# VEGETATIVE RESISTANCE TO FLOW IN SOUTH FLORIDA: SUMMARY OF VEGETATION SAMPLING AT SITES NESRS3 AND P33, SHARK RIVER SLOUGH, APRIL, 1996 

Virginia Carter, Henry Ruhl, Nancy B. Rybicki, Justin Reel, and Patricia T. Gammon

#### Abstract

The U.S. Geological Survey is one of many agencies participating in the effort to restore the south Florida Everglades. We are sampling and characterizing the vegetation at selected sites in the Everglades as part of a study to quantify vegetative flow resistance. The objectives of the vegetative sampling are (1) to provide detailed information on species composition, vegetative characteristics, vegetative structure, and biomass for quantification of vegetative resistance to flow, and (2) to use this information to classify the vegetation and to improve existing vegetation maps for use with numerical models of surface-water flow. Vegetative sampling was conducted in the Shark River Slough in April, 1996. The data collected and presented here include live, dead, and periphyton biomass, vegetation characteristics and structure, and leaf area index.

## INTRODUCTION

The Florida Everglades is a vast, diverse wetland ecosystem characterized by small groundsurface slopes, slowly moving surface waters, and dense aquatic vegetation. The south Florida ecosystem has been greatly altered during the last 100 years. A complex water-management system that includes levees, canals, pumps, and additional water-control structures regulates flooding and provides a steady supply of fresh water to urban areas and agriculture. Drainage projects have diverted much of the water that originally flowed slowly southward from Lake Okeechobee through the Everglades. Restoration and management of the Everglades ecosystem requires understanding and manipulating the amount and timing of water flows throughout the ecosystem.

The spatial and temporal distribution of water and water-borne contaminants in the Everglades must be understood if degradation of the ecosystem is to be halted and reversed. To understand how water moves through the Everglades ecosystem, it is necessary to quantify the forces affecting the flow. The resistance exerted on the flow by the vegetation is a dominant but little understood force affecting Everglades surface-water flows. The aquatic vegetation affects both the depth of water and the rate at which it moves. The presence of living and dead plant material in the water column creates drag forces on the moving water. Water flows most slowly and the surface-water slope is largest in areas where the vegetation is the most dense.

We are sampling and characterizing the vegetation at selected sites in the Everglades as part of a study to quantify vegetative flow resistance. This information will be used to improve numerical models of surface water flow. The objectives of the vegetative sampling are:
(1) To provide detailed information on species composition, vegetative characteristics, vegetative structure, and biomass for quantification of vegetative resistance to flow, and
(2) To use this information to classify the vegetation and to improve existing vegetation maps for use with models of surface-water flow.

## STUDY METHODS

NESRS3 and P33 sites in the Shark River Slough were selected to provide sawgrass communities of varying densities for the purpose of making water velocity and surface slope measurements (Figure 1). At both sites a grid composed of $15 \mathrm{~m} \times 15 \mathrm{~m}$ squares was established on the first sampling trip in April, 1996-the grid at the NESRS3 site had 12 squares and the grid at P33 had 16 squares (Figures 2 and 3). Vegetation was sampled in 12 of the grid cells at NESRS and 14 of the grid cells at P33 (Table 1).

Vegetation was sampled at sites where velocity measurements were made (Lee and Carter, 1996). A $0.5 \mathrm{~m} \times 0.5 \mathrm{~m}$ quadrat was delimited by poles and the vegetation was cut and bagged in layers starting with the layer $>100 \mathrm{~cm}$ above the sediment/water interface. Layers were 20 cm in height from 40 to 100 cm and were 10 cm in height between 0 and 40 cm above the sediment/water interface. All periphyton was collected in layers below the water surface.

Plant material in each layer was sorted by species after all dead material and periphyton were separated out. Sawgrass was separated into leaves and culms: leaves were separated into small, medium, and large leaves and culms into small and large culms and counted. The widths of six leaves in each group was measured. Live rush and grass stems were counted and their width estimated. All other plants were counted as individual stems with attached leaves. Numbers of leaves, culms, or stems were normalized to a square meter. Leaf area index (LAI) was calculated for each layer as meters squared of plant material per square meter using the formula:
$L A I=L L \times A W_{L L}+M L \times A W_{M L}+S L \times A W_{S L}+L C \times A W_{L C}+S C \times A W_{S C} \times$ height of layer,
where $\mathrm{AW}=$ average width in meters, $\mathrm{LL}=$ number of large leaves, $\mathrm{ML}=$ number of medium leaves, $\mathrm{SL}=$ number of small leaves, $\mathrm{LC}=$ number of large culms, and $\mathrm{SC}=$ number of small culms. In this case, LAI accounts only for the resistance of the live leaves. In order to account for the resistance of the dead leaves, we determined the ratio of dead/live dry weight biomass for each layer and then multiplied the LAI by the ratio to calculate a dead LAI. This second dead LAI was added to the live LAI to form a corrected LAI for each layer.

The live and dead plant material and the periphyton were dried at $105^{\circ} \mathrm{C}$ for 8 to 12 hours and then weighed. Biomass was expressed as grams dry weight per square meter (gdw/ $\mathrm{m}^{2}$ ).

Quadrats were sorted into vegetative communities based on biomass and species composition. Plant communities were further subdivided into density classes based on total biomass minus periphyton: sparse $=0-500 \mathrm{gdw} / \mathrm{m}^{2} ;$ medium $=500-1000 \mathrm{gdw} / \mathrm{m}^{2} ;$ dense $=1000-2000 \mathrm{gdw} / \mathrm{m}^{2}$; and very dense $=>2000 \mathrm{gdw} / \mathrm{m}^{2}$.

## RESULTS AND SAMPLE ANALYSES

The results of the analyses of vegetation samples from two sites in Shark River Slough are summarized in the tables and illustrations below. Table 2 gives the biomass and plant community based class, total biomass minus periphyton biomass, periphyton biomass, and live biomass of the NESRS3 and P33 quadrats from April, 1996. Table 3 summarizes the mean biomass of the eight classes found in the April quadrats. Appendix A contains the individual layer-by layer biomass for each April quadrat and accompanying illustration. Appendix B contains the individual layer-by-layer vegetative characteristics of each quadrat and the accompanying illustration. Appendix C contains the layer-by-layer LAIs and the corrected LAIs.
