STUDIES RELATED TO AMRAP

The U.S. Geological Survey, is required by the Alaska National Interests Lands Conservation Act (Public Law 96-487, 1980), to survey certain Federal lands to determine their mineral values, if any. Results from the Alaska Mineral Resource Assessment Program (AMRAP) must be made available to the public and be submitted to the President and the Congress. This report is one in a series of publications that presents geochemical and mineralogical data determined during the mineral assessment study of the Killik River quadrangle, Alaska. In this report, we present analytical results of aqua-regia leach studies of the stream sediments collected during the geochemical reconnaissance of the Killik River quadrangle, Alaska. In addition, we have included the emission spectrographic results obtained from NURE stream-sediment samples collected from the quadrangle generally south of 68° 45′ N. latitude.

INTRODUCTION

The Killik River quadrangle is located in the central Brooks Range and the Arctic foothills of northern Alaska about 250 mi north of Fairbanks (figure 1). Access is by chartered aircraft into privately owned gravel air strips from Bettles, Alaska. Sampling in the quadrangle began in 1981 field season and continued intermittently through 1986. Field teams from the U.S. Geological Survey collected stream-sediment samples from the southern part of the quadrangle. Semiquantative spectrographic results, along with some analyses by atomic absorption, from samples collected in 1981 are reported in Barton and others (1982) and for samples collected in 1983 and 1984 are reported in Sutley and others (1984).

The topographic relief in the Brooks Range portion of the study area exceeds 4000 ft with a maximum elevation of 7,420 ft. North of the Brooks Range, the Arctic foothills slope gently north with little relief. The climate is arctic.

GENERAL GEOLOGY

The southern boundary of the quadrangle is approximately coincident with the Brooks Range continental divide. Rocks of the Hunt Fork Shale, the Noatak Sandstone, the Kanayut Conglomerate, the Kayak Shale, the Lisburne Group, and the Siksikpuk, Otuk, and Shublik Formations form the Brooks Range in the southern Killik River quadrangle. These rocks, which are dominantly marine, range in age from Devonian through Jurassic. Early geologic mapping was reported by Brosgé and others (1960, 1979). The rocks of Killik River quadrangle in the Brooks Range have been severely deformed by thrusting. These rocks form the southern third of the quadrangle. North of the mountains, the Arctic foothills consist of Cretaceous to Tertiary age deltaic rocks derived from the Brooks Range. The clastic rocks of the

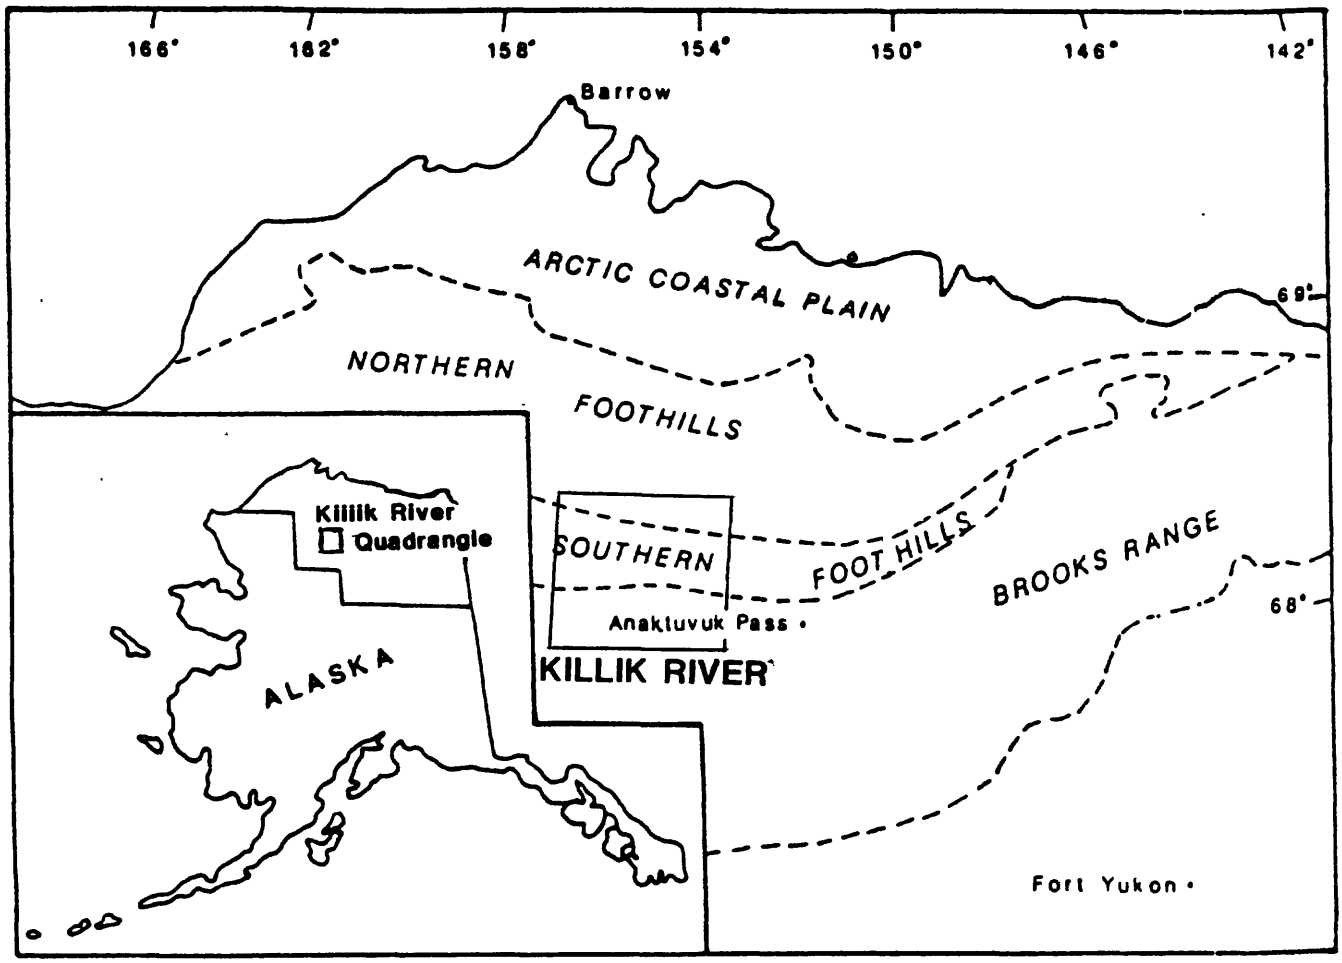

Figure 1. Index map of the central Brooks Range showing the location of the Brooks Range and Arctic foothills province and the outline of the Killik River quadrangle.

Arctic foothills were deformed into east-west trending anticlines and synclines and underlie the northern part of the quadrangle.

METHODS OF STUDY

Sample Media

Geochemical results presented in this report are from stream-sediment samples that were collected from active channels of perennial first-order (unbranched) streams and second-order (below the junction of two first-order) streams, as determined from topographic maps (scales 1:250,000 and 1:63,360). Sampling density was approximately 1 sample site per 2 mi^2 in the mountainous areas and 1 sample per 5 mi^2 in the foothills. The sample localities are shown on plate 1. Analyses of the stream-sediment samples represent the chemistry of the rock material eroded from the drainage basin upstream from each sample site. Such information is useful in identifying those basins which contain concentrations of elements that may be related to mineral deposits.

In general, the northern half of the Killik River quadrangle was not sampled by the U.S. Geological Survey because this area had been sampled previously during the National Uranium Resource Evaluation (NURE) program (Los Alamos National Laboratory, 1982). We have analyzed the samples located south of about 68°45′ N. latitude by both direct current-arc emission spectrographic methods (Grimes and Marranzino, 1968) and by aqua-regia leach methods for comparison with previously published results. The sample localities are shown on plate 2; samples analyzed are indicated by the field numbers. Only the last four digets of the field number are shown on the plate to simplify the map.

Sample Collection

The stream-sediment samples collected in the Killik River quadrangle (Barton and others, 1982; Sutley and others, 1984) were used for the ICP determinations. A total of 336 stream-sediment samples were collected by the U.S. Geological Survey in the quadrangle. The samples were wet-sieved on site to minus 2.0 mm (10-mesh) using a stainless steel sieve and a 14-inch gold pan. Composite samples within individual streams were collected whenever possible. At all sites, a representative portion of the sediment was taken directly from the gold pan and saved as the stream-sediment sample. The samples were air-dried in the field and then shipped to the laboratory for analysis.

Sample Preparation

In the laboratory, the stream-sediment samples were sieved using either a 30-mesh (0.59 mm) or an 80-mesh (0.177 mm) stainless steel sieve. The portion of the sediment that passed

through the sieve was saved. This minus-30-mesh or minus-80-mesh sediment was then ground to approximately minus-100-mesh (0.15 mm) and used for chemical analysis.

Sample Analysis using ICP Methods

One gram of prepared stream-sediment sample was weighed into a 50 mL beaker for digestion. Sample weights were determined to a precision of ±2 percent. The sample was first wetted with a small amount of 10 percent HCl (v/v) to react any carbonate minerals present. Following the completion of this reaction, 15 mL of aqua regia (1:3; HNO_3:HCl) was added to each sample. Initial oxidation of the nonsilicate phases present in the sample usually occurred as an immediate, vigorous reaction. When necessary, this reaction was contained by quenching with distilled water from a squirt bottle. The samples were then placed on a hot plate that was set at a constant temperature of approximately 80°C. The oxidation reaction was usually complete after the samples had been gently heated for approximately ten minutes. The low temperature of the hot plate is necessary to prevent spattering of the samples during the evaporation process. The solution was then taken slowly to dryness. Several mL of 20-percent HCl (v/v) were added to the sample residue and the sample was gently heated. Sample solutions were then filtered through Whatman no. 41 filter paper that had been previously wetted with 10 percent HCL (v/v) and the samples were diluted to constant final volume, usually 10 mL. These sample solutions were aspirated directly into the plasma for analysis.

The Inductively Coupled Plasma (ICP) instrumentation used is commercially available from Applied Research Laboratories. Two instruments were used, the earlier measurements were made on the ICPQ model and the later measurements on a model 34000 ICP. The two instruments have very similar spectral arrays, but the 34000 also had the capability of measuring some of the alkali elements (sodium, potassium, and lithium), and zirconium.

Corrections for spectral interferences and determination of qualifiers designating lower limits of determination and trace concentrations were determined using the procedures described by Church (1981) and Church and others (1983). Because the chemistry of each sample is different and analytical results from ICP utilize a fixed spectral array, the effect of spectral interferences on each element in each sample must be evaluated. This requires that the lower limit of determination for the elements in each sample be checked for possible spectral interferences. The lower limit of determination (N) will also vary because dilutions of the solutions analyzed may be required during analysis. This condition occurs when the sample must be diluted, usually so that the calcium or iron concentrations in the solution analyzed would be within the calibration range of the instrument, so that corrections for possible spectral interferences could be applied. This problem was particularily accute in this study because of the presence of high

concentrations of calcium from the limestones and the phosphatic members of the Lisburne Group. In table 1, we report the minimum determinate concentration for each element in ppm in column 2. We have summarized, in column 3 of table 1, the recommended value of N to be used for each element in tables 3 to 5 along with the number of samples to which this value applies. In column 4 of table 1, we list the number of samples which have higher values of N in tables 3 to 5. Values of N that are higher than the recommended N are indicated in tables 3 and 4 in parentheses, for example N(0.8). We suggest that the values for N assigned in table 1 be used for this data set if a single lower limit (N) is needed. Qualified values (<, trace concentrations) indicate that less than half, but more than one tenth of the total signal measured by the ICP remained after correction for spectral interferences (Church and others, 1983). Analytical results for 336 samples reported in tables 3 and 4 are expressed in parts per million and all values are rounded to two significant figures. Analytical results for 454 NURE samples reported in table 5 also are expressed in parts per million and all values are rounded to two significant figures. The major elements are listed first, followed by the minor and trace elements listed by group as shown on the periodic chart of the elements.

Previous studies of stream-sediment leachates analyzed by ICP have shown that the aqua-regia leach procedure can be effectively applied in regional geochemical exploration. Replicate analysis of geochemical exploration standards (USGS, GXR series; Allcott and Lakin, 1974) using ICP analysis of aqua-regia leachates has indicated an analytical precision of approximately 10 percent (Church and others, 1983). They also demonstrated that recoveries for the ore-related metals of greater that 85 percent. Church (1978) evaluated different digestion procedures for use in exploration geochemistry and showed that the aqua-regia leach was the most effective in releasing metals bound in many nonsilicate phases. Further studies (Church and others, 1987) demonstrated that the aqua-regia leach technique resulted in almost complete recovery of elements bound in the hydromorphic oxide phases. They also demonstrated that the application of the aqua-regia leach procedure resulted in high recoveries (generally greater than 90 percent) of metals bound in many carbonate, sulfide, and crystalline iron- and manganese-oxide minerals. These observations were verified by studies of hand-picked mineral separates (purity generally 90-99 percent). In contrast, the effect of leaching rock samples that contain largely silicate phases (standard silicate rocks were used) indicate that much lower total concentrations of transition metals were released from the silicate phases. The aqua-regia leach procedure can therefore be used to enhance the contrast between mineralization and lithologic background in regional geochemical exploration studies (Church and others, 1983; 1987).

Sample Analysis using Emission Spectrographic Methods

We analyzed 457 NURE stream-sediment samples (Los Alamos National Laboratory, 1982) for 31 elements using a semiquantitative, direct current-arc emission spectrographic method (Grimes and Marranzino, 1968). None of the lake-sediment samples collected during the NURE sampling in the quadrangle were analyzed. The elements analyzed and their lower limits of determination are listed in table 2. Spectrographic results were obtained by visual comparison of spectra derived from the sample against spectra obtained from standards made from pure oxides and carbonates. Standard concentrations are geometrically spaced over any given order of magnitude of concentration as follows: 100, 50, 20, 10, and so forth. Samples whose concentrations are estimated to fall between those values are assigned values of 70, 30, 15, and so forth. The precision of the analytical method is approximately plus or minus one reporting interval at the 83 percent confidence level and plus or minus two reporting intervals at the 96 percent confidence level (Motooka and Grimes, 1976). Values determined for the major elements (magnesium, calcium, iron, and titanium) are given in weight percent; all others are given in parts per million (micrograms/gram). Analytical results are reported in table 6.

ROCK ANALYSIS STORAGE SYSTEM

These analytical results were entered into a computer-based file called Rock Analysis Storage System (RASS). This data base contains both descriptive geological information and the analytical data. Any or all of this information may be retrieved and converted to a binary form (STATPAC) for computerized statistical analysis or publication (VanTrump and Miesch, 1977).

DESCRIPTION OF DATA TABLES

Tables 3 and 4 lists the ICP aqua-regia leachate data for the two suites of stream-sediment samples collected by the USGS and table 5 lists the ICP aqua-regia leachate data for the NURE stream-sediment samples from the Killik River quadrangle. Table 6 lists the emission spectrographic analyses for the NURE stream-sediment samples. For the four tables, the data are arranged so that column 1 contains the assigned field sample numbers. In table 6, columns in which the element headings show the letter "s" below the element symbol are emission spectrographic analyses. A letter "N" in the tables indicates that a given element was looked for but not detected at the lower limit of determination shown for that element in tables 1 and 2. If an element was observed but was below the lowest reporting value, a "less than" symbol (<) was entered in the tables in front of the lower limit of determination. If an element was observed but was above the highest reporting value, a "greater than" symbol (>)

was entered in the tables in front of the upper limit of determination. If an element was not looked for in a sample, two dashes (--) are entered in place of an analytical value.

The spectrographic determinations for As, Au, Bi, Cd, Sb, Th, and W in NURE stream-sediment samples were all below the lower limits of determinations shown in table 2; consequently, the columns for these elements have been deleted from table 6.
