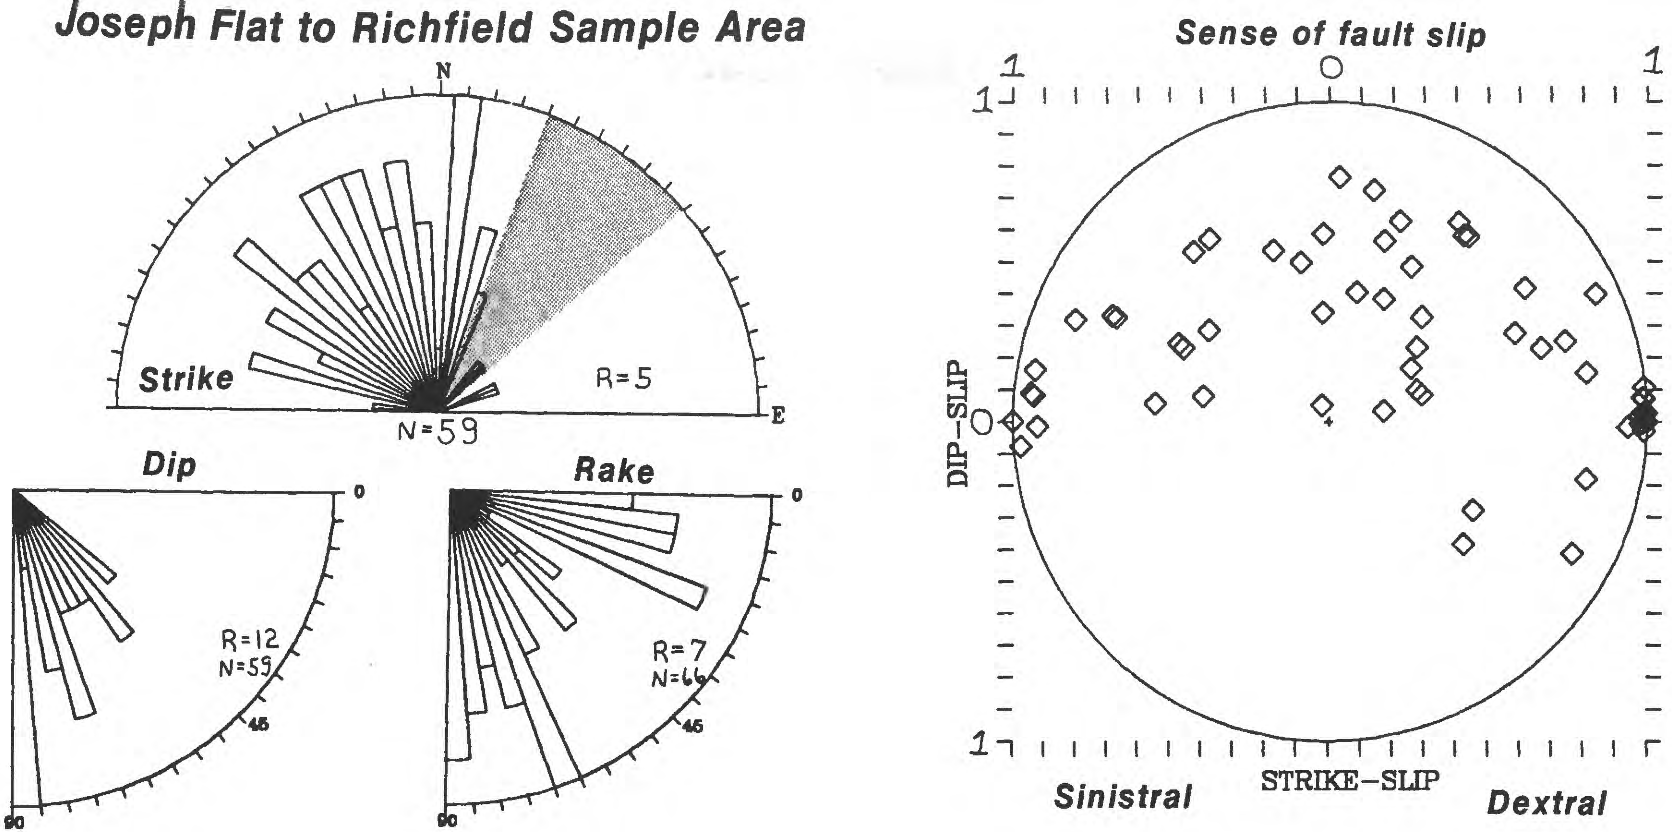

FIGURE 15.--Histograms of strike, dip, and rake, and plot of dip-slip versus strike-slip components of fault slip for faults along the southeast margin of the Pavant Range between Joseph Flats and Richfield. For the sense of fault-slip diagram, the ratio of the strike-slip to net slip is plotted along abscissae and the ratio of the dip slip component to net slip is plotted along ordinate. This plot reveals the complex mixture of strike-slip, dip-slip, and oblique-slip faulting that characterizes this sample area. Compare this fault-slip diagram with the simple pattern of dip-slip faulting along the same range front to the northeast of Richfield (fig. 19). The patterned sector on the strike plot shows the average trend, 35° ± 15°, of the Pavant range front. Symbols are the same as for figure 10.

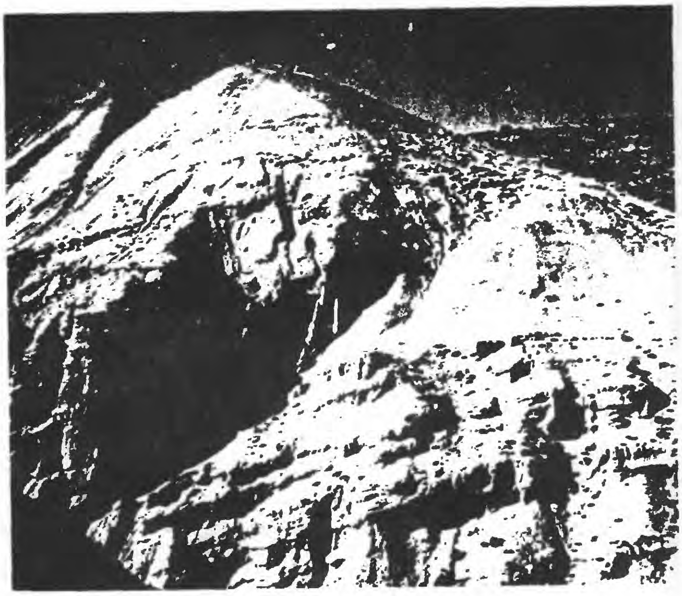

FIGURE 16.--View looking west in Flat Canyon north of Elsinore showing offset contact between smooth- and rough-weathering beds of gently southwest-dipping sandstone, siltstone, and claystone belonging to the Bald Knoll Formation of Eocene age. The fault that separates the offset sections is approximately vertical, strikes 005°, and has an estimated down-to-the-east throw of 10 m. At first glance this fault, and another nearby fault of similar orientation and displacement but out of camera view appear to be steep dip-slip faults that repeat the strata by down-to-the-east (lower right) displacements. However, as with the faults at locality C along the Clear Creek downwarp, these faults are sinistral strike-slip faults having rakes of 3° and 13° to the south.

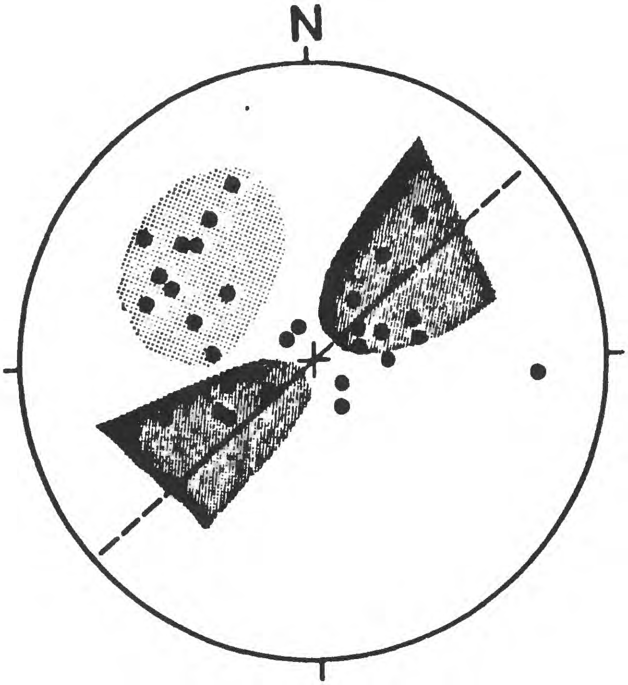

FIGURE 17.--Lower Hemisphere stereographic plot of poles to bedding along the flank of the Pavant Range between Joseph Flats and Richfield. Dark pattern embraces poles that represent first-phase stratal tilting to the northeast and southwest on generally northwest-trending faults. Light pattern embraces poles representing second-phase monoclinal tilting to the southeast. Locally the northeast-dipping block-faulted strata in the range can be traced continuously into the monocline.

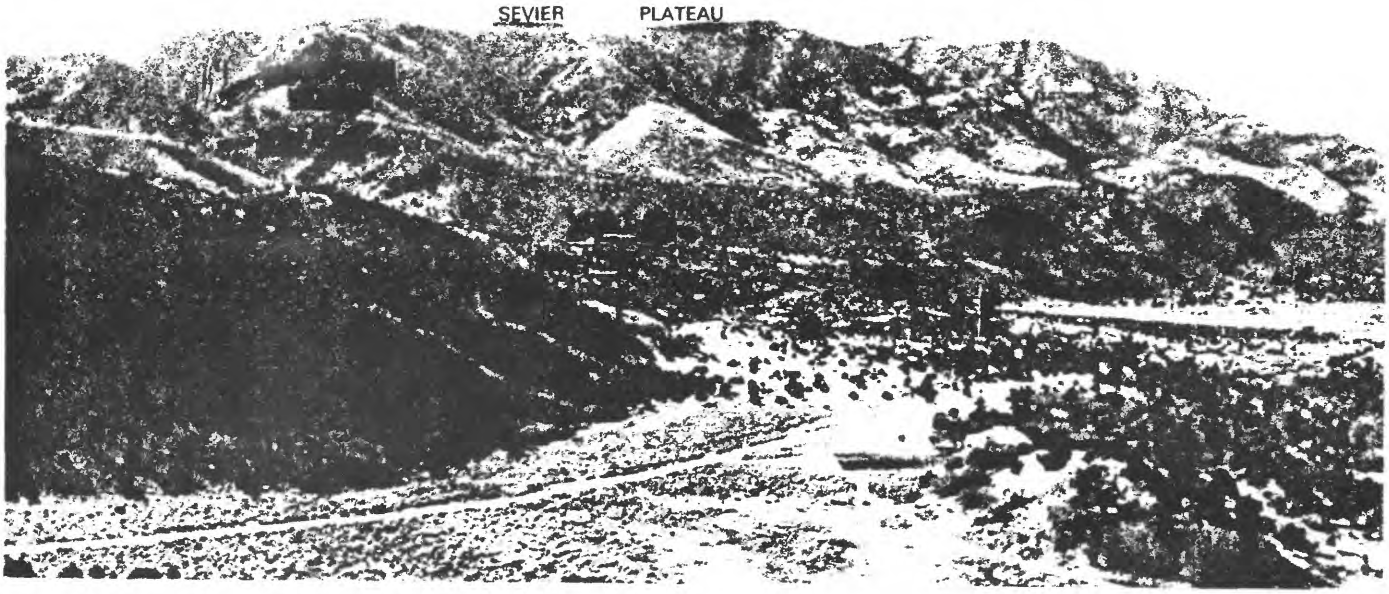

FIGURE 30.--Photograph looking south across northeast-trending main strand of the Sevier fault toward the Glenwood Mountain part of the western Sevier Plateau. Geomorphic surfaces labeled A, B, and C terminate to the northwest against conspicuous scarps that mark the trace of the Sevier fault. Lettered arrows A, B, and C below the respective surfaces point to localities where scarp profiles shown in figure 29 are measured. Irregularly forested area beneath scarps is part of a structurally complex graben containing clastic sediments of Miocene to Quaternary age. In contrast, linear elements of the Glenwood Mountain skyline as well as crudely banded vegetation patterns beneath skyline reflect the structural simplicity of that structural block. The uplifted remnants of surface C that are found on both sides of Water Creek Canyon are interpreted to be parts of a once-continuous surface that predates cutting of the canyon. That surface is smoothly graded across the alluvium-bedrock contact high in the plateau margin, with no suggestion there of displacements by young faults.

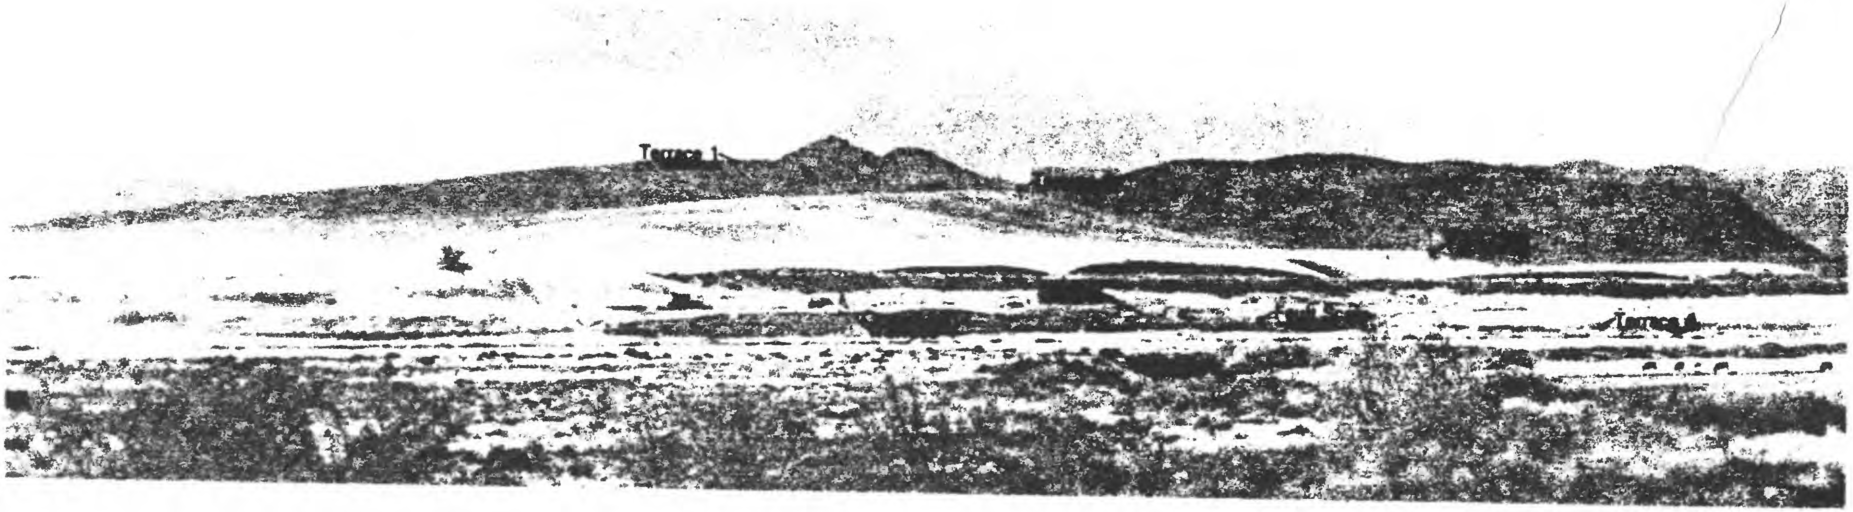

FIGURE 34.--View looking south showing terraces (numbers) that have progressively greater height and greater eastward tilts with greater age. Age is inferred from height above grade of Sevier River and degree of erosional dissection. The conspicuous shaded scarps below terrace 3 are excavations for an irrigation ditch; those below terrace 4 result from erosional trimming by Sevier River. Slopes of the terraces are given in figure 33. Access was denied to area where fault scarp could be studied. Only relative ages of terraces are known.

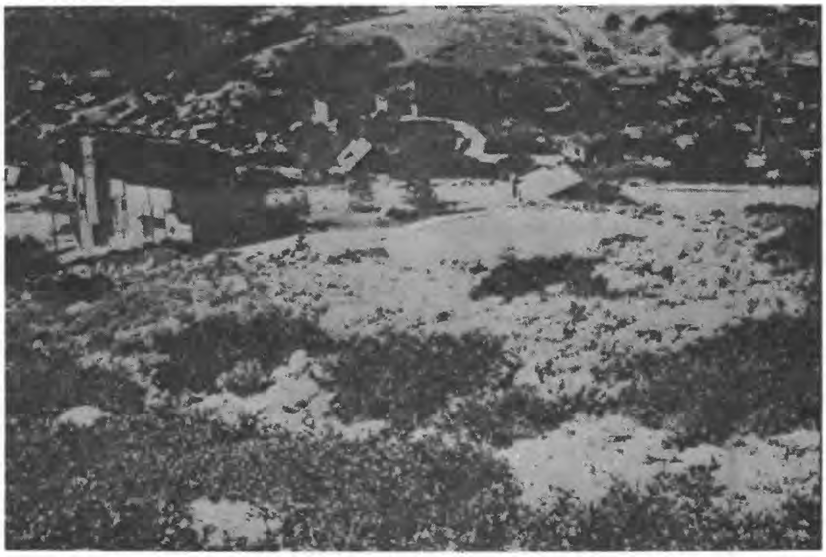

Figure 4: Glacial moraine surface in a subdivision below the Bells Canyon reservoir, Salt Lake City. View is toward the west. Rock clasts which dot the surface of the moraine are Precambrian quartzites and Tertiary quartz monzonites. The maximum rock clast diameter is approximately 2m.

Figure 5: Alluvial fan at mouth of Big Willow Creek, Salt Lake City. Tertiary quartz monzonite rock clasts may dislodge and move during an earthquake. The average large size of clasts is approximately 0.75m and the maximum size is almost 3m. The fan is above the highest level of Lake Bonneville and probably has not been disturbed by lake processes, however, cultural construction may have altered the density of rock clasts near the bottom of the slope. Note the triangular facetted spur face in the middle distance. View is to the southwest.

Figure 6: Lake Bonneville bench near Centerville. Many large rock clasts are perched precariously on a steep slope above development. All clasts are Precambrian metamorphic rocks such as gneisses, amphibolites, and quartzites. The Maximum size is appproximately 1.5m and the average large size is about 0.5m. The elevation ranges from 5200 feet at the slope crest to 4800 feet at the base of the slope. View is to the northeast.

Figure 7: Retaining wall in subdivision in Olympus Cove area, Salt Lake City. Rock clasts in and around the wall are approximately 1m in diameter. There is no infilled mortar between the rock clasts which will be ready to move during an earthquake.

Figure 8: Rock fall runout due to Borah Peak earthquake at Challis, Idaho. Homes and property were damaged but no loss of life was caused due to rock fall. The largest rock clast is approximately 2m. Weakly cemented and open-jointed volcanic rocks make up the greater than 30m high cliff which provided the clasts. View is to the east. Photo by Harold E. Gill, Nov. 1983.

Figure 9 : North side of the mouth of Little Cottonwood Canyon, Salt Lake City, showing vegetated and open talus slopes with larger rock fall clasts. Rock outcrop on left skyline is Precambrian quartzite which has been intruded by a Tertiary quartz monzonite shown on the right skyline. View is to the northeast.

Figure 10 View looking north of mountain spur on north side of mouth of Big Cottonwood Canyon, Salt Lake City. Prominent feature in the middle distance is the Big Cottonwood delta which was deposited while the valley was occupied by Pleistocene Lake Bonneville. The mountain spur above the lake bench is composed of Precambrian quartzite which outcrops at bench level near the right edge of the photograph and in the middle foreground behind the Big Cottonwood water treatment plant. The Holladay Gun Club is located on the lake bench.

Figure 11 Subdivision near the mouth of Emigration Canyon, Salt Lake City, looking east. Homes are situated at the base of Mesozoic sandstone slopes which may fail because of natural or human causes, there are children on the outcrop behind the white house.

Figure 12: Subdivision at mouth of Big Cottonwood Canyon, Salt Lake City, looking south. Homes are located within runout zone of rock clasts from outcrops at the crest of the slope. Rock clasts consist of Precambrian quartzite and Tertiary quartz monzonite.
