SURFACE-WATER-QUALITY ASSESSMENT OF THE UPPER ILLINOIS RIVER BASIN IN ILLINOIS, INDIANA, AND WISCONSIN: DATA ON AGRICULTURAL ORGANIC COMPOUNDS, NUTRIENTS, AND SEDIMENT IN WATER, 1988-90

by Daniel J. Sullivan and Paul J. Terrio

ABSTRACT

This report describes the sampling design and methods and presents data collected to determine the distribution of agricultural organic compounds, nutrients, and sediment in selected areas of the upper Illinois River Basin as part of the National Water-Quality Assessment program. Four stations in small watersheds (two urban, two agricultural) were sampled in 1988 and 1989. Seventeen stations in an agricultural subbasin were sampled in 1990. Samples were collected before, during, and after runoff events from late spring to midsummer to determine concentrations of agricultural organic compounds in surface waters resulting from storm runoff, as well as background concentrations. Over 200 water samples were analyzed for agricultural organic compound, nutrient, and suspended-sediment concentrations. The agricultural organic compounds included triazine and chlorophenoxy-acid herbicides, and organophosphorus insecticides.

INTRODUCTION

In 1986, the U.S. Geological Survey (USGS) began a National Water-Quality Assessment (NAWQA) program to (1) provide nationally consistent descriptions of the current status of water quality for a large, diverse, and geographically distributed part of the Nation's water resources; (2) define trends in water quality that have occurred in recent decades and provide a baseline for evaluating future trends in water quality; and (3) identify and describe the relations of both the status and the trends in water quality to relevant natural factors and the history of land use and land- and waste-management practices (Cohen and others, 1988; Hirsch and others, 1988). This information will be useful for planning future management actions and examining their likely consequences.

The NAWQA program selected seven pilot-project areas to test and modify, if necessary, assessment concepts and approaches in preparation for possible full implementation of the program. The seven pilot studies include four surface-water and three ground-water areas. The surface-water pilot-study areas are the Yakima River Basin in Washington; the lower Kansas River Basin in Kansas and Nebraska; the upper Illinois River Basin (UIRB) in Illinois, Indiana, and Wisconsin; and the Kentucky River Basin in Kentucky.

One of the specific objectives of the NAWQA program is to determine the distribution of agricultural organic compounds in the water of the Nation's riverine systems. The production and use of these compounds has substantially increased over the past 50 years, and the result has been a gradual decrease in the quality of the Nation's surface water (Smith and others, 1988). The UIRB contains large areas of intensive row-crop agriculture as well as urban areas where pesticides are used by municipalities and homeowners.

The data contained in this report are analytical results of surface-water samples collected to determine concentrations of agricultural organic compounds used as herbicides or insecticides in selected areas of the UIRB. These pesticides are used in row-crop agriculture, as well as for home and municipal applications, to help control harmful vegetation and insects. Information on the quantities of various pesticides used in the UIRB is available in Pike and others (1990) and Taylor and others (1989). Samples were collected before, during, and after storm events that were of sufficient intensity to produce runoff to surface waters.

Purpose and Scope

This report presents the analytical results and documents the methods used in the collection, handling, and laboratory analyses of water samples used to determine the distribution of agricultural organic compounds in selected areas of the UIRB from April 1988 through August 1990. Data presented for agricultural organic compounds include concentrations of triazine and chlorophenoxy-acid herbicides, and organophosphorus insecticides for samples collected in 1988 and 1989, and concentrations of triazine herbicides for samples collected in 1990. Data presented for related constituents include nutrients and suspended-sediment concentrations. In addition, quality-assurance and quality-control (QA/QC) measures are documented.

Description of the Study Area

The UIRB drains 10,949 mi^2 of northeastern Illinois, northwestern Indiana, southeastern Wisconsin, and southwestern Michigan (fig. 1). The percentages of total basin drainage for those States are 62, 28, 10, and less than 1, respectively.

The basin is drained by three principal rivers--the Kankakee, Fox, and Des Plaines Rivers. The Kankakee River and its major tributary, the Iroquois River, drain 47.2 percent of the study area; the Fox River drains 24.3 percent; and the Des Plaines River drains 19.3 percent. The Kankakee and Des Plaines Rivers join near Morris, Ill., to form the Illinois River. The Fox River discharges into the Illinois River at the southwestern boundary of the UIRB near Ottawa, Ill. The Illinois River, downstream from the study area, flows west and southwest 240 mi to the Mississippi River.

The UIRB lies in what was formerly a prairie plain. Today, two types of land use are dominant in the UIRB: the urban and industrial area of metropolitan Chicago and rural areas of row-crop agriculture typical of the Midwest.

Figure 1.--Location of the upper Illinois River Basin.

Agriculture accounts for about 75 percent of the land use in the basin. Corn is the principal crop, followed by soybeans. Urban and industrial areas account for about 18 percent of the land use in the basin. The remaining 7 percent of land use is forest and pasture lands. The population in the study area is approximately 7 million, of which 6 million live in the Des Plaines River Basin. A more detailed description of the UIRB is presented in Mades (1987, p. 4-15).

SAMPLING DESIGN

The Illinois Environmental Protection Agency (IEPA) has been monitoring pesticide concentrations in streams in the UIRB for several years. The sampling program described in this report was designed to compliment the IEPA programs. The IEPA monitoring programs include fixed-interval sampling at three sites on large rivers with sample analysis for herbicides and organophosphorus insecticides. Ongoing sampling efforts in the UIRB are described by the IEPA (1990, p. 111-115).

Overview of Sampling Design

The NAWQA sampling program for pesticides in surface water was designed to target areas where and times when the largest concentrations of pesticides were expected. Instream concentrations of agricultural organic compounds applied to the land as agricultural and lawn pesticides generally are largest during storm events that cause overland runoff. Most pesticide sampling in the UIRB by other agencies does not target runoff events but is usually done on a fixed schedule. Studies also have shown that pesticide concentrations are often larger in smaller streams (Baker, 1988). Pesticide sampling in urban areas often has been neglected. Based on the estimated use of pesticides in urban areas by Taylor and others (1989), streams in urban areas have the potential for large concentrations of pesticides from storm runoff. The UIRB NAWQA pilot project addressed these considerations by (1) sampling during storm events sufficient to produce runoff, (2) sampling at sites in small watersheds, and (3) sampling at sites in both agricultural and urban areas.

Sampling for agricultural organic compounds was conducted in two phases. Phase I was designed to determine which compounds were detected most often in the UIRB. Phase II was designed to determine the spatial distribution of the compounds identified in Phase I for a selected part of the study area (the Kankakee River Basin). Phase I sampling took place in 1988 and 1989, and Phase II sampling took place in 1990.

Phase I sampling stations were selected by several criteria. Two stations were in areas with homogeneous urban land use and two stations were in areas with homogeneous agricultural land use, in order to be able to relate observed pesticide concentrations to land use. The sampling stations also were in small watersheds where concentrations of the targeted compounds were expected to be large. The stations were all at USGS streamflow-gaging stations. These gaging

stations furnished real-time information on streamflow conditions, which helped to achieve representative sampling of the entire runoff hydrograph. These stations also furnished discharge data for each sample collected. Selected information on the Phase I sampling stations is provided in table 1, and the location of each station is shown in figure 2.

Phase II sampling stations were selected to determine the spatial distribution of pesticides throughout the Kankakee River Basin. The Kankakee River Basin is composed of two major rivers--the Kankakee and Iroquois Rivers. Seventeen stations were sampled in the Kankakee River Basin, six of which were in the Iroquois River subbasin. The stations in the Iroquois River subbasin included five stations on the Iroquois River main stem and one on a major tributary. In this report, these stations will be referred to as "Iroqouis River stations." The remaining 11 stations will be referred to as "Kankakee River stations." All stations were at USGS streamflow-gaging stations. One station, the Iroquois River near Chebanse, was sampled essentially continuously throughout the late spring/midsummer period using an automatic sampler. Selected information on each of the Phase II stations is provided in table 2, and the location of each station is shown in figure 3.

The Kankakee River stations were sampled at or near the peak of the runoff event. Low-flow samples were collected to provide information on background concentrations present in the streams. Data were collected to describe other streamflow and drainage-basin characteristics that may or may not affect the observed concentrations of pesticides. These data included instantaneous discharge at the time the sample was collected, notation of the limb of the hydrograph (rising, peak, or falling) when the sample was collected, the time and magnitude of peak discharge of the event, and suspended-sediment and nitrite plus nitrate nitrogen concentrations. Table 3 presents the date, time, and peak discharge at each station for runoff events that were sampled.

The Iroquois River stations were sampled at intervals throughout entire runoff events, providing a nearly continuous record of pesticide concentrations. From these data, loads at each station can be calculated, and relations of loads and peak concentrations to the streamflow and drainage-basin characteristics can be evaluated. These data also can be used to determine relations between discharge, suspended-sediment concentration, nitrite plus nitrate nitrogen concentration, and pesticide concentrations.

In a concurrent but separate study, over 200 samples were collected by an automatic sampler at the Iroquois River near Chebanse, Ill., for analysis of triazine compounds. These samples were collected as part of a U.S. Geological Survey study of herbicides in water of the midwestern United States (Thurman and others, 1992). These samples were collected at regular intervals during low and medium flows and at an increased frequency during runoff events. Because of the similarities between collection efforts, these data can be used with data collected at the other Iroquois River stations.

Constituents of Interest

Water samples were analyzed for polar, hydrophilic agricultural organic compounds. The compounds analyzed for are pesticides and in Phase I included chlorophenoxy-acid and triazine herbicides and organophosphorus insecticides (table 4). During Phase II, samples were analyzed for triazine herbicides only but were analyzed two different ways. Discrete samples collected at the Iroquois River stations were analyzed using enzyme-linked immunosorbent assay (ELISA) (Pomes and others, 1991) that provided a semiquantitative measure of triazine (as atrazine) concentrations. Composite samples (see sample collection section) were analyzed for total recoverable and dissolved triazines by gas chromatography/mass spectrometry (GC/MS). The dissolved analyses can be used to confirm and further quantify the ELISA analyses and provide a breakdown of the specific compounds detected and their concentrations. Total-recoverable analyses can be used to confirm that most of the triazines are in dissolved form in surface waters. According to Pike (1987), triazines are the most widely used herbicides in agricultural areas in Illinois.

In conjunction with the samples collected during Phase II, additional samples were collected to determine total nitrite plus nitrate nitrogen concentrations. Table 4 includes selected information on samples submitted for nitrogen analysis.

Samples also were collected for analyses of suspended-sediment concentrations and particle size. Suspended-sediment data can be used to evaluate relations between suspended-sediment and pesticide concentrations.

Field measurements of the physical characteristics of the stream water collected during runoff-event sampling included measurements of stage, which were used to estimate discharge, and measurements of specific conductance, which relates to the total amount of dissolved solids present. Specific conductance was measured in 1988 and 1989 but not in 1990. Table 4 includes selected information on field measurements made during the pesticide sampling.

METHODS

Samples were collected, handled, and analyzed according to techniques adopted by the USGS, except where noted. The equipment and techniques used to make field measurements and to collect samples are described in this section. In addition, QA/QC measures are described.

Sample Collection

Water samples for the determination of pesticide concentrations were collected in open-mouth, 1-L, baked-glass bottles. The bottles were placed in a weighted sampler suspended on a rope and lowered and raised through the water column by hand. Depending on the size of the stream, between one and three verticals were used to collect the water. A single vertical was used for small

[1]Refers to number in U.S. Geological Survey's National Water-Quality Laboratory services catalog used to request a specific type of analytical procedure for a given constituent.
[2]National WATer Data STOrage and REtrieval system; number identifies parameter in computer data base.
[3]Smallest unit results reported for that constituent or compound.

streams, but three verticals were needed to define pesticide concentrations in large streams. When the stream width exceeded 10 ft, samples were collected using the equal-width-increment method and a constant vertical transit rate, as discussed in Ward and Harr (1990, p. 7-8).

At some stations, composite samples representing each of the rising, peak, and falling limbs of runoff hydrographs were collected. Because of the expense of herbicide analyses, numerous discrete samples collected during the entire runoff event were not analyzed individually. Instead, composite samples were obtained from the discrete samples, and these composites were analyzed to determine herbicide concentrations during each limb of the runoff hydrograph. Generally, between 4 and 10 discrete samples were used to obtain a composite sample representative of a limb. Composite samples for the rising, peak, and falling limbs of the hydrograph were obtained by combining discharge-weighted parts of the discrete samples collected during the particular hydrograph limbs. Volumes used from each discrete sample were determined using the following equation:

$$V_s = 1{,}000\,(Q_i/Q), \tag{1}$$

where

V_s is volume, in milliliters, needed from the sample;
Q_i is instantaneous discharge, in cubic feet per second, at time of sample collection;
Q is summation of instantaneous discharges for all samples used in the composite; and
1,000 is a constant that gives a composite sample volume of 1 L.

Bottles containing the discrete samples were shaken to ensure adequate mixing. The calculated volume was then withdrawn and poured into the composite sample.

In 1990, nutrient samples were collected each time a pesticide sample was collected. Nutrient samples were collected in the same manner as the pesticide samples; however, nutrient samples were not composited to coincide with the limbs of runoff hydrographs.

Suspended-sediment samples also were collected whenever a pesticide sample was collected. Suspended-sediment samples were collected using a DH-59 depth-integrating sampler and standard USGS techniques, as presented in Edwards and Glysson (1988). Suspended-sediment samples were collected at the same verticals at which pesticide and nutrient samples were collected. Suspended-sediment samples were not composited.

Measurements of specific conductance and observations of stream and weather conditions were made. Specific-conductance measurements were made in the field during the 1988 and 1989 sampling efforts using portable field meters. The meters were calibrated in the field using specific-conductance standards. No measurements of specific conductance were made in 1990. Notes of stream conditions were recorded, including stage and discharge readings; whether the stage was rising, falling, steady, or peaking; water color and clarity; presence of aquatic vegetation; and other pertinent information.

Observations of weather conditions were noted, including cloud cover, air temperature, wind conditions, and precipitation.

Sample Handling

The sample-handling methods, including processing and preservation methods used to prepare the water-quality samples for analyses at the laboratory, varied according to the type of analyses to be performed on the water sample. Samples analyzed for total-recoverable pesticide concentrations required minimal preparatory work. For these analyses, sample water was collected in 1-L clear or amber baked-glass bottles and placed in a cooler with ice to maintain a temperature of approximately 4°C. Clear bottles were covered with aluminum foil to prevent exposure to light. The samples were shipped to the laboratory by overnight mail within 3 working days after collection.

Samples analyzed for dissolved pesticide concentrations were filtered before being shipped to the laboratory. The sample was passed through a 0.45-µm pore-size glass-fiber filter and collected in 125-mL baked-glass bottles. The 125-mL bottles were immediately capped, covered with aluminum foil, and placed in a cooler with ice. The samples were mailed to the laboratory by overnight mail within 3 working days after collection.

The filtering apparatus and associated equipment used to process the samples were thoroughly washed with laboratory-grade soap, rinsed with deionized water, rinsed with methyl alcohol, and rinsed a final time with organic-free water. All surfaces that would contact sample water were covered with clean aluminum foil until they were used to process subsequent samples.

Nutrient samples collected in 1990 were analyzed for total-recoverable nitrite plus nitrate nitrogen concentrations. The water used for the nutrient analyses was transferred directly from the collection bottle to a 250-mL brown polypropylene bottle. Nutrient samples were preserved by the addition of 1 mL of mercuric chloride/sodium chloride preservative, chilled to 4°C, and shipped to the laboratory with the pesticide samples.

Suspended-sediment samples required no processing. The samples were collected and shipped to the laboratory, generally within 2 weeks, to prevent algal growth and degradation of the sample prior to analysis.

Sample Analysis

The laboratory methods used to determine concentrations of pesticides are listed in table 4. The National Water-Quality Laboratory (NWQL) in Denver, Colo., analyzed samples for total-recoverable pesticide concentrations using GC/MS techniques as presented in Wershaw and others (1987). The Organic Geochemistry Research Laboratory (OGRL) in Lawrence, Kans., analyzed samples for dissolved pesticide concentrations using GC/MS techniques. The OGRL also analyzed samples for triazine concentrations and chloro-acetanilide herbicides using ELISA.

The ELISA procedure was developed as an inexpensive screening tool for storm runoff samples from streams. The following description of the ELISA procedure is from Pomes and others (1991). Res-I-Quantl kits consisting of microtitre plates and reagents were used to analyze triazine and chloro-acetanilide herbicides concentrations. There are 96 wells on the polystyrene microtitre plate, each of which is coated with polyclonal antibodies that adsorb either triazine or chloro-acetanilide herbicide molecules, depending on the analysis. Res-I-Quantl kits additionally used an enzyme conjugate prepared by covalently binding atrazine or alachlor molecules to horseradish peroxidase. The microtitre plate was set up with four standards in triplicate, and duplicates of each of the stream samples. Eighty µL (microliters) of laboratory standards and stream samples were added to the plate, immediately followed by 80 µL of enzyme conjugate. The plate was then covered with parafilm and incubated for 1 hour at room temperature while being rotated at 180 rpm (revolutions per minute) on an orbital shaker. The plate was then flushed and rinsed five times with deionized water, then dried with compressed air. After that, 160 µL of a mixture of substrate and chromogen (mixed in that order) were pipetted into each well. The plate was covered again with parafilm and allowed to incubate for 30 minutes while rotating on an orbital shaker at 180 rpm. The substrate and chromogen reacted with the enzyme conjugate to produce a blue color, which was inversely proportional to the analete concentration. This reaction was halted with the addition of 40 µL of sulfuric acid (2.5 normal) solution, which caused the color of the substrate-chromogen mixture to change to yellow. The plate reader then determined the optical absorbances in all of the wells based on the standards readings, and output the standard curve and concentrations for all the samples.

Analyses of nitrite plus nitrate nitrogen concentrations were performed at the NWQL using methods documented in Fishman and Friedman (1989). Table 4 lists selected information on the nitrite plus nitrate nitrogen analyses performed and the methods used.

Analyses of suspended-sediment concentrations and the percentage of suspended sediment finer than 0.062 mm in diameter were performed by the USGS sediment laboratory in Iowa City, Iowa. The analytical technique used to determine the concentration was the evaporation method described by Guy (1969, p. 11). Particle-size determination was made by sieving, as presented in Guy (1969, p. 28). During the 1990 Phase II sampling, suspended-sediment samples were analyzed for concentration only. Table 4 lists selected information on the suspended-sediment analyses performed and the methods used.

Quality Assurance and Quality Control

Adherence to established QA/QC procedures is vital to the NAWQA program in order to assure national consistency and comparability of data from different areas of the country. General QA/QC guidelines for the NAWQA program are presented in Mattraw and others (1989). The QA/QC for the UIRB NAWQA pesticides sampling program was monitored through the use of sample splits and spiked samples.

The purpose of sample splits was to determine the variation in concentration caused by sample handling procedures. A sample split involved collecting a water sample using the methods previously described and dividing the sample into two distinct samples. These individual samples were then processed separately. Laboratory results from sample splits may be compared to determine differences attributable to sample handling by the field personnel.

The value of sample splits to determine differences attributable to sample handling is contingent upon good laboratory techniques and accurate analyses of the samples. At the USGS laboratories, QA/QC monitoring is an ongoing activity. Sufficient analyses of the analytical methods used and the results obtained have been performed so that excessive variation in sample splits can be identified and attributed to sample collection or handling activities.

During the Phase I sampling in 1989, two sets of sample splits were collected at two stations--Sugar Creek at Milford, Ill., on May 26 and Salt Creek at Rolling Meadows, Ill., on May 20. The results of these samples are presented in table 5.

Spiking of water samples was performed to monitor laboratory analytical techniques and to determine the degradation of compounds between the time of collection and analysis. A sample was collected at Sugar Creek at Milford, Ill., during the Phase I sampling in 1989 and was split into four distinct subsamples. From these four samples, an unspiked split sample was submitted to the laboratory to determine the ambient concentrations of pesticides in the sample. Two samples were spiked in the field by adding known concentrations of pesticides. These two spiked samples were used to determine the extent of interferences on analyte recovery from the ambient water matrix. The relative percentages of difference between the duplicate spike analyses can be calculated to assess the analytical precision of the spike. The final sample was spiked at the laboratory and was used to determine the effects on the analytical results of shipping and storage time prior to analysis. The results of the analyses of the spiked samples are presented in table 6.

The QA/QC measures for the Phase II sampling were incorporated into the concurrent USGS study of herbicides in surface water of the midwestern United States (Thurman and others, 1992). The two studies used comparable sampling and analyses methods. The results of the QA/QC analyses are not presented in this report.

DATA ON AGRICULTURAL ORGANIC COMPOUNDS, NUTRIENTS, AND SEDIMENT IN WATER

Tables 7-10 (at end of report) contain the analytical results of pesticide samples collected as part of the UIRB NAWQA program and associated QA/QC samples. Tables 7 and 8 present the results of the laboratory analyses and field measurements for the Phase I sampling efforts in 1988 and 1989, respectively. Tables 9 and 10 present the results of the laboratory analyses and field measurements of samples collected during the Phase II sampling efforts. Table 9 presents the results of the ELISA analyses and nutrient and suspended-sediment concentrations, and table 10 presents the results of GC/MS analyses.

These tables include the location, date, and time of sample collection; the laboratory that analyzed the sample; and the results of the analyses. Results of the analyses of the samples collected by the automatic sampler at the Iroquois River near Chebanse are not included in this report because they were collected for a separate study. The following information is included as an aid to interpreting the data contained in tables 7-10.

Time.--The sample-collection times indicated are expressed in 24-hour standard time. For example, 0030 is 12:30 a.m., and 1330 is 1:30 p.m.

Missing data.--Missing data will appear in the data tables as dashes.

Parameter codes.--Each column heading has a number that is the parameter code used in the U.S. Geological Survey WATer Data STOrage and REtrieval System (WATSTORE) to reference parameters related to water quality (Hutchison, 1975). The collecting agency and analyzing agencies identified by the parameter codes in tables 7-10 are as follows:

81700 - USGS field personnel,
80020 - USGS National Water Quality Laboratory, and
82013 - Organic Geochemistry Research Laboratory.

Remarks.--The value for each water-quality parameter may be qualified by a remark. The remark and the corresponding symbol that may be printed in the data tables are listed below.

Symbol	Remark
<	Actual value is known to be less than the value shown.
