FLOOD MAGNITUDE AND FREQUENCY OF CHANDLERS RUN AT TWO SITES, AT PENNSAUKEN TOWNSHIP, NEW JERSEY

By Paul Dunne

ABSTRACT

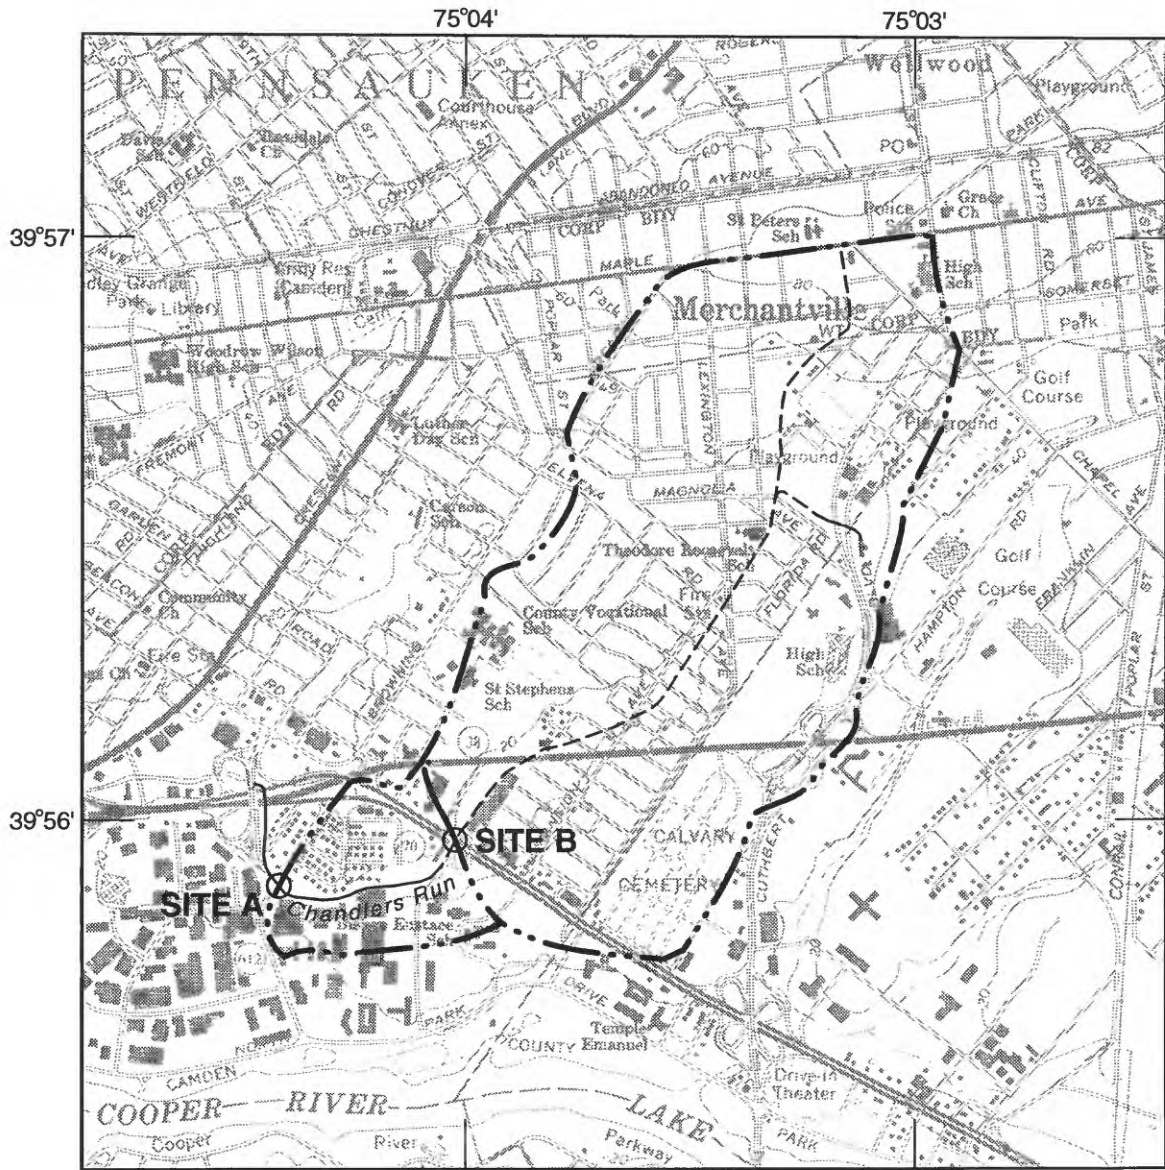

Six methods were used to estimate the magnitude and frequency of floods at Chandlers Run at the culvert on New Jersey Route 612 and at a second site about 2,100 feet upstream, at New Jersey Route 70, at Pennsauken Township, New Jersey. Flood magnitude and frequency calculated by the six methods, as well as drainage-basin characteristics, are included in this report. The 100-year-flood estimates for the culvert site on New Jersey Route 612 range from 268 cubic feet per second to 2,050 cubic feet per second. The 100-year-flood estimates for the upstream site at New Jersey Route 70 range from 246 cubic feet per second to 2,320 cubic feet per second. Flood magnitude and frequency estimates obtained by using the New Jersey Department of Environmental Protection Special Report 38 method and other previously published estimates fall within the range of values estimated by using the U.S. Geological Survey transfer method with data collected from three nearby crest-stage gages.

INTRODUCTION

Information on the magnitude and frequency of floods is critical to the planning and design of highway culverts and bridges. Such information is not available for many stream crossings in New Jersey. To fulfill this information need, the U.S. Geological Survey (USGS), in cooperation with the New Jersey Department of Transportation, began an analysis of flood data from stream-crossing sites on New Jersey streams. This report presents results of the analysis for Chandlers Run at the culvert on N.J. Route 612, at Pennsauken Township, N.J., (site A) and at a second site (site B) about 2,100 ft upstream from site A at N.J. Route 70 (fig. 1). The drainage area upstream from site A is 1.03 mi². The drainage area upstream from site B is 0.92 mi². A field reconnaissance was performed on June 9, 1993, to verify the locations of the drainage divides and land use. Because the direction of storm-sewer drainage in some parts of the basin is uncertain, the calculated drainage area is approximate.

The flooding problem in this area has been depicted in newspaper articles. According to a report in a local newspaper (Courier-Post Newspaper, 1989) 4.38 inches of rain fell during 6 hours, causing flooded homes, traffic problems, collapsed dams, and electric- power outages. A few bridges and roads were damaged or washed out near the study sites. The recurrence interval and discharge of this flood are undetermined.

The flood-insurance study for Pennsauken Township (Federal Emergency Management Agency, October 1976) did not include a detailed study of this part of Chandler Run; therefore, flood discharges were not determined previously.

METHODS USED TO ESTIMATE FLOOD MAGNITUDE AND FREQUENCY

Various flood magnitude and frequency methods were used to determine the flood magnitudes that are likely to be exceeded at this site within a given number of years (recurrence interval). The methods used include the rational method (Chow and others, 1988), New Jersey Department of Environmental Protection (NJDEP) Special Report 38 method (Stankowski, 1974), U.S. Geological Survey (USGS) index-flood method (Thomas, 1964), USGS transfer method (N.J. Department of Environmental Protection, 1988), U.S. Soil Conservation Service (SCS) Technical Release 55 (TR-55) method (U.S. Soil Conservation Service, 1986), and the U.S. Army Hydrologic Engineering Center (HEC) Special Projects Memo 480 method (U.S. Army Corps of Engineers, 1977).

Data and computations used in this study can be obtained from the U.S. Geological Survey, 810 Bear Tavern Road, Suite 206, West Trenton, NJ 08628.

Rational Method

The rational method is based on the concept that if a rainfall of a particular intensity begins instantaneously and continues indefinitely across a watershed, the runoff rate will increase until the time of concentration is reached, which is the time when the entire watershed is contributing to the flow at the outlet (Chow and others, 1988). The time of concentration (the time needed for water to travel from the farthest point in the watershed to the outlet) is computed by summing the travel times for consecutive components of a drainage system (U.S. Soil Conservation Service, 1986). Many factors, including channel shape, surface roughness, and slope, affect the time of concentration.

The equation that expresses this method is:

$$Q = CiA,$$

where Q is the rate of peak discharge at the time of concentration, in cubic feet per second; i is the rainfall intensity, in inches per hour; A is the watershed area, in acres; and C is the runoff coefficient. The runoff coefficient depends on various watershed characteristics, including the composition and condition of the soil, the type and condition of land use, and the percent imperviousness of the watershed. Appropriate runoff-coefficient values based on these watershed characteristics were chosen from a table (N.J. Department of Environmental Protection and Energy, 1993). This method is recommended for the calculation of peak discharges in homogeneous drainage areas up to 0.5 mi² in size (N.J. Department of Environmental Protection and Energy, 1993).

Special Report 38 Method (New Jersey Department of Environmental Protection)

This method consists of the development and use of a set of regression equations for the 2-, 5-, 10-, 25-, 50-, and 100-year floods based on the watershed characteristics drainage area, basin storage (percent area of lakes and swamps, plus 1.0 percent in order to avoid zero values), and impervious cover (based on population density). This method is recommended for use in drainage areas of 1 to 1,000 mi² (Stankowski, 1974).

Index-Flood Method (U.S. Geological Survey)

Flood estimates are made with this method by using two graphical curves. One curve expresses the relation between the mean annual flood and the size of the drainage basin; the other expresses the ratio between the mean annual flood and floods of other recurrence intervals. The mean annual flood is adjusted on the basis of the percentage of lakes and swamps in the drainage basin. This method is recommended for drainage areas greater than 4 mi² and is most accurate for drainage areas of 10 to 200 mi² (Thomas, 1964).

Technical Release 55 Graphical Peak Discharge Method (U.S. Soil Conservation Service)

For this method, a SCS curve number, which represents the overall soil type, land use, and antecedent soil-moisture conditions, is determined for the basin. This curve number is used to account for the initial abstraction and infiltration losses. Other required input parameters are the 24-hour rainfall associated with the desired frequency, the drainage-basin area, and the time of concentration (total travel time). The time of concentration for a basin is determined by using a set of equations describing the travel time for the overland-flow or sheet-flow segment, the shallow-concentrated-flow segment, and the open-channel-flow segment. The time of concentration is the sum of the ratios of flow length to flow velocity for each segment. This value depends on the surface type, hydraulic radius, cross-sectional-flow area, wetted perimeter, land slope, channel slope, and Manning's roughness coefficient. This method is recommended for drainage areas of less than 5 mi² (U.S. Soil Conservation Service, 1986).

Special Projects Memo 480 Method (U.S. Army Hydrologic Engineering Center)

This method is based on multiple-regression equations for the mean, standard deviation, and skewness of the logarithms of the annual peak flows at 58 long-record streamflow-gaging stations; the equations are based on three watershed characteristics (drainage area, main channel slope, and forest cover). An adjustment is made by estimating a generalized skew coefficient based on the log-Pearson Type III distribution (Interagency Advisory Committee on Water Data, 1982). This method is recommended for use for drainage areas of 10 to 300 mi² (Interagency Advisory Committee on Water Data, 1982).

Transfer Method (U.S. Geological Survey)

The relation that is used to calculate flood estimates is based on a ratio of drainage areas raised to an exponent:

$$\frac{Q_{PI}}{Q_{PG}} = \left(\frac{A_{PI}}{A_{PG}} \right)^{0.75}$$

where Q_{PI} is the design flood at the point of interest, Q_{PG} is the design flood at the gaged point, A_{PI} is the drainage area at the point of interest, and A_{PG} is the drainage area at the gaged

point. An exponent of 0.75 is used; the exponent is based on studies of 10-year recurrence interval floods in New Jersey (New Jersey Department of Environmental Protection and Energy, 1993). This method is recommended for drainage areas that are either less than twice or more than half the drainage area of the gaged point (New Jersey Department of Environmental Protection and Energy, 1993).

COMPARISON OF RESULTS

The explanatory variables used in applying the methods described above at site A and site B are listed in tables 1 and 2, respectively. The flood-magnitude and -frequency estimates for both sites obtained by using each of the various methods are shown in tables 3 and 4, respectively. The range in the estimates is large; estimates of the 100-year-flood discharge at site A range from 268 to 2,050 ft³/s, and the estimates of the 100-year-flood discharge at site B range from 246 to 2,320 ft³/s.

Flood data from nearby streamflow-gaging or crest-stage gaging stations provide a good indication of the flood magnitude and frequency that can be expected at an ungaged site, particularly if drainage area and other basin characteristics are similar and the record length is sufficiently large. The estimates developed by using the various methods are compared with discharge data that have been transferred to the culvert sites by using the USGS transfer method.

In New Jersey, for streams that drain areas between 1 and 5 mi², the NJDEP Special Report 38 method and the TR-55 method (New Jersey Department of Environmental Protection and Energy, 1993) are the most frequently used. The drainage area of site A falls within these limits. The discharge values estimated by using the TR-55 method, as well as the rational method and the HEC Special Project Memo 480 method, are much greater than the values estimated by using the USGS transfer method with data collected from three nearby crest-stage gages (stations 01467057, 01467305, and 01467317; Bauersfeld and others, 1993). The estimates obtained by using the NJDEP Special Report 38 method fall within the range of peak discharges estimated by using the USGS transfer method.

For streams draining areas between 0.5 and 1 mi², the TR-55 method (New Jersey Department of Environmental Protection and Energy, 1993) is the most frequently used. The drainage area of site B falls within this limit. The estimates obtained by using the TR-55 method were from 3 to 7 times the values estimated by using the USGS transfer method with data collected from the three nearby crest-stage gages. Newton and Herrin (1982) summarized a U.S. Water Resources Council report on estimating flood magnitude and frequency for ungaged sites by using various methods and concluded that the TR-55 method tends to overestimate flood magnitudes. The drainage area of site B falls just outside the recommended range for using the NJDEP Special Report 38 method; however, estimates obtained by using the NJDEP Special Report 38 method fall within the range of values estimated by using the USGS transfer method with data collected from the three nearby crest-stage gages.

Drainage areas of both sites are outside the recommended ranges for using the USGS index-flood method (Thomas, 1964) and the HEC Special Project Memo 480 method (U.S. Army Corps of Engineers, 1977). The rational method is not recommended by the New Jersey Department of Environmental Protection and Energy (1993) for sites with these drainage areas. The use of the NJDEP Special Report 38 method seems to be appropriate for both sites.

The consulting firm Urban Engineers, Inc., completed a study of Chandlers Run in 1992 for the New Jersey Department of Transportation (Urban Engineers, Inc., 1992). Flood-frequency estimates made for the two sites are included in tables 3 and 4. These estimates were made by using the TR-55 method with some site-specific modifications in the computations. The modifications were made to account for some of the hydraulic peculiarities in this basin. The estimates made by Urban Engineers, Inc., fall within the range of values estimated by using the USGS transfer method with data collected from the three nearby crest-stage gages.
