OPEN-FILE REPORT 03-113
Sheet 2

Geology of Kanaga Volcano

Kanag a Volcano is a 1,300 m (4,287-foot) high, historically active cone-shaped stratovolcano located on the north end of Kanaga Island in the Andreanof Islands Group of the Aleutian Islands. The volcano is undissected, symmetrical in profile, and is characterized by blocky andesitic lava flows, with well-developed levees and steep flow fronts, that emanate radially from, or near, the 200-m-wide summit crater. The lack of dissection of the cone suggests the entire edifice was constructed in post-glacial Holocene time. Historical eruptions were reported in 1791, 1827, 1829, 1904-1906, and 1993-95 (Miller and others, 1998); questionable eruptions occurred in 1763, 1768, 1786, 1790, and 1933. The upper flanks of the cone are very steep (>30°) and flows moving down these steep flows commonly fragment into breccias and lahars. A non-vegetated lahar, or group of lahars, extends from high on the southeast flank of the cone down to the northeast shore of the intracaldera lake. This lahar deposit was observed in 1999 but does not appear to be present on aerial photos taken in 1974 and is assumed to be part of the 1994-95 eruption.

Most recent eruptions of Kanag a, including the 1994-95 eruption, were primarily effusive in character with a subordinate explosive component. Lava was extruded from, or near, the summit vent and moved down the flank of the cone in some cases reaching the ocean. In 1994, lava flows going down the very steep north and west flanks broke up into incandescent avalanches tumbling over steep truncated sea cliffs into the Bering Sea. A common feature of Kanaga central vent eruptions is the occurrence of widespread ballistics and accompanying craters. Steam and fine ash plumes rose to 7.5 km ASL and drifted a few tens of kilometers downwind. Plumes such as these are unlikely to deposit significant (i.e., sufficiently thick to leave a permanent record) tephras on other islands downwind.

Se veral recent non-vegetated flow fields (labeled Qhlf on the geologic map) are identifiable on the east-northeast, south, southwest, west-southwest, and northwest flanks of the volcano with the latter three fields extending to the ocean. Older lava flows and flow fields (labeled Qholf) are vegetated to varying degrees but retain fresh-appearing surface features such as levees, pressure ridges and steep lobate flow fronts. In the past, lava flows from both units may have broken out from points below but near the summit. Pyroclastic flows and pumiceous debris flows along the southern base of the volcano contain abundant silicic pumice clasts. The source domes for this material appear to have been overridden by andesitic flows that form the present-day Kanaga edifice.

Kanag a Volcano is composed primarily of porphyritic two-pyroxene andesite; phenocrysts are chiefly plagioclase, clinopyroxene, orthopyroxene, and Fe-oxide minerals with traces of olivine and hornblende. The groundmass is usually a pale to light-brown glass with microlites of plagioclase and pyroxene. Kanaga volcanic rocks are medium-K, calcalkaline in character; samples from the present edifice show a relatively narrow compositional range from 51 to 66 percent SiO_2 with an average of 56 percent.

Pumices from the p yroclastic flows, airfalls, and debris flows are more silicic ranging from 63 to 66 percent SiO_2 (dacitic). Multiple dome collapse is the most likely origin for these deposits and, although dacite domes have not been identified at Kanaga, the location and pumice clast size of the pyroclastic deposits suggests their parent domes are buried by still more recent lava flows from the Kanaga cone.

Silicic andesite domes crop out in the southern part of the caldera in and adjacent to the intra-caldera lake. These domes are compositionally different from the silicic pumices and are thought to represent an earlier eruptive phase more closely related to the andesite edifice.

Kanag a Volcano is partly surrounded by, and in fault contact with, overlapping volcanic cones. Coats (1955) and Brophy (1990) consider the oldest of these cones to be exposed along the north coast of the island immediately east of Kanaga Volcano. This composite cone consists chiefly of massive, thick-bedded, altered K-rich andesite lava flows and volcanic breccias. The cone is overlain by over 450 m of basaltic andesite and andesite flows and volcanic breccias that form most of Kanaton Ridge.

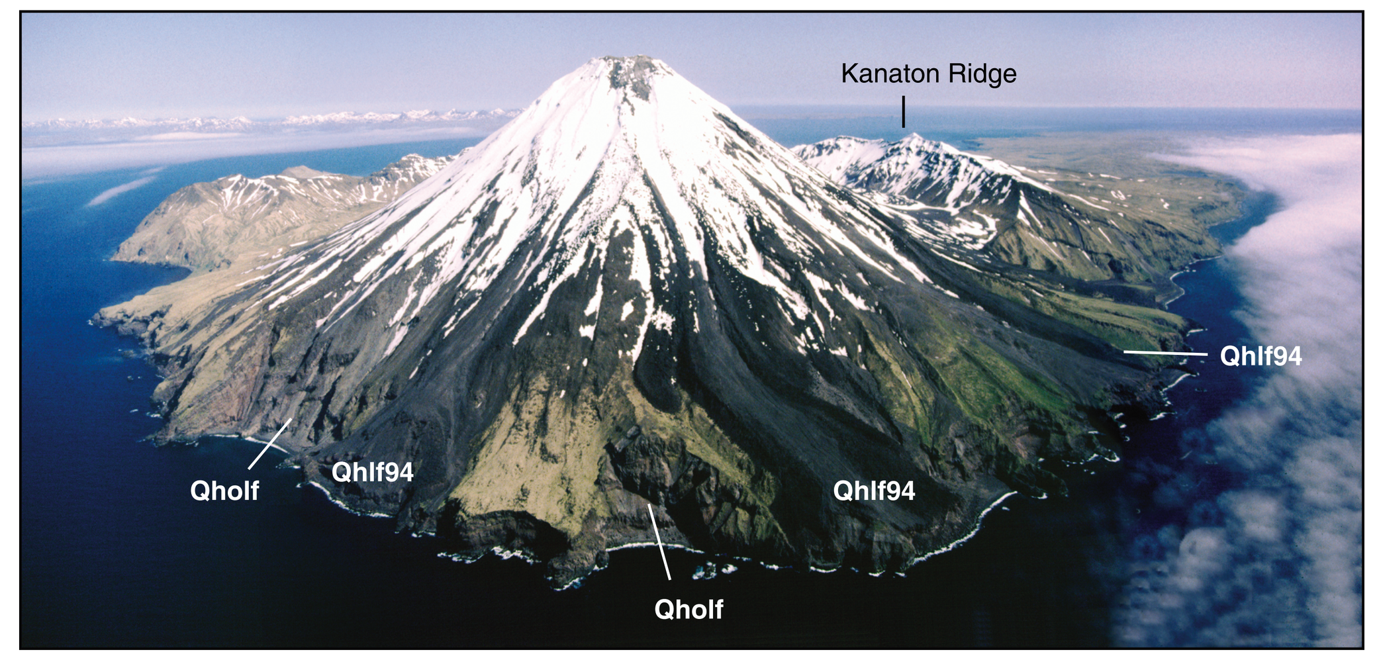
Kanag a Volcano is partly enclosed on its south and east sides by Kanaton Ridge, a prominent scarp-like feature sculpted into the side of a large ancestral basaltic andesite cone named Mt. Kanaton by Coats (1955). This crescent-shaped feature is either the remnant of 1) a typical island-arc collapse caldera-rim now breached to the north, or more likely the 2) the scarp of an avalanche caldera resulting from directed edifice failure to the north and west.

Typical Aleutian arc collapse calderas are surrounded by voluminous pyroclastic flow or tephra deposits representing the catastrophic caldera-forming eruption (Miller and Smith, 1987). Pyroclastic flow deposits are uncommon on Kanaga Island south of Kanaton Ridge and tephra deposits, although abundant, do not seem sufficiently thick or coarse enough to represent a caldera-forming eruption and are absent in some areas where deposition would have been expected. The lack of suitable pyroclastic flanking deposits could also be explained if Kanaton Ridge is a somma-like feature representing an avalanche scarp of northward-directed edifice failure. This failure may or may not have been associated with voluminous explosive volcanic activity and thus could have occurred without leaving voluminous deposits on Kanaga Island itself. These observations could be explained by assuming a Pleistocene age for the formation of Kanaton caldera. Subsequent glaciation could have resulted in the erosion of deposits from the caldera-forming eruption. The thick section of pumice-rich, cross-bedded outwash found in the central part of the island indicates at least some silicic explosive volcanism occurred prior to the Holocene and indeed pumice in the deposit may represent material from a caldera-forming eruption.

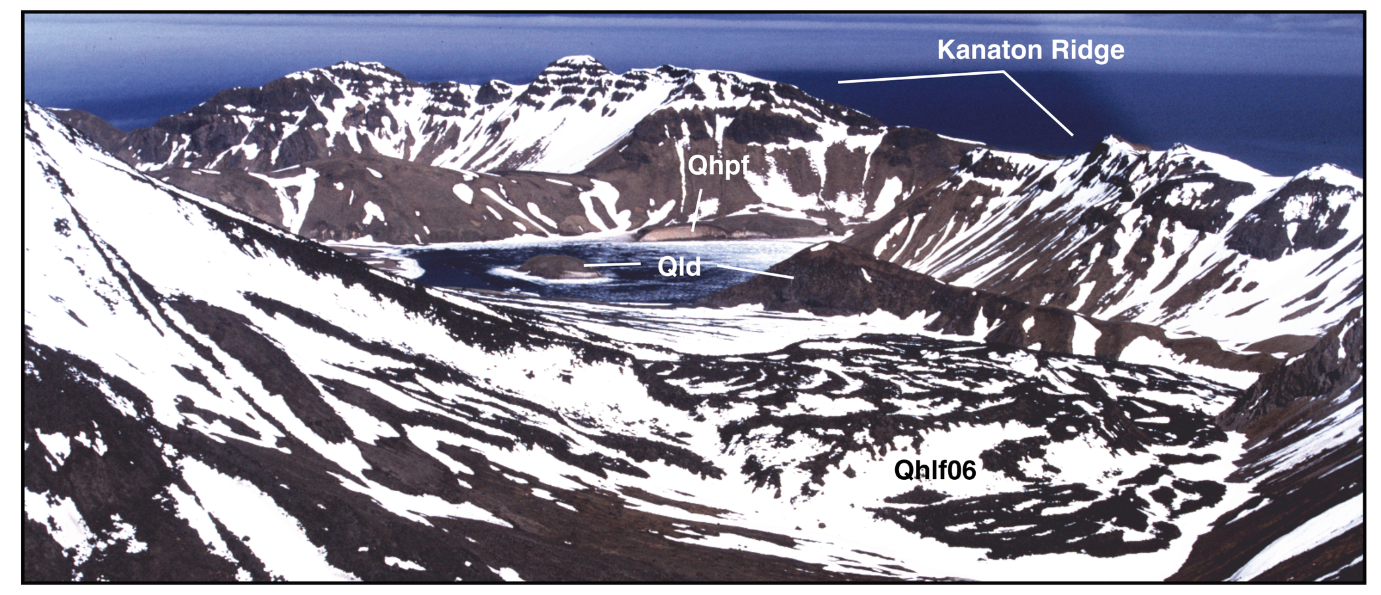
An intracaldera lak e about 1.5 km long occurs in the southeast corner of the caldera at an elevation of about 330 m (1,000 feet) above sea level. A flat-topped lava dome in the center of the lake and a beveled pumice deposit on the southeast shore of the lake are indicative of higher lake levels in the past. A fan-shaped lahar deposit that contains cobble and small boulder size clasts of pumice and lithics extends from the southwest slope of Kanaga volcano to the ocean and may be evidence of catastrophic release of water from the southwest corner of the caldera through the southwest corner of the caldera, possibly associated with a dome eruption during a higher stand of the lake. The lahar is now separated from the caldera by a young (1906) lava flow.

Hot springs are scattered o ver an east-west area of about 100 m x 20 m along the south side of stream about 500 feet above sea level and about 1 km from Weed Bight. Temperatures of up to 92°C were measured in several places but several small (5-10 cm high) geysers were noted in inaccessible locations suggesting higher temperatures; some of these geysers were surrounded by cones of travertine (?) up to 20 cm high and 70 cm wide.

Fumarolic activity. Coats (1955), who climbed the volcano in 1946, reported fumaroles near the summit of the volcano on the southeast, south, and southwest sides and several fumaroles in the bottom of the 60 m deep summit crater. Aerial observations in 1999 indicate much the same situation prevailed. Coats (1955) measured temperatures of 104°C at these fumaroles and also noted the presence of sulfur crusts and a faint odor of hydrogen sulfide. Aerial photographs taken in 1974 suggest a fissure striking NE may extend through the summit vent for a few hundred kilometers on either side of the vent. Photographs of the 1994-1955 eruption indicated a "leaky" summit vent with fumarolic activity spread around the outside of the vent; a particularly vigorous vent was noted down the southeast flank several hundred meters from the summit on strike with the apparent summit fissure.



Kanaga Volcano, July 2000, view is to the southeast. Selected geologic units indicated by map symbols. Photograph by C.J. Nye, Alaska Division of Geological and Geophysical Surveys.



Kanaga Volcano, July 2000, view is to the east across intracaldera lake. Selected geologic units indicated by map symbols. Photograph by C.F. Waythomas, U.S. Geological Survey.
