Last report date: 2016-03-28

Site name(s): Liberty

Site type: Prospect

ARDF no.: HE028

Latitude: 63.263 **Quadrangle:** HE B-6

Longitude: 149.538

Location description and accuracy:

The Liberty prospect is at an elevation of about 2,700 feet on the broad flat ridge between Costello Creek and Colorado Creek. It is in sec. 18, T. 19 S., R. 10 W., of the Fairbanks Meridian. Access to the prospect is from the road to the Dunkle Coal mine. The prospect is approximately 200 feet east of the road and approximately 500 feet south of the airstrip. The location is accurate to within 500 feet. This is locality 3 of Cobb (1978: OFR 78-1062).

Commodities:

Main: Ag, Au

Other:

Ore minerals: Arsenopyrite

Gangue minerals: Quartz

Geologic description:

Thick Quaternary glacial deposits and Upper Tertiary sedimentary cover the older rocks in this area, which consist of Upper Jurassic to Upper Triassic(?) crystal tuff, argillite, chert, graywacke, and limestone. The older rocks are intruded by Late Cretaceous quartz diorite dikes, mainly along the nearby Chulitna fault (Wilson and others, 1998). The Liberty deposit consists of arsenopyrite-bearing quartz veins, reportedly in silicified limestone. Samples from trenches and pits contain 0.06-0.14 ounce of gold per ton and 1.2-8.6 ounces of silver per ton (Ross, 1933). Hawley and others (1978) report values of 0.005 to 0.06 ounce of gold per ton and traces of silver in samples from the same trenches sampled by Ross (1933).

Alteration:

Age of mineralization:

Probably Late Cretaceous (70-65 Ma) or younger, assuming deposit is related to the diorite dikes.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1987; model 36a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Inactive

Workings/exploration:

Surface trenching and pitting. Samples from trenches and pits contain 0.06-0.14 ounce of gold per ton and 1.2-8.6 ounces of silver per ton (Ross, 1933). Hawley and others (1978) report values of 0.005 to 0.06 ounce of gold per ton and traces of silver in samples from the same trenches sampled by Ross (1933).

Production notes:

None.

Reserves:

None.

Site name(s): Lucrata; Lucrative Group

Site type: Prospect

ARDF no.: HE029

Latitude: 63.265 **Quadrangle:** HE B-6

Longitude: 149.529

Location description and accuracy:

The Lucrata prospect is at an elevation of about 2,700 feet on the west bank of Costello Creek, about 0.3 mile south of the Dunkle mine camp. It is in sec. 18, T. 19 S., R. 10 W., of the Fairbanks Meridian. Accuracy of location is to within 500 feet. This is locality 2 of Cobb (1978: OFR 78-1062).

Commodities:

Main: Ag, Au

Other: Cu

Ore minerals: Arsenopyrite, chalcopyrite

Gangue minerals: Quartz

Geologic description:

The general area of this prospect is characterized by thick Quaternary glacial deposits and Upper Tertiary sedimentary strata that mostly cover Upper Jurassic to Upper Triassic(?) crystal tuff, argillite, chert, graywacke, and limestone (Wilson and others, 1998). Upper Cretaceous quartz diorite dikes cut the mesozoic bedded rocks, mainly along the nearby Chulitna fault. At the Lucrata prospect, arsenopyrite-chalcopyrite pods up to 4 feet thick and 5 feet long area in a quartz stockwork in gabbro and basalt along the Chulitna fault zone. Assay values as high as 1.26 ounces of gold per ton and 3.8 ounces of silver per ton are reported by Hawley and Clark (1974); average grades of 0.49 ounce of gold per ton and 1.03 ounces of silver per ton are reported by Bundtzen (1983).

Alteration:

Quartz-sericite-pyrite alteration.

Age of mineralization:

Late Cretaceous or younger, assuming that the deposit is related to the intrusion of the quartz diorite.

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Undetermined

Site Status: Active

Workings/exploration:

There has been both surface and underground exploration; a 15 ft tunnel was driven in 1920. Assay values as high as 1.26 ounces of gold per ton and 3.8 ounces of silver per ton are reported by Hawley and Clark (1974); average grades of 0.49 ounce of gold per ton and 1.03 ounces of silver per ton are reported by Bundtzen (1983).

Production notes:

None.

Reserves:

None.

Additional comments:

The Lucrata prospect has also been referred to as the Dunkle mine. This should be dropped as it invites comparison to the Dunkle coal mine, a separate deposit.

Site name(s): Eagle; Northern Light

Site type: Prospect

ARDF no.: HE030

Latitude: 63.266 **Quadrangle:** HE B-6

Longitude: 149.524

Location description and accuracy:

The Eagle prospect is at an elevation of about 2,800 feet on Costello Creek, about 0.3 mile south-southwest of the Dunkle mine camp. It is near the east-central boundary of sec. 18, T. 19 S., R. 11 W., of the Fairbanks Meridian. Access to the Eagle prospect is via the road to the Dunkle Coal Mine. The location is accurate within 500 feet. Published maps showing this prospect are Hawley and Clark (1974) and Hawley and others (1978). This is location 1 of Cobb (1978: OFR 78-1062).

Commodities:

Main: Ag, Au, Cu, Zn

Other: Sb

Ore minerals: Arsenopyrite, chalcopyrite, sphalerite, stibnite

Gangue minerals: Quartz

Geologic description:

The Eagle prospect, formerly called the Northern Light was developed by a tunnel 62 feet long and several small cuts (Ross, 1933). He reported that the country rock is chloritic and cherty argillite and tuff, with some lava in the vicinity. The average trend is northeast, but locally the beds trend northwest, probably because of faulting. The average trend of the mineralized zones is somewhat east of north, but there is much local variation, resulting in part from irregular deposition, in part from later faulting. The dip is generally steep to the east. If the pits are all on the same lode, it has a known length of about 300 feet, but it is doubtful if underground development would show continuous ore throughout this distance. The width of the mineralized shear zones varies in different exposures, ranging from 1 to 10 feet. The vertical range between the tunnel and the highest cut is roughly 185 feet. The shear zones generally contain bands of white, coarsely crystalline quartz from a few inches to 2 1/2 feet in width. Locally, the quartz contains numerous vugs. Most of the sulfides were deposited along fissures, and the best samples are reported to have been taken along the fissures that traverse the bedding at considerable angles. Most of the rock in and near the shear zones contains sparsely disseminated sulfides, mainly pyrite. There are a few lenses of massive arsenopyrite with a little pyrite, which are several inches wide. Small amounts of somewhat oxidized chalcopyrite are present at some places. Two samples were taken in the cut immediately north of the tunnel, which is reported to contain the best ore so far exposed. One of these, taken across a quartz lens somewhat more than 2 feet wide, yielded 0.20 ounce of gold and 6 ounces of silver to the ton. The other, taken across the full 4 feet of exposed lode, yielded 0.18 ounce of gold and 9.10 ounces of silver to the ton. A sample probably from the quartz lens in this pit contained 0.56 ounce of gold and 3.20 ounces of silver to the ton. Capps (1919) stated that at the time of his visit in 1917 the area of heaviest mineralization had been traced along the surface for a distance of about 800 feet, considerably farther than Ross (1933) could trace it in 1931. Capps (1919) noted the presence of arsenopyrite, pyrite, chalcopyrite, sphalerite, and a little stibnite.

Thick Quaternary glacial deposits and Upper Tertiary sedimentary strata cover most of the older bedrock in this area. Regionally, the main geologic feature is the northeast-trending Chulitna fault, which separates a sequence of Upper Jurassic to Upper Triassic(?) crystal tuff, argillite, chert, graywacke, and limestone on the north, from Upper Devonian to Lower Triassic volcanogenic and sedimentary rocks on the south.

Faulting and shearing of the rocks has occurred, along with intrusions of Late Cretaceous dikes and stocks. The Eagle prospect is a 3-foot wide quartz vein that contains pods of arsenopyrite, chalcopyrite, sphalerite, and stibnite up to 1 foot wide. The vein is spatially associated with one or more dikes. The sulfide pods contain substantial Au and Ag values. Seven chip samples of the veins averaged 0.23 ounce of gold per ton and 4.55 ounces of silver per ton (Hawley and Clark, 1974; Ross, 1933; Bundtzen, 1983). The deposit is discontinuous, owing to post mineralization faulting and to pinch-and-swell structure of the vein. The Eagle vein is subparallel and about 400 feet east of the Lucrata segment of Upper Chulitna fault.

Alteration:

Age of mineralization:

Probably Late Cretaceous or younger.

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Undetermined

Site Status: Active

Workings/exploration:

Exploration includes a 62-foot tunnel and open cuts over a strike length of 300 to 800 feet (Ross, 1933).

Production notes:

None.

Reserves:

The pits suggest that approximately 12,000 tons of mineralized rock exists in this lode above the level of Costello Creek. Discontinuity resulting from numerous minor faults is likely to prove a handicap in development. (Ross, 1933).

Last report date: 2016-03-28

Site name(s): Riverside; Flaurier

Site type: Prospect

ARDF no.: HE033

Latitude: 63.2388 **Quadrangle:** HE A-6

Longitude: 149.6121

Location description and accuracy:

The Riverside prospect is on the south bank of the West Fork Chulitna River, about 0.7 mile upstream from the mouth of Bryn Mawr Creek. It is about 0.3 mile west of the center of section 26, T.19 S., R. 11 W. The location is accurate. This is apparently the modern name for the old Flaurier prospect (HE036).

Commodities:

Main: Ag, Au

Other: Cu, Pb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Quartz

Geologic description:

Ross (1933) reported that the principal cuts he saw disclosed two nearly parallel lodes about 80 feet apart, both of which are replacement deposits that approximately follow the bedding of limestone lenses. The eastern lode strikes N 15 W and dips about 70 NE. Ore deposition has in part been controlled by poorly defined sheeting that trends N 25 W. The maximum observed width of mineralization is 5.5 feet, most of the ore is contained within a total width of 8 feet. This lode has been traced for about 60 feet along the strike. The second lode is similar, but its average strike is north and it stands nearly vertical. It has been traced for fully 80 feet on the strike, and the ore averages about 8 feet in width. Small cuts and outcrops in the general vicinity show that there are several other lenses of mineralized rock. One of these lenses parallels the bedding of banded limestone which dips vertical and trends N. 60 E., suggesting faulting or other structural disturbance.

The lode is composed irregular bunches and lenses of vein quartz and sulfides, in partly silicified and chloritized limestone. The principal sulfide is arsenopyrite, but pyrrhotite, pyrite, and chalcopyrite are also abundant, and sphalerite and galena are locally present. There is a very small amount of supergene chalcocite. Within a few inches of the surface the lode is thoroughly oxidized and in part clayey (Ross, 1933).

The rocks surrounding the Riverside prospect are Triassic, redbed sandstone, conglomerate, and limestone that have been intruded by a dike of hornblende, quartz diorite. The deposit is in hornfelsed bedded rocks and consists chiefly of quartz-sulfide veins, stockworks, and disseminated sulfides. The sulfide minerals are arsenopyrite, chalcopyrite, galena, pyrite, pyrrhotite, and sphalerite. Small, sulfide-bearing skarn deposits are in marble adjacent to the dike (unpublished report by Addwest Minerals International Ltd., 1997). Samples contained 0.02 to 0.72 ounce of gold per ton and 0.3 to 2.10 ounces of silver per ton (Ross, 1933). The relatively high gold and silver values may be due to supergene enrichment. A fault may truncate the deposit to the south. The Riverside deposit is similar in mineralogy and type to other deposits satellite to the Golden Zone Mine (HE043). The Riverside is the old Flaurier prospect that was briefly described by Capps (1919).

The 5-foot-wide Wells vein at the Riverside prospect was exposed and chip sampled by Hidefield Gold PLC in 2006 (Alix Resources Corp., 2011). Some notable intervals were 25.9 grams of gold per tonne across 0.79 meters; 34.6 grams of gold per tonne across 1.49 meters; and 30.9 grams of gold per tonne

across 1.40 meters. The Riverside prospect was drilled in 2011 by Alix Resources Corp. (2012). The two holes successfully intercepted the Well vein. The vein in one hole was 1.50 meters thick and averaged 11.43 grams of gold per tonne, 24.57 grams of silver per ton, and 0.23 percent copper. In the other hole, the vein was 1.78 meters thick and contained 19.1 grams of gold per tonne, 48.63 grams of silver per tonne, and 0.77 percent copper.

Alteration:

Narrow phyllic alteration haloes around and in porphyry dikes typically consists of sericite, quartz, and pyrite. In addition, skarn alteration is present as garnet, pyroxene, and epidote.

Age of mineralization:

Late Cretaceous (70-65 Ma), assuming that the deposit is a satellite to the Golden Zone Mine (HE043).

Generic deposit model:

Deposit model:

Cu skarn; Polymetallic veins (Cox and Singer, 1986; models 18b, 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b, 22c

Production Status: None

Site Status: Active

Workings/exploration:

Ross (1933) reported numerous cuts and pits on the property and several tunnels had been started, but none were carried far.

There are reports of a 10-foot tunnel and 15-foot shaft that are now caved. Recent geochemical exploration has identified a broad soil anomaly that outlines the deposit. The 5-foot-wide Wells vein at the Riverside prospect was exposed and chip sampled by Hidefield Gold Plc. in 2006 (Alix 2011). In 2011, two holes were drilled at the Riverside prospect and cut the Wells vein (Alix Resources Corp. (2012).

Production notes:

None.

Reserves:

None.

Site name(s): Mayflower

Site type: Prospect

ARDF no.: HE040

Latitude: 63.216 **Quadrangle:** HE A-6

Longitude: 149.643

Location description and accuracy:

The Mayflower prospect is at an elevation of about 3,400 feet, on the west side of Bryn Mawr Creek. It is in the NW1/4 of sec. 3, T. 20 S., R. 11 W., of the Fairbanks Meridian. The location is accurate to within 400 feet.

Commodities:

Main: Ag, Au, Cu

Other: As, Pb, Sb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Ankerite, quartz

Geologic description:

The country rocks in the area of the Mayflower prospect include Devonian to Triassic clastic, carbonate, volcanic, and volcaniclastic strata, which are intruded by a plug and dikes of Upper Cretaceous (70-65 Ma) quartz diorite porphyry (Swainbank and others, 1977). The Mayflower prospect is associated with a dike-like extension of the intrusive plug at the Golden Zone mine (HE043). Major faults trend northeast-southwest and have imparted a strong northeast-trending fabric to the host rocks. These faults have controlled the emplacement of intrusive rocks. At the Mayflower there is evidence that northwest-trending faults predated intrusion, as the dike trends northwest before swinging back to the northeast. The northwest-trending shear zone was also important during mineralization (unpublished report by Addwest Minerals International Ltd., 1997).

There are three types of deposits: sulfide disseminations, veins, and skarns. The dike contains disseminated sulfides and stockwork quartz-sulfide veinlets. Limonite and ankerite alteration is widespread. Adjacent to the dike, calc-silcate skarn bodies up to 15 feet thick contain 0.1 ounce of gold per ton and 10 percent combined lead and zinc. The skarn comprises pyrrhotite, pyrite, chalcopyrite, and arsenopyrite (up to 10 percent by volume) in a epidote, garnet, and actinolite (unpublished report by Addwest Minerals International Ltd., 1997).

Alteration:

Alteration consists of a combination of skarn (epidote, garnet and actinolite), silica flooding, ankerite, pyrite and sericite. Limonite and uncommon chalcocite are oxidation and supergene mineral assemblages.

Age of mineralization:

The Mayflower prospect is a satellite of the nearby Golden Zone mine (HE043) which has been dated at 70-65 Ma (Late Cretaceous) (Swainbank and others, 1977).

Generic deposit model:

Deposit model:

Combination of polymetallic vein and Au-Ag breccia pipe or Cu-Au porphyry (Cox and Singer, 1986; models 22c, 20c), with Cu skarn (Cox and Singer, 1986; model 18b)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c, 20c, 18b

Production Status: Undetermined

Site Status: Active

Workings/exploration:

The Mayflower prospect comprises two claims adjoining the Golden Zone on the north and was developed only by a few pits at the time of Ross's (1933) visit. The rock is brecciated, iron-stained, and soaked with quartz, so that identification is difficult, but it appears to be, at least in part, a continuation of the fine-grained intrusive mass of the Golden Zone (HE043). The lode can be traced with fair accuracy by means of the pits for a length of 350 feet trending N 30-35 E and dipping 70 SE. One of the pits shows mineralization off the line of this lode. The most northerly pit is the largest and the only one in which bedrock was satisfactorily exposed at the time of Ross's visit. There the well-mineralized part of the zone of shearing and brecciation was 32 inches wide. A sample across it yielded on assay 0.07 ounce of gold and 2.60 ounces of silver to the ton. Some specimens from the pit contain considerable chalcopyrite, but the average copper content of the lode as exposed was low. Samples collected by Henry Stevens of the Bureau of Mines in 1929, yielded the between 0.06 and 0.34 ounces of gold and 1.20 to 15.80 ounces of silver to the ton and as much 5.3 percent copper.

The prospect was explored by a reconnaissance IP and CS-AMT survey and by 1,500 feet of trenching. One shallow shaft was dug (during the 1930s?) and since has collapsed (Hawley and Clark, 1974).

Production notes:

None.

Reserves:

None.

Site name(s): Golden Zone

Site type: Mine

ARDF no.: HE043

Latitude: 63.2138 **Quadrangle:** HE A-6

Longitude: 149.6493

Location description and accuracy:

The Golden Zone Mine is at the headwaters of Bryn Mawr Creek, a tributary of the West Fork Chulitna River. It is at an elevation of about 3,500 feet, on the north bank of the creek, and about 2,000 feet southwest of the Golden Zone mine symbol on the 1:63,360-scale topographic map. Access is via dirt road from Colorado Station on the Alaska Railroad. The mine is about 0.5 mile west-northwest of the center of section 3, T. 20 S., R. 11 W.. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other: As, Pb, Sb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, galena, pyrite, sphalerite, tetrahedrite

Gangue minerals: Calcite, quartz, sericite

Geologic description:

The country rocks in the vicinity of the Golden Zone Mine are Devonian to Triassic clastic, carbonate, volcanic, and volcaniclastic rocks that are intruded by a plug of Upper Cretaceous biotite-quartz-diorite porphyry (Perry and others, 2005; Hidefield, 2008; Kerr and Loveday, 2011). The deposit is in a breccia pipe that measures 250 feet by 300 feet at the surface and tapers downward. The contacts of the pipe dip steeply except on the northern side where the dips appear to flatten to the north. Drilling has confirmed that the pipe reaches a depth of 650 feet and possibly 1,500 feet. The pipe is almost entirely contained in the plug of biotite-quartz-diorite porphyry that is about 600 by 1,000 feet in size at the surface. The breccia pipe was produced by magmatic devolatilization, either from the diorite porphyry or from a related intrusion at depth. Both the breccia and the porphyry have been dated at 65-70 Ma. Major faults in the area trend northeast and have imparted a strong northeast-trending fabric to the host rocks. Differential motion along these faults has localized the subsequent emplacement of the biotite-quartz diorite porphyry and mineralizing fluids. Postmineral northwest-trending faults cut the breccia (unpublished report by Addwest Minerals International, Ltd., 1997). Early brecciation produced angular clasts cemented by vuggy, pale-gray quartz and minor arsenopyrite, pyrite, pyrrhotite, chalcopyrite and sphalerite. Several younger, sulfide-dominated events have overprinted the earlier, relatively barren, quartz-dominated brecciation, producing breccia containing over 10 percent sulfides. The younger breccia can be subdivided into early arsenic-rich zones and older copper-rich zones; the former contain better gold grades, in places up to 5 ounces of gold per ton.

The Golden Zone pipe is marked by extensive alteration and mineral zonation. A lead and zinc halo extends up to 2 miles from the pipe; the gold/silver ratios in arsenopyrite and chalcopyrite show a systematic variation; red bed units around the plug show widespread bleaching (C.C. Hawley, oral communication, 1999). Propylitic haloes consisting of epidote, carbonate minerals, and chlorite are present at the margin of the quartz diorite plug, and hornfels-skarn zones are developed in carbonate-rich country rock. Sericite is the dominant alteration mineral in the breccia; argillic overprinting (?), quartz flooding and Fe-carbonates are also reported, but their paragenesis is unclear.

Since its discovery in 1906, the Golden Zone Mine has been explored on the surface, in underground

workings, and by extensive drilling. Through 2008, the property was explored by about 20,100 meters of core and reverse-circulation drilling, extensive trenching, and about 1,200 meters of underground workings on three levels. The details of the exploration and the many companies that have been involved are well documented in Perry and others (2005) and Kerr and Loveday (2011). Close-spaced helicopter aeromagnetic and EM geophysical surveys have been flown over the mine; some ground-based IP work has been done as well. The State of Alaska sponsored an aeromagnetic survey in 1996 that included the mine site (Burns, 1997).

In 2011, Alix Resources Corp. (2012) drilled 7 holes. Two holes totaling 574 meters were in the breccia pipe; the best intercept was 256 meters with 1.50 gram of gold per tonne, 12.15 grams of silver per ton and 0.11 percent copper. Three holes were drilled at the GAS prospect south of the breccia pipe; numerous intercepts contained more than 0.1 gram of gold per ton but the highest was only 0.80 gram of gold per tonne. Two holes were drilled across the BLT zone on the northeast side of the breccia pipe. One was abandoned at 22 meters. The other was 178 meters deep; the best intercept was 4.0 meters with 0.77 gram of gold per tonne, 4.5 grams of silver per tonne, and 0.03 percent copper.

The mine produced 49,169 grams of gold, 267,990 grams of silver, and 19 tonnes of copper between 1941 and 1942 (Hawley and Clark, 1974).

Alix Resources Corp. entered into option agreement with Hidefield Gold Inc. and Mines Trust Company on the Golden Zone mine in 2010 and commissioned a new study of the deposit using new and reinterpreted drilling and analyses (Kerr and Loveday, 2011). The work included a new estimate of the resources in 0.5-grams-of-gold-per-tonne steps from 0.5 gram to 4.0 grams. The estimate is lengthy and should be consulted in its entirely for a complete picture. However, to use an estimate near the midpoint of their cutoff grades: 1) at a cutoff of 1.5 grams of gold per tonne, the Golden Zone has a combined measured and indicated resource of about 1.679 million tonnes with an average grade of 4.33 grams of gold per tonne, 20.94 grams of silver per tonne, and 0.11 percent copper; and 2) at a cutoff grade of 1.0 gram of gold per tonne, it has an inferred resource of 186,181 tonnes with an average grade of 1.52 grams of gold per tonne, 6.49 grams of silver per tonne, and 0.4 percent copper.

In 2016, Avidian Gold Inc. purchased Hidefield Gold PLC’s 29.4 percent interest outright, and entered into a purchase agreement with Chulitna & Mines Trust to acquire the remaining 70.6 percent interest in the Golden Zone property (Athey and Werdon, 2017).

Alteration:

The Golden Zone pipe is marked by extensive alteration and mineral zonation. Propylitic haloes consisting of epidote, carbonate minerals, and chlorite are present at the margin of the quartz diorite plug, and hornfels-skarn zones are developed in carbonate-rich country rock. Sericite is the dominant alteration mineral in the breccia; argillic overprinting(?), quartz flooding and Fe-carbonates are also reported, but their paragenesis is unclear.

Age of mineralization:

The Golden Zone is a magma-driven breccia pipe. Both the intrusion and the breccia minerals are Late Cretaceous (65-70 Ma) (Swainbank and others, 1977).

Generic deposit model:

Deposit model:

Polymetallic vein and Au-Ag breccia pipe or Cu-Au porphyry (Cox and Singer, 1986; models 22c, 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c, 20c

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Since its discovery in 1906, the Golden Zone Mine was been explored on the surface, in underground workings, and by extensive drilling. Through 2008, the property has been explored by about 20,100 meters of core and reverse-circulation drilling, extensive trenching, and about 1,200 meters of underground workings on three levels. Closely-spaced helicopter aeromagnetic and EM geophysical surveys have been flown over the mine; some ground-based IP work has been done as well. The State of Alaska sponsored an aeromagnetic survey in 1996 that included the mine site (Burns, 1997). As of early 2011, the Golden Zone Mine has been optioned by the Alix Resources Corp. who drilled 7 holes in 2011.

Production notes:

The mine produced 49,169 grams of gold, 267,990 grams of silver, and 19 tonnes of copper between 1941 and 1942 (Hawley and Clark, 1974).

Reserves:

Kerr and Loveday (2011) estimated the resources of the Gold Zone Mine in 0.5-grams-of-gold-per-tonne steps from 0.5 gram to 4.0 grams. The estimate is lengthy and should be consulted in its entirely for a complete picture. However, using an estimate near the midpoint of their cutoff grades: 1) at a cutoff of 1.5 grams of gold per ton, the Golden Zone has a combined measured and indicated resource of 1,679,596 tonnes of ore with an average grade of 4.33 grams of gold per tonne, 20.94 grams of silver per tonne, and 0.11 percent copper; and 2) at a cutoff grade of 1.0 gram of gold per tonne, it has an inferred resource of 186,181 tonnes with an average grade of 1.52 grams of gold per tonne, 6.49 grams of silver per tonne, and 0.4 percent copper.

The Golden Zone property hosts a number of high-grade gold occurrences, and in 2016, Avidian released a NI 43-101-compliant indicated gold resource of 4.187 million tonnes of material at a grade of 1.99 grams of gold per tonne, for total contained 267,400 ounces of gold, at a cut-off grade of 0.5 gram of gold per tonne in one of the occurrences that remains open and not fully tested (Avidian, 2016).

Site name(s): Lindfors

Site type: Prospect

ARDF no.: HE046

Latitude: 63.208

Quadrangle: HE A-6

Longitude: 149.653

Location description and accuracy:

The Lindfors prospect is at an elevation of about 3,900 feet on the divide at the head of Bryn Mawr Creek. It is in the SE1/4 of sec. 4, T. 20 S., R. 11 W., of the Fairbanks Meridian. The location is accurate to within 500 feet. This is location 11 of Cobb (1978: OFR 78-1062).

Commodities:

Main: Au, Cu, Zn

Other: Pb, Sb

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The Lindfors prospect lies at the head of Bryn Mawr Creek adjoining the Golden Zone claims. According to Ross (1933) no work had been done here for some time, but the prospect had been restaked in the summer of 1931. He reported development comprised a number of trenches and shallow ditches from which a very small amount of ground sluicing was done. Most of the trenches did not expose bedrock and were in frost-shattered material, largely rusty dioritic porphyry but including representatives of the clastic rocks of the vicinity. Capps (1919) noted that at the time of his visit in 1917 one open cut exposed a vein of massive arsenopyrite 4 to 20 inches thick on the contact of a decomposed dike and altered tuff. Another cut showed disseminated sulfides and veinlets containing sulfides, quartz, and a carbonate resembling ankerite, in calcareous strata. He reported that arsenopyrite, pyrite, chalcopyrite, and sphalerite were present there and that gold was reported in encouraging amounts.

The Lindfors prospect is about 1,500 feet south-southwest of the Golden Zone mine (HE043). The country rocks at the prospect are Permo-Triassic redbed sandstones, conglomerates, limestones and volcaniclastic sediments, which are intruded by Upper Cretaceous quartz diorite dikes. The deposit consists of quartz veins containing arsenopyrite, chalcopyrite, galena, pyrite, sphalerite, and tetrahedrite. Surface geochemistry values of 0.2 to 14 ppm gold, high silver, arsenic, lead, antimony and zinc have been reported (Hawley and Clark, 1974). The Lindfors deposit probably is a continuation of the deposit at the Golden Zone mine.

Alteration:

Quartz, sericite (?), and pyrite.

Age of mineralization:

Synchronous with the Golden Zone mineralization, dated as Late Cretaceous.

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
22c

Production Status: None

Site Status: Active

Workings/exploration:
Early development comprised a number of trenches and shallow ditches from which a very small amount of ground sluicing was done. Most of the trenches did not expose bedrock and were in frost-shattered material, largely rusty dioritic porphyry but including representatives of the clastic rocks of the vicinity. Capps (1919) noted that at the time of his visit in 1917 one open cut exposed a vein of massive arsenopyrite 4 to 20 inches thick on the contact of a decomposed dike and altered tuff. Another cut showed disseminated sulphides and veinlets containing sulphides, quartz, and a carbonate resembling ankerite, in calcareous strata. He reported that arsenopyrite, pyrite, chalcopyrite, and sphalerite were present there and that gold was reported in encouraging amounts.

One drill hole has explored the Lindfors zone at depth; there is a report of a shallow shaft, now collapsed, dug in the 1920s. Surface exploration consists of numerous pits and trenches. Close-spaced helicopter aeromagnetic and EM geophysical surveys have been flown over this prospect. In 1996, the State of Alaska flew a wider-spaced helicopter aeromagnetic survey that included this prospect (Burns, 1997).

Surface geochemistry values of 0.2 to 14 ppm gold, high silver, arsenic, lead, antimony and zinc have been reported (Hawley and Clark, 1974).

Production notes:
None.

Reserves:
None.

Last report date: 2016-03-28

Site name(s): Long; Copper King; Hector Group; Long Creek

Site type: Prospect

ARDF no.: HE049

Latitude: 63.1958 **Quadrangle:** HE A-6

Longitude: 149.6575

Location description and accuracy:

The Copper King prospect is at an elevation of about 3,450 feet near the head of Long Creek. The site is near the center of the east boundary of section 9 , T. 20 S., R. 11 W. The location is accurate to within 0.2 mile.

Commodities:

Main: Ag, Au, Cu

Other: Mo, Zn

Ore minerals: Chalcopyrite, molybdenite, pyrite, pyrrhotite

Gangue minerals: Quartz, skarn minerals

Geologic description:

Ross (1933) reported the mineralized rock comprises lenses and seams of massive pyrrhotite and chalcopyrite in silicified limestone containing chlorite and probably other silicates. The larger masses parallel the bedding of the cherty rocks. The strike of the beds in this vicinity ranges from N 20 E to N 55 E with the average closer to the latter. The main trench showed mineralization at intervals throughout its length of about 70 feet but exposed massive sulfide only over a width of 2 or 3 feet about 15 feet from its northwest end. A sample of freshly blasted material yielded on assay 0.22 ounce of gold and 4.90 ounces of silver to the ton and 7.34 percent of copper. Trenches about 45 feet to the southwest on the line of strike show little mineralization. The continuation of the same beds in bluffs about 1,000 feet to the northeast contained no visible copper minerals. A very little copper stain and a little pyrite were present in a limestone bed on the approximate line of strike in the gorge of Long Creek about 2,000 feet to the southwest. There are several scattered pits in the vicinity, but copper was not observed in any of them.

The Copper King prospect is primarily a skarn deposit. The country rocks are hornfelsed Permo-Triassic redbeds that consist of calcareous siltstone, and conglomerate; these have been intruded by Upper Cretaceous(?) quartz porphyry dikes. The deposit chiefly consists of massive chalcopyrite, pyrite, and pyrrhotite in a skarn zone 20 to 40 feet thick that is exposed for about 200 feet at the surface. Subsidiary zones of quartz-stockwork veins and disseminated sulfides also occur (unpublished report by Addwest Minerals International Ltd., 1997). The pattern of mineralization suggests a zonal distribution of copper around quartz porphyry intrusions. This is the only prospect in the district explored primarily for copper and is also the only prospect in the area where arsenopyrite has not been found (Hawley and Clark, 1974). In addition, molybdenite is more abundant here than at other nearby prospects; e.g., the Golden Zone Mine (HE043). Ross (1933) reported a sample yielded 7.34 percent copper, 4.9 ounces of silver, and 0.22 ounce of gold per ton.

Through 1999, the exploration included geochemical soil surveys, 1,500 feet of trenching, and 9 drill holes that totaled 1,700 feet. As part of the Golden Zone project, there was some work done at or near this prospect from 2001 to 2005 (Hidefield, 2005 and 2008). The work included some initial ground geophysical surveys. One hole was drilled in 2005. The best interval contained 2.04 grams of gold per tonne across 1.5 meters. In 2011, Alix Resources Corp. drilled 4 holes totaling 434 meters to test the stratigraphy of the redbeds. The results were encouraging with many intercepts up to 9 meters long that contained more than

0.1 gram of gold per ton. But the richest, 1.5 meters long, only contained 0.90 gram of gold per tonne.

Alteration:

Skarn zones contain diopside, epidote, sericite, and anhydrite.

Age of mineralization:

Late Cretaceous?

Generic deposit model:

Deposit model:

Cu skarn (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Active

Workings/exploration:

Ross (1933) reports several trenches were dug in August 1931 for exploration. The main trench showed mineralization at intervals throughout its length of about 70 feet but exposed massive sulfide only over a width of 2 or 3 feet about 15 feet from its northwest end. A sample of freshly blasted material yielded on assay 0.22 ounce of gold and 4.90 ounces of silver to the ton and 7.34 percent of copper. Trenches about 45 feet to the southwest on the line of strike show little mineralization.

Through 1999, the exploration included geochemical soil surveys, 1,500 feet of trenching and 9 drill holes that totaled 1,700 feet. As part of the Golden Zone project, there was some work done at or near this prospect from 2001 to 2005 (Hidefield, 2005 and 2008). The work included some initial ground geophysical surveys; one hole was drilled in 2005. Alix Resources Corp. drilled 4 holes in 2011 (Alix Resources Corp., 2012).

Production notes:

None.

Reserves:

None.

Site name(s): Ready Cash

Site type: Prospect

ARDF no.: HE057

Latitude: 63.15 **Quadrangle:** HE A-6

Longitude: 149.86

Location description and accuracy:

The Ready Cash prospect is at an elevation of about 2,700 feet on Canyon Creek, a northern tributary to Ohio Creek. The map site is in the SW1/4 of sec. 28, T. 20 S., R. 12 W., of the Fairbanks Meridian. This is locality 21 of Cobb (1978: OFR 78-1062).

Commodities:

Main: Ag, Au, Cu, Pb, Sn, Zn

Other: Sb

Ore minerals: Argentite, arsenopyrite, cassiterite, chalcopyrite, covellite, galena, pyrite, pyrrhotite, sphalerite, tennantite, tetrahedrite

Gangue minerals: Calcite, quartz

Geologic description:

Ross (1933) examined the site and reported that the bedrock in the vicinity of the tunnel is uniformly a coarse, somewhat chloritic rock without discernible bedding, which microscopic examination shows to be altered andesite or related rock. Three segments of quartz veins exist. The segment on the west side of Canyon Creek is 3 feet wide, strikes about N 58 W, and stands vertical. There are several minor quartz stringers and lenses of oxidized sulfide south of this vein. The main vein contains rather sparsely disseminated arsenopyrite, galena, and other sulfides. A sample yielded on assay 0.01 oz. of gold and 4.20 ounces of silver to the ton and 0.52 percent of lead. Some of the rusty lenses south of it were probably high in sulfide before oxidation, but none of these are more than a few inches wide and apparently none much more than 2 feet long.

Another vein segment is exposed for about 30 feet on the east side of Canyon Creek about 80 feet above the tunnel portal. It strikes about N 25 E and stands vertical. Its walls are curved so that their strike ranges from N 40 E to N 20 E. At the north end of the exposure the vein is about 10 feet wide. A sample contained a trace of gold and 0.70 ounce of silver to the ton. Its lead content was not determined but is obviously small. About 25 feet to the south the vein has a width of only 4 feet. On the east wall there are slickensides which dip 65 N. Sulfides are less abundant in this vein segment than in that to the west and occur mainly in small streaks and bunches. They include arsenopyrite, pyrite, and some chalcopyrite. Most of the quartz has been fractured and locally is stained and impregnated with the oxidation products of iron, copper; and manganese. The tunnel below trends N 83 E for 169 feet and hence extends well beyond the line of the vein as exposed 80 feet above it. The tunnel exposes only broken ground and minor stringers of quartz and calcite with small amounts of sulfides, mainly pyrite (Ross, 1933).

The third vein segment is exposed on the hillside above and east of the segment just described. A tunnel in the face of a steep bluff has been driven 60 feet to this vein, and a drift tunnel off from it to the southeast follows the vein for a distance of 16 feet. The vein as exposed in this tunnel is 5 feet wide, strikes N 20 W, and dips about 60 NE. The face of the lower tunnel is within 120 feet of the point where this vein would be if projected northwestward with the same strike and dip. A sample across the southeast face of the drift yielded on assay a trace of gold and 1.80 ounces of silver to the ton, but no lead. This vein contains numerous stringers and bunches of sulfides, some as much as 10 inches wide. They include arsenopyrite,

pyrrhotite, pyrite, galena, chalcopyrite, and sphalerite, listed roughly in the order of decreasing abundance. Most of the bands of nearly pure sulfide consist mainly of arsenopyrite. Some of the pyrite is in imperfect cubes as much as an inch wide. There are small amounts of supergene covellite. The gangue is white, rather coarsely crystalline quartz, somewhat fractured (Ross, 1933).

The country rocks in the area of the Ready Cash prospect consist of several hundred meters of Upper Triassic interbedded limestone, marble, basalt, metachert, and argillite. The strata are intruded by quartz diorite porphyry dikes of probable Late Cretaceous to Early Tertiary age, and by Tertiary tourmaline-bearing granite. The Ready Cash prospect consists of quartz-calcite-sulfide veins, and pods of skarn. The ore minerals consist chiefly of arsenopyrite, pyrite, chalcopyrite, galena and sphalerite, accompanied by minor amounts of tetrahedrite, tennantite, argentite, and cassiterite. The skarn consists of pyrite, pyrrhotite and chalcopyrite in a matrix of calc-silicate minerals and sparse quartz. The deposit can be subdivided into: a) copper-rich pods of skarn having grades of 0.5 to 0.9 percent copper (Hawley and Clark, 1974); b) arsenopyrite-quartz veins, containing 0.08 ounce of gold per ton, 1.06 ounce of silver per ton, and 0.33 percent copper; and c) high silver-lead-tin veins containing up to 20.8 ounces of silver per ton, 4.0 percent lead, and 0.5 percent tin (Hawley and others, 1978). The several types of deposits may be related to two or more magmatic events in the area.

The deposit at the Ready Cash prospect is more or less continuous with the deposit at the Canyon Creek prospect (HE055), encompassing an area about 2.5 miles long and 1 mile wide.

Alteration:

There probably have been multiple alteration events; including skarn formation and silicification.

Age of mineralization:

Probably Late Cretaceous and (or) younger.

Generic deposit model:

Deposit model:

Cu skarn and younger Ag-Pb-Sn veins (Cox and Singer, 1986; models 18b, 15b)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b, 15b

Production Status: None

Site Status: Active

Workings/exploration:

The ground wras located in May 1915 by Otto Tangel, J.P. Frisly, William Murry, and E. Miller; later ownership was acquired by J.H McCallie, who patented the property in 1927; there are nine claims covering an area of 132.627 acres, developed by two tunnels and nine discovery pits. It appears from the description by Capps that all this work had done prior to his visit in July 1917. The two tunnels and their relations to the veins found are shown in plate 26 of Ross (1933). As mentioned above the two tunnels are 169 feet and 60 feet long, with a 16 foot drift (Ross, 1933).

The deposit can be subdivided into: a) copper-rich pods of skarn having grades of 0.5 to 0.9 percent copper (Hawley and Clark, 1974); b) arsenopyrite-quartz veins, containing 0.08 ounce of gold per ton, 1.06 ounce of silver per ton, and 0.33 percent copper; and c) high silver-lead-tin veins containing up to 20.8 ounces of silver per ton, 4.0 percent lead, and 0.5 percent tin (Hawley and others, 1978).

Production notes:

None.

Reserves:

The two principal silver-rich veins on the prospect contain approximately 200,000 tons of ore carrying 10

to 20 ounces of silver per ton and 0.5 percent tin (C. Hawley, personal communication, 1999). This estimate does not include the skarn deposits.

Last report date: 2016-03-28

Site name(s): Red Mountain Creek; WTF (Western Tundra Flats); Dry Creek

Site type:

Prospect

ARDF no.: HE122

Latitude: 63.92 **Quadrangle:** HE D-1

Longitude: 147.38

Location description and accuracy:

This site represents an area of about a square mile between upper Red Mountain Creek and Dry Creek. The map site is at an elevation of about 4,300 feet, on the west wall of the valley of upper Red Mountain Creek, in the SW1/4 of sec. 33, T. 11 S., R. 2 E., of the Fairbanks Meridian. This is locality 7 of Cox and others (1989).

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals: Chlorite, feldspar, quartz, white mica

Geologic description:

The country rocks in the area of this prospect are mapped as the Lower Mississippian to Middle Devonian Totatlanika Schist, composed predominantly of metavolcanic and metavolcaniclastic rocks, and subordinate amounts of intercalated metasedimentary rocks (Wilson and others, 1998). The dominant structural fabric on the property is a strong mylonitic foliation, and there is a consistent east-northeasterly lineation that plunges at about 20-30 degrees. The deposit is in greenschist-grade metasedimentary rocks and altered rhyolite schist, and consists of stratiform bodies of massive sulfides that occur on the northern and southern limbs of an east-trending synclinal fold. The southern limb of the syncline contains three ore horizons that dip to the north at about 70 to 80 degrees (Schuster, 1998). These are referred to as the DC zones, which have been subdivided into the DC-North, DC-South, and DC-17 zones.

The DC-North zone is defined by a 2-kilometer-long EM conductor. This zone has been further subdivided into three areas: Discovery, which roughly bisects the EM anomaly; Lago Creek, which is 200-400 meters west of the Discovery area; and Fosters Creek, about 800 meters west of the Discovery area. In the Fosters Creek area, drilling has intercepted a 29-meter interval (true width) grading 6.22 percent zinc, 2.56 percent lead and 0.22 percent copper, as well as 182.8 grams silver and 1.03 grams gold per tonne. A 3.7-meter intercept in the hole produced assay results as high as 23.58 percent zinc, 8.46 percent lead, 1.02 percent copper, and 531.5 grams silver and 2.24 grams gold (Schuster, 1998). The DC-South zone is virtually unexplored except for a few reconnaissance drill holes. The DC-17 zone is a 15-meter-thick bed of pyrite (with minor amounts of lead and zinc) that is believed to be genetically related to other zones.

The northern limb of the syncline dips gently to the south and hosts the WTF zone, a layer of massive sulfides 0.3 to 5 meters thick that has been tested by 26 widely-spaced drill holes (Schuster, 1998).

Alteration:

The footwall schist contains chlorite and sericite.

Age of mineralization:

Mineralization was syngenetic with the Lower Mississippian to Middle Devonian host rocks.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active

Workings/exploration:

Exploration of the area includes an EM geophysical survey and extensive drilling. Press releases indicate that over 60 drill holes totaling approximately 7600 m have been drilled to date (Robertson, 1998; The Northern Miner, 1998 and 1999: v. 84, nos. 26 and 52).

In February 2016, White Rock Minerals Ltd. announced the proposed acquisition of the Red Mountain polymetallic volcanogenic massive sulfide (VMS) project in the north-central Alaska Range, with two known deposits: Dry Creek (101 historical drill holes for 13,831 m) and West Tundra Flats (26 historical drill holes for 5,349 m). As of May 2016, White Rock acquired 100 percent ownership of the property. In March 2016, White Rock Minerals Ltd. staked 85 new mining claims in the Bonnifield district. In June through August 2016, White Rock focused on identifying high-priority magnetic, conductivity, and geochemical targets for future follow-up work utilizing geochemical vector analysis, detailed geologic maps published by DGGS, and contracted detailed interpretation of a DGGS airborne magnetic and electromagnetic survey of the area (Burns and others, 2016). The resulting integrated assessment led to an additional 114 claims being staked and prioritization of the ReRun, Smog (HE126) and Glacier target areas as highly prospective for additional VMS deposits, which are included within 30 geochemical-geophysical targets classified as of high interest (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

Reserves for part of this deposit have been estimated at 1.10 million tonnes grading 0.15 percent copper, 2.5 percent lead, 7.9 percent zinc, and 270 grams silver, and 1.9 grams of gold per tonne (Nokleberg and others, 1987). An estimate based on 38 of 60 holes drilled to test the southern limb of the syncline gave an inferred resource of 2.9 million tonnes grading 4.4 percent zinc, 1.9 percent lead, 0.2 percent copper, and 0.55 gram gold and 93.6 grams silver per tonne. Included in this estimate is a higher-grade core of 1.5 million tonnes grading 6.4 percent zinc, 2.9 percent lead, 0.3 percent copper, and 0.79 gram gold and 123.8 grams silver per tonne. The bulk of the resource is in the Fosters Creek and Discovery zones, respectively in pyritic sedimentary rocks and intensely altered rhyolite. On the north limb of the syncline, the WTF resource currently (1999) stands at 2.8 million tonnes grading 6 percent zinc, 2.5 percent lead, 0.1percent copper, and 0.9 gram gold and 178.2 grams silver per tonne (The Northern Miner, 1998 and 1999: v. 84, nos. 26 and 52).

Site name(s): Honolulu

Site type: Prospect

ARDF no.: HE131

Latitude: 63.03 **Quadrangle:** HE A-5

Longitude: 149.48

Location description and accuracy:

The Honolulu prospect is at an elevation of about 2,950 feet in the headwaters of Honolulu Creek. The location is accurate to within 0.5 mile. The map site is in the SW1/4 of sec. 4, T. 22 S., R. 10 W., of the Fairbanks Meridian. This is location 36 of Cox and others, 1989; location D-22 of Balen (1990: OFR 34-90).

Commodities:

Main: Ag, Au, Cu

Other: Pb, Sn, Zn

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals: Quartz

Geologic description:

The area of the Honolulu prospect is underlain by Lower Cretaceous to Upper Jurassic graywacke and argillite cut by Tertiary granites. The deposit is in highly altered granitic rock and consists of sulfide-rich quartz veinlets (Balen and others, 1991). The sulfide minerals are chalcopyrite, galena, and sphalerite. High tin assays suggest that cassiterite also is present. One channel sample collected across a 60-foot exposure of altered granite contained 1.09 ounce of silver per ton, 0.03 ounce of gold per ton, 1.5% copper, and 250 ppm tin. The highest grade samples contained 141 ounces of silver per ton, 0.05 ounce of gold per ton, 2.3% copper, 6.3% lead, 6% zinc, and 795 ppm tin (Balen, 1990: OFR 34-90; Balen and others, 1991).

In 2016, Honolulu Prospect Corp. conducted a multi-phase exploration program on their Honolulu project. Select hand samples include: sheeted arsenopyrite veins from Tiki Chute with 0.17 ounce of gold per ton and 1.35 ounces of silver per ton; disseminated arsenopyrite in drusy quartz from Bertram Gulch with 0.03 ounce of gold per ton and 7.3 ounces of silver per ton; and oxidized sulfide veins from Tempest with 8.26 percent lead, 6.47 percent zinc, and 223.8 ounces of silver per ton. Honolulu Prospect Corp. is planning a significant drilling campaign in 2017, along with geochemical and geophysical surveys and geologic mapping (Athey and Werdon, 2017).

Alteration:

Extensive silicification and phyllic alteration.

Age of mineralization:

The sulfide minerals are in altered Tertiary granite.

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
22c

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Surface workings, and two shallow Winkie holes drilled in the mid-1970s (unpublished report for the New Alaska Syndicate, 1976). One channel sample collected across a 60-foot exposure of altered granite contained 1.09 ounce of silver per ton, 0.03 ounce of gold per ton, 1.5% copper, and 250 ppm tin. The highest grade samples contained 141 ounces of silver per ton, 0.05 ounce of gold per ton, 2.3% copper, 6.3% lead, 6% zinc, and 795 ppm tin (Balen, 1990: OFR 34-90; Balen and others, 1991).

In 2016, Honolulu Prospect Corp. conducted a multi-phase exploration program on their Honolulu project, which included 16 drill holes, collecting 1,505 sediment and 124 rock samples, defining a 1,000-foot strike length and up to 200-foot-wide mineralized structural zone with multiple mineralized fault splays containing continuous high-grade mineralization, and identification of four new areas with anomalous silver, copper, and gold. The 16 holes were drilled from 5 pads for a total of 8,645 feet. Select hand samples include: sheeted arsenopyrite veins from Tiki Chute with 0.17 ounce of gold per ton and 1.35 ounces of silver per ton; disseminated arsenopyrite in drusy quartz from Bertram Gulch with 0.03 ounce of gold per ton and 7.3 ounces of silver per ton; and oxidized sulfide veins from Tempest with 8.26 percent lead, 6.47 percent zinc, and 223.8 ounces of silver per ton. Honolulu Prospect Corp. is planning a significant drilling campaign in 2017, along with geochemical and geophysical surveys and geologic mapping (Athey and Werdon, 2017).

Location description and accuracy:

When this record was initially compiled there was little information on this deposit and another nearby prospect. Subsequent exploration and drilling has blurred the distinction between the two, expanded the area of the property to encompass both of them and added much new information on the property that is now the 'Gold Hill, Su', ARDF site HE172. The data that was in this record has been integrated into that record. The ARDF number in this record has been preserved only for accounting purposes.

Site type: Prospects

ARDF no.: HE172

Latitude: 63.0985 **Quadrangle:** HE A-2

Longitude: 147.745

Location description and accuracy:

The Gold Hill prospects extend southwest for about a half mile from the high point of ridge at the northeast end of the prospects, which is locally called Gold Hill. It is about 3.5 miles northwest of the junction of Wickersham and Butte Creeks. The center of these prospects is about 0.4 mile northeast of the center of section 16,T. 21 S., R. 1 W., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Au, Cu, Mo

Other: As

Ore minerals: Arsenopyrite, chalcopyrite, enargite?, gold, molybdenite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The Gold Hill prospect was first located in 1972 by the New Alaska Syndicate, who carried out considerable geochemical surveys, trenching, and sampling; they also drilled 22 diamond-drill holes (Friberg, 2004) . Dome Mines continued the work in 1977, followed by several other companies, including Stevens Exploration Management, GCO Minerals, Amax Exploration, and Hemlo Mines. At the end of this activity in 1996, the work included 27 diamond drill holes that totaled 9,588 feet, 21 reverse-circulation holes totaling 5,885 feet, several geochemical surveys and much rock sampling, and both ground and airborne geophysical surveys. In 2004, MAX Resource Corp. acquired the property that then consisted of a large block of claims.

The rocks in the vicinity of this prospect are deformed Jurassic and Cretaceous metasedimentary and metavolcanic rocks of the Maclaren Metamorphic Belt that have been intruded by dikes and stocks of Early Tertiary quartz monzonite and hornblende diorite (Wilson and others, 1998; Smith and others, 1975).

The mineralization occurs mainly in and at the periphery of the intrusions, and locally along shears and fractures. It consists of quartz veins, stockworks, veinlets, and disseminations, The ore minerals include various combinations of pyrite, pyrrhotite, arsenopyrite, chalcopyrite, possibly enargite, molybdenite, and gold. The rocks are hornfelsed near the intrusion and there are several zones of propylitic and argillic alteration associated with the mineralization. Four distinct target areas are spread along about a half mile were defined by the soil surveys and geophysics.

Most of the drilling prior to 2004 was for gold, numerous intercepts contained more than 1 part per million (ppm) gold. Some notable intercepts are 3.5 feet that contained 54.3 ppm gold, 5 feet that contained 3.96 ppm gold, 5 feet that contained 6.36 ppm gold, 5 feet that contained 15.94 ppm gold, 5 feet that contained 8.02 ppm gold, and 5 feet that contained 22.90 ppm gold.

In 2007, MAX drilled 4 holes, primarily to test the molybdenum potential of the prospect. The best intercepts were 250 feet of 0.048 percent molybdenum, 750 feet of 0.044 percent molybdenum, 250 feet of 0.0361 percent molybdenum, and 352 feet of 0.0434 percent molybdenum. They drilled another 10 holes that totaled 7,664 feet in 2008 (Max Resource Corporation, 2009). The best hole cut quartz-pyrite-molybdenite mineralization for 536 feet that averaged 0.048 percent molybdenum. Copper varied from 0.009 to 0.0425 percent in the holes.

Alteration:

Silicification, propylitic and argillic alteration, hornfelsing near the intrusion.

Age of mineralization:

Tertiary based on the age of the intrusion that is apparently the source of the mineralization.

Generic deposit model:

Deposit model:

Porphyry Cu-Mo-Au (Cox and Singer, 1986; model 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site name(s): Caribou Dome; Denali Copper

Site type: Prospect

ARDF no.: HE191

Latitude: 63.1385 **Quadrangle:** HE A-1

Longitude: 147.1444

Location description and accuracy:

The Caribou Dome prospect is at an elevation of about 4,500 feet in the Clearwater Mountains on the northwest side of the pass between Windy Creek and the South Fork of Pass Creek. The location is at the massive sulfide outcrop known as Lense 6 or Number 6 and is near the center of section 34, T. 20 S., R. 3 E., of the Fairbanks Meridian.

Commodities:

Main: Cu

Other: Ag, Zn

Ore minerals: Azurite, bornite, chalcocite, chalcopyrite, malachite, native copper, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The Caribou Dome prospect is near the upper contact of the Nikolai Greenstone, a thick sequence of Upper Triassic marine andesite and basalt, and subordinate clastic and carbonate units (Stevens, 1971; Wilson, and others, 1998). At the prospect, the strata dip up to 80 degrees northwest and strike northeast. About a mile northwest of the prospect, the Nikolai Greenstone is intruded by a strongly fractionated pluton dated by K-Ar methods at 130 to 143 Ma (Smith, 1981).

The prospect consists of delicately-layered to massive beds of chalcopyrite and pyrite in black argillaceous limestone and black calcareous argillite (Stevens, 1971, 2008). The massive, dominantly chalcopyrite beds are up to 12 inches thick and assay up to 12 percent copper. Pyrite commonly occurs as framboids. Minor bornite, chalcocite, and native copper, and sparse sphalerite occur locally. Gossan overlies the sulfide bodies and contains malachite, azurite, chalcocite, and minor chalcopyrite. A prominent gossan consisting of a jet-black earthy residue with relict bedding overlies the highest-grade portions of the sulfide horizons (D. L. Stevens, personal observation). The rocks in this region were regionally metamorphosed to prehnite-pumpellyite facies (Stevens, 1971, 2008), but the very fine-grained sulfide minerals in the deposit were not recrystallized, as shown by chalcopyrite grains as small as 1 micron. Several major northeast-trending, strike-slip faults traverse the area. The most important occurs in the footwall just south of the main sulfide horizon; it is marked by a zone of fault gouge 20 to 50 feet wide. Movement along this fault has developed drag-folds with amplitudes of up to 50 feet in the steeply-dipping sulfide horizon. Northwest-dipping thrust faults were encountered underground on the 4630-level adit. These faults offset the main horizon about 30 feet (Stevens, 1971). Regional mapping also shows a major southeast-dipping thrust fault that strikes northeast.

The main sulfide horizon, on which most of the exploration effort has occurred is up to 400 feet long and 30 feet wide; it extends at least 1,000 feet below the surface outcrop as confirmed by drilling. The sulfide horizons are characterized by pinching and swelling along strike as well as down dip. As one horizon pinches, other horizons may swell. One of the holes of the 2009 drilling had a 7-foot intercept in a new zone of mineralization; the intercept averaged 1.83 percent copper. A 6.8 foot interval in the other hole averaged 0.51 percent copper in what was probably the extension of one of the mineralized horizons. The prospect remains open at depth and along strike both to the northeast and southwest on at least four of the known ore

horizons. The 2010 trenching revealed numerous intervals with greater than 0.5 percent copper, including a one meter interval that contained 8.92 percent copper and many intervals 2 to 7 meters in length that contained over 2 percent copper and up to 27.6 grams of silver per tonne. Seven of the 2011 drill holes cut mineralization (Caribou King Resources, 2011). The best intercept was 3.4 meters with 3.36 percent copper and 5.54 grams of silver per tonne.

This sulfide prospect is interpreted to have formed in a reducing or euxinic marine basin with abundant organic matter and sulfate-reducing bacteria (Stevens, 1971, 2008). Sulfur isotope ratio analyses of the chalcopyrite and pyrite averaged -28.35 permil with a standard deviation range of only 1.01 permil (Stevens, 1971, 2008). These values confirm the biogenic reduction of sea water sulfate to produce the sulfide ion and suggest the possibility of a closed system. The copper was probably derived by weathering of the subaerial copper-rich volcanic rocks adjacent to the marine basin.

Coventry Resources Ltd.’s 2016 program at the sediment-hosted Caribou Dome copper project included 22 drill holes for a total of 6,520 m. Near-surface, high-grade mineralization was extended for greater than 120 meters along strike and to greater than 300 meters depth to the northeast. Coventry better defined the extents of very-high-grade, shallow mineralization and identified an area for a potential starter open-pit mine (Athey and Werdon, 2017).

Alteration:

There is no hydrothermal alteration associated with the sulfide mineralization (Stevens, 1971; Roberts and Stevens, 2015).

Age of mineralization:

Syngenetic in Late Triassic rocks (Stevens, 1971; Wilson, and others, 1998).

Generic deposit model:

Deposit model:

Basaltic Cu (Cox and Singer, 1986; model 23).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

23

Production Status: None

Site Status: Active

Workings/exploration:

The Caribou Dome prospect (formerly the Denali Copper prospect) was discovered by M. A. Kaufman in 1963 while mapping for the State of Alaska Division of Mines and Minerals (Stevens, 2008). It subsequently was staked by prospectors working for Leo Mark Anthony. From 1964 through 1968, exploration consisted of trenching, geologic mapping, geochemical and geophysical surveys, and diamond core drilling.

In 1969, a 1,400-foot-long adit was driven from a portal at an elevation of 4,630 feet (Stevens, 2008). This adit was driven to intersect and follow the drill-indicated trend of the widest known part of the deposit, which was informally called the main horizon. A crosscut was driven into the hanging wall approximately orthogonal to the main ore horizon to provide drill stations to intersect the down-dip extension. Slightly inclined percussion drill holes from this adit tested the adjacent areas out to about 100 feet. Surface diamond drilling tested the other four or five known ore horizons.

In 1970, an 1,800 foot long, minus-15-degree spiral decline was driven to provide drill stations for deep intercepts of the mineralized horizon, and to obtain bulk samples of the deposit. The main horizon has been tested by drilling as deep as 1,000 feet below outcrop. Drill testing of the other ore horizons has rarely been deeper than 300 feet. Bulk samples for metallurgical testing were collected in 1969 and 1970 as part of the underground exploration program. In 1999, Ahtna Resources Ltd. optioned the property; their work included geochemical and geophysical surveys, three core holes, detailed geologic mapping, and additional

metallurgical testing.

The Caribou Dome prospect was acquired by Caribou Copper Resources Ltd. (formerly YOW Capital Management) in 2008 (Caribou Copper Resources, Ltd., 2010). They drilled two holes from the surface in 2009 that totaled 2,038 feet (Caribou Copper Resources Ltd., 2009). In the summer of 2010, they dug 9 trenches and collected numerous samples (Caribou Copper Resources, Ltd., 2010b). In 2011, Caribou King Copper drilled 9 holes from 7 locations to test mineralization found in the 2010 trenching.

In 2014 geologic mapping and sampling was completed for Hatcher Resources Inc. Over 5 days, 18 rock and 27 stream sediment samples were collected on the Caribou Dome prospect (Roberts and Stevens, 2015).

Coventry Resources completed a three-dimensional induced polarization (3DIP) geophysical survey and diamond drilling at Caribou Dome in 2015. The 3DIP survey covered 1500 meters along strike of mineralization and found a strong, continuous 500 meter long anomaly coinciding with known mineralization (Coventry Resources, 2015a). Over ten drill holes were completed in order to verify historic drill results and to target under-explored targets. Initial drill assay highlights include 10.1 meters with 7.1 percent copper and 12.2 meters with 3.2 percent copper (Coventry Resources, 2015b).

Coventry Resources Ltd.’s 2016 program at the sediment-hosted Caribou Dome copper project included 22 drill holes for a total of 6,520 m. Near-surface, high-grade mineralization was extended for greater than 120 meters along strike and to greater than 300 meters depth to the northeast. Coventry better defined the extents of very-high-grade, shallow mineralization and identified an area for a potential starter open-pit mine. Coventry delineated multiple new high-priority induced-potential targets over 7 kilometers of strike. Soil sampling defined a new, 5-kilometer-long, copper-in-soil anomaly at the Senator prospect, located 11 kilometers from the Caribou Dome deposit, and follow-up rock-chip sampling revealed sediment-hosted copper mineralization with assays up to 12.1 percent copper. Coventry also conducted a metallurgy test for Lense 4/5/6 and Lense 7/8, which indicates greater than 99 percent recoveries; concentrates grading greater than 27.4 percent Cu were achieved. An economic assessment and scoping study are scheduled for completion in early 2017 (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

R.H. Seraphim (unpublished report, 1970, cited in Stevens, 2008) estimated the drill-indicated reserves of the main horizon as 550,000 tons that contain an average of 5.84 percent copper, 0.3 ounce of silver per ton, and a trace of gold.

Site name(s): Gold Hill; Accident

Site type: Prospect

ARDF no.: HE209

Latitude: 63.1902 **Quadrangle:** HE A-1

Longitude: 147.2809

Location description and accuracy:

The Gold Hill prospect is at an elevation of about 4,800 feet, just west of the summit of Gold Hill between Lucky Gulch and White Creek. It is about 0.4 mile south of the center of section 12, T. 20 S., R. 3 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Fe, Pb, Sb, Zn

Other:

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Ankerite, quartz

Geologic description:

The Gold Hill prospect is one of four deposits that was explored by CanAlaska Resources Ltd. from 1983 to at least 1996 in the Rainbow Hill project. It and the nearby Lucky Top (HE210), Lucky Saddle (HE215), and TMC (HE211) prospects share a similar origin and general characteristics. The Rainbow Hill project is described in considerable detail by Adams (1996) and Freeman (2002) and most of what follows is based on their work.

The rocks in the area consist of folded Jurassic to Cretaceous argillite, graywacke, siltstone, and mafic tuff that were intruded by small stocks and dikes of Tertiary and Cretaceous gabbro and diorite. The rocks underwent lower-greenschist- to amphibolite-grade metamorphism in the Cretaceous and early Tertiary. Airborne geophysical data suggest that the Gold Hill/Lucky Top area that roughly coincides with the Rainbow project is underlain by a shallow, structurally deformed meta-igneous complex. The regional structure is dominated by a set of east-trending thrust faults and cross-cutting high-angle faults. A set of northwest-trending, high-angle faults and dikes associated with the mineralization is offset by northwest- and northeast-trending faults.

The mineralization in the Rainbow project consists of zones of stacked, sulfide-bearing, ankerite-quartz veins and stockworks that strike east and dip variably to the north and south. The sulfides in the veins and stockworks are mainly pyrite and arsenopyrite; minor amounts of pyrrhotite, chalcopyrite, galena, stibnite, and sphalerite occur widely, as does visible gold. Abundant sulfides usually indicates high gold values. The auriferous zones typically have a central area of intense silicification, sericitization, and carbonatization, that weakens outward. Sericite from the veins has been dated at 57.6 to 63.1 Ma by argon-argon methods.

Although there had been some earlier work on the gold veins in the Gold Hill/Lucky Top area (Moffit, 1912; Ross, 1933; Tuck, 1938), the first extensive exploration in the area was in 1983 when CanAlaska began a program of surface mapping, outcrop sampling, soil geochemical surveys, trenching, and ground geophysical surveys. The work identified numerous zones of hornfels alteration and diorite dikes. In 1996, they drilled 5 holes totaling 1,400 feet on the Gold Hill prospect. The drilling intersected numerous diorite dikes and breccia zones. Most of the holes ware in pervasive sericite-carbonate-quartz and tourmaline alteration; numerous sections of the holes intersected persistent anomalous gold values up to 1,950 parts per billion. The drilling did not penetrate the Gold Hill diorite stock which is exposed on the surface less than

1,000 feet west of the drill sites; the stock was considered an attractive target.

Alteration:

The mineralization is associated with pervasive sericite-carbonate-quartz alteration; local hornfelsing and tourmalinization.

Age of mineralization:

About 60 Ma based on the age of sericite from the quartz veins.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Although there had been some earlier work on the gold veins in the Gold Hill/Lucky Top area (Moffit, 1912; Ross, 1933; Tuck, 1938), the first extensive exploration in the area was in 1983, when CanAlaska began surface mapping, sampling, and trenching. In 1996, they drilled 5 holes totaling 1,400 feet on the Gold Hill prospect.

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Lucky Top

Site type: Prospect

ARDF no.: HE210

Latitude: 63.1889

Quadrangle: HE A-1

Longitude: 147.2498

Location description and accuracy:

The Lucky Top prospect is at an elevation of about 5,000 feet about 0.2 mile northwest of the top of Lucky Hill. It is about 0.5 mile south-southwest of the center of section 7, T. 20 S., R. 3 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Fe, Pb, Sb, Zn

Other:

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, pyrite, pyrrhotite, stibnite, sphalerite

Gangue minerals: Ankerite, quartz

Geologic description:

The Lucky Top prospect is one of four deposits that was explored by CanAlaska Resources Ltd. from 1983 to at least 1996 as the Rainbow Hill project. It and the nearby Gold Hill (HE209) Lucky Saddle (HE215), and TMC (HE211) prospects share a similar origin and general characteristics. The Rainbow Hill project is described in considerable detail by Adams (1996) and Freeman (2002) and most of what follows is based on their work.

The rocks in the area consist of folded Jurassic to Cretaceous argillite, graywacke, siltstone, and mafic tuff that were intruded by Tertiary and Cretaceous gabbro and diorite in small stocks and dikes (Smith, 1981). The rocks underwent lower-greenschist- to amphibolite-grade metamorphism in the Cretaceous and early Tertiary. The airborne geophysical data suggest that the Gold Hill/Lucky Top area that roughly coincides with the Rainbow Hill project is underlain by a shallow, structurally deformed meta-igneous complex. The regional structure is dominated by a set of east-trending thrust faults and cross-cutting high-angle faults. A set of northwest trending, high-angle faults and dikes associated with the mineralization is offset by northwest- and northeast-trending faults.

The mineralization in the Rainbow Hill project consists of zones of stacked sulfide-bearing, ankerite-quartz veins and stockworks that strike east and dip variably to the north and south. The sulfides in the veins and stockworks are mainly pyrite and arsenopyrite; minor amounts of pyrrhotite, chalcopyrite, galena, stibnite, and sphalerite occur widely as does visible gold. Abundant sulfides usually indicate high gold values. The auriferous zones typically have a central area of intense silicification, sericitization, and carbonatization, that weakens outward. Sericite from the veins has been dated at 57.6 to 63.1 Ma by argon-argon methods.

Although there had been some earlier work on the gold veins in the Gold Hill/Lucky Top area (Moffit, 1912; Ross, 1933; Tuck, 1938), the first extensive exploration in the area was in 1983 when CanAlaska began a program of surface mapping, outcrop sampling, soil geochemical surveys, trenching, and ground geophysical surveys.

The mineralization at the Lucky Top prospect consists of tourmaline-carbonate-quartz breccia with sparse sulfides; it is near the contact of a metamorphosed diorite intrusion. Grab samples from an old dump contained up to 0.11 ounce of gold per ton.

Alteration:

Age of mineralization:

About 60 Ma based on the age of sericite from the quartz veins.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

There was some early work on on the gold veins in the Gold Hill/Lucky Top area, notably a short adit on the Lucky Top prospect (Moffit, 1912; Ross, 1933; Tuck, 1938). But the first extensive exploration in the area was in 1983 when CanAlaska began a program of surface mapping, outcrop sampling, soil geochemical surveys, trenching, and ground geophysical surveys. Some surface work was done on the Lucky Top prospect but no drilling.

Production notes:

None.

Reserves:

None.

Additional comments:

This vein is the probable source area of the placer gold and large nuggets in Lucky Gulch (HE207) below it.

Site name(s): TMC

Site type: Prospect

ARDF no.: HE211

Latitude: 63.1786 **Quadrangle:** HE A-1

Longitude: 147.2483

Location description and accuracy:

This prospect is about 0.5 mile south of the top of Lucky Hill between Roosevelt Creek and White Creek south of upper Valdez Creek.. The prospect is about 0.2 mile south of the center of section 18, T. 20 S., R. 3 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Fe, Pb, Sb, Zn

Other:

Ore minerals:

Gangue minerals: Ankerite, quartz

Geologic description:

The TMC prospect is one of four deposits that was explored by CanAlaska Resources Ltd. from 1983 to at least 1996 as the Rainbow Hill project. It and the nearby Gold Hill (HE209), Lucky Top (HE210), and Lucky Saddle (HE215) prospects share a similar origin and general characteristics. The Rainbow Hill project is described in considerable detail by Adams (1996) and Freeman (2002) and most of what follows is based on their work.

The rocks in the area consist of folded Jurassic to Cretaceous argillite, graywacke, siltstone, and mafic tuff that were intruded by small stocks and dikes of Tertiary and Cretaceous gabbro and diorite. The rocks underwent lower-greenschist- to amphibolite-grade metamorphism in the Cretaceous and early Tertiary. Airborne geophysical data suggest that the Gold Hill/Lucky Top area that roughly coincides with the Rainbow project is underlain by a shallow, structurally deformed meta-igneous complex. The regional structure is dominated by a set of east-trending thrust faults and cross-cutting high-angle faults. A set of northwest-trending, high-angle faults and dikes associated with the mineralization is offset by northwest- and northeast-trending faults.

The mineralization in the Rainbow project consists of zones of stacked, sulfide-bearing, ankerite-quartz veins and stockworks that strike east and dip variably to the north and south. The sulfides in the veins and stockworks are mainly pyrite and arsenopyrite; minor amounts of pyrrhotite, chalcopyrite, galena, stibnite, and sphalerite occur widely, as does visible gold. Abundant sulfides usually indicate high gold values. The auriferous zones typically have a central area of intense silicification, sericitization, and carbonatization, that weakens outward. Sericite from the veins has been dated at 57.6 to 63.1 Ma by argon-argon methods.

Although there had been some earlier work on the gold veins in the Gold Hill/Lucky Top area (Moffit, 1912; Ross, 1933; Tuck, 1938), the first extensive exploration in the area was in 1983 when CanAlaska began a program of surface mapping, outcrop sampling, soil geochemical surveys, trenching, and ground geophysical surveys. The TMC zone was discovered a few years later. In 1989, CanAlaska drilled 7 holes on it that totaled 1,507 feet, and in 1990 they drilled 45 holes that totaled 14,772 feet. The drilling defined a series of stacked gold-bearing zones that were intersected over a vertical distance 600 feet. The drilling indicated that the mineralization continued along strike for about 1,000 feet, to a depth of 200 feet. They estimated that the total 'drill-inferred gold resource in 5 blocks of the TMC zone contained an estimated 90,285 ounces of gold with an average grade of 0.21 ounce of gold per ton' (at a cut-off grade of 0.03 ounce

of gold per ton). The average true width of the mineralization is 17 feet; segments up to 70 feet in length averaged 0.475 ounce of gold per ton. Geophysical evidence suggests that the mineralization continues for another 1,000 feet along strike and at least 500 feet down dip.

Alteration:

The mineralization is associate with pervasive sericite-carbonate-quartz alteration; local hornfelsing and tourmalinization.

Age of mineralization:

About 60 Ma based on the age of sericite from the quartz veins.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Although there had been some earlier work on the gold veins in the Gold Hill/Lucky Top area (Moffit, 1912; Ross, 1933; Tuck, 1938), the first extensive exploration in the area was in 1983 when CanAlaska began a program of surface mapping, outcrop sampling, soil geochemical surveys, trenching, and ground geophysical surveys. The TMC zone was discovered a few years later. In 1989, they drilled 7 holes on it that totaled 1507 feet; in 1990, they drilled 45 holes that totaled 14,772 feet.

Production notes:

None.

Reserves:

Based on 52 drill holes and considerable surface exploration, CanAlaska estimated that the total 'drill-inferred gold resource in 5 blocks of the TMC zone contained an estimated 90,285 ounces of gold with an average grade of 0.21 ounce of gold per ton' (at a cut-off grade of 0.03 ounce of gold per ton. The average true width of the mineralization is 17 feet; segments up to 70 feet long averaged 0.475 ounce of gold per ton.

Site name(s): Lucky Saddle

Site type: Prospect

ARDF no.: HE215

Latitude: 63.1827 **Quadrangle:** HE A-1

Longitude: 147.2476

Location description and accuracy:

The Lucky Saddle prospect is about 0.3 mile south of the top of Lucky Hill between Roosevelt Creek and White Creek. It is about 0.2 mile north-north west of the center of section 18, T. 20 S., R. 3 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Fe, Hg, Pb, Sb, Zn

Other:

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Ankerite, quartz

Geologic description:

The Lucky Saddle prospect is one of four deposits that was explored by CanAlaska Resources Ltd. from 1983 to at least 1996 as the Rainbow Hill project. It and the nearby Gold Hill (HE209), Lucky Top (HE210), and TMC (HE211) prospects share a similar origin and general characteristics. The Rainbow Hill project is described in considerable detail by Adams (1996) and Freeman (2002); most of what follows is based on their work.

The rocks in the area consist of Jurassic to Cretaceous, argillite, graywacke, siltstone, and mafic tuff intruded by small stocks and dikes of Tertiary and Cretaceous gabbro and diorite (Smith, 1981). The rocks were subject to lower-greenschist-grade to amphibolite-grade metamorphism in the Cretaceous and early Tertiary. Airborne geophysical data suggest that the Gold Hill/Lucky Top area that roughly coincides with the Rainbow project is underlain by a shallow, structurally deformed, metamorphosed igneous complex. The regional structure is dominated by a set of east-west trending thrust faults and by cross-cutting high-angle faults. A set of northwest trending, high-angle faults and dikes associated with the mineralization is offset by northwest- and northeast-trending faults.

The mineralization in the Rainbow Hill area consists of zones of stacked sulfide-bearing, ankerite-quartz veins and stockworks that strike east and dip variably to the north and south. The sulfides in the veins and stockworks are mainly pyrite and arsenopyrite; minor amounts of pyrrhotite, chalcopyrite, galena, stibnite, and sphalerite occur widely, as does visible gold. Abundant sulfides usually indicate high gold values. The auriferous zones typically have a central area of intense silicification, sericitization, and carbonatization that weakens outward. Sericite from the veins has been dated at 57.6 to 63.1 Ma by argon-argon methods.

Although there had been some earlier work on the gold veins in the Gold Hill/Lucky Top area (Moffit, 1912; Ross, 1933; Tuck, 1938), the first intensive exploration in the area began in 1983 when CanAlaska began a program of surface mapping, outcrop sampling, soil geochemical surveys, trenching, and ground geophysical surveys. The work resulted in the discovery of the Lucky Saddle prospect on a northeast-trending soil anomaly in gold, about 3,400 feet long and 800 feet wide. Trenches dug across the prospect in 1989 exposed metamorphosed hornfels and diorite dikes cut by a shear zone about 200 feet wide. Chip samples in the trenches contained 0.415 ounce of gold per ton across 5 feet and 0.05 ounce of gold per ton across 20 feet. The samples were also highly anomalous in arsenic, lead, and zinc, and contained some antimony, silver, and mercury.

Alteration:

Age of mineralization:

About 60 Ma based on the age of sericite from the quartz veins.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Although there had been some earlier work on the gold veins in the Gold Hill/Lucky Top area (Moffit, 1912; Ross, 1933; Tuck, 1938), the first extensive exploration in the area started in 1983 with a program of surface mapping, outcrop sampling, soil geochemical surveys, trenching, and ground geophysical surveys by CanAlaska. The work resulted in the discovery of the Lucky Saddle prospect on a northeast-trending soil anomaly in gold. Several trenches were dug on the mineralization in 1989.

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Cohio

Site type: Prospect

ARDF no.: HE216

Latitude: 63.1304 **Quadrangle:** HE A-6

Longitude: 149.7626

Location description and accuracy:

The Cohio prospect is along the ridge about 1.3 miles north of VABM 5048 'Copeland' and and about 5.5 miles north-northwest of the junction of Copeland Creek and Ohio Creek. It is about 0.5 mile north of the center of section 1, T.21 S., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

The Cohio prospect was found by Hidefield Gold PLC in 2006 (Alix Resources Corp., 2011). Three consecutive grab samples collected along 1 kilometer of the ridge contained 9.7, 15.0, and 111 parts per million gold. The rocks along the ridge in the prospect area are part of a northeast-trending band of Devonian andesitic tuffs and flows that interfinger with several long lenses of serpentine and silica-carbonate rock of unknown age (Kerr and Loveday, 2011).

Alteration:

Not noted.

Age of mineralization:

Little basis to assign; however Alix (2011) suggests that this mineralization here may be the extension of the belt of deposits that extend northeast to the Golden Zone Mine (HE043) where the mineralization is 65-70 Ma.

Generic deposit model:

Deposit model:

Insufficient evidence to assign.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Only a few samples collected at the surface.

Production notes:

None.

Reserves:

None.

Site name(s): Salmon River

Site type: Mine

ARDF no.: HG012

Latitude: 58.9205 **Quadrangle:** HG D-6

Longitude: 161.715

Location description and accuracy:

This placer mine is along the Salmon River, which is the main drainage on the east side of Red Mountain. Its mouth is on Kuskokwim Bay is about 10 miles south of the community of Platinum. Dredge mining took place from the mouth of Boulder Creek (HG026), downstream for about five miles to within 11/4 mile of the mouth of the river. The map site is at the approximate midpoint of the dredge tailings near the center of section 36, T. 14 S, R. 75 W.

Commodities:

Main: Au, PGE

Other: Cr, diamond, Hg

Ore minerals: Chromite, cinnabar, diamond, gold, ilmenite, iron-platinum alloy with 8 to 30 percent Fe, iron-platinum alloy with minor osmiridium inclusions, magnetite, mercury, osmiridium, sperrylite, tetraferroplatinum

Gangue minerals:

Geologic description:

This placer mine is located in the present valley of Salmon River. Dredge mining took place from the mouth of Boulder Creek (HG026), a west tributary, downstream about five miles to within 11/4 mile of the mouth of the river. The dredge tailings commonly are a few hundred feet wide and confined to the active drainage. The pay streak was 300 to 450 feet wide, except near the mouth of Platinum Creek (HG014) where it was up to 600 feet wide (Mertie, 1969). Overburden gravel, sand, and silt deposits vary from 30 to 80 feet thick and do not change systematically in thickness. The gravels are mostly well-rounded pebbles and cobbles up to 2 feet across interbedded with sand and silt; clay is not present. The pay is on an uneven, non-weathered bedrock surface that is locally incised up to 20 feet; in the overlying 2 feet of gravels; and in 2 feet of fractured bedrock. The tenor of the worked pay streak was 0.002 to 0.026 ounce of platinum group metals (PGM) per cubic yard (Fechner, 1988). PGM grains become smaller southward through the Salmon-River pay streak, from 0.2 to less than 0.002 inch in diameter. Four samples of tailings from this mine contained up to 0.0037 ounce of PGM per cubic yard (Fechner, 1988, p. 190, 193). PGM grains from Salmon River valley and bench tailings contain 0.6 to 1.1 percent rhenium, 0.4 to 0.7 percent ruthenium, 60.3 to 85.5 percent platinum, 3.8 to 25.6 percent iridium, 1.2 to 6.3 percent osmium, and 5.9 to 8.9 percent iron (Fechner, 1988). The PGM-bearing phases identified in these samples included iron-platinum alloy containing 8 to 30 percent iron; iron-platinum alloy with minor osmiridium inclusions; and osmiridium, sperrylite, and tetraferroplatinum (Fechner, 1988). Small amounts of cinnabar and traces of native mercury have been identified in dredge concentrates (Mertie, 1976). Two small diamonds were identified in the nondissolved residue from 8 PGM granules (Mertie, 1976). The Salmon River placer is continuous with the placer in Platinum Creek (HG014) and with the placers in some of its other west tributaries. The pay streak apparently ends or becomes uneconomic at the south end of the mine workings. The workings there are all below 150 feet in elevation and their proximity to the coastline and low elevation suggests that Quaternary sea level changes could have influenced placer development.

XP Platinum Ltd. purchased the property which consisted of 1,531 Federal placer mining claims and 42

Federal lode mining claims in 2007 and by 2008 all permits had been approved to begin mining (Amarant Mining, 2011, 2012). In 2009, XP Platinum Ltd. began a sampling program of the tailings. Watts, Griffis, and McQuat collected samples with a 10-inch drill and operated a 300-ton-per-hour processing plant from July to October (Szumigala and others, 2010). In 2011, a recovery plant with a single production line capable of producing 1,700 ounces of platinum group metals (per season?) was in operation and produced an unstated but probably substantial amount of PGMs. As of November, 2011, Amarant Mining Ltd. has taken control of XP Platinum by ownership of more than 50 percent of its stock (Amarant Mining, 2011, 2012).

Amarant Mining (2011, 2012) estimates the resources of their ground on the Salmon River and its tributaries as 65 million of material with an average grade of 0.0258 ounce of PGM per ton, i.e, 1,677,000 ounces of PGM. About 45 million tons of the resources are in the old dredge tailings; the other 20 million tons are in virgin ground.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

PGM-gold placer (Cox and Singer, 1986; model 39b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39b

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

The Salmon River valley paystreak was worked by dredge starting in 1937, and several parallel channels that total about 15 to 20 miles of workings up to 60 feet deep have been made. Considerable exploration drilling was completed to delineate the paystreak. In 2009, XP Platinum Ltd. began a sampling program of the tailings. Watts, Griffis, and McOuat collected samples with a 10-inch drill and operated a 300-ton-per-hour processing plant from July to October (Szumigala and others, 2010). In 2011, a recovery plant with a single production line capable of producing 1,700 ounces of platinum group metals (per season?) was in operation and produced an unstated but probably substantial amount of PGMs.

Production notes:

A large part of the 650,000 ounces of PGM and 15,600 ounces of Au produced from the Salmon River area was recovered from the Salmon River. In 2009, XP Platinum Ltd. began a sampling program of the tailings. Watts, Griffis, and McQuat collected samples with a 10-inches drill and operated a 300-ton-per-hour processing plant from July to October. An unknown amount of platinum-group metals was recovered. In 2011, a recovery plant with a single production line capable of producing 1,700 ounces of platinum group metals was in operation and produced an unstated but probably substantial amount of PGMs.

Reserves:

Fechner (1988) concluded that since the dredge recovered only about 60 percent of the PGMs that went through it, the mine tailings were a low-grade resource. He estimated that over 40 million cubic yards of tailings were present that could contain 0.0013 to 0.017 ounce of PGM per cubic yard.

Amarant Mining (2011, 2012) estimates the resources of their ground on the Salmon River and its tributaries as 65 million of material with an average grade of 0.0258 ounce of PGM per ton, i.e, 1,677,000

ounces of PGM. About 45 million tons of the resources are in the old dredge tailings; the other 20 million tons are in virgin ground.

Site name(s): Suzie Mountain

Site type: Prospect

ARDF no.: HG016

Latitude: 58.96 **Quadrangle:** HG D-5

Longitude: 161.652

Location description and accuracy:

This prospect is on the west ridge of Suzie Mountain and along the west side of Suzie Creek. The site is on the ridge crest at an elevation of about 900 feet and about 3.5 miles northeast of Goodnews Mining Camp. It is in the NE1/4 of section 20, T. 14 S., R. 74 W., of the Seward Meridian. The prospect is accurately located. Cobb's locality number 2 (1972 [MF 362]; 1980 [OF 80-909]) appears to be at this location.

Commodities:

Main: Pt

Other: Cu

Ore minerals:

Gangue minerals:

Geologic description:

This prospect is on the west ridge of the Suzie Mountain ultramafic complex, a composite dunite, peridotite, and clinopyroxenite pluton that is inferred to be Jurassic in age (Hoare and Coonrad, 1978; Alaska Earth Sciences, 2000). A geochemical survey in the area of this prospect in 2000 defined 700-meter-long and up to 100-meter-wide soil anomaly that averages 130 parts per billion platinum; the maximum platinum value in the anomaly is 345 ppb Pt (Alaska Earth Sciences, 2000). The anomaly extends northwest from Suzie Creek across the ridge crest at this locality.

In 2004, the Calista Corporation did extensive rock and soil sampling over the prospect and did detailed total field , magnetic susceptibility, and resistivity surveys (Calista Corp., 2004). One rock sample contained 2.5 part per million platinum and many of the soil samples were anomalous in platinum. A coherent zone of ore grade mineralization could not be defined at the surface but the data suggest the potential for deeper mineralization.

A. L. Clark (Cobb, 1972; Cobb, 1980) noted that copper minerals had been found at this locality. Alaska Earth Science (2000) noted that in the Salmon River area traces of chalcopyrite, pyrite, or pyrrhotite are common in surface outcrops of hornblende-bearing rocks in marginal parts of the ultramafic complexes.

Alteration:

Age of mineralization:

Jurassic, the inferred age of the ultramafic plutons in the area (Hoare and Coonrad, 1978).

Generic deposit model:

Deposit model:

Alaskan PGE (Cox and Singer, 1986; model 9).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
9

Production Status: None

Site Status: Active

Workings/exploration:
There has been surface soil and rock sampling at this location (Alaska Earth Sciences, 2000). An aeromagnetic survey was flown over the Salmon River area in 1994, a gravity survey has been completed, and some controlled-source audio magneto-telluric lines have been run over selected parts of the ultramafic complexes (Alaska Earth Sciences, 2000). In 2004, the Calista Corporation did extensive rock and soil sampling over the prospect and did detailed total field , magnetic susceptibility, and resistivity surveys.

Production notes:
None.

Reserves:
None.

Last report date: 2008-03-04

Site name(s): Drenchwater-East

Site type: Prospect

ARDF no.: HW002

Latitude: 68.5694 **Quadrangle:** H C-5

Longitude: 158.6833

Location description and accuracy:

The Drenchwater-East prospect is near the southwest corner of section 15, T. 10 S., R. 29 W., about 3.3 miles southwest of the junction of Wager Creek and Drenchwater Creek. It is part of a belt of similar mineralization that extends for about a mile to the northwest (also see HW003 and HW004).

Commodities:

Main: Pb, Zn

Other: Ag, As, Ba, Cu, Sb

Ore minerals: Barite, galena, marcasite, pyrite, sphalerite

Gangue minerals: Fluorite, quartz

Geologic description:

The Drenchwater deposits were found in 1975 by the U.S. Geological Survey and several comprehensive studies were done by the USGS and the U.S. Bureau of Mines from 1977 to 1992 that included detailed mapping, geochemical and geophysical surveys, and much sampling (Jansons and Baggs,1980; Jansons, 1982; Nokleberg and Winkler, 1978,1982; Kurtak and others, 1995). Anaconda Exploration explored the deposits in 1980 and in 1993 the Arctic Slope Regional Corporation and Kennecott Exploration applied for a permit to drill. The permit was turned down by the Bureau of Land Management because the area was part of the National Petroleum Reserve that is closed to exploration and mining.

The Drenchwater-East deposit is one of three similar deposits that form a belt about 1.2 miles long (see also Drenchwater Creek (HW004) and Drenchwater-West (HW003)). The deposits are in the Drenchwater Fenster, where the Key Creek sequence consists of the Kuna, Siksikpuk, Otuk and Okpkkruak Formations of Mississippian to Cretaceous age. The structure of the area is dominated by a series of south-dipping thrust faults that intensely deformed the rocks. The stratiform mineralization is mostly in carbonaceous shale and silicified mudstone, associated with altered volcanic rocks, mainly submarine felsic tuffs, and lesser mafic volcanics including trachyte, trachyandesite, and basalt. The mineralization is associated with silicification of the shale, mudstone, and volcanic rocks.

There are four types of mineralization: semi-massive; disseminated; layered diagenetic; and breccia-cemented. Sphalerite is the dominant sulfide; variable amounts of pyrite, marcasite, and galena occur; there are rare fluorite and barite; and anomalous silver, arsenic, and antimony show up in assays of the ore. Samples contained up to 23 percent zinc, 5.1 percent lead, 1,150 parts per million (ppm) copper and 15 ppm silver. Biotite from volcanic rocks interbedded with the mineralization has K-Ar ages of 319+10 and 330+17 Ma. A sample of galena has a Pb-isotope model age of 200 Ma. Most of those who have studied the deposits interpret them to be volcanogenic massive-sulfide deposits.

Alteration:

Widespread silicification of shale and volcanic host rocks.

Age of mineralization:

Biotite from volcanic rocks interbedded with the mineralization has K-Ar ages of 319+10 and 330+17 Ma.

A sample of galena has a Pb-isotope model age of 200 Ma.

Generic deposit model:

Deposit model:

Volcanogenic lead-zinc massive sulfide deposit (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Workings/exploration:

Several detailed studies of the prospect from 1975 to 1992 by the U.S. Geological Survey and the U.S. Bureau of Mines included geological mapping, geochemical and geophysical surveys, and considerable sampling. Explored by Anaconda Exploration in 1980.

Production notes:

None.

Reserves:

None.

Site name(s): Story Creek

Site type: Prospect

ARDF no.: HW015

Latitude: 68.3829 **Quadrangle:** H B-4

Longitude: 157.9374

Location description and accuracy:

The Story Creek prospect is at the head of several, north-flowing tributaries to Story Creek. The most extensive mineralization is about 1.6 miles north of peak 1272 (in meters), about 0.5 mile southwest of the center of section 23, T. 12 S., R. 26 W.

Commodities:

Main: Pb, Zn

Other: Ag, Au, Cu

Ore minerals: Anglesite, barite, cerussite, chalcopyrite, galena, hematite, hydrozincite?, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Story Creek prospect was found in 1978 by the U.S. Bureau of Mines and was studied by them and the U.S. Geological Survey at various times through 1995 (Ellersieck and others, 1982; Kurtak and others, 1995). Anaconda Minerals, the Arctic Slope Regional Corporation, and Kennecott Exploration explored the deposit from 1980 to 1992. This work included geologic mapping in the area, extensive geochemical and geophysical surveys, and much sampling. The work included beneficiation tests of a bulk sample by the U.S. Bureau of Mines.

The mineralization is largely confined to the Lower Mississippian Isikut Formation, which is overlain by the Mississippian Kayak Shale and underlain by the the Struver Member of the Upper Devonian Kanayut Conglomerate (Ellersieck and others, 1982; Kurtak and others, 1995). The Isikut Formation is thrust over younger rocks and as a result is intensely deformed into an imbricate stack of overturned folds. Numerous minor thrust faults separate the folds. The mineralization occurs as a series of elongate bodies that generally parallel the axes of the folds in the area; the bodies trend about N55E. The bodies vary from 5 to more than 60 meters wide and are irregularly aligned for about 2,000 meters along strike. Most of the mineralization is seen in float and rubblecrop; there is only minor outcrop. The mineralized zones may once have been continuous but have been displaced by northwest-trending high-angle faults. The numerous mineralized bodies are scattered over a east-northeast-trending area about 1,000 meters wide by 2,000 meters long. The largest body is about 400 meters long and about 100 meters wide.

The mineralization occurs as quartz veinlets, banded massive-sulfide veins, and quartz-sulfide breccia. Sphalerite and galena are the dominant ore minerals (Ellersieck and others, 1982; Kurtak and others, 1995). Less abundant are chalcopyrite and pyrite; barite, hematite, cerussite, anglesite, and hydrozincite(?) are present. The mineralization is associated with widespread silicification. The sulfide veins consist mainly of massive sphalerite with lesser galena and quartz. The breccia mineralization generally consists of sphalerite and galena as interstitial cement to the broken host rock; some of the breccia consists of sphalerite clasts rimmed with galena. Open-space-filling textures and the low degree of alteration indicates that the mineralization is epigenetic. Some of the more notable samples include: 1) samples of banded, vein-type mineralization contained 30 percent lead, 696 grams of silver per tonne, 55.6 percent zinc, and 775 parts per billion (ppb) gold; 2) a series of continuous chip samples across 8.5 meters of rubblecrop averaged 14.2 percent zinc, 3.9 percent lead, 159 grams of silver per ton, and 111 ppb gold. Lead isotope analyses of

galena give a late Mississippian model age for the lead of about 310-320 Ma.

In an unpublished report (cited in Kurtak and others, 1995), Kennecott Minerals estimated an indicated resource of 1.05 million tonnes with a grade of 8.1 percent zinc, 12.4 percent lead, and 1,028 grams of silver per ton; they estimated an addition inferred resource of 11 million tonnes. The U.S. Bureau of Mines estimated an inferred resource of 2.9 million tonnes with a grade of 14.2 percent zinc, 3.9 percent lead, and 159 grams of silver per tonne (Kurtak and other, 1995).

Alteration:

Mineralization is accompanied by widespread silicification.

Age of mineralization:

Mississippian or younger based on the age of the host rock and Mississippian based on lead-isotope analyses of galena.

Generic deposit model:

Deposit model:

Epigenetic, sediment-hosted vein and brecciated Pb-Zn-Ag deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The Story Creek prospect was found in 1978 by the U.S. Bureau of Mines and was studied by them and the U.S. Geological Survey at various times through 1995. Last report date: 2010-04-18

Site name(s): Unnamed (west end of Koiyaktot Mountain)

Site type: Occurrence

ARDF no.: HW017

Latitude: 68.2169 **Quadrangle:** H A-1

Longitude: 156.2926

Location description and accuracy:

This occurrence is plotted near the center of a north-trending area about 0.7 mile long in the west portion of Koiyaktot Mountain; it is about 4.4 mile northeast of Inyorurak Pass near the center of section 34, T. 33 N., R. 11 E.

Commodities:

Main: Ag, Pb, Zn

Other: Au, Cu

Ore minerals: Galena, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area consist of northwest-trending, southwest-dipping Upper Devonian to Lower Mississippian, Kanayut Conglomerate and Noatak Sandstone that are repeated by thrust faults. Four small, separate zones of mineralization occur along a north-trending zone about 0.7 mile long (Kurtak and others, 1995). The mineralization is in sandstone and consists of quartz-cemented breccia with sphalerite and galena. Samples from one area about 15 meters by 90 meters in size contained 43.9 percent zinc, 3.27 percent lead, and 404 parts per million (ppm) copper. About 950 meters to the north, samples from another area about 15 meters by 152 meters in size contained up to 16.2 percent zinc, 64.4 grams of silver per tonne, and 336 parts per billion gold.

Alteration:

Not noted.

Age of mineralization:

Possibly Mississippian by analogy with other lead-zinc deposits in the western Brooks Range.

Generic deposit model:

Deposit model:

Remobilized, lead-zinc sandstone deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling and mapping by the U.S. Bureau of Mines.

Production notes:

None.

Reserves:

None.

Additional comments:

MAS number 0020200015.

Site name(s): Unnamed (east end of Koiyaktot Mountain)

Site type: Occurrence

ARDF no.: HW018

Latitude: 68.1891 **Quadrangle:** H A-1

Longitude: 156.1382

Location description and accuracy:

This occurrence is at the east end of Koiyaktot Mountain about 0.9 mile southeast of peak 1302 (in meters). It is near the center of section 9, T. 32 N., R. 12 E.

Commodities:

Main: Ag, Pb, Zn

Other: Cu, Sb

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The rocks in the area are northwest-trending, southwest-dipping Upper Devonian to Lower Mississippian Kanayut Conglomerate and Noatak Sandstone that are repeated by thrust faults. Quartz veins and breccia with sphalerite and galena occur in siltstone of the Noatak Sandstone (Kurtak and others, 1995). The mineralization occurs in float and rubblecrop of unknown extent along a north-trending zone. Samples contained up to 39.9 percent lead, 23.9 percent zinc, 1,404 parts per million (ppm) cadmium, and 1,838 grams of silver per tonne. A breccia sample contained 1,3756 ppm copper and one sample of sphalerite and galena contained more than 2,000 ppm antimony.

Alteration:

Age of mineralization:

Possibly Mississippian by analogy with other lead-zinc deposits in the western Brooks Range.

Generic deposit model:

Deposit model:

Remobilized, lead-zinc sandstone deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Site name(s): Unnamed (west of Kivliktort Mountain)

Site type: Occurrence

ARDF no.: HW020

Latitude: 68.3002 **Quadrangle:** H B-2

Longitude: 156.6432

Location description and accuracy:

This occurrence is about 3.2 miles west-northwest of the summit of Kivliktort Mountain, near the center of section 31, T. 34 N., R. 10 E.

Commodities:

Main: Ag, Pb, Zn

Other: Ba

Ore minerals: Barite, galena, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area consist of Upper Devonian to Lower Mississippian, Kayayut Conglomerate and Kayak Shale(?). The mineralization is mostly in massive to crossbedded sandstone of the Kanayut Conglomerate but some is in red-brown, carbonate-cemented, interbedded sandstone, siltstone, coal, and shale that may be part of the Kayak Shale, or a lateral equivalent (Kurtak and others, 1995).

The mineralization is along a probable, southeast-dipping, low angle thrust-faulted zone at the base of Kivliktort Mountain (Kurtak and others, 1995). The structure in the area is complex and there are numerous repeated sections of the Kayayut Conglomerate and Kayak Shale. There are four types of mineralization: breccia, vein, replacement, and disseminated. The mineralization is accompanied by silicification and bleaching of the sandstone. Abundant mineralized float with galena and sphalerite extends over a northeast-trending area about 20 meters by 100 meters in size. Breccia along the thrust faults is cemented by quartz, sphalerite, and galena. Disseminated sphalerite occurs in sandstone near the thrust faults and sphalerite replaces coal. Sphalerite veins and late barite veins occur locally. Selected samples contained up to 31.5 percent zinc, 2.8 percent lead, and 26.1 grams of silver per tonne. There is considerable evidence for remobilization of the sulfides from what may have originally been a sandstone-type lead-zinc deposit. Lead isotope values from galena are: Pb 206/204 = 18.632; Pb 207/204 = 15.617, and Pb 208/204 = 38.353. These data suggest a Mississippian to Pennsylvanian model age and remobilization of the sulfides.

Alteration:

Widespread silicification and bleaching of the sandstone.

Age of mineralization:

Probably Mississippian by analogy with other lead-zinc deposits in the western Brooks Range.

Generic deposit model:

Deposit model:

Remobilized, lead-zinc sandstone deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling and mapping by the U.S. Bureau of Mines is documented.

Production notes:

None.

Reserves:

None.

Additional comments:

Last report date: 2010-04-18

Site name(s): Unnamed (east of Kivliktort Mountain)

Site type: Occurrence

ARDF no.: HW021

Latitude: 68.2576 **Quadrangle:** H B-1

Longitude: 156.4527

Location description and accuracy:

This occurrence is about 2.4 miles east-southeast of the summit of Kivliktort Mountain in the headwaters of a small unnamed stream; it is about 0.1 mile southwest of the center of section 13, T. 33 N., R. 10 E.

Commodities:

Main: Ag, Pb, Zn

Other: Cd, Cu

Ore minerals: Galena, malachite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area are Upper Devonian to Lower Mississippian, Noatak Sandstone overlain by Kanayut Conglomerate. The rocks are thrust faulted and some of the mineralization is along a thrust surface.

Float of mineralized, brecciated, quartz-cemented sandstone occurs along a small creek (Kurtak and others, 1995). A sample contained 19.6 percent zinc, 1,062 parts per million (ppm) cadmium, and 394 ppm copper. At an elevation of about 800 meters along the creek, quartz-cemented sandstone rubble over an area about 5 meters by 15 meters contained up to 4.3 percent lead and 82.6 ounces of silver per ton. A rubble sample of iron-stained conglomerate at the head of the creek contained 0.4 percent zinc.

Alteration:

Probably some silicification in addition to quartz veining.

Age of mineralization:

Late Devonian or younger based on the age of the host rock; possibly Mississippian by analogy with other lead-zinc deposits in the western Brooks Range.

Generic deposit model:

Deposit model:

Sandstone lead-zinc deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling and mapping by the U.S. Bureau of Mines.

Production notes:

None.

Reserves:

None.

Location description and accuracy:
The Lakeview barite occurrence is about 0.4 mile northeast of lake 573. It is about 0.6 mile east-northeast of the center of section 3, T. 10 S., R. 24 W.

Commodities:

Main: Ba

Other:

Ore minerals: Barite

Gangue minerals:

Geologic description:
The Lakeview barite occurrence is in Lower to Upper Mississippian black chert and minor tuffaceous volcanic rocks of the Lisburne Group (Kurtak and others, 1995). The barite occurs in a single bed 7.6 to 18.3 meters thick that can be traced for about 427 meters. A grab sample contained 95.8 percent barite with a specific gravity of 4.0 The Lakeview occurrence may be part of the same bed exposed at the Longview occurrence (HW034) about 0.7 mile to the north-northeast but the intervening distance is covered by tundra. Kelly and others (1993) estimated that the Lakeview occurrence has an inferred reserve of 3,778,000 metric tons of barite with a specific gravity of 4.13.

Alteration:
Unaltered.

Age of mineralization:
Mississippian.

Generic deposit model:

Deposit model:
Sedimentary barite (Cox and Singer, 1986; model 31b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
31b

Site name(s): Abby Creek

Site type: Occurrence

ARDF no.: HW024

Latitude: 68.5615 **Quadrangle:** H C-3

Longitude: 157.5301

Location description and accuracy:

This barite occurrence is on a small knoll between two minor tributaries in the headwaters of Cutaway Creek. The occurrence is about 1.0 mile north of hill 1064 (in meters) about 0.3 mile east-northeast of the center of section 21, T. 10 S., R. 24 W.

Commodities:

Main: Ba

Other:

Ore minerals:

Gangue minerals: Calcite

Geologic description:

This barite occurrence is in black siliceous mudstone and chert of the Mississippian Lisburne Group in an area of imbricate thrust faulting (Kelly and others, 1993; Kurtak and others, 1995). The barite is exposed in rubble crops and float over an area about 64 by 155 meters in size; the barite probably forms a lens about 30 meters thick. Kelly and others (1993) estimate that the deposit has an inferred resource of about 406,000 tonnes with a grade of 95.1 percent barite.

Alteration:

Age of mineralization:

Syngenetic deposit in Mississippian rocks.

Generic deposit model:

Deposit model:

Sedimentary barite (Cox and Singer, 1986; model 31b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31b

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling by the U.S. Bureau of Mines and the U.S. Geological Survey.

Production notes:

None.

Reserves:

Kelly and others (1993) estimate that the deposit has an inferred resource of about 406,000 tonnes with a grade of 95.1 percent barite.

Additional comments:

MAS number 0020200019.

Last report date: 2010-04-18

Site name(s): Bion

Site type: Occurrence

ARDF no.: HW025

Latitude: 68.6034 **Quadrangle:** H C-3

Longitude: 157.5932

Location description and accuracy:

The Bion occurrence is about 2.4 miles west of Lake 573 between the two main headwater forks of Cutaway Creek. It is about 0.5 mile west of the center of section 5, T. 10 S., R. 24 W. The location is accurate.

Commodities:

Main: Ba

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The rocks in the vicinity of the Bion barite occurrence are chert, organic shale, and petroliferous limestone of the Upper Mississippian or Lower Pennsylvanian, Lisburne Group (Kelly and others, 1993; Kurtak and others, 1995). The occurrence is a series of mounds of barite rubblecrop about 70 meters by 130 meters in size. Kurtak and others (1995) estimate that the largest barite body is at least 41 meters thick and is intermittently exposed for about 343 meters along strike. At the largest mound, the barite is interbedded with shale, chert, and limestone. It is uncertain whether there are separate lenses of barite or a single body repeated by thrusting. A 1.2 mGal gravity anomaly coincides with the western part of the barite body. Kelly and others (1993) estimate that the occurrence has an inferred resource of about 10,051,000 tonnes of barite.

Alteration:

Age of mineralization:

Bedded deposit in Late Mississippian or Early Pennsylvanian sedimentary rocks.

Generic deposit model:

Deposit model:

Bedded barite (Cox and Singer, 1986; model 31b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31b

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling by government agencies.

Production notes:

None.

Reserves:

Kelly and others (1993) estimate that the occurrence has an inferred resource of about 10,051,000 metric tons of barite.

Additional comments:

MAS number 0020200020.

Site type: Occurrence

ARDF no.: HW026

Latitude: 68.6001 **Quadrangle:** H C-3

Longitude: 157.5012

Location description and accuracy:

The Stack barite occurrence is near a limestone monolith (the Stack) just south of lake 573 which is about 3.1 mile northwest of Rim Butte. The occurrence is about 0.5 mile southwest of the center of section 3, T. 10 S., R. 24 W.

Commodities:

Main: Ba

Other:

Ore minerals:

Gangue minerals: Calcite

Geologic description:

The rocks in the area are part of the Lower to Upper Mississippian Lisburne Group exposed in a fenster (Kelly and others, 1993; Kurtak and others, 1995). The barite is exposed in a series of rubblecrop mounds, interbedded with petroliferous limestone, chert, sandstone, and carbonaceous shale. The rubblecrop exposures suggest that the barite bed is about 30 meters thick and extends along strike for about 136 meters. Grab samples averaged 95.8 percent barite. The barite bed has an indicated resource of 2,900,000 metric tons with a specific gravity of 4.21 (Kurtak and others, 2002).

Alteration:

Unaltered.

Age of mineralization:

Mississippian.

Generic deposit model:

Deposit model:

Sedimentary barite (Cox and Singer, 1986; model 31b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31b

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling and mapping by the U.S. Geological Survey and U.S. Bureau of Mines.

Production notes:

None.

Reserves:

The barite bed has an indicated resource of 2,900,000 metric tons with a specific gravity of 4.21 (Kurtak and others, 2002).

Additional comments:

Last report date: 2010-04-18

Site name(s): Ekakevik

Site type: Occurrence

ARDF no.: HW028

Latitude: 68.6211 **Quadrangle:** H C-4

Longitude: 156.9482

Location description and accuracy:
The Ekakevik occurrence is in a series of low ridges about 2.6 miles north-northeast of the highest peak of Ekakevik Mountain; it is near the center of section 36, T. 9 S, R. 22 W.

Commodities:

Main: Ba

Other:

Ore minerals: Barite, witherite

Gangue minerals:

Geologic description:
The Ekakevik occurrence consist of barite and minor witherite, interbedded with Mississippian Lisburne Group chert, shale, and limestone (Kelly and others, 1993, Kurtak and others, 1995). Bedding is not exposed but the barite is estimated to be about 20 meters thick and can be traced for about 165 meters along strike. The deposit has an indicated resource of 2,275,000 metric tons of barite with a specific gravity of 3.9.

Alteration:

Age of mineralization:
Mississippian?

Generic deposit model:

Deposit model:
Bedded barite (Singer and Cox, 1986; model 31b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
31b

Production Status: None

Site Status: Inactive

Workings/exploration:
Only sampling by government agencies.

Production notes:

None.

Reserves:

The deposit has an indicated resource of 2,275,000 metric tons of barite with a specific gravity of 3.9.

Additional comments:

MAS number 0020200023.

Site name(s): Unnamed (headwaters of Safari Creek)

Site type: Occurrence

ARDF no.: HW030

Latitude: 68.3498 **Quadrangle:** H B-3

Longitude: 157.7223

Location description and accuracy:

This occurrence is on an unnamed tributary in the headwaters of Safari Creek. It is about 0.9 mile east-northeast of peak 950 and about 0.5 mile northeast of the center of section 16. T. 34 N., R. 5 W.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals:

Geologic description:

This occurrence is at the eastern margin of the Safari Creek Window where Upper Devonian Noatak Sandstone is thrust over Early Mississippian Kayak Shale (Kurtak and others, 1995). The Noatak Sandstone here consists of thick bedded, light gray to white sandstone with numerous quartz veinlets.

A 3-meter-wide zone with massive pods and lenses of galena, sphalerite, and minor chalcopyrite can be traced for 350 meters in float and rubble of silicified Noatak Sandstone. A 1.1-meter-thick chip sample across this zone assayed 25.2 percent lead, 8.5 percent zinc, 178 grams of silver per ton, and 925 parts per million copper. Several faults are present and there is evidence of post-mineralization movement. There is also stringer and disseminated mineralization adjacent to the massive mineralization. A 7.80-meter-wide chip sample averaged 11 percent lead, 7 percent zinc, and 274 grams of silver per ton. A VLF geophysical survey line across the mineralization showed no response.

Lead-isotope values on galena are: Pb 206/204 = 18.281; Pb 207/204 = 15.608; and Pb 208/204 = 38.152. Kurtak and others (1995) suggest that these values could be explained mixing upper crustal lead with lead such as found in Devonian volcanogenic-massive-sulfide deposits in the Ambler District on the south side of the Brooks Range. They also suggest that the mineralization is the result of hydrothermal fluids which flowed along the thrust fault during the Cretaceous, Brooks Range orogeny.

Alteration:

The Noatak Sandstone host rock is silicified.

Age of mineralization:

Younger than the Devonian host rock and probably Cretaceous.

Generic deposit model:

Deposit model:

Epigenetic, galena-sphalerite pods and lenses in Upper Devonian sandstone.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only sampling and examination by government agencies.

Production notes:

None.

Reserves:

None.

Site type: Occurrence

ARDF no.: HW031

Latitude: 68.3828 **Quadrangle:** H

Longitude: 158.2917

Location description and accuracy:
This occurrence is about 0.6 mile northeast of Triangulation Station Apex and about 7.4 miles north of the north end of Feniak Lake. It is about 0.7 mile southwest of the center of section 20, T. 12 S., R. 27 W.

Commodities:

Main: Cu, Pd, Pt

Other: Ni

Ore minerals: Malachite

Gangue minerals:

Geologic description:
This occurrence is in Jurassic olivine gabbro of the Misheguk Mountain allochthon. During a brief stop, Kurtak and others (1995) sampled gabbro with malachite staining. The sample contained 6,943 parts per million (ppm) copper, 15 parts per billion (ppb) platinum, 8 ppb palladium, and 24 ppm nickel.

Alteration:
None noted.

Age of mineralization:
Magmatic deposit in Jurassic gabbro.

Generic deposit model:

Deposit model:
Copper-platinum-palladium in gabbro (Singer and Cox, 1986, model 5a or 5b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
5a or 5b

Production Status: None

Site Status: Undetermined

Workings/exploration:
Only sampling by the U.S. Bureau of Mines.

Site name(s): Unnamed (near Ipnavik River)

Site type: Occurrences

ARDF no.: HW032

Latitude: 68.3571 **Quadrangle:** H B-3

Longitude: 157.27177

Location description and accuracy:

These occurrences are in a saddle about 3.3 miles south of the mouth of Friendly Creek on the Ipnavik River. They are near the center of section 9, T. 34 N., R. 7E. The location is accurate.

Commodities:

Main: Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area consist of undivided, Upper Devonian to Lower Mississippian, Kanayut Conglomerate and Noatak Sandstone, and mafic igneous rocks. Kurtak and others (1995) describe scattered occurrences of disseminated sphalerite with minor galena and pyrite, along a west-northwest, 1000-meter-long trend through a saddle. The sulfides are in a gossanous silicified sandstone that locally contains boxworks structures with sphalerite. Samples contained up to 3.4 percent zinc and 1,920 parts per million lead.

Alteration:

Age of mineralization:

Late Devonian to Early Mississippian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Sandstone lead-zinc deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only limited sampling by U.S. Bureau of Mines.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (near Ipnavik River)

Site type: Occurrences

ARDF no.: HW033

Latitude: 68.3631 **Quadrangle:** H B-3

Longitude: 157.351

Location description and accuracy:

These occurrences are about 0.8 mile east of peak 1143 (in meters) and about 3.7 miles south-southwest of the mouth of Friendly Creek on the Ipnavik River. They are about 0.5 mile northwest of the center of section 7, T. 34 N., R. 7 E.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals:

Geologic description:

The rocks in the area are Upper Devonian to Lower Mississippian, Kanayut Conglomerate, Noatak Sandstone, and Kayak Shale that are in both stratigraphic and fault contact. The rocks have been folded into a southwest plunging anticline that is exposed in a window through a thrust fault whose upper plate is Noatak Sandstone and Kanayut Conglomerate.

At the most prominent area of mineralization, massive layers, stringers, and disseminated galena and minor sphalerite and chalcopyrite occur in silicified and brecciated Noatak(?) sandstone just above a siltstone that may be part of the Kayak Shale or Noatak Sandstone (Kurtak and others, 1995). Near the mineralization, the sandstone is brecciated and silicified, giving the rocks a bleached appearance. Samples from an area about 3 meters by 92 meters in size contained up to 36 percent lead, 4 percent zinc, and 439 grams of silver per tonne. A representative chip sample across a 2-meter-wide zone of rubblecrop contained 9.5 percent lead and 140 grams of silver per tonne. A sample of apparently barren, silicified sandstone about 10 meters from the sulfide-bearing sandstone contained 1,466 parts per million (ppm) lead and 1,526 ppm zinc. Several other samples of bleached sandstone collected in an area about a mile long also contained anomalous lead and zinc. An isotopic analysis of galena gave the following values: Pb 206/204 = 18.482; Pb 207/204 = 15.586, and Pb 208/204 = 38.233. These values indicate a Mississippian model age which is comparable to other Mississippian shale-hosted deposits and vein occurrences in Devonian sandstone and conglomerate in the western Brooks Range.

Alteration:

The sandstone near the mineralization is silicified, brecciated, and bleached.

Age of mineralization:

Probably Mississippian based on lead isotope analyses.

Generic deposit model:

Deposit model:

Sandstone lead-zinc deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only sampling by the U.S. Bureau of Mines.

Production notes:

None.

Reserves:

None.

Last report date: 2010-04-18

Site name(s): Longview

Site type: Occurrence

ARDF no.: HW034

Latitude: 68.6159 **Quadrangle:** H C-3

Longitude: 157.4548

Location description and accuracy:

The Longview barite occurrence is about 1.4 miles north-northeast of lake 573. It is near the center of section 35, T. 9 S., R. 24 W.

Commodities:

Main: Ba

Other:

Ore minerals: Barite

Gangue minerals:

Geologic description:

The Longview barite occurrence is underlain by orange-weathering siliceous mudstone and is overlain by light gray, green, and black chert (Kelly and others, 1993; Kurtak and others, 1995). The sedimentary rocks are part of the Mississippian Lisburne Limestone. The barite occurrence is a tabular body that is along or parallels imbricate thrust sheets. The barite body strikes about N35E and dips 65SE; it is estimated to be about 27 meters thick and is intermittently exposed for about 686 feet. A chip sample across 3 meters contained 97.1 percent barite. The Lakeview occurrence (HW023) about a 0.7 mile to the south-southwest may be part of the same bed but the intervening distance is covered by tundra. The Longview barite bed is estimated to have an inferred reserve of 29,5000 tonnes of barite with a specific gravity of 4.13 (Kelly and others, 1993; Kurtak and others, 1995).

Alteration:

Unaltered.

Age of mineralization:

Mississippian.

Generic deposit model:

Deposit model:

Sedimentary barite (Cox and Singer, 1986; model 31b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31b

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only sampling and mapping by the U.S. Geological Survey and U.S. Bureau of Mines.

Production notes:

None.

Reserves:

The Longview barite bed is estimated to have an inferred reserve of 29,5000 tonnes of barite with a specific gravity of 4.13 (Kelly and others, 1993; Kurtak and others, 1995).

Additional comments:

Site name(s): Unnamed (in tributary to Memorial Creek)

Site type: Occurrence

ARDF no.: HW035

Latitude: 68.345 **Quadrangle:** H B-3

Longitude: 157.4439

Location description and accuracy:
This unnamed occurrence is in one of the small tributaries at the head of Memorial Creek, about a mile south of peak 1305 (in meters). It is about 0.5 mile east of the center of section 15, T. 34 N., R. 6 E.

Commodities:

Main: Ba, Pb, Zn

Other: Sr

Ore minerals: Sphalerite

Gangue minerals:

Geologic description:
The rocks in the area are interbedded sandstone, siltstone, and shale of the Upper Devonian or Lower Mississippian, Kanayut Conglomerate (Kurtak and others, 1995). In following up a geochemical anomaly, samples were collected from rubblecrop of red-brown siltstone; they contained 9,423 parts per million (ppm) zinc, 1,122 ppm barium, and more than 2,000 ppm strontium. No sulfides were identified but the high zinc content indicates fine-grained sphalerite. Not enough work was done to determine the extent of the mineralization.

Alteration:
Not noted.

Age of mineralization:
Possibly Devonian or Mississippian based on the age of the host rock and by analogy to other zinc deposits in the western Brooks Range.

Generic deposit model:

Deposit model:
Zinc sandstone deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:
Only sampling and mapping by the U.S. Bureau of Mines is documented.

Production notes:

None.

Reserves:

None.

Additional comments:

MAS number 0020200016.

Site name(s): Unnamed (in headwaters of Tukuto Creek)

Site type: Occurrence

ARDF no.: HW036

Latitude: 68.3651 **Quadrangle:** H B-2

Longitude: 157.1652

Location description and accuracy:

There are some inconsistencies in the location given in Kurtak and others (1995) but this occurrence probably is about 0.8 mile northeast of hill 809 (in meters) in the headwaters of Tukuto Creek. This location is accurate to within a half mile and the occurrence is probably in the northwest quarter of section 12, T. 34 N., R. 7 E.

Commodities:

Main: Pb, Zn

Other:

Ore minerals: Galena?, sphalerite?

Gangue minerals:

Geologic description:

Kurtak and others (1995) briefly examined this site and collected a sample of iron-stained lithic tuff that contained 1,838 parts per million (ppm) zinc and 1,686 ppm lead. No ore minerals were visible in the sample but the values are distinctly anomalous and suggest a continuation of the mineralization they discovered several miles to the west (HW032 and HW033). Most of the rocks in the area are Lower Mississippian Kayak Shale.

Alteration:

None noted.

Age of mineralization:

Insufficient data.

Generic deposit model:

Deposit model:

Zinc and lead mineralization in lithic tuff.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only sampling by the U.S. Bureau of Mines.

Last report date: 2010-04-18

Site name(s): Tolstoi

Site type: Prospect

ARDF no.: ID008

Latitude: 62.91543 **Quadrangle:** ID D-2

Longitude: 156.98975

Location description and accuracy:

The Tolstoi prospect is at an elevation of about 3,400 feet on a steep saddle at the head of one of the headwater tributaries of Tolstoi Creek. It is about 0.5 mile south-southeast of peak 3970 and 0.1 mile northwest of the southeast corner of section 26, T. 33 N., R. 41 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, As, Cu

Other: Au, Be, Bi, Cd, Pb, Sb, Sn, Te

Ore minerals: Arsenopyrite, boulangerite, chalcopyrite, galena, pyrite, stromeyerite

Gangue minerals: Axinite, fluorite, quartz, tourmaline, white mica

Geologic description:

The Tolstoi prospect consists of several tabular-to-pipe- shaped, sulfide-bearing, tourmaline-quartz breccia zones in a cupola of the 70.3 Ma, Beaver Mountains stock (Bundtzen and Laird, 1982; Bundtzen and Miller, 1997; Miller, Bundtzen, and Gray, 2005). The tourmaline-axinite-quartz breccia bodies are 6 to 65 feet thick and contain 1 to 8 percent arsenopyrite, chalcopyrite, and pyrite. Stromeryite and boulangerite, possibly the source of the high silver values in samples, have been identified in polished sections. The Tolstoi prospect is similar to a nearby unnamed prospect (ID006) although the sulfides at the Tolstoi prospect are more disseminated and the boron metasomatism in the form of tourmaline and axinite is more extensive. Grab samples of the mineralization at the Tolstoi prospect contained up to 10.0 percent copper, 500 parts per million (ppm) silver, 2.0 percent arsenic, more than 2.0 percent lead, 2.0 percent zinc, 1.0 percent antimony, 1,400 parts per billion (ppb) gold, 39 ppm bismuth, 200 ppm cadmium, and 200 ppm tin (McGimsey and others, 1988; Bundtzen and Laird, 1982). Grab samples collected by Battle Mountain Mining Company in 1990 contained up to 1,137 ppb gold, 86.1 ppm silver, 2.03 percent lead, more than 2.00 percent arsenic, and 81 ppm tin (Szumigala, 1993).

In 2007, Alaska Ventures, Inc. (Bundtzen, 2008) staked 84 Alaska mining claims that covered much of the north-central Beaver Mountains and most of the high-grade copper-silver-gold(-tin) prospects and occurrences in the area. Two high-grade samples were analyzed that came from veinlets in the Tolstoi deposit. They contained 3.09 to 4.43 grams of silver per ton, 5.91 to 87.3 grams of bismuth per ton, and 0.13 to 7.17 grams of tellurium per ton. The high bismuth and tellurium values suggest silver-rich zones in the deposit.

Alteration:

Extensive greisen development marked by tourmaline, quartz, white mica, and fluorite.

Age of mineralization:

Undated; may be related to emplacement of the Beaver Mountains stock, which has been dated at 70.3 Ma. (Bundtzen and Laird, 1982).

Generic deposit model:

Deposit model:

Sn-polymetallic veins (Cox and Singer, 1986; model 20b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20b

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was mapped and sampled by the Alaska Division of Geological and Geophysical Surveys and the U.S. Geological Survey from 1979 to 1986. Anaconda Minerals Company sampled and mapped the prospect in 1981 (D. Obolewicz, oral communication, 1981). Noranda Exploration examined the property in 1983 (John Dunbier, oral communication, 1983). The prospect was studied by Battle Mountain Mining Company in 1990 (Szumigala, 1993,1996). In 2007, Alaska Ventures, Inc. (Bundtzen, 2008) staked 84 Alaska mining claims that covered much of the north-central Beaver Mountains and most of the high-grade copper-silver-gold(-tin) prospects and occurrences in the area, including the Tolstoi deposit.

Production notes:

None.

Reserves:

None.

Gangue minerals: Axinite, fluorite, quartz, tourmaline

Geologic description:

The Cirque prospect consists of a series of parallel, tourmaline-axinite- quartz-sulfide fracture fillings and breccia bodies in monzonite and quartz syenite of the Beaver Mountains stock. The major fractures strike N75E and dip steeply to vertically; they are discontinuously exposed for about 2 miles. An unnamed deposit about a mile to the northeast may be an easterly extension of this mineralized zone. The Cirque prospect is one of the best-exposed lode deposits in the Iditarod quadrangle.

The most extensive zone of mineralization lies along the side of a steep cirque headwall where nearly massive chalcopyrite-tourmaline pods up to 6 feet wide are exposed for almost 65 feet along strike. Lesser amounts of galena, pyrite, sphalerite, and bismuth-antimony sulfosalts, including boulangerite and stromeyerite, are in a gangue of tourmaline, fluorite, and quartz. Axinite alteration is conspicuous in the walls of the deposit. Excellent exposures allow for a three-dimensional estimate of the size of the main zone; it is about 500 feet long, 10 feet thick, and extends for about 800 feet vertically. Szumigala (1993) placed the Cirque prospect in the center of a large mineralized area he called the 'south quartz zone'. Samples contained up to 21.0 percent copper, 1,108 parts per million (ppm) silver, 1,400 parts per billion (ppb) gold, more than 2,000 ppm arsenic, 570 ppm bismuth, 60 ppm cadmium, more than 2.00 percent lead, 0.70 percent antimony, 200 ppm tin, 100 ppm tungsten, and 0.50 percent zinc (Bundtzen and Laird, 1982; Bundtzen and Miller, 1997; McGimsey and others, 1988; Miller, Bundtzen, and Gray, 2005).

Systematic surface sampling and excellent exposure suggests an inferred resource of 190,000 tons of material with an average grade of 3.50 percent copper and 445 ppm silver in the main mineralized zone at the Cirque prospect (Bundtzen and Miller, 1997; Miller, Bundtzen, and Gray, 2005).

In 2007, Alaska Ventures, Inc. (Bundtzen, 2008) staked 84 Alaska mining claims that covered much of the north-central Beaver Mountains and most of the high-grade copper-silver-gold(-tin) prospects and occurrences there. Four high-grade samples were analyzed that came from veinlets at the Cirque deposit. They contained 2.67 to 47.80 grams of silver per ton, 38.6 to 464 grams of bismuth per ton, and 0.47 to 88.1 grams of tellurium per ton. The high bismuth and tellurium values suggest silver-rich zones in the deposit and the minerals hessite (Ag2S) and weibullite (Pb6Bi8(S,Se)18) were identified in the samples by microprobe.

Alteration:

Greisenization marked by tourmaline, quartz, and white mica in the mineralized zone, and by axinite in the wall rocks.

Age of mineralization:

Undated; may be related to emplacement of the Beaver Mountains stock that has been dated at 70.3 Ma (Bundtzen and Laird, 1982).

Generic deposit model:

Deposit model:

Sn-polymetallic veins (Cox and Singer, 1986; model 20b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20b

Production Status: None

Site Status: Active

Workings/exploration:

Several groups have conducted surface sampling at the Cirque prospect. The U.S. Geological Survey and Alaska Division of Geological and Geophysical Surveys sampled the prospect between 1981 and 1986. Anaconda Minerals sampled the property in 1981. Noranda Exploration sampled the prospect in 1983 (John Dunbier, oral communication, 1983). Battle Mountain Mining Company sampled the prospect in 1990 (Szumigala, 1993). In 2007, Alaska Ventures, Inc. (Bundtzen, 2008) staked 84 Alaska mining claims that covered much of the north-central Beaver Mountains and most of the high-grade copper-silver-gold(-tin) prospects and occurrences in the area, including the Cirque deposit.

Production notes:

None.

Reserves:

The systematic surface sampling and excellent exposure suggests an inferred resource of 175,000 tonnes of material with an average grade of 3.50 percent copper and 445 ppm silver for the main mineralized zone at the Cirque prospect (Bundtzen and Miller, 1997; Miller, Bundtzen, and Gray, 2005).

Site name(s): Ganes Creek

Site type: Mine

ARDF no.: ID022

Latitude: 62.9673 **Quadrangle:** ID D-2

Longitude: 156.5226

Location description and accuracy:

The Ganes Creek placer extends along the valley bottom and on benches for about 6 miles in the Iditarod quadrangle. It extends about the same distance in the Ophir quadrangle to its mouth on the Innoko River which is about 5 miles southeast of Ophir. Most of the mining has taken place in the Iditarod quadrangle but much of the information of record cannot be assigned to one quadrangle. For this record, the site is placed near the mouth of Six Gulch in section 8, T. 33 N., R. 38 W., near the Discovery claim. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cr, Sb, W

Ore minerals: Arsenopyrite, gold, ilmenite, magnesiochromite, pyrite, scheelite, stibnite

Gangue minerals:

Geologic description:

Ganes Creek rises in the Beaver Mountains and flows northeasterly for more than 50 miles into the Innoko River. Upper Ganes Creek formerly flowed north into the Beaver Creek drainage from a point near the mouth of Last Chance Creek about 4 miles above the mouth of Spaulding Creek. At some time in the Pleistocene, headwater erosion captured the upper drainage of Ganes and Beaver Creeks. Prior to that time, ancestral Ganes Creek eroded sedimentary rocks of the Upper Cretaceous Kuskokwim Group and the igneous rocks intruded into them; the older bench gravels deposited during this time lack glacial material. Subsequent to capture, glacial debris from the Beaver Mountains entered lower Ganes Creek (Mertie, 1936; Bundtzen, 1980 [GR 63]).

The placer gold and associated heavy minerals in the Ganes Creek placer were probably liberated from bedrock prior to stream capture of upper Ganes Creek. Paleochannels that formed before capture contain rich gold deposits that in part were eroded into present Ganes Creek. The flood plain of Ganes Creek is composed mainly of coarse-grained, cobble gravels and sand with clasts of plutonic and volcanic rocks derived from the glaciated Beaver Mountains. The coarse gravels in the Ganes Creek flood plain are glacial outwash deposits of Late Pleistocene and early Holocene age (Mertie, 1936, Bundtzen, 1980 [GR 63]; Bundtzen and Miller, 1997). Although diluted with barren material, Ganes Creek was rich enough to support a dredge that mined a flood plain at least 500 feet wide (Mertie, 1936). The dredge encountered shallow bedrock at a depth of about 6 to 20 feet. Most of the pay was on slate bedrock; relatively fine gold, with a few nuggets to about 1.5 ounces, were accompanied by abundant black sand. Most alluvial gravels on the flood plain of Ganes Creek are thawed; tributary gulches contain some frozen ground.

At least two levels of ancestral paleochannels or terraces occur on the northwest and southeast flanks of Ganes Creek. Paleochannels are well exposed below the mouth of Spaulding Creek. All the clasts in these older fluvial paleochannels are of local origin and the older channels formed prior to the beheading of upper Beaver Creek in mid-to-Late Pleistocene time. The paleochannels are well known sources of coarse placer gold. The Baumeister Bench has produced gold-quartz nuggets that weighed up to 122 ounces. In 2002, gold nuggets that weighed up to 5.0 ounces were found by handheld metal detectors in Ganes Creek near the

present Ganes Creek mining camp. The coarse gold nuggets, often with significant intergrown coxcomb quartz attached to them, suggest an epithermal lode source.

The Ganes Creek placer gold varies from 817 to 874 fine, and averages 846 (Bundtzen, Cox, and Veach, 1987; Bundtzen and Miller, 1997). The heavy minerals also include magnesiochromite, scheelite, stibnite, and arsenopyrite. Most of the placer gold on Ganes Creek is believed to be derived from the mineralized sedimentary rocks and the igneous rocks along the northeast-trending Ganes-Yankee Creek fault (Bundtzen and Laird, 1982; Bundtzen and Miller, 1997). However, some placer gold in Late Quaternary alluvial deposits of Ganes Creek could be derived from gold lodes in the Beaver Mountains, (i.e., ID005; ID006, ID008, and ID012), as suggested by Szumigala (1993).

Placer gold was discovered on Ganes Creek during the summer of 1906 by Thomas Gane, F.C.H. Spencer, Mike Roke, and John Maki in gravel bars below the mouth of Ganes Creek (Maddren, 1910). In September 1906, the Discovery claim was located about 9 miles upstream near the mouth of Last Chance Gulch (now Six Gulch). The entire length of Ganes Creek was staked from source to mouth until it was found that gold-bearing gravel did not continue more than a mile upstream from the mouth of Spaulding Creek. Claims were numbered from 83 Above Discovery to 58 Below Discovery (Mertie, 1936).

Early mining was mainly from open cuts dug by horse-drawn scrapers, and the rich terraces such as the Baumeister Bench (ID027) were the first to be exploited (Eakin, 1914). Gold in the main valley proved more difficult to mine because the wet, thawed ground precluded simple open-cut mining.

The valley was later successfully mined by bucket line dredges. The first dredge, constructed by the Innoko Dredging Company and freighted in from Greenstone Creek in the Ruby district began operations during 1923 and mainly mined gravel upstream of Number 5 above Discovery. In 1926, the Guinan and Ames flume dredge, which formerly operated on the Seward Peninsula, was freighted into Ganes Creek and began operations on 13 Above Discovery (Mertie, 1936). Both dredges operated intermittently through World War II; the Innoko Dredging Company dredge was rebuilt by Warren Magnuson in 1955, and operated until 1965.

Mechanized, open cut mining began in the 1930s. Toivo Rosander, Neal Beaton, and Frank Molitor mined with bulldozer and dragline on Ganes Creek during the 1940s and early 1950s. Magnuson Mining Company operated mechanized placer mines on Ganes Creek nearly continuously from 1955 to 1990. The Clark-Wiltz partnership acquired the Magnuson claims in 1993 and in 1994 began mining with mechanized equipment. In 2010, Ganes Creek was still being mined from a conventional open pit by Clark-Wiltz Mining (Szumigala and others 2011). As of early 2012, the property consisted of 90 patented mining claims and 238 Alaska state mining claims.

Since 2002, Ganes Creek has also supported a recreational mine for clients with emphasis on metal detectors (Clark-Wiltz Mining, 2012). Yearly production information is not available for the conventional mine but the recreational mining which began in 2002 has been notably productive of large gold nuggets. Since 2002, 6 nuggets have been found that weighed from 20.1 to 88 ounces and in 2006, 120 ounces of gold were found during the recreational mining. As of early 2012, the property consisted of 90 patented mining claims and 238 Alaska state mining claims.

Continual mining suggests that upper Ganes Creek still has placer gold resources but they are not a matter of public record. Unidentified resources of placer gold probably exist on lower Ganes Creek; it has been drilled in recent years by Magnuson Mining Company and the Clark-Wiltz partnership but the results are not available.

Alteration:

Age of mineralization:

Paleochannel placer deposits probably formed in Pleistocene time prior to the capture of upper Ganes Creek. Older deposits were eroded and reconcentrated in the later Pleistocene (?) and Holocene.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au deposit (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Active

Workings/exploration:

Placer gold was discovered on Ganes Creek during the summer of 1906 by Thomas Gane, F.C.H. Spencer, Mike Roke, and John Maki in gravel bars below the mouth of Ganes Creek (Maddren, 1910). In September 1906, the Discovery claim was located about 9 miles upstream near Last Chance Gulch (now Six Gulch). The entire length of Ganes Creek was staked from source to mouth until it was found that gold-bearing gravel did not exist above a point about 1 mile upstream from the mouth of Spaulding Creek. Claims were numbered from 83 Above Discovery to 58 Below Discovery (Mertie, 1936).

During the first period of activity, mining was mainly from open cuts dug by horse-drawn scrapers, and the rich terraces such as the Baumeister Bench (ID027) were the first to be exploited (Eakin, 1914). Gold in the main valley proved more difficult to mine because the wet, thawed ground precluded simple open-cut mining.

The valley was later successfully mined by bucket line dredges. The first dredge, constructed by the Innoko Dredging Company and freighted in from Greenstone Creek in the Ruby district began operations during 1923 and mainly mined gravel upstream of Number 5 above Discovery. In 1926, the Guinan and Ames dredge, which formerly operated on the Seward Peninsula, was freighted into Ganes Creek and began operations on 13 Above Discovery (Mertie, 1936). Both dredges operated intermittently through World War II; the Innoko Dredging Company dredge was rebuilt by Warren Maguson in 1955, and operated until 1965. The remains of the old Guinan and Ames flume dredge can be found along the Ophir road.

Mechanized, open cut mining began in the 1930s. Toivo Rosander, Neal Beaton, and Frank Molitor mined with bulldozer and dragline on Ganes Creek during the 1940s and early 1950s. Magnuson Mining Company operated mechanized placer mines on Ganes Creek nearly continuously from 1955 to 1990. The Clark-Wiltz partnership acquired the Magnuson claims in 1993 and have operated mechanized placer mines on Ganes Creek and tributaries since 1994. In 2002, recreational miners recovered nuggets of coarse gold from tailings piles.

Ganes Creek is the largest producer of placer gold in the Innoko Mining District. From 1906 to 2002, Ganes Creek and its tributaries produced 104,000 ounces of gold and 13,318 ounces of silver from fluvial paystreaks in the Iditarod quadrangle; addition production has come from lower Ganes Creek in the Ophir quadrangle. The gold-bearing paystreaks can be traced for at least 7 miles in the Iditarod quadrangle and an additional 6 miles in the Ophir quadrangle, making it one of the longest gold placers in southwest Alaska (Bundtzen, 1980 [MIRL]; Bundtzen and Miller, 1997).

Production notes:

Ganes Creek is the largest producer of placer gold in the Innoko Mining District. From 1906 to 2002, Ganes Creek and its tributaries produced 104,000 ounces of gold and 13,318 ounces of silver from fluvial paystreaks in the Iditarod quadrangle; addition production has come from lower Ganes Creek in the Ophir quadrangle. Last report date: 2012-04-01

Site name(s): Independence Mine

Site type: Mine

ARDF no.: ID031

Latitude: 62.9442 **Quadrangle:** ID D-1

Longitude: 156.4772

Location description and accuracy:

The Independence Mine is on a northwest-trending ridge about 2.2 miles southwest of the junction of Ganes Creek and Six Gulch. It is at an elevation of about 1740 feet near the southwest corner of section 15, T. 33 N., R. 38 W., of the Seward Meridian. The mine is accurately located.

Commodities:

Main: Au

Other: Ag, As, Hg, Pb, Sb, Sn

Ore minerals: Arsenopyrite, chalcocite, chalcopyrite, cinnabar, gold, magnetite, pyrite, stephanite, stibnite

Gangue minerals: Quartz, siderite

Geologic description:

The deposit at the Independence Mine as a quartz-carbonate-sulfide vein about 1.5 to 3 feet thick on the hanging wall of an altered composite andesite-granite porphyry dike. According to Eakin (1914) the vein exposed in underground workings averaged about 2 feet thick. The dike strikes N55-70E and dips steeply SE. The granite porphyry which may be dominant phase averages about 32 feet thick and can be traced in rubble for about 1,000 feet. The altered andesite phase is exposed in trenches above the underground workings (Bundtzen and Laird, 1982).

About 1 to 5 percent sulfides, principally arsenopyrite, pyrite, and stibnite and minor cinnabar and stephanite, are disseminated in the vein and adjacent dike rock. Gold occurs in iron-stained crevices and vugs in quartz. Eakin (1914) reported microscopic native gold embedded in magnetite in vein material. Grab samples of the vein reported by McGimsey and others (1988) and Bundtzen and Miller (1997) contained up to 180.0 parts per million (ppm) gold, 13.0 ppm silver, 2.10 percent arsenic, 20 ppm bismuth, 0.56 percent antimony, more than 10.0 ppm mercury, 1,500 ppm lead, and 300 ppm tin.

The vein was developed by an adit and possibly several hundred feet of inclined and level workings. About 470 tonnes of ore mined in 1911 and 1912 produced 479 ounces of gold.

The Independence deposit is similar to other gold-polymetallic veins along the Ganes-Yankee Creek fault and dike swarm (Miller and Bundtzen, 1994; Bundtzen and Miller, 1997). Anomalous tin is present at the Independence Mine, and is known elsewhere in the region in rocks about 70 Ma, for example in felsic plutonic rocks at Donlin Creek prospect (ID167). Mineralization at the Independence and nearby deposits along the Ganes-Yankee Creek fault and dike swarm has been compared to the Donlin Creek mineralization by Miller and Bundtzen (1988) and Bundtzen and Miller (1997).

Warren Magnuson explored the mine area with trenches and open cuts in the 1960s and 1970s. Westgold explored the area in the early 1990s. Placer Dome Exploration conducted a detailed soil survey over the Independence Mine and drilled two core holes totaling about 500 feet in 1996-97 (St. George, 1998). Although the full details of the Placer Dome Exploration exploration are not available, gold-bearing veins are known to have been intersected below the mine workings.

In early 2010, the property was owned and operated by Clark-Winze Mining (Grady, 2009). In 2007 and 2008, Great Basin Gold Ltd. explored the property after compiling the work from the six exploration groups who had worked on the property since 1988. Their work consists of more than 32,000 meters of trenching

and continuous chip sampling of the trenches, as well as 83.6 line miles of IP, TMF, and HLEM ground geophysical surveys.

As described by Grady (2009), the Independence Mine and a newly discovered prospect on Potosi Ridge (ID181), are in the cores of major northeast-striking antiforms in Cretaceous Kuskokwim Group flysch. The hinges of the antiforms are thickened and marked by chevron folding and high angle faulting. In some cases, the cores of the some of the antiforms are deformed into brittle melange. The prospects are associated with northeast-striking swarms of mafic to granitic dikes and older biotite granodiorite to aplite sills. The dike swarms have been offset by numerous north-northwest high-angle faults and joints and often have marginal dip-slip faults.

The mineralization is marked by quartz-carbonate veins along fractures. The veins typically have early quartz-carbonate margins and later cores of clear to white quartz and carbonates. Occasionally, the veins contain late-stage gold and quartz, with iron carbonate and sericite. Sparse pyrite and arsenopyrite occur in the veins and wall rock. Rare, chalcopyrite, galena, and chalcocite are present in the high-grade veins. Samples from a 2-inch-wide quartz vein that extends for 6 meters along dip at the mine contained 592 to 2,140 ppm gold.

3D modeling of gridded IP surveys show that anomalies are associated with high copper, nickel, lead, and zinc values. Resistivity data outlines the the dike swarms; ground magnetic highs correspond to felsic intrusives and magnetic lows outline silicification and brecciation.

Alteration:

Local silicification and development of siderite and other carbonate minerals in an altered dike; secondary oxidation.

Age of mineralization:

The granite-porphyry dike at the Independence Mine has been dated at 70.4 Ma (T.K. Bundtzen, unpublished data, 1998).

Generic deposit model:

Deposit model:

Low sulfide gold-quartz vein (Singer and Cox (1986) model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes

Site Status: Active

Workings/exploration:

According to Eakin (1913), the underground work during 1912 consisted of a 60-foot adit, a 60-foot winze driven at the end of the adit, and two drifts about 30 and 50 feet long. The equipment at the mine site included a 12-horsepower engine and a Little Giant crusher and stamp mill. In 1979, the portal's entrance had caved and exposed the winze. Remnants of the stamp mill are about 650 feet south of the underground workings in a unnamed gulch.

Warren Magnuson explored the mine with trenches and open cuts in the 1960s and 1970s. Westgold explored the area in the early 1990s. Placer Dome Exploration conducted a detailed soil survey over the Independence Mine and drilled two core holes totaling about 500 feet in 1996-97 (St. George, 1998).

In early 2010, the property was owned and operated by Clark-Winze Mining (Grady, 2009). In 2007 and 2008, Great Basin Gold Ltd. explored the property after compiling the work from the six exploration groups who had worked on the property since 1988. Their work consists of more than 32,000 meters of trenching and continuous chip sampling of the trenches, as well as 83.6 line miles of ground IP, TMF, and HLEM geophysical surveys.

Production notes:

The only production was in 1911 and 1912 when the Carter Creek Mining Company produced 479 ounces of gold from the underground workings.

Reserves:

None published.

Site name(s): Broken Shovel

Site type: Prospect

ARDF no.: ID081

Latitude: 62.6148 **Quadrangle:** ID C-3

Longitude: 157.1711

Location description and accuracy:

The Broken Shovel prospect is about 0.3 mile southeast of hill 2225 and 1.2 mile northwest of the Moore Creek placer mine (ID084). It is at an elevation of about 1,700 feet, about 0.3 mile southwest of the center of section 9, T. 29 N., R. 42 W., of the Seward Meridian. The location is accurate. Work in 2007 nearby identified nearby mineralization in the Spring and Troy Zones.

Commodities:

Main: Ag, Au

Other: As, Cu, Pb, Sb, Zn

Ore minerals: Arsenopyrite, gold, lead-antimony sulfosalts, scheelite, tetrahedrite

Gangue minerals: Dolomite, quartz, tourmaline

Geologic description:

The Broken Shovel prospect is a N20E-trending, steeply dipping quartz-dolomite-sulfide vein in medium-grained monzonite of the Upper Cretaceous, Moore Creek pluton (Bundtzen, Laird, and Lockwood, 1988; Miller, Bundtzen, and Gray, in press). The pluton has been dated at 68.9 Ma (Miller, Bundtzen, and Gray, 2005) The Broken Shovel vein, as defined in prospect trenches and rubble, is about 5 feet thick and can be traced along strike for about 650 feet. Both walls of the vein are sericitized and a pocket of tourmaline is exposed near the its southwest end (Bundtzen, Laird, and Lockwood, 1988). Grab and chip-channel samples contained up to 555 parts per million (ppm) silver, 1,600 parts per billion (ppb) gold, 4,860 ppm copper, 1,430 ppm lead, 760 ppm zinc, 5,500 ppm arsenic, and 2,400 ppm antimony (Bundtzen, Laird, and Lockwood, 1988; McGimsey and others, 1988). Arsenopyrite, scheelite, visible gold, and lead-antimony sulfosalts have been identified in both hand specimen and by microprobe analysis; gold and tungsten values may be understated in the chemical analyses of the samples.

The Broken Shovel prospect has been investigated intermittently since the 1930s by placer miners from Moore Creek, notably Elmer Keturi and Jules Stuver, who prospected the lode in the 1940s and 1950s (Don Harris, oral communication, 1983). When the prospect was examined in 1983 by the Alaska Division of Geological and Geophysical Surveys, it had been explored both by modern bulldozer cuts and much older hand-dug prospect pits (Bundtzen, Laird, and Lockwood, 1988).

On the basis of numerous chip-channel surface samples, Bundtzen, Laird, and Lockwood, (1988) estimated that the Broken Shovel prospect contains an inferred resource of about 16,000 tons of material that contained about 150.0 ppm silver, and about 1.0 percent combined base metals. The average gold grade was not determined.

In early 2008, Full Metals and Highbury Projects, Inc. were jointly exploring the area under a letter of agreement (Full Metal Minerals, 2008, Moore Creek; 2008, Trenching) . They dug numerous trenches and identified three zones with multiple types of mineralization. In the Spring Zone, sheeted quartz-tourmaline veins contain coarse gold and disseminated sulfides. Several notable samples across widths of from 4.0 to 11.0 meters contained 2.17 to 8.86 grams of gold per ton. The mineralization in the Troy Zone consists of gold-quartz veins in a wider zone of lower grade gold mineralization. Notable samples of the veins included 0.2 meters with 88.5 grams of gold per ton and 0.2 meters with 36.0 grams of gold per ton; these occur

within a 3.0-meter-long channel sample that averaged 7.6 grams of gold per ton. The Broken Shovel zone is a steeply dipping quartz vein; twelve samples contained from a trace to 3.84 grams of gold per ton and 2.0 to 1,105 grams of silver per ton, along with anomalous bismuth, arsenic, and mercury.

Alteration:

The rocks adjacent to the vein have been altered to sericite, dolomite, and tourmaline.

Age of mineralization:

Unknown; the Moore Creek pluton that hosts some of the mineralization is 68.9 Ma (Bundtzen, Laird, and Lockwood, 1988).

Generic deposit model:

Deposit model:

Gold-silver-quartz veins with sulfides.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Broken Shovel prospect has been investigated intermittently since the 1930s by placer miners from Moore Creek, notably Elmer Keturi and Jules Stuver, who prospected the lode in the 1940s and 1950s (Don Harris, oral communication, 1983). When the prospect was examined in 1983 by the Alaska Division of Geological and Geophysical Surveys, it had been explored both by modern bulldozer cuts and by much older hand-dug prospect pits (Bundtzen, Laird, and Lockwood, 1988). The U.S. Geological Survey also investigated the prospect in 1985 (McGimsey and others, 1988). In early 2008, Full Metals and Highbury Projects, Inc. were jointly exploring the area under a letter of agreement (Full Metal Minerals, 2008, Moore Creek, 2008). They dug numerous trenches and identified three zones with multiple types of mineralization: the Spring, Troy, and Broken Shovel zones.

Production notes:

None.

Reserves:

Based on numerous chip-channel surface samples, Bundtzen, Laird, and Lockwood, (1988) estimated that the Broken Shovel prospect contains an inferred resource of about 16,000 tons of material with about 150.0 ppm silver, and about 1.0 percent combined base metals. The average gold grade was not determined.

Last report date: 2008-03-04

Site name(s): Unnamed (southwest of upper Granite Creek)

Site type: Prospect

ARDF no.: ID135

Latitude: 62.3645 **Quadrangle:** ID B-2

Longitude: 156.9514

Location description and accuracy:

This prospect is at an elevation of about 1,100 feet on a flat terrace east of the head of Granite Creek. It is about 0.7 mile southwest of hill 1235, near the center of the north boundary of section 7, T. 26 N., R. 41 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Hg, Sb

Ore minerals: Stibnite

Gangue minerals: Calcite, quartz

Geologic description:

This prospect consists of a series of shear zones associated with thin quartz-sulfide veinlets in a light-colored granitic rock of alaskite composition and quartz-calcite veins in sandstone (Bundtzen, Miller, and Laird, 1986; Miller and Bundtzen, 1994, and Miller, Bundtzen, and Gray, 2005). The alaskite forms two dikes, each about 30 feet thick; they contain thin, 0.4- to 1-inch-thick quartz-sulfide veins on fractures and joints. The dikes strike N82-88E and are vertical. Quartz-calcite veins occur in sandstone adjacent to the dike rocks. The dikes are part of the same dike swarm that hosts gold-antimony mineralization at the Wyrick lode nearby (ID133). Grab samples of mineralization contained 500 parts per billion (ppb) silver, 48 parts per million (ppm) antimony, 560 ppb mercury, and 40 ppm arsenic. Although gold was not detected in these samples, fine gold was panned from an exploration trench (L.E. Wyrick, oral communication, 1986; Bundtzen, Miller, and Laird, 1986).

Alteration:

Age of mineralization:

Unknown; a nearby intrusion has a 40K/40Ar age of 71.1 Ma (Miller and Bundtzen, 1994).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Prospect pits were sunk on the property sometime before 1984. In 1985, L.E. Wyrick cut a 160-feet-long trench, which was sampled by Bundtzen, Miller, and Laird (1986). Battle Mountain Mining Company explored the area in the 1980s (Szumigala, 1993).

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Unnamed (south of hill 1735)

Site type: Prospect

ARDF no.: ID139

Latitude: 62.366 **Quadrangle:** ID B-2

Longitude: 156.9318

Location description and accuracy:

This prospect is about 0.3 mile south of hill 1735, near the divide between head of Granite Creek and the Little East Fork of George River. The occurrence is at an elevation of about 1,400 feet, near the southwest corner of section 5, T. 26 N., R. 41 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Sn

Other: As, B, Cu, Hg, Pb, Sb, Zn

Ore minerals: Gold, pyrite, stibnite

Gangue minerals: Quartz, sericite, tourmaline

Geologic description:

This deposit was originally described as a quartz breccia zone with limonite and tourmaline in hornfelsed sandstone of the Upper Cretaceous, Kuskokwim Group (Bundtzen, Miller, and Laird, 1986; Miller and Bundtzen, 1994; Miller, Bundtzen, and Gray, 2005). The zone is adjacent to a small body of biotite quartz monzonite. The mineralized breccia covers an area about 160 by 500 feet in size that is oriented northeast. The monzonite contains a stockwork of numerous small quartz-tourmaline-sericite veins. The quartz monzonite is undated, but a similar intrusive body exposed about 0.3 mile to the south has a 40K/40Ar age of 71.1 Ma . Grab samples of mineralization contained up to 1,000 parts per million (ppm) tin, 1,000 parts per billion (ppb) silver, 500 ppm copper, 350 ppm zinc, 100 ppm lead, 160 ppm arsenic, 54 ppm antimony, and 1,200 ppb mercury (McGimsey and others, 1988).

Battle Mountain Mining Company explored the property in the late 1980s and diamond drilled two holes; the results were not released. Placer Dome USA flew an aeromagnetic survey over the Upper Granite Creek area but that survey has not been made public (L.E. Wyrick, oral communication, 2003).

In 2008, Full Metals Minerals (2008) negotiated an exploration agreement on this property. The claims probably include another nearby unnamed property (ID135) with similar mineralization. They cite multiple styles of mineralization including granitic stocks with hornfelsed contact zones cut by sheeted quartz-tourmaline veins; swarms of altered rhyolite dikes and sills with disseminated sulfides; and gold-stibnite-pyrite veins along northeast-trending faults. Two samples of quartz-stibnite veins collected by Placer Dome in the mid-1990s contained 10.5 and 17.5 grams of gold per tonne, and four channel samples across an antimony-rich shear zone contained from 343 to 686 ppb gold.

Alteration:

Development of quartz-tourmaline-sericite greisen in quartz monzonite pluton and hornfels.

Age of mineralization:

Possibly related to a nearby quartz monzonite intrusion that has a 40K/40Ar age of 71.1 Ma.

Generic deposit model:

Deposit model:

Several styles of polymetallic gold-antimony(-tin) mineralization related to a small Cretaceous granitic stock.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Samples were collected by the U.S. Geological Survey and Alaska Division of Geological and Geophysical Surveys in the 1980s (McGimsey and others, 1988). Battle Mountain Mining Company explored the occurrence in the late 1980s and drilled two holes. Placer Dome U S flew an aeromagnetic survey over the Upper Granite Creek area but that survey has not been made public (L.E. Wyrick, oral communication, 2003). In 2008, held by Full Metals Minerals, who did at least some work on the property.

Production notes:

None.

Reserves:

None.

Site name(s): Donlin Creek

Site type: Prospect

ARDF no.: ID167

Latitude: 62.0434 **Quadrangle:** ID A-5

Longitude: 158.209

Location description and accuracy:

The Donlin Creek prospect is a large mineralized area about 3.5 by 2 kilometers in size that has been extensively drilled and is being developed as an open-pit mine. The center of the area is about 1.4 miles east of the junction of American Creek and Crooked Creek and about 0.3 mile north of the center of section 35, T. 23 N., R. 49 W., of the Seward Meridian. The location is accurate within a few hundreds of feet.

Commodities:

Main: Au

Other: Ag, As, Be, Cd, Cu, Hg, Mo, Pb, Se, Sb, Sn, Te, W, Zn

Ore minerals: Arsenopyrite, bornite, boulangerite, cassiterite, chalcocite, chalcopyrite, cinnabar, covellite, galena, marcasite, millerite, molybdenite, native arsenic, native copper, pyrite, pyrrhotite, realgar, stibnite, scheelite, sphalerite, tennantite, tetrahedrite

Gangue minerals: Carbonate minerals, garnet, quartz

Geologic description:

The Donlin Creek prospect is a large porphyry-gold deposit about 3.5 by 2 km in size that has been extensively drilled and studied since 2001 as a joint venture between NovaGold Resources Alaska Inc. and the Barrick Gold Corporation (NovaGold, 2010). In early 2010, the work had outlined a potential open pit mine that could ultimately cover a northeast-trending area about 2 by 3 kilometers in size. A second-generation feasibility plan was completed in 2009 (Hanson and others, 2009).

Placer gold was discovered in the area in 1909 and placer mining continues nearby (see ARDF sites ID162 to ID166 and ID168). The modern search for the lode source of the placer gold began in 1974 when Resource Associates of Alaska sampled a soil grid and dug three trenches on mineralization (McCoy and others, 1997; Szumigala and others, 2000; Hanson and others, 2009). The Calista Corporation, Cominco Alaska, Kennecott Exploration, and Lyman Resources then worked in the area from 1984 to 1987, mostly through limited surface sampling and auger drilling. From 1988 to 1989, Western Gold Exploration and Mining Company did an airborne geophysical survey and soil sampled a large area. They cut 13,525 meters of trench, drilled 3,106 meters of core hole, and 404 meters of auger drilling, and 10,423 meters of reverse circulation drilling. They identified seven areas of mineralization and prepared the first mineral-resource estimate. Teck Exploration Ltd. trenched and sampled soils in 1993. From 1995 to 2000, Placer Dome U.S. Inc. drilled 87,383 meters of core hole, drilled 11,909 meters of reverse-circulation holes, and did 8,493 meters of trenching. In 2001, NovaGold began working at the property and in early 2010 continued to develop the property under the joint agreement with Barrick Gold (NovaGold, 2010).

Approximately 1,676 exploration and development holes were drilled from 1988 to 2007; 88 percent are core holes and 12 percent are reverse-circulation holes (Hanson and others, 2009). About half were drilled in 2006 and 2007. In 2008, another 109 core holes were drilled to explore pit expansion and potential satellite deposits and for facility and geotechnical studies.

The rocks in the area are Cretaceous sedimentary rocks intruded by a swarm of 65 to 74 Ma dikes, sills, and small stocks. The sedimentary rocks are part of the Cretaceous Kuskokwim Group, mostly graywacke on the north side of the area and shaly rocks on the south side (Cady and others, 1955). The sedimentary

rocks are generally monoclinal to the north and form a broad, open, east-trending fold to the south. There are two main types of igneous rocks (Szumigala and others, 2000; Hanson and others, 2009). The oldest are 74 to 72 Ma, mafic sills and dikes; they are not abundant. The more voluminous are 70 to 65 Ma granite porphyry or rhyodacite dikes and sills, a few feet to 60 meters wide, that form a northeast-trending belt 8 kilometers long and 3 kilometers wide. Five varieties of rhyodacite dikes are distinguished by their textures; they are the 'fine grained porphyry'; 'crowded porphyry'; 'lath rich porphyry'; aphanitic porphyry'; and 'blue porphyry'. There is little alteration of the sedimentary rocks adjacent to the dikes and sills.

The Donlin prospect is between two regional-scale northeast-trending faults; the immediate area has numerous north-northeast to east-northeast and northwest to west-northwest lineaments that probably represent steeply-dipping strike-slip faults (Szumigala and others, 2000; Hanson and others, 2009). These faults offset many of the dikes and sills. The mineralization is strongly controlled by the north-northeast-trending faults, especially in competent host rocks. The mineralization is best developed in the igneous rocks but also does occur in the sedimentary rocks.

There are two distinct styles of mineralization: the ACMA-Lewis style and the Dome-Duqum style (McCoy and others, 1997, Szumigala and others, 2000; Hanson and others, 2009). (The names are based on specific centers of mineralization within the the prospect.) The ACMA-Lewis style, which is the main type, consists mainly of sheeted quartz, quartz-carbonate and sulfide (only) veins characterized by abundant arsenopyrite and pyrite. Disseminated arsenopyrite occurs widely. Most of the gold is in the lattice structure of the arsenopyrite. Stibnite, realgar, and native arsenic are common, but are associated with relatively little gold compared to the arsenopyrite veins. The ACMA-Lewis-style mineralization was deposited by a late, low-temperature, low-sulfidation epithermal system. The Dome-Duqum mineralization is an earlier higher-temperature, porphyry-style of mineralization characterized by quartz veins that contain various proportions of copper, zinc, bismuth, silver, tellurium, selenium and native gold. The Dome-Duqum mineralization is not included in the 2008 resource/reserve estimates by Hanson and others (2009).

The main ore minerals in the deposit are pyrite, stibnite, and gold-bearing arsenopyrite. Native gold is rare, minor hydrothermal pyrrhotite and marcasite are present. Copper, lead, and zinc minerals are rare, but chalcopyrite, chalcocite, covellite, tennantite, tetrahedrite, bornite, native copper, galena, sphalerite, boulangerite, molybdenite, and millerite have been identified. Microscopic cinnabar is generally absent or exceedingly rare.

There have been several generations of resource estimates as the drilling has proceeded. The latest in early 2010 was by Hanson and other (2009). They estimate that on December 31, 2008, the Donlin Creek deposits contained: 1) 1.2 million tonnes of measured resources with an average grade of 2.19 grams of gold per tonne; 2) 93.4 million tonnes of indicated resources with an average grade of 1.98 grams of gold per tonne; 3) 8.4 million tonnes of proven reserves with a grade of 2.59 grams of gold per tonne; and 4) 375.4 million tonnes of probable reserves with a grade of 2.37 grams of gold per tonne.

Alteration:

The alteration is marked by sericite, illite, kaolinite. dickite, carbonate minerals, and pyrite (Szumigala, Dodd, and Arribas, 2000); there is little alteration of the sedimentary rocks adjacent to the igneous rocks.

Age of mineralization:

The felsic intrusions which predate the mineralization have 40K/40Ar ages of from 65.1 to 70.9 Ma (Miller and Bundtzen, 1994).

Generic deposit model:

Deposit model:

Mostly epithermal gold-arsenopyrite-quartz veins and disseminated auriferous arsenopyrite; earlier, higher temperature polymetallic porphyry-style mineralization (Cox and Singer, 1986; model 22c, 25).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c, 25

Production Status: None

Site Status: Active

Workings/exploration:

The Donlin Creek prospect is a large porphyry-gold deposit that has been extensively drilled and studied since 2001 as a joint venture between NovaGold Resources Alaska Inc. and the Barrick Gold Corporation (NovaGold, 2010). In early 2010, the work had outlined a potential open pit mine that could ultimately cover a northeast-trending area about 2 by 3 kilometers in size. A second-generation feasibility plan was completed in 2009 (Hanson and others, 2009).

Placer gold was discovered in the area in 1909 and placer mining continues nearby (see ARDF sites ID162 through ID166 and ID168. The modern search for the lode source of the placer gold began in 1974 when Resource Associates of Alaska sampled a soil grid and dug three trenches on mineralization (McCoy and others, 1997; Szumigala and others, 2000; Hanson and others, 2009). The Calista Corporation, Cominco Alaska, Kennecott Exploration, and Lyman Resources then worked in the area from 1984 to 1987, mostly through limited surface sampling and auger drilling. From 1988 to 1989, Western Gold Exploration and Mining Company did an airborne geophysical survey and soil sampled a large area. They cut 13,525 meters of trench, drilled 3,106 meters of core hole, and 404 meters of auger drilling, and 10,423 meters of reverse circulation drilling. They identified 7 areas of mineralization and prepared the first mineral-resource estimate. Teck Exploration Ltd. trenched and sampled soils in 1993. From 1995 to 2000, Placer Dome U.S. Inc. drilled 87,383 meters of core hole, drilled 11,909 meters of reverse-circulation holes, and did 8,493 meters of trenching. In 2001, NovaGold began working at the property and in early 2010 continued to develop the property under the joint agreement with Barrick Gold (NovaGold, 2010).

Approximately 1,676 exploration and development holes were drilled from 1988 to 2007; 88 percent are core holes and 12 percent are reverse-circulation holes (Hanson and others, 2009). About half were drilled in 2006 and 2007. In 2008, another 109 core holes were drilled to explore pit expansion and potential satellite deposits and for facility and geotechnical studies.

Production notes:

None.

Reserves:

There have been several generations of resource estimates as the drilling has proceeded. The early 2010 update was by Hanson and other (2009). They estimate that on December 31, 2008, the Donlin Creek deposits contained: 1) 1.2 million tonnes of measured resources with an average grade of 2.19 grams of gold per tonne; 2) 93.4 million tonnes of indicated resources with an average grade of 1.98 grams of gold per tonne; 3) 8.4 million tonnes of proven reserves with a grade of 2.59 grams of gold per tonne; and 4) 375.4 million tonnes of probable reserves with a grade of 2.37 grams of gold per tonne.

In early 2012, an updated 43-101 report by Lipiec (2011) estimated that as of July 11, 2011, the Donlin Creek deposits contained 1) 7.7 million tonnes of measured resources with an average grade of 2.52 grams of gold per tonne; 2) 533.6 million tonnes of indicated resources with an average grade of 2.24 grams of gold per tonne; 3) 92.2 million tonnes of inferred resources with an average grade of 2.02 grams of gold per tonne.

Last report date: 2016-03-15

Site name(s): Donlin Creek

Site type: Prospect

ARDF no.: ID167

Latitude: 62.0434 **Quadrangle:** ID A-5

Longitude: 158.209

Location description and accuracy:

The Donlin Creek prospect is a large mineralized area about 3.5 by 2 kilometers in size that has been extensively drilled and is being developed as an open-pit mine. The center of the area is about 1.4 miles east of the junction of American Creek and Crooked Creek and about 0.3 mile north of the center of section 35, T. 23 N., R. 49 W., of the Seward Meridian. The location is accurate within a few hundreds of feet.

Commodities:

Main: Au

Other: Ag, As, Be, Cd, Cu, Hg, Mo, Pb, Se, Sb, Sn, Te, W, Zn

Ore minerals:

Gangue minerals: Carbonate minerals, garnet, quartz

Geologic description:

The Donlin Creek prospect is a large porphyry-gold deposit about 3.5 by 2 km in size that has been extensively drilled and studied since 2001 as a joint venture between NovaGold Resources Alaska Inc. and the Barrick Gold Corporation (NovaGold, 2010). In early 2010, the work had outlined a potential open pit mine that could ultimately cover a northeast-trending area about 2 by 3 kilometers in size. A second-generation feasibility plan was completed in 2009 (Hanson and others, 2009).

Placer gold was discovered in the area in 1909 and placer mining continues nearby (see ARDF sites ID162 to ID166 and ID168). The modern search for the lode source of the placer gold began in 1974 when Resource Associates of Alaska sampled a soil grid and dug three trenches on mineralization (McCoy and others, 1997; Szumigala and others, 2000; Hanson and others, 2009). The Calista Corporation, Cominco Alaska, Kennecott Exploration, and Lyman Resources then worked in the area from 1984 to 1987, mostly through limited surface sampling and auger drilling. From 1988 to 1989, Western Gold Exploration and Mining Company did an airborne geophysical survey and soil sampled a large area. They cut 13,525 meters of trench, drilled 3,106 meters of core hole, and 404 meters of auger drilling, and 10,423 meters of reverse circulation drilling. They identified seven areas of mineralization and prepared the first mineral-resource estimate. Teck Exploration Ltd. trenched and sampled soils in 1993. From 1995 to 2000, Placer Dome U.S. Inc. drilled 87,383 meters of core hole, drilled 11,909 meters of reverse-circulation holes, and did 8,493 meters of trenching. In 2001, NovaGold began working at the property and in early 2010 continued to develop the property under the joint agreement with Barrick Gold (NovaGold, 2010).

Approximately 1,676 exploration and development holes were drilled from 1988 to 2007; 88 percent are core holes and 12 percent are reverse-circulation holes (Hanson and others, 2009). About half were drilled in 2006 and 2007. In 2008, another 109 core holes were drilled to explore pit expansion and potential satellite deposits and for facility and geotechnical studies.

The rocks in the area are Cretaceous sedimentary rocks intruded by a swarm of 65 to 74 Ma dikes, sills, and small stocks. The sedimentary rocks are part of the Cretaceous Kuskokwim Group, mostly graywacke on the north side of the area and shaly rocks on the south side (Cady and others, 1955). The sedimentary rocks are generally monoclinal to the north and form a broad, open, east-trending fold to the south. There are two main types of igneous rocks (Szumigala and others, 2000; Hanson and others, 2009). The oldest are

74 to 72 Ma, mafic sills and dikes; they are not abundant. The more voluminous are 70 to 65 Ma granite porphyry or rhyodacite dikes and sills, a few feet to 60 meters wide, that form a northeast-trending belt 8 kilometers long and 3 kilometers wide. Five varieties of rhyodacite dikes are distinguished by their textures; they are the 'fine grained porphyry'; 'crowded porphyry'; 'lath rich porphyry'; aphanitic porphyry'; and 'blue porphyry'. There is little alteration of the sedimentary rocks adjacent to the dikes and sills.

The Donlin prospect is between two regional-scale northeast-trending faults; the immediate area has numerous north-northeast to east-northeast and northwest to west-northwest lineaments that probably represent steeply-dipping strike-slip faults (Szumigala and others, 2000; Hanson and others, 2009). These faults offset many of the dikes and sills. The mineralization is strongly controlled by the north-northeast-trending faults, especially in competent host rocks. The mineralization is best developed in the igneous rocks but also does occur in the sedimentary rocks.

There are two distinct styles of mineralization: the ACMA-Lewis style and the Dome-Duqum style (McCoy and others, 1997, Szumigala and others, 2000; Hanson and others, 2009). (The names are based on specific centers of mineralization within the the prospect.) The ACMA-Lewis style, which is the main type, consists mainly of sheeted quartz, quartz-carbonate and sulfide (only) veins characterized by abundant arsenopyrite and pyrite. Disseminated arsenopyrite occurs widely. Most of the gold is in the lattice structure of the arsenopyrite. Stibnite, realgar, and native arsenic are common, but are associated with relatively little gold compared to the arsenopyrite veins. The ACMA-Lewis-style mineralization was deposited by a late, low-temperature, low-sulfidation epithermal system. The Dome-Duqum mineralization is an earlier higher-temperature, porphyry-style of mineralization characterized by quartz veins that contain various proportions of copper, zinc, bismuth, silver, tellurium, selenium and native gold. The Dome-Duqum mineralization is not included in the 2008 resource/reserve estimates by Hanson and others (2009).

The main ore minerals in the deposit are pyrite, stibnite, and gold-bearing arsenopyrite. Native gold is rare, minor hydrothermal pyrrhotite and marcasite are present. Copper, lead, and zinc minerals are rare, but chalcopyrite, chalcocite, covellite, tennantite, tetrahedrite, bornite, native copper, galena, sphalerite, boulangerite, molybdenite, and millerite have been identified. Microscopic cinnabar is generally absent or exceedingly rare.

There have been several generations of resource estimates as the drilling has proceeded. The latest in early 2010 was by Hanson and other (2009). They estimate that on December 31, 2008, the Donlin Creek deposits contained: 1) 1.2 million tonnes of measured resources with an average grade of 2.19 grams of gold per tonne; 2) 93.4 million tonnes of indicated resources with an average grade of 1.98 grams of gold per tonne; 3) 8.4 million tonnes of proven reserves with a grade of 2.59 grams of gold per tonne; and 4) 375.4 million tonnes of probable reserves with a grade of 2.37 grams of gold per tonne.

The Donlin project is being proposed as a large open-pit gold mine by Donlin Gold, LLC, a 50/50 partnership between Barrick Gold Corp. and NovaGold Resources Inc. Their preferred design for the Donlin project anticipates a throughput of approximately 59,000 tons (53,524 tonnes) per day. Donlin Gold's proposal to power the mine includes a 14-inch-diameter, 315-mile-long natural gas pipeline starting in Beluga, Alaska, passing north through the Alaska Range, and continuing to the mine site. Donlin Gold estimates the project would take 3 to 4 years to construct, with a projected mine life of approximately 27.5 years, and is estimated to produce (on average) approximately one million ounces of gold per year (Lipiec and others, 2012).

In 2016, Donlin Gold’s major milestones included advancement of the permitting and technical work at the Donlin project, including completion of a six-month public comment period on the draft Environmental Impact Statement (EIS) completed by the U.S. Army Corps of Engineers, and completion of public working sessions attended by all cooperating agencies to address comments on key topics and how to address them in the final EIS, which is expected to be completed in early 2018 (Athey and Werdon, 2017).

Alteration:

Age of mineralization:

The felsic intrusions which predate the mineralization have 40K/40Ar ages of from 65.1 to 70.9 Ma (Miller and Bundtzen, 1994).

Generic deposit model:

Deposit model:

Mostly epithermal gold-arsenopyrite-quartz veins and disseminated auriferous arsenopyrite; earlier, higher temperature polymetallic porphyry-style mineralization (Cox and Singer, 1986; model 22c, 25).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c, 25

Production Status: None

Site Status: Active

Workings/exploration:

The Donlin Creek prospect is a large porphyry-gold deposit that has been extensively drilled and studied since 2001 as a joint venture between NovaGold Resources Alaska Inc. and the Barrick Gold Corporation (NovaGold, 2010). In early 2010, the work had outlined a potential open pit mine that could ultimately cover a northeast-trending area about 2 by 3 kilometers in size. A second-generation feasibility plan was completed in 2009 (Hanson and others, 2009).

Placer gold was discovered in the area in 1909 and placer mining continues nearby (see ARDF sites ID162 through ID166 and ID168. The modern search for the lode source of the placer gold began in 1974 when Resource Associates of Alaska sampled a soil grid and dug three trenches on mineralization (McCoy and others, 1997; Szumigala and others, 2000; Hanson and others, 2009). The Calista Corporation, Cominco Alaska, Kennecott Exploration, and Lyman Resources then worked in the area from 1984 to 1987, mostly through limited surface sampling and auger drilling. From 1988 to 1989, Western Gold Exploration and Mining Company did an airborne geophysical survey and soil sampled a large area. They cut 13,525 meters of trench, drilled 3,106 meters of core hole, and 404 meters of auger drilling, and 10,423 meters of reverse circulation drilling. Reporter(s): T.K. Bundtzen (Pacific Rim Geological Consulting, Inc.), M.L. Miller (U.S. Geological Survey); and C.C. Hawley (Hawley Resource Group); D.J. Grybeck (Contractor, U.S. Geological Survey); V.C. Zinno (Alaska Earth Sciences, Inc.); M.B. Werdon (DGGS)

Last report date: 2017-08-26

Site name(s): Unnamed (near Ganes Creek)

Site type: Prospect

ARDF no.: ID181

Latitude: 62.9662 **Quadrangle:** ID D-1

Longitude: 156.4988

Location description and accuracy:

This prospect is along the ridge--locally known as Potosi Ridge--between Six Gulch, a west-flowing tributary to Ganes Creek and the first tributary to the north which is locally called Potosi Creek. The prospect is about 0.7 mile east of the junction of Six Gulch and Ganes Creek, about 0.2 mile north-northwest of the center of section 9. T. 33 N., R. 38 W. The location is accurate.

Commodities:

Main: As, Au, Cu, Pb

Other:

Ore minerals: Arsenopyrite, chalcocite, chalcopyrite, galena, pyrite

Gangue minerals: Carbonates, quartz, sericite

Geologic description:

This deposit was first described by Grady (2009) as a result of recent work in the Ganes Creek area that included the nearby and better-known Independence Mine (ID031). The prospect is in an area that has been explored by at least six companies since 1988, notably Great Basin Gold Ltd. in 2007 and 2008. The total work of these companies included more than 32,000 meters of trenching and continuous chip sampling of the trenches, as well as 83.6 line miles of ground IP, TMF, and HLEM geophysical surveys. In early 2010, the property was owned and operated by Clark-Winze Mining (Grady, 2009).

This prospect and the Independence mine are within the cores of major northeast-striking antiforms in Cretaceous Kuskokwim Group flysch. The hinges of the antiforms are thickened and marked by chevron folding and high angle faulting. In some cases, the cores of the some of the antiforms are deformed into brittle melange. The prospects are associated with northeast-striking swarms of mafic to granitic dikes and older biotite granodiorite to aplite sills. The dike swarms are offset by numerous north-northwest high-angle faults and joints and often have marginal dip-slip faults.

The mineralization in the area is marked by quartz-carbonate veins along fractures. The veins typically have early quartz-carbonate margins with cores of clear to white quartz and carbonates. Occasionally, the veins contains late-stage quartz, iron carbonates, and sericite. Sparse pyrite and arsenopyrite occur in the veins and wall rock. Rare chalcopyrite, galena, and chalcocite are present in the high-grade veins. Two samples contained 14 part per million gold; the sample were taken from quartz-carbonate veins that cut mafic sills and and shear zones.

3D modeling of gridded IP surveys show that geophysical anomalies are associated with high copper, nickel, lead, and zinc values in soils. Resistivity data outlines the the dike swarms; magnetic highs correspond to felsic intrusives and magnetic lows outline silicification and brecciation.

Alteration:

Silicification.

Age of mineralization:

Cretaceous or younger based on the age of the host rock.

Generic deposit model:

Deposit model:
Low-sulfide gold-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:
This deposit was first described by Grady (2009) in conjunction with recent work in the Ganes Creek area that also included the nearby and better-known Independence Mine (ID031). This prospect is within an area that has been explored by at least six companies since 1988, notably Great Basin Gold Ltd. in 2007 and 2008. Their work included more than 32,000 meters of trenching and continuous chip sampling of the trenches, as well as 83.6 line miles of IP, TMF, and HLEM ground geophysical surveys. In early 2010, the property was owned and operated by Clark-Winze Mining (Grady, 2009).

Production notes:
None.

Reserves:
None.

Last report date: 2010-04-02

Site name(s): 37 Skarn

Site type: Prospect

ARDF no.: IL002

Latitude: 59.7914 **Quadrangle:** IL D-7

Longitude: 155.5116

Location description and accuracy:

The 37 Skarn prospect is about 0.5 mile south of the Koktuli River at an elevation of about 1,000 feet. The prospect is about 3.8 miles west-northwest of Sharp Mountain and about 0.4 mile north of the center of section 32, T. 4 S., R. 36 W. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other: As, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, magnetite, marcasite, pyrrhotite, sphalerite

Gangue minerals: Actinolite/tremolite, dolomite, epidote?, garnet, quartz

Geologic description:

Five holes drilled in 2002 by Northern Dynasty Minerals Ltd. on a copper-gold geochemical anomaly found the first skarn mineralization in the Pebble claim block here (Rebagliati, 2003; Haslinger and others, 2004; Rebagliati and Payne, 2005; Gaunt and others, 2010). The host rocks are fine- to medium-grained basalt, basaltic breccias, and minor interbeds of lithic sandstone, siltstone, and mudstone. The basalts and associated rocks are pervasively altered to actinolite/tremolite, epidote, and chlorite. Most of the mineralization is in fracture-controlled veinlets and veins of epidote, dolomite, light-brown garnet, potassium feldspar, pyrrhotite, chalcopyrite, and magnetite. Sphalerite occurs in minor amounts. Some notable intercepts in the 2002 drilling were: 79 meters with 1.0 grams of gold per tonne and 0.40 percent copper; 2.32 meters with 8.19 grams of gold per tonne, 2.460 percent copper, 446 parts per million (ppm) zinc, and 15.6 grams of silver per tonne; 0.43 meters with 14.81 grams of gold per tonne, 4.430 percent copper, 714 ppm zinc, and 33.8 ppm silver; and 1.86 meters with 9.74 grams of gold per tonne, 3.14 percent copper, 692 ppm zinc, and 46.8 ppm silver.

Two more holes were drilled in 2003 on a strong northeast-trending magnetic anomaly (Haslinger and others, 2004). They encountered altered diorite and gabbro. The propylitic alteration suite is characterized by epidote, calcite, chlorite, and magnetite. The mineralization consists of scattered quartz-calcite-chlorite-marcasite veinlets with chalcopyrite, sphalerite, and galena. The best intercepts in the 2003 drilling were 4.7 meters with 0.61 grams of gold per tonne, 0.37 percent copper, 1,802 ppm zinc, and 7.8 ppm silver; and 0.8 meters with 16.50 grams of gold per tonne, 1.00 percent copper, 660 ppm zinc, 10 ppm silver, and 435 ppm arsenic.

Alteration:

Basalts and associated rocks are pervasively altered to actinolite/tremolite, epidote, and chlorite. Diorite and gabbro are propylitically altered to epidote, calcite, chlorite, and magnetite.

Age of mineralization:

Probably Late Cretaceous, about 90 Ma, by proximity to the nearby Pebble deposit (IL007).

Generic deposit model:

Deposit model:

Copper-gold skarn; probably related to porphyry copper-gold deposit (Cox and Singer, 1986; models 18b and 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b, 20c

Production Status: None

Site Status: Active

Workings/exploration:

The area has been covered by extensive geochemical and geophysical surveys beginning in about 1986 as part of the exploration of the Pebble block of claims first by Cominco and through early 2011 by Northern Dynasty Minerals Ltd. Mapped and sampled at the surface. Five holes drilled in 2002 by Northern Dynasty Minerals Ltd. on a copper-gold geochemical anomaly found the first skarn mineralization in the Pebble claim block. Two more holes were drilled in 2003 on a strong northeast-trending magnetic anomaly.

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-28

Site name(s): 52 Porphyry Zone

Site type: Prospect

ARDF no.: IL003

Latitude: 59.8081 **Quadrangle:** IL D-7

Longitude: 155.5102

Location description and accuracy:
The 52 Porphyry Zone prospect is at an elevation of about 1,400 feet on the side side of a knob about 4.2 miles northwest of Sharp Mountain. The center of the drilling is about 0.5 mile north of the center of section 29, T. 4 S., R. 36 W.

Commodities:

Main: Cu

Other: Ag?, Au?, Mo?

Ore minerals: Chalcopyrite

Gangue minerals: Quartz

Geologic description:
The 52 Porphyry Zone was discovered by drill testing a copper soil-geochemistry anomaly coincident with an IP geophysical anomaly (Rebagliati, 2003). Four holes were drilled in an area about 400 meters long. Surface rubble and drill core indicate that the entire area is underlain by black fine- to medium-grained basalt similar to that found as the '37 Skarn' prospect (IL002) about a mile to the south. The basalt has been weakly propylitically altered to epidote and chlorite. Modest amounts of chalcopyrite occur in fracture fillings with potassium feldspar and chlorite. The prospect has low-grade copper mineralization with porphyry affinities as suggested by the nearby Pebble prospect (IL007) and other prospects in the Pebble claim block.

Alteration:
Weak propylitic and potassium-feldspar alteration.

Age of mineralization:
Probably Late Cretaceous, about 90 Ma, by analogy with the nearby Pebble deposit (IL007).

Generic deposit model:

Deposit model:
Chalcopyrite along fractures in basalt. Probable porphyry copper affinities.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The area has been covered by extensive geochemical and geophysical surveys beginning in about 1986 as part of the exploration of the Pebble block of claims Teck-Cominco, and through early 2011 by Northern Dynasty Minerals Ltd. Considerable mapping and sampling at the surface; 4 holes drilled in 2002.

Production notes:

None.

Reserves:

None.

Site name(s): 38 Porphyry; 38 Zone

Site type: Prospect

ARDF no.: IL004

Latitude: 59.7981 **Quadrangle:** IL D-7

Longitude: 155.4219

Location description and accuracy:

The center of the 38 Porphyry prospect is about 1.6 miles northwest of Sharp Mountain, near the center of section 26, T. 4 S., R. 36 W., Seward Meridian. The location is accurate.

Commodities:

Main: Cu

Other: Ag, Au, Mo

Ore minerals: Chalcopyrite, galena, molybdenite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The 38 Porphyry prospect is a classic copper-gold-molybdenum porphyry deposit on the southeast flank of a granodiorite-tonalite batholith of Late Cretaceous (about 90 Ma) age (Detterman and Reed, 1980).

The 38 Porphyry was discovered in 2002 by Northern Dynasty Minerals Ltd. by drilling an IP geophysical anomaly covered with about 25 meters of glacial gravel (Rebagliati, 2003; Haslinger and others, 2004; Rebagliati and Payne, 2005; Gaunt and others, 2010). The main host for the mineralization is porphyritic hornblende quartz monzonite and granodiorite, with a core of granite to quartz monzonite. The deposit has classic porphyry-style alteration. There is a central zone of fracture-controlled, pervasive potassium feldspar alteration. It is succeeded outward by a large zone of secondary biotite alteration that has the best copper values and about 1.5 percent pyrite. Both the potassium feldspar and biotite alteration are overprinted by phyllic or sericitic alteration. There are several phases of mineralization which generally follows the pattern: 1) quartz with potassium feldspar halos; 2) quartz or quartz-pyrite with chalcopyrite and/or molybdenite; 3) quartz-pyrite with quartz-sericite-pyrite halos, 4) calcite; and 5) clay along fractures. Almost all the copper is in chalcopyrite; bornite and tetrahedrite are rare. The chalcopyrite occurs in three principal ways: 1) as pervasive disseminated grains associated with secondary biotite replacement of hornblende phenocrysts; 2) as coatings with pyrite along fracture surfaces; and 3) in the core or along the margins of quartz, quartz-pyrite, and quartz-pyrite-molybdenite veinlets. Native gold is rarely seen under the microscope but there seems to be a consistent ratio of 1 gram of gold per tonne to 1 percent copper. Molybdenite is widespread but sporadic; it typically is in quartz or quartz-pyrite veinlets. Sphalerite and galena are present in few calcite and quartz veinlets.

Northern Dynasty drilled 17 holes in 2002 and 2003. Some of the notable intercepts were: 37.7 meters with 0.40 percent copper, 0.45 gram of gold per tonne, and 0.02 percent molybdenum; 30.5 meters with 0.41 percent copper and 0.31 gram of gold per tonne; 149 meters with 0.42 percent copper, 0.41 gram of gold per tonne, and 0.01 percent molybdenum.

Alteration:

The deposit has classic porphyry-style alteration. There is a central zone of fracture-controlled, pervasive potassium feldspar alteration. It is succeeded outward by a large zone of secondary biotite alteration that has the best copper values and about 1.5 percent pyrite. Both the potassium feldspar and biotite alteration are overprinted by phyllic or sericitic alteration.

Age of mineralization:

Probably Late Cretaceous, approximately 90 Ma, assuming contemporaneity with the nearby Pebble deposit (IL007).

Generic deposit model:

Deposit model:

Porphyry copper-gold-molybdenum deposit (Cox and Singer, 1986; models 20c or 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c, 21a

Production Status: None

Site Status: Active

Workings/exploration:

The 38 Porphyry was discovered in 2002 by Northern by Northern Dynasty Minerals Ltd. by drilling an IP geophysical anomaly covered with about 25 meters of glacial gravel. Northern Dynasty drilled 17 holes in 2002 and 2003.

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-28

Site name(s): 25 Zone; 25 Gold

Site type: Prospect

ARDF no.: IL005

Latitude: 59.8548 **Quadrangle:** IL D-7

Longitude: 155.3289

Location description and accuracy:

At least 15 holes have been drilled at the 25 Zone prospect; the center of the work is about 1.5 miles southwest of the center of lake 943, locally called Frying Pan Lake. The center is about 0.4 mile south-southeast of the center of section 5, T. 4 S., R. 35 W. The drill sites are scattered over much of the southeast corner of section 5. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The 25 Zone prospect is associated with a brecciated intrusive complex that covers about 8 square kilometers (Rebagliati, 2003; Haslinger and others, 2004; Rebagliati and Payne, 2005; Gaunt and others, 2010). The complex consists of pyroxenite and gabbro, intruded by irregular bodies and dike swarms of fine-grained monzonite. The mineralization consists of: 1) polymetallic veins and veinlets with gold, sphalerite, galena, chalcopyrite, and minor disseminated chalcopyrite in the wall rocks; 2) zones with 3-8 percent pyrite associated in some place with quartz-carbonate breccia and in others with strong chlorite-epidote alteration; and 3) quartz veins, replacement patches, and breccia with minor pyrite. The alteration is dominated by a chlorite-epidote-calcite-pyrite propylitic assemblage that occurs as disseminations, phenocryst replacements, and rims around breccia clasts. The rocks locally exhibit silica veining, flooding, and brecciation. Skarn-type alteration occurs along the monzonite dikes. The higher-grade gold intervals in the drill holes are associated with the propylitic and skarn alteration that is ubiquitous in the breccia complex. The mineralization is probably about 90 Ma based on its proximity to the Pebble prospect (IL007),

The prospect and surrounding area has been covered by extensive geologic mapping and sampling, and geochemical and geophysical surveys beginning in about 1986 as part of the exploration of the Pebble block of claims, first by Cominco and then by Northern Dynasty Minerals Ltd., the operator as of early 2011 Northern Dynasty drilled least 15 holes in 2002. Some notable intersects are: 6.10 meters with 28.90 grams of gold per tonne and 0.013 percent copper; 0.31 meter with 260.78 grams of gold per tonne and 0.007 percent copper; and 1.74 meters with 19.27 grams of gold per tonne, 0.20 percent copper, more than 1 percent lead and zinc, and 47.0 parts per million silver. Many intercepts contained 1.0 gram of gold per tonne or more.

Alteration:

The alteration is dominated by a chlorite-epidote-calcite-pyrite propylitic assemblage that occurs as disseminations, phenocryst replacements, and rims around breccia clasts. The rocks locally exhibit silica veining, flooding, and brecciation. Skarn-type alteration occurs along the monzonite dikes.

Age of mineralization:

Probably 90 Ma based on its proximity to the nearby Pebble prospect (IL007).

Generic deposit model:

Deposit model:

Polymetallic quartz veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Covered by extensive geochemical and geophysical surveys beginning in about 1986 as part of the exploration of the Pebble block of claims first by Cominco and as of early 2011 by Northern Dynasty Minerals Ltd. Mapped and sampled at the surface; at least 15 holes drilled by 2002.

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-28

Site name(s): Unnamed (near Frying Pan Lake)

Site type: Prospect

ARDF no.: IL006

Latitude: 59.8588 **Quadrangle:** IL D-7

Longitude: 155.3286

Location description and accuracy:

This prospect is centered on hill 1760 about 1.3 miles west of lake 943, locally called Frying Pan Lake. The site is near the center of section 5, T. 4 S., R. 35 W.

Commodities:

Main: Fe

Other: Ti, V

Ore minerals: Ilmenite, magnetite

Gangue minerals:

Geologic description:

This prospect is now mainly of local or historical interest as of 2011 in view of the great amount of exploration that has been done on the Pebble copper prospect (IL007) several miles to the northeast and the drilling on the '25 Zone' prospect (IL005) less than a half mile to the south.

This prospect is a body of breccia that consists of angular, magnetite-bearing pyroxenite fragments in a matrix of Tertiary or Cretaceous granodiorite (Reed and Detterman, 1965). Pyroxenite clasts constitute 50-90 percent of the breccia, and magnetite occurs in crystal aggregates as much as 1 inch across. Sixteen samples of breccia collected by Reed and Detterman (1965) contained 16 to 24 percent FeO, about 1.3 percent TiO2, 0.1 to 3.2 percent P2O5, and 0.1 to 0.15 percent V2O5. A magnetic concentrate of the material contained about 3.5 percent TiO2, reflecting the presence of ilmenite or titaniferous magnetite. Samples collected by Fischer (1975) contained about 0.02 percent V2O5, less than was reported by Reed and Detterman. Fischer's magnetite-rich concentrate from pyroxenite contained 40-60 percent iron, 3.1 percent TiO2, and 0.3-0.5 percent vanadium (Fischer, 1975). Bouley and others (1995) reported considerable iron in two samples of biotite pyroxenite they collected. Their sample 10 contained 18.78 percent iron (as Fe203). The rocks are also highly potassic and are similar to alkali ultramafic rocks in composite plutons elsewhere in the central Alaska Range (Foley and others, 1997).

Alteration:

Not noted.

Age of mineralization:

The pyroxenite is probably Late Cretaceous but possibly predates the 90 Ma Pebble Copper deposit (IL007).

Generic deposit model:

Deposit model:

Magnetite-bearing pyroxenite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Exploration has been limited to geologic mapping and surface sampling at this locale but see ARDF IL005 for drilling at a copper prospect about a mile to the south.

Production notes:

None.

Reserves:

Fischer (1975) estimated a resource of 7 billion tons of magnetite-bearing breccia that contained 7 million tons of vanadium.

Site name(s): Pebble

Site type: Prospect

ARDF no.: IL007

Latitude: 59.8991 **Quadrangle:** IL D-7

Longitude: 155.2807

Location description and accuracy:

In plan view as of late 2011, the Pebble prospect covers an area about 1.9 by 2.8 miles and consists of two contiguous segments, West Pebble and East Pebble. The coordinates are at about the center of the prospect, about 9.2 miles north-northeast of Sharp Mountain and 18.7 miles northwest of Iliamna. It covers most of sections 26 to 28, T. 3 S., R. 35 W.

Commodities:

Main: Ag, Au, Cu, Mo

Other: As, Pb, Sb, Te, Zn

Ore minerals: Bornite, chalcocite, chalcopyrite, covellite, digenite, galena, goethite, gold, magnetite, molybdenite, pyrite, pyrrhotite, sphalerite, telluride minerals, tennantite-tetrahedrite

Gangue minerals: Quartz

Geologic description:

Pebble is a classic calc-alkalic copper-gold-molybdenum porphyry deposit. As of early 2011, the Pebble prospect extends over an area about 1.9 by 2.8 miles and has been explored to a depth of at least 5,000 feet (Gaunt and others, 2010). The Pebble prospect consists of two contiguous segments, Pebble West and Pebble East. Pebble West was discovered by Cominco American Inc. in 1988; it is amenable to open pit mining. Pebble East was discovered in 2005 by Northern Dynasty Minerals Inc. by drilling. Pebble East does not come to the surface and is covered by a wedge of postmineral volcanic and sedimentary rocks. It has been considered for underground mining by block caving.

In 2001, Northern Dynasty acquired the right to earn a 100 percent interest in Pebble from Teck-Cominco. As of 2006, Northern Dynasty had earned the 100 percent interest, subject only to royalties on production. In 2007, Northern Dynasty agreed to a partnership with Anglo American PLC to advance the Pebble project and as of early 2011, that partnership is in force as 'The Pebble Partnership' (2011).

From 1985 to 1997, Pebble was explored by Cominco American and Teck-Cominco, from 2001 to 2007 by Northern Dynasty, and from 2007 to early 2011 by The Pebble Partnership (Gaunt and others, 2010). The property has been covered by extensive geologic mapping and sampling, by several geochemical surveys, and by several ground and aerial geophysical surveys using a variety of techniques. As of December 2009, 1,085 holes, totaling 270,107 meters, have been drilled on Pebble. The drilling consisted of 568 exploration holes, 227 geotechnical holes, 60 holes for metallurgical samples, and 230 environmental holes. As the Northern Dynasty work has progressed, there has been a succession of profession technical reports describing the deposit and the work in detail; the latest is Gaunt and others (2010). (The others are in the reference list.)

The host rocks for the Pebble deposit are Jurassic and Cretaceous flysch that has been invaded by a variety of 96 to 99 Ma intrusive rocks including diorite sills, gabbro, alkali monzonite, a breccia complex, and granodiorite sills. Those rocks have been invaded by five 89-91 Ma granodiorite stocks, two of which are the principal sources of the mineralization in West Pebble and East Pebble. The East Pebble ore body is covered by a wedge of Upper Cretaceous to Tertiary sedimentary and volcanic rocks.

The mineralization consists mainly of pyrite, chalcopyrite, and molybdenite in and adjacent to two 90 Ma

granodiorite stocks (Gaunt and others, 2010). These ore minerals are disseminated and in zones of high-density quartz-vein stockworks, in the upper parts of the stocks, along granodiorite dikes that extend laterally from the stocks, and in the adjacent hornfelsed flysch and intrusive host rocks. Pebble West, which is exposed at the surface has an oxidized zone, usually no more than several tens of meters thick, and a supergene zone with deposition of chalcocite and covellite. The hornfelsed country rock is cut by a variety of veins including quartz veins, magnetite-bearing veins, pyrite-dominated veins, and polymetallic quartz-calcite veins with sphalerite galena, chalcopyrite, pyrrhotite, telluride minerals, and tetrahedrite-tennantite.

The mineralization was accompanied by several types of alteration. From younger to older, these include: 1) pre-hydrothermal hornfelsing; 2) deep sodic-calcic alteration; 3) early potassium feldspar-biotite-magnetite alteration that is associated with most of the copper-gold-molybdenum mineralization; 4) peripheral propylitic alteration; 5) an illite overprint of the the potassium silicate alteration; 6) younger advanced argillic alteration; and 7) young peripheral quartz-sericite-pyrite alteration.

As of November, 2010, the resources of the Pebble prospect have been calculated at 4 levels of copper-equivalent cut-off (CuEQ) (Ghaffari and others, 2011; Pebble Partnership, 2010). The measured and indicated mineral resources with a CuEQ of from 0.30 to 1.00 percent are from 5,942 million tonnes with a grade of 0.0.42 percent copper, 0.35 gram of gold per tonne, and 250 parts per million (ppm) molybdenum to 1,449 million tonnes with a grade of 0.76 percent copper, 0.52 gram of gold per tonne, and 341 ppm molybdenum. The inferred mineral resources with a CuEQ of from 0.30 to 1.00 percent are from 4,835 million tonnes with a grade of 0.24 percent copper, 0.26 gram of gold per tonne, and 215 ppm molybdenum to 353 million tons with a grade of 0.69 percent copper, 0.45 gram of gold per tonne, and 379 ppm molybdenum.

Alteration:

Last report date: 2012-04-01

Site name(s): Fog Lake

Site type: Prospect

ARDF no.: IL030

Latitude: 59.5116 **Quadrangle:** IL C-4

Longitude: 154.3639

Location description and accuracy:

This record represents an approximately 4,000-foot-long mineralized area along locally-named Fog Creek, a northwest-flowing tributary of Fog Lake (Fog Pond on some older maps). The site is in the approximate center of the area, in the NE1/4 SW1/4 sec. 3, T. 8 S., R. 30 W., Seward Meridian. The location is accurate within 0.1 mile for the center of the prospect area. The prospect is number 14 of Detterman and Cobb (1972) and number 12 of Reed (1967).

Commodities:

Main: Au, Cu

Other: Ag, Zn

Ore minerals: Azurite, chalcopyrite, gold, malachite, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The Fog Lake prospect is mainly in volcanic rocks exposed in the canyon of locally-named Fog Creek, a southeast tributary of Fog Lake.
The volcanic rocks and subordinate interbedded sedimentary rocks unconformably overlie Jurassic plutonic rocks at shallow depth (Retherford and Klemmick, 1999). From their base up, the strata are: (1) plutonic-cobble conglomerate of probable early Tertiary age; (2) green polymict conglomerate of probable early Tertiary age that possibly correlates with the upper conglomerate member of the Copper Lake Formation (Detterman and Reed, 1980); (3) dacite/dacite breccia of probable late Eocene to early Oligocene age; (4) dacite/quartz porphyry breccia similar in age to unit 3; (5) lahar flow breccia; (6) quartz-porphyry tuff breccia of probable late Eocene to early Oligocene age; (7) rhyodacite crystal tuff; and (8) argillized dacite. The volcanic rocks are cut by dacite dikes 2 to 20 feet in width (Retherford and Klemmick, 1999). Depending on their original composition, the volcanic rocks are widely propylitized and locally sericitized, silicified, and argillized. The dacite/dacite breccia of unit 3 may be coeval with intrusive rocks exposed about 6 miles east of Fog Lake that have been dated at about 36 Ma (Detterman and Reed, 1980). The Fog Lake deposit apparently is aligned northwesterly, subparallel to a fault along Fog Creek nearly coincident with the axis of a syncline. The deposit locally may extend east to northeast along cross faults or dacite dikes.

The Fog Lake deposit consists of gold- and sulfide-bearing quartz-calcite veins and sulfide disseminations (Butherus and others, 1981; Moller and others, 1982; Freeman and Farnham, 1983; Retherford and Klemmick, 1999). Pyrite and chalcopyrite are disseminated in all of the volcanic rocks but are most abundant in units 1 through 5. Swarms of sulfide veinlets up to an inch or so thick occur in northeast, northwest, and east-west fracture sets. Maximum vein density is about 8 per foot. Sulfides, mainly pyrite and chalcopyrite, along with subordinate olive-colored sphalerite, form small masses in quartz-calcite gangue. Azurite and malachite occur locally in gossan. Gold appears to correlate with sulfide content, and probably is free milling; it can be panned along about 2,200 feet of Fog Creek. Rock samples locally contain more than 1 ounce of gold per ton (Reed, 1967; Retherford and Klemmick, 1999). The deposit has been explored by shallow trenches. The maximum gold content in various samples from the trenches was

1.5 parts per million, and the maximum copper content was 11 percent (Freeman and Farnham, 1983). A gold-in-soil anomaly along Fog Creek is about one-half mile long and 700 feet wide. An exceptional soil sample contained 18.8 parts per million gold. Gold in soil correlates moderately well with copper and zinc.

As of 2008, Andover Ventures is exploring the deposit under an agreement with the Bristol Bay Native Corporation (Andover Ventures, 2006, Fog Lake; 2007, Progress Report). They have yet to drill the property but they have provided a map of the areas of interest and indicate several zones where numerous samples are anomalous in gold, copper, silver, and zinc (Andover Venures, 2008, Map of Fog Lake).

Alteration:

Extensive propylitic alteration in the darker volcanic rocks; local argillic, sericitic, and silicic alteration. Oxidation of iron and copper minerals.

Age of mineralization:

Possibly about 36 Ma, the age of intrusive rocks about six miles east of Fog Lake.

Generic deposit model:

Deposit model:

Epithermal gold-copper deposit, possibly grading downward into porphyry copper-gold deposit (Cox and Singer, 1986; models 25b and 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25b, 20c?

Production Status: None

Site Status: Inactive

Workings/exploration:

The deposit was discovered in 1967 by B. L. Reed of the U.S. Geological Survey. Reed collected samples that contained anomalous copper and silver and as much as 37.7 parts per million gold (Reed, 1967). The prospect was subsequently staked by St. Eugene Mining Company, but abandoned without significant work. It was explored by Resource Associates of Alaska (RAA) for several years (Butherus and others, 1981; Moller and others, 1982; Freeman and Farnham, 1983). Soil samples were collected on a grid totaling more than 24,000 lineal feet (Butherus and others, 1981). Soil sampling was followed by detailed geologic mapping along Fog Creek, by trenching, and by magnetic and VLF surveys (Moller and others, 1982).

As of 2008, Andover Ventures is exploring the deposit under an agreement with the Bristol Bay Native Corporation (Andover Ventures, 2006, Fog Lake; 2007, Progress Report). They have yet to drill the property but they have provided a map of the areas of interest and indicate several zones where numerous samples are anomalous in gold, copper, silver, and zinc (Andover Venures, 2008, Map of Fog Lake).

Production notes:

None.

Reserves:

None.

Site name(s): KUY

Site type: Prospects

ARDF no.: IL035

Latitude: 59.2631 **Quadrangle:** IL B-5

Longitude: 154.611

Location description and accuracy:

The KUY prospects are about five miles south of the east end of Gibraltar Lake. They are in, and on the east and west flanks of, the incised north-trending canyon of informally-named Katrina Creek, in the SE1/4 sec. 35, T. 10 S., R. 32 W., Seward Meridian. Mineralization related to the KUY deposit may extend into the SW1/4 sec. 36, same township, and into the NE1/4 sec. 2, T. 11 S., R. 32 W.. For this record, the location is at an elevation of about 1,300 feet in the canyon, and is accurate for the center of this large and complex mineralized system.

Commodities:

Main: Au, Cu, Mo, Te

Other: Ag, Zn

Ore minerals: Chalcopyrite, gold, gold and silver tellurides?, magnetite, molybdenite, pyrite

Gangue minerals: Clay, quartz

Geologic description:

The KUY prospects explore deposits potentially valuable for gold and copper-molybdenum. The geologic setting of the prospects has been interpreted in different ways. From 1979 until 1984, Resource Associates of Alaska (RAA) mapped the country rocks as Cretaceous or Tertiary andesite and dacite flows that locally dip 50 degrees. As interpreted by RAA, the flows are cut by an irregular zone of breccia as much as 2,500 feet across composed mostly of fragments of dacite tuff that forms the center of a caldera about 8,000 feet across (Butherus and others, 1981). Retherford and Hickok (1990) subsequently proposed that the volcanic rocks are intruded by a Cretaceous or Tertiary quartz diorite stock, and that the breccia is a diatreme immediately north of the stock.

About 60 percent of the breccia is pervasively altered and contains 3 to 5 percent sulfides, mostly pyrite and subordinate chalcopyrite. The breccia is locally cut by quartz-magnetite veins, vuggy gold-bearing quartz veins, and pyritic clay veins. Silicification and intense argillization are probably superimposed on widespread propylitization. Retherford and Hickok (1990) proposed that there is a core zone of potassium silicate alteration and a zone of sericitic alteration between stock and diatreme (breccia).

In 1978, rich gold- and silver-bearing quartz veins were found by RAA in informally named Katrina Creek canyon at about 1,600 feet elevation. The RAA-named Discovery vein strikes NNE and dips about 55 SE; the subsequently discovered Amethyst vein strikes west-northwest and dips about 70 SW (Anderson and others, 1979). A sample of the Discovery vein assayed about 106 ounces of gold and 103 ounces of silver per ton (Anderson and others, 1979; Butherus and others, 1981). The gold occurs in masses about 2 mm across; gold and silver tellurides are also reported. The rich veins are about 10 inches or less thick and traceable for a maximum distance of about 200 feet. The auriferous part of the deposit was drilled in 1980 with little success, leading to the interpretation that the veins are in discontinuous gash fissures. There reportedly were core recovery problems and the rich veins remain an intriguing target. Two other types of gold-bearing veins are reported: pyritic clay veins that assay as much as 0.37 ounce of gold per ton, and quartz-pyrite-magnetite veins.

The exploration to 2006, suggested that a porphyry copper-molybdenum(-gold) system might underlie the

highly altered volcanic complex. Freeman and Farnham (1983) reported that samples from the Hercules and Minerva trenches contained up to 495 parts per million (ppm) copper and and 45 ppm molybdenum. One sample from Minerva 1 trench contained 1.23 ppm gold. Butherus (1984) followed up Freeman and Farnham's work with more trenches in the same area. His samples from the Minerva 3 trench contained as much as 1,175 ppm copper, 193 ppm lead, and 307 ppm zinc, and generally elevated values of molybdenum. Several reports suggest that rich gold veins are near the top of the mineralized system (Butherus, 1981; Freeman and Farnham, 1983; Butherus, 1984).

As of 2008, Andover Ventures (2006, Nov 13; 2006, News; 2006, KUY) holds the property. They sampled the property and carried out ground induced polarization surveys in 2006. They drilled four holes in 2007, totaling 793 meters (Andover Ventures, 2007, Progress Report) and cut significant intervals with silica flooding, quartz stockworks, clay alteration, and up to 15 percent sulfides. The mineralization was mainly pyrite with zones of chalcopyrite in veinlets and disseminated in the altered dacitic rocks.

Alteration:

Widespread propylitic alteration (chlorite, magnetite, and epidote) followed by argillization (kaolinite), and silicification (Butherus and others, 1981). Retherford and Hickok (1990) mapped a core zone of potassium silicate alteration extending outward through sericite alteration to peripheral propylitic alteration.

Age of mineralization:

Probably Late Cretaceous or Early Tertiary.

Generic deposit model:

Deposit model:

Epithermal low-sulfide gold-quartz veins; possibly overlying a porphyry copper-molybdenum system (Cox and Singer, 1986; models 36a and 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a, 21a?

Production Status: None

Site Status: Active

Workings/exploration:

Rich gold veins were discovered in 1978 by geologists of Resource Associates of Alaska (Anderson and others, 1979). Other veins were found in 1979, and the prospect was drilled in 1980, but the drill holes did not encounter rich ore. In addition to the drilling, the deposit has been trenched. Butherus (1984) followed up Freeman and Farnham's work with more trenches in the same area. As of 2008, Andover Ventures (2006, Nov 13; 2006, News; 2006, KUY) holds the property and did sampling and ground induced polarization surveys in 2006. They drilled four holes in 2007, totaling 793 meters (Andover Ventures, 2007, Progress Report) and cut significant intervals with silica flooding, quartz stockworks, clay alteration, and up to 15 percent sulfides. The mineralization was mainly pyrite with zones of chalcopyrite in veinlets and disseminated in the altered dacitic rocks.

Production notes:

None.

Reserves:

None.

Last report date: 2008-03-04

Site name(s): Kamishak (Painted River)

Site type: Prospect

ARDF no.: IL047

Latitude: 59.2329 **Quadrangle:** IL A-4

Longitude: 154.4713

Location description and accuracy:

The Kamishak prospect is in the SE1/4 SE1/4 section 10, T. 11 S., R. 31 W. It is at an elevation of about 1,500 feet on the northwest wall of a southwest-trending canyon that continues into adjacent section 15. The location is accurate within 500 feet.

Commodities:

Main: Au, Cu

Other: Ag, Fe

Ore minerals: Bornite, chalcopyrite, magnetite, malachite, pyrite

Gangue minerals: Quartz

Geologic description:

The Kamishak prospect is a breccia pipe at least 300 feet in diameter in Jurassic(?) intermediate and mafic igneous rocks (Detterman and Reed, 1980; Alaska Geologic Materials Center, 1995; P. Thurston, written communication, 2003). The strongest mineralization in the pipe is near its walls, and consists of angular blocks of intensely sericitized, fine- to medium- grained gabbro, with 1 to 5 percent sulfides, in a matrix of coarse amphibole, biotite, and plagioclase. Weaker mineralization occurs in less-brecciated to massive gabbro and diorite, containing irregular clots of amphibole, biotite, chlorite, and sulfides. Minor phases of the breccia include hornblende gabbro and gabbroic anorthosite; the anorthosite locally contains a few percent of disseminated magnetite.

The sulfide minerals are chiefly pyrite and chalcopyrite; bornite locally makes up as much 5 percent of the breccia. Malachite coats joint faces of the mineralized rock which also contains up to about 3 percent magnetite. Samples of the breccia locally contain significant gold and copper and up to about 0.3 ounce of silver per ton. American Copper and Nickel Company (ACNC) drilled the deposit in 1990 and 1991 for a total of 5,300 feet (Alaska Geologic Materials Center, 1995). In drill hole 83523, the interval between 166 and 235 feet contained as much as 1,990 parts per billion gold and 2.58 percent copper; none of the core contained less than 102 parts per billion gold and 0.255 percent copper. Drill holes 83521 and 83524 through 83527 are also appreciably mineralized.

Alteration minerals in the breccia include chlorite, biotite, potassium feldspar, and sericite. Relatively high gold values appear to accompany coarse secondary biotite and apparently do not correlate with copper content.

Full Metal Minerals and Andover Ventures drilled 5 holes on this prospect in 2006 that totaled 750 meters (Andover Resources, 2008a, 2008b). Three of the 5 holes cut mineralization. Notable intercepts were: 1) 73.5 meters that contained 0.31 percent copper and 0.28 gram of gold per ton, 2) 51.0 meters that contained 0.48 percent copper and 0.46 gram of gold per ton, and 3) 7.50 meters that contained 0.36 percent copper and 0.53 gram of gold per ton. Two areas of mineralized breccia were identified. The westernmost breccia is a pipelike body about 30 by 50 meters in size; it is cut by a narrow fault with malachite and by thin sulfide- and magnetite-rich veins. The other breccia is a mineralized, pipelike body about 75 by 150 meters in size that extends to a depth of at least 75 meters. It has disseminated copper minerals as well as sulfide-bearing veinlets. This breccia locally contains abundant biotite, is strongly silicified, and also has sericite-pyrite, and

chlorite alteration.

In January, 2008 Alix Resources Corp. acquired the property from Full Metals Minerals and proposed future drilling to test two models of the deposit (Alix Resources Corp., 2008). One is that breccia mineralization is related to a porphyry-copper-type deposit. The other is that the breccia is structurally controlled and related to a northwest-striking structure across the property, i.e., the mineralization postdates the diorite and gabbro host rocks.

Alteration:

Propylitic and potassic: development of secondary biotite and potassium feldspar; local sericitization.

Age of mineralization:

Jurassic?

Generic deposit model:

Deposit model:

Porphyry copper-gold? (Cox and Singer, 1986; model 20c?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c?

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was discovered by Andy Snyder of the Spokane office of American Copper and Nickel Company (P. Thurston, written communication, 2003). The company core drilled 18 holes in 1990 and 1991 for a total of 5,300 feet. Full Metal Minerals and Andover Ventures drilled 5 holes on this prospect in 2006 that totaled 750 meters (Andover Resources, 2008a, 2008b). In 2008, Alix Resources Corp. acquired the property.

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): 308 Zone

Site type: Prospect

ARDF no.: IL053

Latitude: 59.7779 **Quadrangle:** IL D-7

Longitude: 155.485

Location description and accuracy:

The 308 Zone prospect is about 2.8 miles west of the top of Sharp Mountain, near the northeast corner of section 1, T. 5 S., R. 37 W. The location is accurate.

Commodities:

Main: Au?, Cu, Mo

Other:

Ore minerals: Chalcopyrite, molybdenite, pyrite

Gangue minerals: Quartz

Geologic description:

A single hole was drilled on the 308 Zone in 2004 by Northern Dynasty Minerals Inc. to test a IP geophysical anomaly in an area where a monzodiorite dike projects from the Kaskanak batholith into an area of well-bedded hornfelsed, Jurassic to Cretaceous argillite and siltstone (Rebagliati and Payne, 2005). The hole was entirely in porphyry-style alteration and mineralization similar to that at the 38 Zone prospect (IL004) about three miles to the northeast. The main-stage mineralization consists of weak, potassium-feldspar alteration with disseminated chalcopyrite, and quartz veins with some chalcopyrite and molybdenite. This mineralization was overprinted by strong sericite-pyrite alteration associated with quartz-pyrite and pyrite veins. Several thin polymetallic veins were intersected in the drill holes. The amount of chalcopyrite decreases markedly with depth, and the density of all of the veins is low along the length of the hole. The extent of this deposit is unknown.

Alteration:

Main stage alteration consists of weak, potassium-feldspar alteration with disseminated chalcopyrite, and quartz veins with some chalcopyrite and molybdenite. The mineralization was overprinted by strong sericite-pyrite alteration associated with quartz-pyrite and pyrite veins.

Age of mineralization:

Probably Late Cretaceous, about 90 Ma, by analogy with the nearby Pebble deposit (IL007).

Generic deposit model:

Deposit model:

Porphyry copper-gold-molybdenum deposit (Cox and Singer, 1986; model 20c or 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c or 21a

Production Status: None

Site Status: Active

Workings/exploration:

The area has been covered by extensive geochemical and geophysical surveys beginning in about 1986 as part of the exploration of the Pebble block of claims first by Cominco, by it successor Teck-Cominco, and through early 2011 by Northern Dynasty Minerals Ltd. Considerable mapping and sampling at the surface; 1 hole drilled in 2004.

Site name(s): Sill

Site type: Prospect

ARDF no.: IL054

Latitude: 59.8513 **Quadrangle:** IL D-6

Longitude: 155.2074

Location description and accuracy:

The Sill prospect is about 9.0 miles northeast of Sharp Mountain near the northeast corner of section 12. T. 4 S. R. 35 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold, pyrite

Gangue minerals: Quartz

Geologic description:

The Sill deposit is in Tertiary (40 Ma) fine-grained, equigranular to porphyritic latite (Bouley and others, 1995; Haslinger and others, 2004). The mineralization consists of narrow gold-quartz veins and quartz breccias in narrow pyritic alteration envelopes.

The Sill deposit was found in 1988 by Teck Cominco; they drilled 24 holes in 1988 and another 15 holes in 1989 for a total of 3,183 meters. Numerous intercepts contained more than 5 grams of gold per tonne including: 0.61 meters with 22.83 grams of gold per tonne, 0.61 meters with 24.34 grams of gold per tonne, 1.37 meters with 34.29 grams of gold per tonne, 0.49 meters with 26.00 grams of gold per tonne, and 0.30 meters with 25.99 grams of gold per tonne (Haslinger and others, 2004, table 8.0). Although the Sill prospect is in the large Pebble claim block held by Northern Dynasty Minerals Inc. as of early 201, they have done no work on the prospect.

Alteration:

Gold-quartz veins are in narrow pyritic alteration envelopes.

Age of mineralization:

40 Ma or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz veins (Cox and Singer, 1956; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Site name(s): Hope

Site type: Prospect

ARDF no.: JU022

Latitude: 58.8815 **Quadrangle:** JU D-4

Longitude: 135.0996

Location description and accuracy:

The Hope prospect is at an elevation of about 2,350 feet, in the Kakuhan Range, 2 miles northeast of Pt. Sherman on Lynn Canal and 1 mile west of Lions Head Mountain. It is approximately 0.2 mile east-southeast of the Ivanhoe Mine in the NE1/4 section 32, T. 34 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cu

Ore minerals: Chalcopyrite, pyrite

Gangue minerals: Quartz

Geologic description:

Note: Beginning in the 1990s, this and several old other mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Hope prospect was discovered in 1895 and by 1902 was developed by 2 adits and an open cut. The prospect is an east-trending quartz vein in metamorphosed basalt, unlike most other veins in the Berners Bay district which typically are hosted in Jualin Diorite. The vein is 8 feet thick in one adit. Samples contained up to 25 ppm gold (Redman and others, 1989).

The Hope prospect is in the Berners Bay district at the north end of the Juneau Gold Belt. The district is characterized by a series of structurally-controlled mesothermal, gold-bearing quartz veins. Most of the veins are in Lower Cretaceous Jualin Diorite, which intrudes Upper Triassic metabasalt (Miller and others, 1995). The age of mineralization in the Berners Bay area is about 55 Ma, the same as the other mesothermal gold vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Alteration:

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Location description and accuracy:

The Ophir prospect (or 'mine' as it is commonly called even though it has no production) is at an elevation of about 1,450 feet, 2 miles northeast of Pt. Sherman on Lynn Canal and 1 mile west-southwest of Lions Head Mountain in the Kakuhan Range. The 'Ophir Mine' is marked on the Juneau D-4 topographic map. It is approximately 3/4 mile northwest of the Kensington Mine (JU029), in the NE1/4 section 5, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Cu, Pb, Sb, Te, Zn

Ore minerals: Arsenopyrite, calaverite, chalcopyrite, galena, gold, hessite, petzite, pyrite, sphalerite, tetrahedrite

Gangue minerals: Albite, ankerite, apatite, calcite, chlorite, ferroan dolomite, muscovite, quartz, rutile, tourmaline

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Ophir prospect consists of several quartz veins and associated quartz-vein stockwork in Jualin Diorite. The Ophir deposit was discovered in 1887; the workings consist of a 350-foot adit with 250 feet of drifts, a 125-foot adit with a 75-foot crosscut, and a 75-foot inclined shaft (Redman and others, 1989). The Ophir workings explored at least 5 quartz veins, the Hartford, Ophir, Chilkat, Selkirk, and Acropolis (Kensington Mines, 1914).

Alteration:

Hydrothermal alteration adjacent to the veins is characterized by reddish-brown ferroan dolomite alteration (Miller and others, 1995). Other alteration includes sericitization of plagioclase, chloritization and sulfidization of mafic minerals, and albitization of feldspars (Leveille, 1991).

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Undetermined

Site Status: Active

Workings/exploration:

The Ophir deposit was discovered in 1887. Workings consist of a 350-foot adit with 250 feet of drifts, a 125-foot adit with a 75-foot crosscut and a 75-foot inclined shaft (Redman and others, 1989). The deposit has been explored by Placid Oil Co. and Echo Bay Mines/Coeur-Alaska, and in 2001 is controlled by Coeur-Alaska.

Production notes:

None.

Reserves:

None.

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Horrible vein was discovered about 1887 and by 1912 it was developed by a 84-foot adit, a 408-foot adit, a 230-foot crosscut and a 20-foot winze (Redman and others, 1989). The deposit has been extensively drilled by Placid Oil Co. and Echo Bay Mines/Coeur-Alaska and is currently (2001) controlled by Coeur-Alaska.

Production notes:

The Horrible mine produced 75 ounces of gold from 500 tons of ore, although 1,500 tons were mined from stopes (Redman and others, 1989).

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Mexican

Site type: Prospect

ARDF no.: JU028

Latitude: 58.867

Quadrangle: JU D-4

Longitude: 135.089

Location description and accuracy:

The Mexican prospect is at an elevation of about 2,050 feet, 2 miles northeast of Pt. Sherman on Lynn Canal and 1 mile west-southwest of Lions Head Mountain in the Kakuhan Range. It is 1/4 mile NW of the Kensington Mine (JU029) in the NW1/4 section 4, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Cu, Pb, Sb, Te, Zn

Ore minerals:

Gangue minerals: Albite, ankerite, apatite, calcite, chlorite, ferroan dolomite, muscovite, quartz, rutile, tourmaline

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Mexican prospect was discovered in 1887 and developed by 2 adits, a 135-foot crosscut, and a 106-foot drift. The deposit consists of a 1- to 8-foot-thick quartz vein, and a quartz-vein stockwork along a shear zone in Jualin Diorite. The zone trends northerly and dips 60-84 degrees east. The vein is possibly the same as the main vein one at the Horrible Mine (JU027) (Redman and others, 1989).

Alteration:

Hydrothermal alteration adjacent to the veins is characterized by reddish-brown ferroan dolomite alteration (Miller and others, 1995). Other alteration includes sericitization of plagioclase, chloritization and sulfidization of mafic minerals, and albitization of feldspars (Leveille, 1991).

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
36a

Production Status: None

Site Status: Active

Workings/exploration:
In its early years, the Mexican prospect was developed by 2 adits, a 135-foot crosscut and a 106-foot drift.

Production notes:
None.

Reserves:
None.

They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The deposit at Northern Belle Mine consists of several quartz veins and associated vein stockwork, including the Northern Belle, Elmira, and Yellowjacket. The veins strike N5-30E and dip 55-70SE. The Northern Belle stockworks is about 35 feet wide and has been traced along strike for 1,500 feet and along dip for 636 feet. The Elmira vein is less well defined than the Northern Belle, and may be the extension of the Yellowjacket vein. It strikes N28E for 1200 feet and is 1-5 feet thick (Kucinski and others, 1985). The Northern Belle deposit was discovered prior to 1896 and was mined between 1896 and 1897. There were 2 adits and 2 open stopes. Nine-hundred and forty ounces of gold was recovered from 2,302 tons of ore. Reportedly, 78 percent of the gold in the deposit was free-milling (Redman and others, 1989).

Alteration:

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Bear Mine is on a quartz vein in Jualin Diorite. It strikes NW and dips 40-70 NE. It has been traced for 500 feet along strike and 350 feet vertically, and has an average width of 5 to 10 feet (Chris Croff, Placid Oil Co., oral communication, 1987; Redman and others, 1989). The Bear deposit was discovered in 1887 and was mined from 1895 to 1897. Workings include an 1,100-foot crosscut, a 200-foot raise, and 3 levels with 850 feet of drifts. From 1895 to 1897, 800 ounces of gold were recovered from 5,900 tons of ore (Redman and others, 1989).

Site Status: Active

Workings/exploration:
The Bear deposit was discovered in 1887 and was mined from 1895 to 1897. Workings include an 1,100-foot crosscut, a 200-foot raise, and 3 levels with 850 feet of drifts.

Production notes:
From 1895 to 1897, 800 ounces of gold were recovered from 5,900 tons of ore (Redman and others, 1989).

Reserves:
None.

Site name(s): Comet

Site type: Mine

ARDF no.: JU036

Latitude: 58.8552 **Quadrangle:** JU D-4

Longitude: 135.0723

Location description and accuracy:

The Comet Mine is at an elevation of about 2,300 feet, about 3 miles east of Pt. Sherman on Lynn Canal and 1.5 miles south-southwest of Lions Head Mountain in the Kakuhan Range. The mine is marked on the Juneau D-4 topographic map. It is in the NE1/4 section 9, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cu, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Calcite, chlorite, ferroan dolomite, quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The deposit at the Comet Mine consists of 2 principal quartz veins about 50 ft apart that strike north and dip 70E. The largest vein is 300-500 feet long; it averages 2 to 3 feet wide at the surface and is up to 9 feet thick in underground exposures. The vein is truncated to the north by a large, left-lateral fault; to the south it crosses a diorite-phyllite contact, where it splits and ends. The veins contain pyrite, chalcopyrite, galena and free gold (Redman and others, 1989).

The Comet Mine is the largest gold producer in the Berners Bay region; it produced 22,485 ounces of gold from 51,463 tons of ore between 1894 and 1900. The deposit was discovered in the 1880s and tunneling began in 1891. A 20-stamp mill was in place by 1892 and production began in 1894. The mine has 9,000 feet of workings on 9 levels, 5 adits, and 1 open stope.

Alteration:

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Comet deposit was discovered in the 1880s and tunneling began in 1891. A 20-stamp mill was in place by 1892 and production began in 1894. The mine has 9,000 feet of workings on 9 levels, 5 adits and 1 open stope. Placid Oil Co. drilled several core holes in 1981.

Production notes:

The Comet Mine is the largest gold producer in the Berners Bay region producing 22,485 ounces of gold from 51,463 tons of ore between 1894 and 1900. The deposit was discovered in the 1880s and tunneling began in 1891. A 20-stamp mill was in place by 1892 and production began in 1894.

Reserves:

None.

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Seward prospect consists of a quartz vein in Jualin diorite. It is 5- to 12-feet thick, strikes N, dips E, and has been traced on the surface for approximately 1,100 feet. Samples collected before 1906 assayed up to 24 parts per million gold (Redman and others, 1989). The quartz contains free gold, but little or no sulfides (Kensington Mines, 1914). Workings include a 63-foot shaft with a 15-foot drift at the bottom, and 2 open cuts. The shaft and open cuts were completed during the 1890s.

Alteration:

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

This deposit is described separately in ARDF as the Kensington (Coeur-Alaska) deposit (JU261). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Cumberland prospect was probably developed before 1909. Workings include a 54-foot adit and an open cut. The adit exposes gray phyllite and felsic phyllite. Thin quartz veins containing minor pyrite occur near the portal and in a small shear near the face of the adit. Although native gold in quartz veins has been identified in dump samples by other workers in the area, U.S. Bureau of Mines samples all contained less than 0.1 part per million gold (Redman and others, 1989).

Location description and accuracy:

The DZ prospect is at an elevation of about 2,350 feet, on the ridge northeast of upper Johnson Creek. It is about 2 miles south-southeast of Lions Head Mountain near the center of section 11, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cu, Pb, Zn

Ore minerals: Pyrite

Gangue minerals: Calcite, chlorite, ferroan dolomite, quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

In 1984, Bear Creek Mining Company identified a N40W-trending, 300- to 800-foot-wide band of quartz veins with disseminated pyrite, that is now called the DZ prospect. The veins carry elevated gold values, accompanied by wallrock alteration similar in style to that at the Jualin Mine (JU044) and Kensington Mine (JU029) (Barnett, 1989). The veins at the DZ prospect are traceable for over 7,000 feet. Bear Creek collected 140 vein samples of which nearly 20 percent assayed 0.05 ounce or more gold per ton; the highest was 1.205 ounces of gold per ton. In 1987 and 1988 additional mapping and sampling was conducted by International Curator Resources, Ltd. (Barnett, 1989).

Alteration:

The alteration adjacent to the veins is characterized by reddish-brown ferroan dolomite alteration, sericitization of plagioclase, chloritization and sulfidization of mafic minerals, and albitization of feldspars (Leveille, 1991).

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

The DZ deposit was discovered and sampled by Bear Creek Mining Company in 1984. International Curator Resources and Placer Dome U.S. conducted additional mapping and sampling in 1987 and 1988.

Production notes:

None.

Reserves:

None.

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Indiana prospect was worked from 1896 to 1901 and was developed to intersect the northern extension of the Jualin (JU044) vein system. But the northern extension of the Jualin system deflects from northerly to northwesterly and the Indiana tunnels failed to reach it. The workings consist of a 1,600-foot adit, a 900-foot adit, and a 400-foot adit. A 10-stamp mill was also installed but not used at this site (Redman and others, 1989). The workings reportedly intersected auriferous quartz veins and stockworks, but no production occurred (Poncin, 1940).

Alteration:

Age of mineralization:

The age of mineralization in the Berners Bay district is about 55 Ma, the same as the other mesothermal gold-quartz-vein deposits in the Juneau Gold Belt (Goldfarb and others, 1997).

Gangue minerals: Albite, ankerite, apatite, calcite, chlorite, ferroan dolomite, muscovite, quartz, rutile, tourmaline

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Jualin deposit was discovered in 1895 and gold recovery began in 1896 when a 10-stamp mill was in operation. In 1914, the first semi-diesel generators in Alaska were installed. Between 1895 and 1929 the mine produced 37,913 ounces of gold from 74,624 tons of ore. The mill recovered 85-90 percent of the gold; 85 percent of the gold was free-milling and the remaining 15 percent was combined with sulfides (Redman and others, 1989).

The Jualin Mine is in Jualin Diorite in a shear zone 400 to 600 feet wide; the shear zone has a strike length of nearly 15,000 feet, and extends from the Jualin Mine area to the Ophir prospect (JU026). The veins in the shear zone generally strike N35W and dip 50-75 NE. The ore bodies pinch and swell along strike; they are as much as 40 feet thick and form ore shoots that exhibit a strong southeast rake (Barnett and others, 1989). Noteworthy veins include the Empire vein, East vein, and the 1, 2, 3, 3E and 4 veins. Production was from relatively high-grade individual veins. The number 1 vein averaged 7 feet thick and contained 0.53 to 0.73 ounce of gold per ton; the number 2 vein averaged 3 feet thick and contained from 0.73 to 0.12 ounce of gold per ton; and the number 3 vein was about 5 feet thick with an average grade of 0.48 ounce of gold per ton (Redman and others, 1989).

Workings at the Jualin Mine include over 15,000 feet of workings on 5 levels. They included two inclined shafts, one 220 deep and the other 160 feet deep; a 310-foot main shaft; a 150-foot shaft; and the 5,000-foot Berners Tunnel (Redman and others, 1989). A 5.5-mile access road was completed from tidewater to the

mine site in July, 1988 (Barnett, 1989). Core drilling as of the end of 1991 totaled 82,337 feet in 126 holes (Bundtzen and others, 1991). Coeur Alaska acquired the rights to the Jualin Mine area from International Curator Resources Ltd. in 1995 (Swainbank and others, 1995).

Alteration:

Hydrothermal alteration adjacent to individual veins is characterized by reddish-brown ferroan dolomite (Miller and others, 1995). Other alteration includes sericitization of plagioclase, chloritization and sulfidization of mafic minerals, and albitization of feldspars (Leveille, 1991). The quartz-carbonate stockworks in the Jualin vein system feature three zones of alteration within and adjacent to the stockworks: 1) an inner zone of intense carbonate-sericite alteration; 2) an intermediate zone of mottled, dark-green diorite marked by cataclastic fabric and increased chlorite +/- sericite; and 3) an outer zone of equigranular diorite with abundant epidote, and locally, potassium feldspar (Barnett and others, 1989).

Age of mineralization:

Hydrothermal muscovite from veins in the Jualin Mine gives ages of from 53.2 Ma to 55.5 Ma (Miller and others, 1994). This coincides with the 55 Ma age of the mesothermal gold-quartz-vein deposits elsewhere in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes

Site Status: Active

Workings/exploration:

Workings at the Jualin Mine include over 15,000 feet of workings on 5 levels. These include two inclined shafts, one 220 deep and the other 160 feet deep; a 310-foot main shaft; a 150-foot shaft; and the 5, 000-foot Berners Tunnel (Redman and others, 1989). A 5.5-mile access road was completed from tidewater to the mine site in July, 1988 (Barnett, 1989). Core drilling as of the end of 1991 totaled 82,337 feet in 126 holes (Bundtzen and others, 1991).

Production notes:

The Jualin deposit was discovered in 1895 and the mine began producing gold in 1896 when a 10-stamp mill was in operation. In 1914, the first semi-diesel generators in Alaska were installed. Between 1895 and 1929, the mine produced 37,913 ounces of gold from 74,624 tons of ore. The mill recovered 85-90 percent of the gold; 85 percent of the gold was free-milling and the remaining 15 percent was combined with sulfides (Redman and others, 1989).

Reserves:

None.

ARDF no.: JU045

Latitude: 58.838 **Quadrangle:** JU D-4

Longitude: 135.0488

Location description and accuracy:

This prospect is in Snowslide Gulch at an elevation of 915 feet. It is 2.5 miles northwest of Berners Bay and 1/3rd of a mile south of the Jualin Mine (JU044) in the NE1/4 section 15, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Pyrite

Gangue minerals: Quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Snowslide Gulch prospect was probably explored in the early 1900s by a 115-foot adit. The deposit consists of pyrite disseminated in quartz-chlorite phyllite and pyrite in a bluish quartz vein. The vein is in a shear zone in the phyllite. No significant metal values were found in samples collected by the U.S. Bureau of Mines (Redman and others, 1989).

Alteration:

Sericitic and chloritic.

Age of mineralization:

Hydrothermal muscovite from veins in the Jualin mine are 53.2 Ma to 55.5 Ma (Miller and others, 1994). This coincides with the 55 Ma age of the other mesothermal gold veins in the Juneau Gold Belt (Goldfarb and others, 1997).

Gangue minerals: Calcite, quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

There are several prospects at this site which is completely covered by colluvium. The area is underlain mainly by sheared and altered Jualin Diorite (Barnett and others, 1988). Workings at the Thomas prospect include a caved adit (Barnett and others, 1988). A sample of dump material had 0.1 part per million (ppm) gold (Redman and others, 1989). The Valentine prospect, located on the Falls and Diana claims, is 300 feet west of the Thomas prospect. Workings include 2 water-filled shafts and a 115-foot adit. The shafts were sunk on felsic (quartz-sericite) phyllite and chlorite phyllite near the contact with the Jualin Diorite. The adit exposes pyritic, quartz-chlorite phyllite. The phyllite hosts a 5-foot band of stratiform pyrite and chalcopyrite which has been traced 150 feet to the southeast. The band contains up to 15 percent chalcopyrite and is in a shear zone in phyllite near the contact with Jualin Diorite (Redman and others, 1989). U.S. Bureau of Mines samples contained up to 161.9 ppm gold, 89.1 ppm silver, and 5.1 percent copper (Redman and others, 1989).

Latitude: 58.8364 **Quadrangle:** JU D-4

Longitude: 135.0166

Location description and accuracy:

The Big Lake prospect is at an elevation of 1,200 feet, about 0.7 mile from the northeast side of Johnson Creek and 1 mile northwest of Berners Bay. It is in the NE1/4 section 14, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cu, Pb, Zn

Ore minerals: Chalcopyrite, malachite, pyrite

Gangue minerals: Ankerite, calcite, hematite, quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Big Lake prospect was discovered in 1988 by International Curator Resources, Ltd. It consists of a series of parallel quartz veins that strike northwest and dip 70NE in Jualin Diorite. The veins crop out along the ridge crest for nearly 1,300 feet; they extend toward the Yankee Boy prospect (JU051), about 2,300 feet away. The Big Lake and Yankee Boy veins are probably part of the same vein system that consists of a zone about 300 feet wide. There are two distinct types of Big Lake quartz veins; one is massive and the other consists of thin, white veinlets. The massive veins are distinguished by a pervasive yellow-brown iron stain, sheared margins, and 1 to 10 percent pyrite; they are in sheared, chloritic diorite that contains about 1 percent disseminated pyrite. The small, white, veinlets range in thickness from one-eighth inch to three feet, and lay parallel to each other in zones up to fifty feet wide. The veins contain isolated blebs of pyrite, chalcopyrite, malachite, and specular hematite. Alteration adjacent to the veins is characterized by sericite, pervasive interstitial carbonate, and moderate to strong silicification (Barnett and others, 1989). In 1988, International Curator Resources Ltd. collected numerous samples of the Big Lake veins and Placer Dome U.S. drilled one core hole in 1989. The average for twenty grab samples collected along strike for 1200 feet was 0.454 ounce of gold per ton (Barnett, 1989). The drill hole had several anomalous intercepts; one 2.5-foot core sample assayed 0.109 ounce of gold per ton (Barnett and others, 1989).

Alteration:

Alteration adjacent to the veins is characterized by sericite, pervasive interstitial carbonate, and moderate to strong silicification. Local oxidation of copper minerals.

Age of mineralization:

Hydrothermal muscovite from veins in the Jualin mine are 53.2 Ma to 55.5 Ma (Miller and others, 1994). This coincides with the 55 Ma age of the other mesothermal gold veins in the Juneau Gold Belt (Goldfarb and others, 1997).

Location description and accuracy:

This prospect is at an elevation of about 350 feet on Johnson Creek. It is 2 miles northwest of Berners Bay and 3/4 mile southeast of the Jualin Mine (JU044), in the SW1/4 section 14, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Fremming prospect was discovered by Frank Fremming in about 1897. Fremming drove a 360-foot adit and sank a 85-foot inclined shaft by 1905. The deposit consists of a 6-foot thick phyllite layer that contains 1 to 3 percent disseminated pyrite and thin, stratiform lenses of pyrite. The stratiform pyrite has been traced on the surface for 800 feet by trenching (Redman and others, 1989). Underground, at the end of the adit, there is a 6-foot-wide zone of sulfide-bearing schist and quartz-calcite stringers that contains pyrite, chalcopyrite, galena, sphalerite, and free gold (Knopf, 1911). A shear zone near the Fremming shaft contains a quartz vein with sphalerite, galena, pyrite, and chalcopyrite (Redman and others, 1989). Redman and others (1989), interpret the Fremming prospect as a volcanogenic massive sulfide deposit. However, exploration of the Fremming prospect area by International Curator Resources Ltd., combined with observations of drill core from both the Jualin mine (JU044) and the Fremming prospect, indicate that the predominant host rock is Jualin Diorite (Barnett and others, 1988). This interpretation is supported by Kaplar (1988) who showed that the diorite loses its textural and mineralogical identity as shearing becomes more intense. Rocks at or near the Fremming workings thus can be classified as greenstone and phyllite but their protolith probably was Jualin Diorite (Kapler, 1988). Exploratory drilling by International Curator Resources Ltd. encountering minor zones of anomalous metal values (Barnett and others, 1988).

Alteration:

Chloritic.

Age of mineralization:

Hydrothermal muscovite from veins in the Jualin mine are 53.2 Ma to 55.5 Ma (Miller and others, 1994). This coincides with the 55 Ma age of the other mesothermal gold veins in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit or a remobilized epigenetic copper-lead-zinc-gold deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Workings consist of a 360-foot adit and an 85-foot inclined shaft.

Production notes:

None.

Reserves:

None.

Site name(s): Berners Tunnel

Site type: Prospect

ARDF no.: JU050

Latitude: 58.8294 **Quadrangle:** JU D-4

Longitude: 135.0172

Location description and accuracy:

The Berners Tunnel is at an elevation of about 150 feet in a short, unnamed north tributary to Johnson Creek. It is 3.5 miles south of Lions Head Mountain and 2 miles north-northwest of Berners Bay, in the SE1/4 section 14, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cu, Pb, Zn

Ore minerals: Chalcopyrite, gold, pyrite

Gangue minerals: Ankerite, calcite, quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Berners Tunnel was begun in 1914 to drain water from the Jualin Mine (Redman and others, 1989). The tunnel, which trends northwesterly was never completed. During construction, workers collected ten-foot rock-chip samples along its 5,000-foot length. Two intervals contained elevated gold values. Between stations 1912 and 2042 from the portal, a 130-foot zone averaged 0.12 ounce of gold per ton; between stations 2112 and 2212, a 100-foot zone averaged 0.087 ounce of gold per ton. The first 400 feet of the tunnel was in glacial till and colluvium and the portal has long since collapsed. In 1989, Placer Dome U.S. drilled 3 core holes along the trace of the Berners Tunnel. The drill holes cut numerous anomalous zones along a major NW-trending shear zone. The richest intercept averaged 0.028 ounce of gold per ton. The drill core consists of moderately to strongly sheared diorite with widespread potassic and sericitic alteration. The potassic alteration suite includes epidote, chlorite, and pyrite. Locally, the sheared diorite is highly silicified giving it a bleached appearance. This silicified diorite contains relatively abundant, disseminated pyrite and chalcopyrite, and quartz-pyrite veinlets (Barnett and others, 1989).

Alteration:

The drill core consists of moderately to strongly sheared diorite showing widespread potassic and sericitic alteration. The potassic alteration suite includes epidote, chlorite, and pyrite. Locally, the sheared diorite is highly silicified giving it a bleached appearance.

Age of mineralization:

Hydrothermal muscovite from veins in the Jualin mine are 53.2 Ma to 55.5 Ma (Miller and others, 1994).

This coincides with the 55 Ma age of the other mesothermal gold veins in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

The site consists of a 5,000-foot tunnel which is caved at the portal. Placer Dome U.S. drilled 3 core holes along the trace of the tunnel in 1989.

Production notes:

None.

Reserves:

None.

Site name(s): Yankee Boy; Yankee

Site type: Prospect

ARDF no.: JU051

Latitude: 58.829 **Quadrangle:** JU D-4

Longitude: 135.0017

Location description and accuracy:

The Yankee prospect is at an elevation of 570 feet,on the north valley wall of Johnson Creek. It is 1 mile northwest of Berners Bay, in the SW1/4 section 13, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au

Other: As

Ore minerals: Arsenopyrite, gold, pyrite

Gangue minerals: Calcite, quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The Yankee Boy vein was discovered about 1911 and explored by a 136-foot adit and 4 open cuts (Redman and others, 1989). The Yankee Boy deposit consists of a single quartz vein in Jualin Diorite that is traceable for 3,000 feet northwest from the Yankee adit. The vein strikes N41W and dips steeply south. The thickness varies from a few inches to five feet and averages two feet. Roehm (1938) describes the vein as banded quartz with a darker, bluish core. The outer bands are nearly barren of sulfides and vary from milky white to glassy. Sulfide minerals are confined mainly to the central bluish band, which varies in width from a few inches to 18 inches but averages less than 12 inches. Pyrite and a little arsenopyrite are the only sulfides in the vein. The vein represents two generations of quartz: a milky white to glassy rim, and grayish blue core (Roehm, 1938). Roehm reports that samples of the vein contained up to 1.6 ounces of gold per ton and 1.0 ounce of silver per ton. In 1988, Curator International Resources Ltd. collected samples of the Yankee vein; one, two-foot chip sample assayed 1.35 ounces of gold per ton (Barnett, 1989).

Alteration:

Age of mineralization:

Hydrothermal muscovite from veins in the Jualin mine are 53.2 Ma to 55.5 Ma (Miller and others, 1994). This coincides with the 55 Ma age of the other mesothermal gold veins in the Juneau Gold Belt (Goldfarb and others, 1997).

Generic deposit model:

Deposit model:
Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
36a

Production Status: None

Site Status: Active

Workings/exploration:
The Yankee prospect was discovered about 1911 and explored by a 136-foot adit and 4 open cuts (Redman and others, 1989). Limited exploration was conducted by International Curator Resources Ltd. in 1988 (Barnett, 1989).

Site type: Prospect

ARDF no.: JU052

Latitude: 58.8267 **Quadrangle:** JU D-4

Longitude: 135.0201

Location description and accuracy:

The Mystery prospect is at an elevation of 350 feet, on the north wall of lower Johnson Creek. It is 1.5 miles northwest of Berners Bay and 1.5 mile southeast of the Jualin mine (JU044), in the NE1/4 section 23, T. 35 S., R. 62 E. of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Pyrite

Gangue minerals: Quartz

Geologic description:

Note: Beginning in the 1990s, this and other old mines and prospects in the vicinity were consolidated by Coeur-Alaska into a single property (Birak, 2006). They have carried out major new drilling and underground exploration that better defines the mineralization, largely blurs the geologic distinction among the old deposits, and extends the ore bodies greatly. They have developed a coherent modern interpretation of the mineralization as a single deposit which Coeur-Alaska intends to mine as a unit. This deposit is described separately in ARDF as the Jualin (Coeur-Alaska) deposit (JU262). For geologic reference purposes and for their historic value, the pre-Coeur-Alaska data for this and the other old mines and prospects that Coeur-Alaska consolidated are retained in ARDF.

The rocks at the Mystery prospect are similar to those at the Fremming prospect (JU049). They consist of light green, chloritic phyllite and greenstone. Redman and others (1989), interpret the Mystery prospect as a stratabound, volcanogenic massive sulfide deposit. However, exploration by International Curator Resources Ltd., combined with observations of drill core from both the Jualin Mine (JU044) and the nearby Fremming prospect (JU049), indicate that the predominant host rock is probably Jualin Diorite (Barnett and others, 1988). This interpretation is supported by Kaplar (1988) who showed that the diorite loses its textural and mineralogical identity as shearing becomes more intense. Rocks at or near the Mystery workings thus can be classified as greenstone and phyllite, but their protolith probably was Jualin Diorite (Kapler, 1988). Workings at the Mystery prospect include a water-filled shaft and several sloughed-in pits. The shaft is sunk on a 3-foot-thick layer of light green phyllite that contains 5-15 percent disseminated pyrite, and massive pyrite layers parallel to the foliation. The pyrite layers are up to 2 inches thick. Samples contain up to 1.4 part per million (ppm) gold, 1.5 ppm silver, and 5,500 ppm copper (Redman and others, 1989).

Alteration:

Chloritic.

Age of mineralization:

Hydrothermal muscovite from veins in the Jualin mine are 53.2 Ma to 55.5 Ma (Miller and others, 1994). This coincides with the 55 Ma age of the other mesothermal gold veins in the Juneau Gold Belt (Goldfarb

and others, 1997).

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit or a remobilized epigenetic copper-lead-zinc-gold deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Workings at the Mystery prospect include a water-filled shaft and several sloughed-in pits.

Production notes:

None.

Reserves:

None.

Site name(s): Herbert Glacier; Herbert Gold

Site type: Prospect

ARDF no.: JU097

Latitude: 58.5309 **Quadrangle:** JU C-3

Longitude: 134.6855

Location description and accuracy:

This prospect is approximately 18.7 miles northeast of Juneau at the south edge of the terminus of Herbert Glacier at an elevation of approximately 500 feet. It is about 2.3 miles northeast of the center of Windfall Lake and about 0.5 mile south-southeast of the center of section 33, T. 38 S., R. 65 E., of the Copper River Meridian. The location site is centered in the area of drilling between 2010 and 2012 along where the Main vein outcrops.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals: Arsenopyrite, galena, gold, pyrite, scheelite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The Herbert Glacier prospect is near the Coastal Shear Zone that parallels the boundary between the Gravina belt to the west and the Taku terrane to the east. The Gravina belt comprises Upper Jurassic to Mid-Cretaceous marine argillite and greywacke, interbedded andesite to basaltic volcanic and volcaniclastic rocks, and plutons ranging from quartz diorite to peridotite (Gehrels and Berg, 1994). The Taku terrane contains older Permian to Triassic age marble, phyllite, pillow basalt, and flysch-related rocks, which are overlain by Upper Jurassic to Mid-Cretaceous greywacke and, likely, related to similar age rocks in the Gravina belt. Metamorphic grade ranges from greenschist to amphibolite facies and generally increases from west to east. Regional metamorphism and deformation, including the Coastal Shear Zone, are broadly linked to emplacement of multiple intrusive rocks in the Coast Mountains that have isotopic ages ranging from 10 to 55 Ma (Gehrels and Berg, 1994).

The Herbert Glacier prospect was discovered in 1986 by Houston Oil and Minerals in outcrops recently exposed by retreating ice (Redman and others, 1989). The deposit consists of five east-trending veins; from north to south these are the North vein, the Goat Creek vein, the Main vein, the Deep Trench vein, and the Floyd vein (Grande Portage Resources Ltd., 2010a; Hale and Hawley, 2011). The veins are in a northwest-trending, fault-bounded band of hornblende-biotite quartz diorite about 800 meters wide. The diorite is bounded to the northeast by gneiss and to the southwest by low-grade metasedimentary rocks.

The veins dip steeply to the north, are composed of quartz and subordinate calcite, and exhibit ribbon texture. They pinch and swell and vary from a few inches to 4 feet thick. The veins are in shear zones perpendicular to the regional foliation, are marked by slickensided cores, and contain native gold, arsenopyrite, pyrite, galena, sphalerite, and scheelite. Fist-size clots of arsenopyrite form up to 20 percent of the principal veins and visible gold occurs in the footwalls of galena-rich parts of the veins. Potassic alteration in the footwalls extends several feet into the wallrock. U.S. Bureau of Mines samples contained up to 37.2 parts per million (ppm) gold, 186.7 ppm silver, more than 1 percent lead, and 0.36 percent zinc (Redman and others, 1989). Samples of the south set of veins contained up to 240.8 ppm gold, 126.9 ppm silver, more than 1 percent lead, and 0.36 percent zinc. The Bureau of Mines collected a 240-pound metallurgical sample for analysis and beneficiation tests in 1988. A gravity separation test recovered 88.8

percent of the gold and 80.7 percent of the silver (Redman and others, 1989).
In July 2016, Grande Portage Resources Ltd. announced it entered into an agreement, through its wholly-owned subsidiary GPG Alaska Resources Inc., with its' joint-venture partner Quaterra Alaska, Inc., the wholly-owned subsidiary of Quaterra Resources Inc., to acquire Quaterra's 35 percent participating interest in the Herbert Gold project (Athey and Werdon, 2017).

Alteration:

Potassic alteration in the footwalls extends several feet into the wallrock (Redman and others, 1989). Sericite, chlorite, and carbonate-altered quartz diorite is observed up to 1 meter adjacent to veining (DuPre and Webb, 2013).

Age of mineralization:

Isotopic dates indicate that the auriferous veins in the Juneau Gold Belt formed between 56 and 55 Ma (Miller and others, 1994; Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Tenneco Minerals and its successor Echo Bay Mining Mining Company drilled at least 7 shallow holes from 1986 to 1988. Some notable intercepts were 1 foot that contained 3.85 ounces of gold per ton, 14 feet that contained 0.98 ounce of gold per ton, and 1 foot that contained 12.64 ounces of gold per ton (Grand Portage Resources Ltd., 2010a).

Grande Portage Resources Ltd. began exploring the Herbert Glacier deposit under an agreement with Quaterra Resources in June of 2010 (Grande Portage Resources Ltd., 2010a). In 2010, they drilled 19 holes in several veins (Grande Portage Resources Ltd., 2010b, 2010c). Some of the notable intercepts were 1.85 meters with 4.012 grams per tonne (g/t) gold; 1.51 meters with 4.84 g/t gold; 0.44 meter with 9.91 g/t gold; 1.14 meters with 17.1 g/t gold; and 0.71 meter with 11.35 g/t gold.

Grande Portage drilled 31 more holes in 2011 on the Goat Creek vein, the Ridge vein, the Main vein, and the Trench vein, and dug 4 trenches (Hale and Hawley, 2011; Grande Portage Resources Ltd., 2011). The tenor of the mineralization on the Main vein was confirmed. Some notable intercepts on the Deep Trench vein were 3.52 meters that averaged 11.53 g/t gold; 4.6 meters that averaged 4.18 g/t gold, and 1.36 meters that averaged 9.26 g/t gold.

In 2012 Grande Portage Resources Ltd. drilled 62 more holes for a total of 8,805 meters (DuPre and Webb, 2013). Highlights of some of the assay results from drilling include 13.23 meters at 4.04 g/t gold, 2.05 meters at 79.41 g/t gold, 1.13 meters at 48.12 g/t gold, and 2.12 meters at 11.72 g/t gold (Grande Portage Resources Ltd., 2012a). The best intercept occurred over 0.71 meter and contained 428 g/t gold. The 2012 drilling help delineate mineralization along strike of the Deep Trench vein for over 400 meters (Grande Portage Resources Ltd., 2012b).

Production notes:

None.

Reserves:

In 2013 DuPre and Webb completed an updated resource estimate for Herbert Glacier. The resource is

based on eight veins, uses 2 grams per tonne (g/t) for a cut-off, and assumes an average gold price of $1,500 per ounce. The inferred resource is 51,611 tonnes grading 7.73 g/t gold yielding 12,819 ounces of gold and the indicated resource is 821,100 tonnes grading 6.91 g/t gold yielding 182,400 ounces of gold (DuPre and Webb, 2013).

As recorded in their NI 43-101 technical report of April 10, 2013, the Herbert Gold project contains an indicated resource of 821,100 tonnes containing 182,400 ounces of gold at 6.91 grams of gold per tonne. Additionally, inferred resources include 51,600 tonnes containing 12,800 ounces of gold at 7.73 grams of gold per tonne (DuPre and Webb, 2013). Drilling has intersected the mineralized vein over a strike length of 370 meters and to a depth of more than 200 m. The vein can be traced at surface over a strike length of 1,000 meters (Athey and Werdon, 2017).

Site name(s): Greens Creek

Site type: Mine

ARDF no.: JU253

Latitude: 58.079 **Quadrangle:** JU A-2

Longitude: 134.6312

Location description and accuracy:

The Greens Creek Mine is at an elevation of 1,500 feet on the south side of Greens Creek on Admiralty Island. The mine is marked on the Juneau A-2 topographic map in the NW1/4 section 9, T. 44 S., R. 66 E. of the Copper River Meridian. The location is accurate to about 1/4 mile.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Ba, Bi

Ore minerals: Acanthite, barite, bornite, chalcopyrite, electrum, freibergite, galena, proustite, pyrite, sphalerite, tetrahedrite, tennantite-tetrahedrite

Gangue minerals: Calcite, graphite, quartz

Geologic description:

The Greens Creek deposit is discontinuous along the contact between a structural hanging wall of thinly laminated, quartz-mica-carbonate phyllite and a structural footwall of black, graphitic, meta-argillite. Fossils in calcareous, black argillite clasts in pyritic massive sulfide ore are Late Triassic in age (Crafford, 1989). The most intense alteration is closest to the copper-rich portions of the orebody and consists of intense silica-pyrite alteration. Three main types of ore have been recognized at the Greens Creek Mine: massive, black, and white. Massive ore is the most common and contains more than 50 percent sulfides, chiefly pyrite, sphalerite and galena, in a matrix of locally barite-bearing silica-carbonate rock. Less-abundant ore minerals include chalcopyrite, tetrahedrite, freibergite, proustite, and electrum. The pyrite content of the massive ore varies from 80 to 90 percent in base-metal-poor ore to 10 to 15 percent in base-metal-rich ore. The black ore is similar to the massive ore, except that it contains appreciable graphite. White ore varies depending upon whether the gangue is primarily barite, silicates, or carbonates. The white ore is pyrite-poor and contains coarse-grained tetrahedrite-tennantite, bornite, freibergite, proustite, galena, sphalerite, chalcopyrite and acanthite. Very high precious metal values are common in base-metal-rich massive sulfides near the stratigraphic hanging wall contact, but gold is common in all three types of ore (Newberry and others, 1997).

The Greens Creek deposit was discovered in 1973 by following up a zinc stream-sediment anomaly (T.C. Crafford, oral communication, 2000). The underground mine and concentrator facility began operation in 1989, but was placed on standby in 1993, followed by a $114-million, 3-year, modernization. Operations resumed in 1996 (Kennecott Minerals Company, 2001) and have continued steadily to 2011. The deposit is serviced by 13 miles of road. In addition to the mine, there is an ore concentrating mill, a tailings impoundment area, a ship-loading facility, camp facilities, and a ferry dock at Hawk Inlet. Ore from the underground trackless mine is milled at the mine site. The mill produces gold-silver dore as well as lead, zinc and bulk concentrates. Concentrates are shipped from a marine terminal about nine miles from the mine site.

The rocks in the surrounding area are mainly Ordovician and Devonian to Triassic, clastic units, mafic-intermediate volcanic rocks, and subordinate limestone. The bedded rocks are intruded and locally metamorphosed by Cretaceous granodiorite (Gehrels and Berg, 1994).

In 2008, Hecla Mining Company acquired a 100 percent interest in the mine from Rio Tinto (Hecla Mining Company, 2011). In 2009, the Greens Creek Mine produced 7,459,170 ounces of silver, 67,278 ounces of gold, 70,379 tons of zinc, and 22,254 tons of lead from 790,871 tons of ore that was milled (Szumigala and others, 2010). In 2009, 39,000 feet of infill and exploration drilling added ore reserves equivalent to the ore that was mined that year. In 2009, the proven and probable ore reserves were 8,314,700 tons with an average grade of 12.1 ounces of silver per ton, 0.10 ounce of gold per ton, 20.3 percent zinc, and 3.6 percent lead.

In 2012, the Greens Creek Mine produced 1) 6,400,000 ounces of silver, 2) 55,496 ounces of gold, 3) 64, 249 tons of zinc, and 21,074 tons of lead from 789,569 tons of ore that was milled (Athey and others, 2013). In 2012, the proven and probable ore reserves were reported as 1) 92,500,000 ounces of silver with an average grade of 11.9 ounces of silver per ton, 2) 713,000 ounces of gold with an average grade of 0.09 ounces of gold per ton, 3) 9.0 percent zinc, and 4) 3.4 percent lead (McDonald and others, 2013).

In 2016, Hecla Mining Company produced 9,253,543 ounces of silver from Greens Creek mine, which was the highest since Hecla acquired 100 percent of the mine in 2008, an increase over the prior year by 9.5 percent; gold production of 53,912 ounces decreased by 11.0 percent from the 2015 level. The mine also yielded 20,596 tons of lead, and 57,729 tons of zinc. The mill operated at an average of 2,229 tons per day for the year, for a total of 815,639 tons. Ore grades milled were 14.55 ounces of silver per ton, 0.10 ounce of gold per ton, 3.11 percent lead, and 8.08 percent zinc. Definition drilling at Greens Creek in 2016 refined the resources of the 9A, Southwest Bench, East Ore and NWW zones (Athey and Werdon, 2017).

Alteration:

The most intense alteration is closest to the copper-rich portions of the orebody and consists of intense silica-pyrite alteration.

Age of mineralization:

Fossils in calcareous, black argillite clasts intercalated with pyritic massive-sulfide ore are Late Triassic (Crafford, 1989).

Generic deposit model:

Volcanogenic massive sulfide deposits (Franklin and others, 2005)

Deposit model:

Kuroko massive sulfide deposit (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: Yes; large

Site Status: Active

Workings/exploration:

The Greens Creek deposit was discovered in 1973. The underground mine and concentrator began operation in 1989. The deposit is serviced by 13 miles of road. In addition to the mine, there is an ore concentrating mill, a tailings impoundment area, a ship-loading facility, camp facilities, and a ferry dock at Hawk Inlet. The mine has been in continuous operation since 1996 after a few year's interruption to modernize the plant. In 2008, Hecla Mining Company acquired a 100 percent interest in the mine from Rio Tinto. In 2009, 39,000 feet of infill and exploration drilling added ore reserves equivalent to the ore that was mined that year.

Exploration at Greens Creek mine is concentrated along the trend of numerous underground volcanogenic massive sulfide ore bodies, and on Hecla Mining Company’s 23-square-mile, surface land package. Exploration work in 2016 increased reserves for the 9A and NWW zones, where approximately 8.3 million ounces of silver and 46,500 ounces of gold were added. Measured and indicated resources were increased with additions in the 9A, NWW, SW, Gallagher zones, and the newly established Upper Plate resource. Inferred resources decreased for silver and gold overall, as they were converted to reserves and indicated

resources at the NWW Zone; all other zones, except 200 South, showed increases in inferred gold and silver resources.

In 2016, exploration drilling was concentrated on the Gallagher Zone and the Mine Syncline, a new exploration target area where the ore horizon has been identified in the north and south-central parts of the mine. Drilling of the NWW Zone’s southern extension continues to define mineralization along the lower fold, continuing from the fold nose and along the upper limb. Mineralization is represented by multiple distinct bands of massive ore and mineralized argillites and has similar geometry and dimensions to the current resource model. Highlights of assay results include 45.4 ounces of silver per ton, 0.20 ounce of gold per ton, 19.0 percent zinc, and 10.3 percent lead over 18.6 feet, and 51.7 ounces of silver per ton, 0.20 ounce of gold per ton, 11.2 percent zinc, and 4.8 percent lead over 10.0 feet. Drilling also targeted the Upper Southwest Zone around previously mined levels, and identified mineralization that extends down to the upper limb of NWW Zone. Highlighted assay results from Upper Southwest Zone include 46.8 ounces of silver per ton, 0.03 ounce of gold per ton, 10.9 percent zinc, and 6.1 percent lead over 10.2 feet. The drilling also identified shallow mineralization east of the Kahuna fault. Recent drilling of the lower 9A Zone has generally confirmed and upgraded the resource model. Initial definition drilling of the East Ore Zone shows that overall the mineralization is thinner than expected compared to the model, but this drilling is advancing into stronger mineralized portions of the resource.

Gallagher Zone exploration drilling targeted a new flat-lying zone above the 4211 Drift that may define an ore-horizon contact that steepens to the east near the Gallagher fault. Deep exploration drilling of the Mine Syncline shows the ore-horizon contact continues steeply down dip from the NWW Zone and could define a broad syncline below the current mine infrastructure that could host mineralization. Drilling of this same syncline in the central part of the mine shows the ore-horizon contact is the down-dip extension of the lower fold limb of the NWW zone (Athey and Werdon, 2017).

Production notes:

In 2009, the Greens Creek Mine produced 7,459,170 ounces of silver, 67,278 ounces of gold, 70,379 tons of zinc, and 22,254 tons of lead from 790,871 tons of ore that was milled (Szumigala and others, 2010).

In 2012, the Greens Creek Mine produced 1) 6,400,000 ounces of silver, 2) 55,496 ounces of gold, 3) 64, 249 tons of zinc, and 21,074 tons of lead from 789,569 tons of ore that was milled (Athey and others, 2013).

In 2016, Hecla Mining Company produced 9,253,543 ounces of silver from Greens Creek mine, which was the highest since Hecla acquired 100 percent of the mine in 2008, an increase over the prior year by 9.5 percent; gold production of 53,912 ounces decreased by 11.0 percent from the 2015 level. The mine also yielded 20,596 tons of lead, and 57,729 tons of zinc. The mill operated at an average of 2,229 tons per day for the year, for a total of 815,639 tons. Ore grades milled were 14.55 ounces of silver per ton, 0.10 ounce of gold per ton, 3.11 percent lead, and 8.08 percent zinc. Definition drilling at Greens Creek in 2016 refined the resources of the 9A, Southwest Bench, East Ore and NWW zones (Athey and Werdon, 2017).

Reserves:

In 2009, the proven and probable ore reserves were 8,314,700 tons of of material with an average grade of 12.1 ounces of silver per ton, 0.10 ounces of gold per ton, 20.3 percent zinc, and 3.6 percent lead. In 2009, 39,000 feet of infill and exploration drilling added ore reserves equivalent to the ore that was mined that year.

In 2012, the proven and probable ore reserves were reported as 92,500,000 ounces of silver with an average grade of 11.9 ounces of silver per ton, 713,000 ounces of gold with an average grade of 0.09 ounces of gold per ton, 9.0 percent zinc, and 3.4 percent lead (McDonald and others, 2013).

As of December 31, 2016, proven and probable reserves at Greens Creek include 7.594 million short tons grading 11.7 ounces of silver per ton, 0.09 ounce of gold per ton, 2.9 percent lead and 7.6 percent zinc, for a contained metal content of 88.87 million ounces of silver, 673,000 ounces of gold, 217,280 tons of lead, and 576,130 tons of zinc. Indicated resources include 1,785,000 tons of material grading 10.8 ounces of silver per ton, 0.09 ounce of gold per ton, 3.1 percent lead and 7.8 percent zinc, for a contained metal content of 19.3 million ounces of silver, 154,000 ounces of gold, 55,980 tons of lead, and 139,660 tons of zinc. Inferred resources include 3,397,000 tons of material grading 11.9 ounces of silver per ton, 0.08 ounce of gold per ton, 2.9 percent lead, and 7.2 percent zinc, for a contained metal content of 40.25 million ounces of silver, 285,000 ounces of gold, 98,380 tons of lead, and 243,220 tons of zinc. The total silver resource in all categories is over 148 million ounces (Hecla Mining Company, 2017).

Site name(s): Kensington (Coeur-Alaska)

Site type: Mine

ARDF no.: JU261

Latitude: 58.8628 **Quadrangle:** JU D-4

Longitude: 135.0801

Location description and accuracy:

This site represents the consolidation by Coeur-Alaska of more than 12 mines and prospects, 53 patented claims, and 377 unpatented claims along a northwest-trending belt about 2 miles long between the head of Johnson Creek and Sherman Creeks. By 2008, Coeur-Alaska had done considerable new underground exploration along this belt, discovered new veins, and connected many of the old workings. The work is far advanced and Coeur-Alaska plans to mine the deposit as a single entity. This site is referred to as the Kensington deposit/property, which is part of Coeur-Alaska's 'Kensington Project' (which also includes the Jualin deposit/property (JU262) to the southeast which is described separately. The coordinates are near the center of the Coeur-Kensington deposit, which is near the site of the old Kensington Mine (JU029). The Coeur-Kensington deposit also includes such old mines and prospects as the Ophir, (JU026), Horrible (JU027), and Comet (JU036) Mines as well as several other mines and prospects (JU022, JU028, JU030, JU031, JU032, JU034, JU036, JU037, and JU039); however, these are still described individually in ARDF for their pre-Coeur-Alaska geologic and historical data. This site is located 0.2 mile southeast from the center of section 4, T. 35 S., R. 62 E., of the Copper River Meridian. The location is accurate, though degree of accuracy is not reported.

Commodities:

Main: Ag, Au, Te

Other: Cu, Fe, Hg, Mo, Pb, Zn

Ore minerals: Altaite, bornite, calaverite, coloradoite, galena, gold, hessite, magnetite, molybdenite, petzite, pyrite, pyrrhotite, sphalerite, volynskite

Gangue minerals: Calcite, ferroan dolomite, quartz

Geologic description:

The modern exploration history of the Kensington project began in 1980 when the Kensington Mine was optioned to Homestake Mining Company and from 1980 to 1985 to Placid Oil Company. Placid drilled 13,626 feet near the old Kensington Mine (JU029) and another 14,076 feet on other targets in the area. Coeur d'Alene Mines Corporation became involved in the property in 1987 in a joint venture with Echo Bay Mines; exploration continued that resulted in a feasibility study in 1993. In 1995, Coeur gained total control of the property under a subsidiary, Coeur-Alaska. By 1997, with the decline of gold prices, the project was considered economically unattractive, but work continued in 1998 that added 300,000 ounces of gold resources. Feasibility and exploration continued and in 2005 Coeur drilled 34,035 feet underground to better identify the resources. As of 2006 (Birak, 2006), the Kensington deposit consisted of more than old 12 mines and prospects, 53 patented claims, and 377 unpatented claims that occur in a northwest-trending belt about 2 miles long between the head of Johnson Creek and Sherman Creeks.

Simultaneous, exploration also started in 1978 to the southeast on a contiguous block of mines, prospects, and claims around the old Jualin Mine. From 1983 to 1993, the area was explored by a succession of companies including Bear Creek Mining Company, International Curator Resources, Granges, and Placer-Dome USA. In 1993, Coeur entered into a joint venture on the property with Curator and in 1994, Coeur acquired a 100 percent interest in the property. Coeur subsequently carried out major drilling and

underground work on the property, which is now the Jualin deposit/property (JU262) of the Kensington Project.

In 2006, Coeur prepared an extensive NI 43-101 report (Birak, 2006) on the Kensington Project that is largely the basis of this description. As of 2006, the Kensington deposit had been defined by 342,000 feet of drilling; it and the continuous Jualin deposit (JU262) had been explored by 27,000 feet of underground workings. The resources of the Kensington Project, that is both the Kensington deposit described here and the contiguous Jualin deposit (JU262) are: 1) 617,000 tons of indicated resources with a grade of 0.436 ounce of gold per ton (at a cut off grade of 0.12 ounce of gold per ton); 2) 2,499,000 tons of inferred resources with a grade of 0.234 ounce of gold per ton (at a cut-off grade of 0.12 ounce of gold per ton); and 3) 4,206,000 tons of probable reserves with a grade of 0.250 ounce of gold per ton (at a cut-off grade of 0.16 ounce of gold per ton), all estimated at a gold price of $375 per ounce.

The mine plant for the project was largely completed by 2008 but the start of production was delayed to resolve permitting and legal issues. The new Kensington Mine began production in June of 2010 with a projected production rate of about 125,000 ounces of gold per year and a projected life of 12.5 years (Coeur Alaska, 2012). The mine produced 43,143 ounces of gold in 2010 from 174,028 tons of ore that was milled and 88,420 ounces of gold in 2011 (Coeur d'Alene Mines Corp., 2012).

The Kensington deposit is largely in the Cretaceous Jualin Diorite, a northwest-trending stock about 5 miles long and 3 miles wide that is bordered on the east by Triassic metavolcanic rocks of the Wrangellia Terrane and to the west by pelitic sedimentary rocks of the Cretaceous Treadwell Formation, part of the Gravina Belt. The structure of the area is dominated by two regional-scale, northwest-trending faults: the Gastineau shear zone which is southwest of the Kensington mineralization and the Kensington shear zone that trends through the mineralization. The Kensington shear zone has several strands and movement along them controlled the development of the veins in the Kensington deposit. Four periods of deformation are recognized in the Kensington shear zone that span the period from 110 Ma (D1) to 53 Ma (D4). The gold veins are coeval with the D3 deformation, which developed a system of right-lateral, reverse, wrench faults.

The Kensington deposit consists of seven mineralized bodies; they form an en echelon series that dips east and extends to at depth of at least 3,500 feet. The individual ore bodies are related to two general structures: 1) large swarms of discontinuous quartz-carbonate-pyrite veins in biaxial sets between right-lateral reverse, conjugate faults; and 2) small massive sulfide-bearing veins in dilation zones along individual shear zones. Large dilation zones typically have a tabular to sigmoidal shape and grade into barren diorite. The vein swarms typically are continuous across the entire width of the mineralized zones but locally contain poorly mineralized rock.

The vein mineralization typically consists of gold tellurides and gold-silver tellurides with minor base metal sulfides in quartz-carbonate gangue (Casey, 2000). Most of the gold is in calaverite ($AuTe_2$) that also contains tiny gold inclusions. Gold also occurs interstitially and along microfractures in pyrite. The veins also contain trace amounts of petzite (Ag_3AuTe_2), hessite (Ag_2S), coloradoite, (HgTe), volynskite ($AgBeTe_2$), and altaite (PbTe), as well as minor chalcopyrite and rare bornite, molybdenite, sphalerite, tetrahedrite, galena, magnetite, and pyrrhotite.

Hydrothermal alteration adjacent to the veins is characterized by reddish-brown ferroan dolomite (Miller and others, 1995). Other alteration includes sericitization of plagioclase, chloritization, sulfidization of mafic minerals, and albitization of feldspars (Leveille, 1991). Calcite is the dominant carbonate; quartz occurs in stages 2 to 4 of the mineralization; and minor ferroan dolomite occurs with the calcite in stage 4. The age of hydrothermal muscovite from veins at Kensington Mine (JU029) varies from 53.4 Ma to 56.5 Ma (Miller and others, 1994).

Alteration:

Hydrothermal alteration adjacent to the veins is characterized by reddish-brown ferroan dolomite (Miller and others, 1995). Other alteration includes sericitization of plagioclase, chloritization, sulfidization of mafic minerals, and albitization of feldspars (Leveille, 1991).

Age of mineralization:

About 50 Ma. Younger than the 1110 Ma, D1 deformation and younger than the Cretaceous Jualin Diorite. Hydrothermal muscovite from the Kensington Mine has been dated at 53.4 Ma to 56.5 Ma (Miller and others, 1994).

Generic deposit model:

Deposit model:

Te-Au pyrite-carbonate-quartz-carbonate-pyrite veins (Cox and Singer, 1986; model 22b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22b

Production Status: Yes

Site Status: Active

Workings/exploration:

The modern exploration history of the Kensington project began in 1980 when the Kensington Mine was optioned to Homestake Mining Company and from 1980 to 1985 to Placid Oil Company. Placid drilled 13,626 feet near the old Kensington Mine (JU029) and another 14,076 feet on other targets in the area. Coeur d'Alene Mines Corporation became involved in the property in 1987 in a joint venture with Echo Bay Mines; exploration continued that resulted in a feasibility study in 1993. In 1995, Coeur gained total control of the property under a subsidiary, Coeur-Alaska. By 1997, with the decline of gold prices, the project was considered economically unattractive, but work continued in 1998 that added 300,000 ounces of gold resources. Feasibility and exploration continued and in 2005, Coeur drilled 34,035 feet underground to better identify the resources. As of 2006 (Birak, 2006), the Kensington deposit consisted of more than old 12 mines and prospects, 53 patented claims, and 377 unpatented claims that occur in a northwest-trending belt about 2 miles long between the head of Johnson Creek and Sherman Creeks.

Simultaneous, exploration also started in 1978 to the southeast on a contiguous block of mines, prospects, and claims around the old Jualin Mine. From 1983 to 1993, the area was explored by a succession of companies including Bear Creek Mining Company, International Curator Resources, Granges, and Placer-Dome USA. In 1993, Coeur entered into a joint venture on the property with Curator and in 1994, Coeur acquired a 100 percent interest in the property. Coeur subsequently carried out major drilling and underground work on the property, which is now the Jualin deposit/property (JU262) of the Kensington Project.

In 2006, Coeur prepared an extensive NI 43-101 report (Birak, 2006) on the Kensington Project that is largely the basis of this description. As of 2006, the Kensington deposit had been defined by 342,000 feet of drilling; it and the continuous Jualin deposit (JU262) had been explored by 27,000 feet of underground workings.

The mine went into production in July 2010.

In 2012, Coeur-Alaska completed 143,796 feet of core drilling primarily devoted to in-fill drilling of Block K and the Raven veins, and identified 151,000 tons with initial proven and probable reserves of 50,400 ounces of gold. The average of 0.33 ounce per ton gold is approximately 51 percent higher than the overall average reserve grade at Kensington. Kensington produced 82,1225 ounces of gold in 2012 (Athey and others, 2012).

In 2016, Coeur Alaska, Inc.’s accelerated surface- and underground-exploration program was focused on potential resource conversion and expansion within the Kensington Main ore body, nearby Raven vein, and newly discovered high-grade Jualin deposit, as well as targeting for growth of several other new veins in the district discovered through surface-sampling programs. Exploration drilling at Kensington Main included four zones (lower Block M, and zones 12, 41, and 44) focusing on the potential expansion of the Kensington Main resource down-dip and to the south of the current resource model; one drill hole returned 3.7 meters of 41.5 grams of gold per tonne. Development of the Jualin decline (64 percent complete at year-end 2016) is allowing better exploration drilling access, and Coeur Alaska, Inc. reports the Jualin Vein #4 (1 of 5 known veins) contains a resource of 179,000 ounces of gold at 0.619 ounce of gold per ton. In addition, drilling in 2016 at the Raven vein targeted the down-plunge extension of a high-grade ore shoot. As of October 2016, a total of 31,586 feet (9,627 m) had been drilled in resource-infill with potential to convert to reserves, out of a total budgeted 60,000 feet (18,288 m). In addition, a total of 16,712 feet (5,094 m) was drilled underground in resource expansion by October 2016, with a total budgeted 25,000 (7,620 m) feet.

Exploration of the high-grade Jualin deposit accelerated following development of a new exploration station; 3 drill holes targeting the potential upgrade and expansion of the Jualin resource were completed. Surface drilling twinning historical Jualin drill holes began in August 2016, and this drill program had six planned holes for a total of 11,000 feet (~3,350 m). A surface-based winter drilling program followed the twinning program, and focused on potential expansion of the Jualin Vein #4; Vein #5 sits 300 feet (~90 m) below Vein #4 and has similar grade-thicknesses in 5 out of 6 holes drilled to this depth. Coeur Alaska, Inc. indicates accelerated surface and underground exploration will continue in 2017 at Kensington Main, Jualin, Raven, and other new vein discoveries in the district (Athey and Werdon, 2017).

Production notes:

About 65,000 ounces of gold was produced in the Berners Bay district prior to WWII. That production is documented individually by site in the ARDF records for the old mines in the vicinity of the Kensington deposit. (See the location field for their ARDF numbers). The new Kensington Mine began production in June of 2010 with a projected production rate of about 125,000 ounces of gold per year and a projected life of 12.5 years (Coeur Alaska, 2010). The mine produced 43,143 ounces of gold in 2010 from 174,028 tons of ore that was milled and 88,420 ounces of gold in 2011 (Coeur d'Alene Mines Corp., 2012).

In 2012, Kensington produced 82,1225 ounces of gold (Athey and others, 2012).

In 2016, Kensington mine produced 124,331 ounces of gold, and 620,209 tons of material were processed through the mill at an average grade of 0.21 ounce of gold per ton, with a 94.7 percent recovery rate. Development of the new Jualin decline was 64 percent complete as of year-end 2016. Capital expenditures are expected to increase in 2017, primarily as a result of ongoing development of the Jualin deposit, where production is expected to begin late in 2017 (Athey and Werdon, 2017).

Reserves:

As of December 31, 2011, the Kensington Mine has proven reserves of 1,164,000 tons with a grade of 0.280 ounce of gold per ton; probable reserves of 4,842,000 tons with an average grade of 0.209 ounces of gold per ton; measured and indicated resources of 3,039,000 tons with an average grade of 0.193 ounce of gold per ton; and an additional inferred resources of 731,000 tons with an average grade of 0.232 ounce of gold per ton (Coeur d'Alene Mines Corp., 2012).

As of January 1, 2013, the Kensington Mine has proven reserves of 647,000 tons (short) with a grade of 0.28 ounces of gold per ton and probable reserves of 4,020,000 tons with an average grade of 0.21 ounces of gold per ton; 3) measured resources of 382,000 tons with an average grade of 0.24 ounces of gold per ton; 4) indicated resources of 2,224,000 tons with an average grade of 0.20 ounces of gold per ton; and 5) inferred resources of 704,000 tons with an average grade of 0.24 ounces of gold per ton. These reserved include the Kensington deposit and the Raven deposit (formerly Horrible, JU027) (Barry, 2013).

As of year-end 2016, Kensington mine contains proven and probable reserves of 2,616,000 short tons grading 0.190 ounce of gold per ton, for a contained metal content of 497,000 ounces of gold; measured and indicated resources of 3,125,000 tons grading 0.279 ounce of gold per ton, for a contained metal content of 871,000 ounces of gold, which is a 350,000-ounce upgrade from 2015; and, total inferred resources for Kensington are 1,579,000 tons grading 0.276 ounce of gold per ton, for a contained metal content of 436,000 ounces of gold (Coeur Mining, 2016).

Additional comments:

The Kensington mine area consists of two contiguous Property Groups controlled by Coeur Alaska: the Kensington Group and Jualin Group. These two Groups constitute the Kensington Consolidated Property Package (Property Package) (Barry, 2013).

The Kensington Group includes the Raven (formerly Horrible, JU027), Kensington (JU261), Eureka (JU031), Johnson, and Elmira mineral deposits (Barry, 2013).

The Jualin Group includes the Jualin and the Empire mineral deposits. Both Groups are held through a combination of federal patented and unpatented lode mining and mill site claims and state of Alaska claims, all of which are either owned or held by lease agreements. The combined land holdings total over 14,000 acres, approximately 1,150 of which are covered by Federal patented lode claims (Barry, 2013).

Last report date: 2017-08-26

Site name(s): Jualin (Coeur-Alaska)

Site type: Mines

ARDF no.: JU262

Latitude: 58.8389 **Quadrangle:** JU D-4

Longitude: 135.0446

Location description and accuracy:

This site represents the consolidation by Coeur-Alaska of more than 10 mines and prospects, 25 patented claims, and 483 unpatented claims along a northwest-trending belt about 2 miles long that extends from the head of Berners Bay along Johnson Creek. By 2008, Coeur-Alaska had done considerable new underground exploration along this belt, discovered new veins, and connected many of the old workings. The work is far advanced and Coeur-Alaska plans to mine the deposit as a single entity. This site is referred to as the Jualin deposit/property, which is part of Coeur-Alaska's 'Kensington Project' which also includes the Kensington deposit/property (JU261) to the northwest, which is described separately. The coordinates are near the center of the Coeur-Jualin deposit. The Coeur-Jualin deposit now covers the old Jualin mine (JU 044) and several other mines and prospects (JU040, JU041, and JU045 to JU052); however, these are still described individually in ARDF for their pre-Coeur-Alaska geologic and historical data. This site is located 0.5 mile east-northeast from the center of section 15, T. 35 S., R. 62 E., of the Copper River Meridian. The location is accurate, though degree of accuracy not reported.

Commodities:

Main: Ag, Au, Te

Other: Cu, Fe, Mo, Pb, Zn

Ore minerals: Chalcopyrite, friedrichite-aikinite, galena, gold, hessite, molybdenite, pavonite, petzite, pyrite, rucklidgeite?, sphalerite, sylvanite

Gangue minerals: Calcite, dolomite, quartz

Geologic description:

The modern history of the Jualin deposit started in 1978 and eventually included a large block of 10 old mines and prospects, 25 patented claims, and 483 unpatented claims. From 1983 to 1993, the area was explored by a succession of companies including Bear Creek Mining Company, International Curator Resources, Granges, and Placer-Dome USA. In 1993, Coeur entered into a joint venture on the property with Curator and in 1994, Coeur acquired a 100 percent interest in the Jualin. Beginning in about 1980, exploration also began at the Kensington deposit (JU261) deposit to the northwest; this involved a succession of different companies on what became another large block of old mines, prospect, and new claims. In 1995, Coeur gained control of the Kensington deposit too Coeur subsequently carried out major drilling and underground work on both properties and as of 2008 the two main components of the Kensington Project are the Jualin deposit and the contiguous Kensington deposit (JU261).

In 2006, Coeur prepared an intensive NI 43-101 report (Birak, 2006) on the Kensington Project that is largely the basis of this description. As of 2006, the Jualin deposit had been defined by 72,000 feet of drilling; it and the contiguous Kensington deposit (JU261) had been explored by 27,000 feet of underground workings. As of 2006, the resources of the Kensington Project, that is, both the Jualin deposit described here and the contiguous Kensington deposit (JU261) are: 1) 617,000 tons of indicated resources with a grade of 0.436 ounce of gold per ton (at a cut off grade of 0.12 ounce of gold per ton); 2) 2,499,000 tons of inferred resources with a grade of 0.234 ounce of gold per ton (at a cut-off grade of 0.12 ounce of gold per ton); and 3) 4,206,000 tons of probable reserves with a grade of 0.250 ounce of gold per ton (at a cut-off grade of 0.16

ounce of gold per ton), all estimated at a gold price of $375 per ounce. The mine plant for the project is largely completed but the start of production is in abeyance pending resolution of permitting and legal issues. As of April, 2008, the current status of the project could be seen at the Coeur-Alaska web site (http://www.kensingtongold.com/).

The Jualin deposit is largely in the Cretaceous Jualin Diorite, a northwest-trending stock about 5 miles long and 3 miles wide that is bordered on the east by Triassic metavolcanic rocks of the Wrangellia Terrane and to the west by pelitic sedimentary rocks of the Cretaceous Treadwell Formation, part of the Gravina Belt. The structure of the area is dominated by two regional-scale, northwest-trending faults: the Gastineau shear zone which is southwest of the Kensington mineralization and the Kensington shear zone that trends through the mineralization. The Kensington shear zone has several strands and movement along them controlled the development of the veins in the Kensington Project. Four periods of deformation are recognized in the Kensington shear zone that span the period from 110 Ma (D1) to 53 Ma (D4). The gold veins are coeval with the D3 deformation, which developed a system of right-lateral, reverse, wrench faults.

As described by Birak (2006), the Jualin deposit consists of two deposits: Jualin Veins 1-4 and the Empire Zone. He recognizes several stages of mineralization, two of which are economically significant. The most important are large high-grade quartz-carbonate veins that often contain several ounces of gold per ton. High-grade portions of these veins were previously mined to a depth of about 300 feet; they typically contained 0.5 to 0.6 ounce of gold per ton. The Number 4 vein was discovered in 1990 by drilling and contains more than 1.0 ounce of gold per ton. The Jualin 1-4 veins strike northwest, parallel the regional structure, and dip steeply northeast. They vary from 2 to 20 feet wide and have been traced down dip more than 1,000 feet. The veins are known over an area about 500 feet wide and extend at least 1,000 feet along strike. The second style of mineralization consists of zones of low-angle, quartz-filled extension fractures between the principal shear-hosted veins. These zones vary from 20 to 50 feet thick and generally extend less than 100 feet along strike or dip; they typically average less than 0.06 ounce of gold per ton. The Empire is the largest and richest of these zones; it is about 50 feet wide, 1,000 feet long and averages about 0.10 ounce of gold per ton.

The Jualin mineralization consists of quartz-dolomite veins and veinlets with pyrite, chalcopyrite, galena, sphalerite, molybdenite, hessite, petzite, sylvanite, and native gold. Even small amounts of sulfides indicates gold in excess of 0.50 ounce of gold per ton. Several old deposits now included in the Coeur-Jualin deposit, the Valentine (JU046) and Flemming (JU049), have characteristics of massive sulfide deposits (Casey, 2000) in that they contain markedly more chalcopyrite and sphalerite than other deposits in the belt. The Valentine also has a unusual suite of bismuth sulfosalts including pavonite ((Ag,Cu)(Bi,Pb)3S5), bismuthinite (Bi2S3), a member of the friedrichite (Pb5Cu5Bi7S18) - aikinite (PbCuBiS3), solid-solution series, and rucklidgeite? ((Bi,Pb)3Te4).

Alteration:

Albitization and silicification adjacent to the veins (Birak, 2006).

Age of mineralization:

About 55Ma. Precedes the 53 Ma deformational event and younger than the Cretaceous Jualin Diorite. Hydrothermal muscovite from the nearby Kensington mine has been dated at 53.4 Ma to 56.5 Ma (Miller and others, 1994).

Generic deposit model:

Deposit model:

Te-Au pyrite-carbonate-quartz-carbonate-pyrite veins (Cox and Singer, 1986; model 22b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22b

Production Status: Yes

Site Status: Active

Workings/exploration:

The modern history of the Jualin deposit started in 1978 and eventually included a large block of 10 old mines and prospects, 25 patented claims, and 483 unpatented claims. From 1983 to 1993, the area was explored by a succession of companies including Bear Creek Mining Company, International Curator Resources, Granges, and Placer-Dome USA. In 1993, Coeur entered into a joint venture on the property with Curator and in 1994, Coeur acquired a 100 percent interest in the Jualin. Beginning in about 1980, exploration also began at the Kensington deposit (JU261) deposit to the northwest; this involved a succession of different companies on what became another large block of old mines, prospect, and new claims. In 1995, Coeur gained control of the Kensington deposit too Coeur subsequently carried out major drilling and underground work on both properties and as of 2008 the two main components of the Kensington Project are the Jualin deposit and the contiguous Kensington deposit (JU261).

In 2006, Coeur prepared an intensive NI 43-101 report (Birak, 2006) on the Kensington Project that is largely the basis of this description. As of 2006, the Jualin deposit had been defined by 72,000 feet of drilling; it and the contiguous Kensington deposit (JU261) had been explored by 27,000 feet of underground workings. The mine plant for the project is largely completed but the start of production is in abeyance pending resolution of permitting and legal issues.

Through the end of 2012, 104,618 ft. of core drilling in 142 holes has been reported at the Jualin and Empire Zones. This drilling has shown that near where Jualin Veins 1, 2 and 3 begin to fade away into weakly mineralized fractures, a new set of strong, well mineralized veins begins (Barry, 2013).

Extensive surface drilling was completed at Jualin in 2014 in order to define the northern extent of mineralization along strike of the Vein number 4 zone and increase the drill density spacing to define an inferred resource. There were 47 drill holes completed totalling 58,363 feet (Beebe and others, 2015).

Production notes:

Although development is well advanced, there has been no production from the Jualin deposit as defined by Coeur-Alaska since the 1990s. About 65,000 ounces of gold was produced in the Berners Bay district prior to WWII. That production is documented individually in the ARDF records for the old mines in the vicinity of the Jualin deposit. (See the location field for their ARDF numbers).

Reserves:

Birak (2006) reported the resources of the Kensington project, including both the Jualin deposit described here and the contiguous Kensington deposit (JU261), were: 1) 617,000 tons of indicated resources with a grade of 0.436 ounce of gold per ton (at a cut off grade of 0.12 ounce of gold per ton); 2) 2,499,000 tons of inferred resources with a grade of 0.234 ounce of gold per ton (at a cut-off grade of 0.12 ounce of gold per ton); and 3) 4,206,000 tons of probable reserves with a grade of 0.250 ounce of gold per ton (at a cut-off grade of 0.16 ounce of gold per ton), all estimated at a gold price of $375 per ounce.

A resource estimate for just the Jualin deposit was made by Beebe and others in 2015. The inferred resource using a cut-off value of 0.123 ounces per ton gold is 289,000 tons grading 0.62 ounces per ton gold containing 179,000 ounces of gold.

Additional comments:

The Kensington mine area consists of two contiguous properties controlled by Coeur Alaska: the Kensington Group and Jualin Group. These two Groups constitute the Kensington Consolidated Property Package (Property Package) (Barry, 2013).

The Kensington Group includes the Raven (formerly Horrible, JU027), Kensington (JU261), Eureka (JU031), Johnson (JU030), and Elmira (JU032) mineral deposits (Barry, 2013).

The Jualin Group includes the Jualin and the Empire mineral deposits. Both Groups are held through a combination of federal patented and unpatented lode mining and mill site claims and state of Alaska claims, all of which are either owned or held by lease agreements. The combined land holdings total over 14,000 acres, approximately 1,150 of which are covered by Federal patented lode claims (Barry, 2013).

Site name(s): Old Glory; Last Chance

Site type: Mine

ARDF no.: KC033

Latitude: 55.6086 **Quadrangle:** KC C-6

Longitude: 131.9977

Location description and accuracy:

The Old Glory mine and adjacent Last Chance prospect are on the southwest foot of Gold Mountain at an elevation of 400-500 feet, and about 1.2 miles northwest of the mouth of Falls Creek. The site is in section 24, T. 72 S., R. 88 E., of the Copper River Meridian. It corresponds to locs. 254-2 to 254-28 and 255 in Maas and others (1995, fig. 46). The location is accurate within 0.1 mile. Figure 48 in Mass and others (1995) is a recent detailed map of the underground workings of the Old Glory Mine.

Commodities:

Main: Au

Other:

Ore minerals: Bornite, chalcopyrite, pyrite

Gangue minerals: Quartz

Geologic description:

The mines and prospects at the head of Smuggler Cove are an almost bewildering succession of companies, names for the mines, personalities, and financial plans if not schemes to fund the work on the deposits. Roppel (1905) has sorted out much of the detail but it is still unclear exactly what deposits were being controlled by which company at any given time in the area. Much of the knowledge of the mines she deciphered is centered on the companies rather than individual mines and prospects and it is not unlikely that the companies controlled different mines, claims, and prospects at various times. The Old Glory mine is probably the centerpiece of most of what Roppel has described in her chapter on 'Smuggler Cove MInes'.

Gold was discovered beyond the head of Smuggler Cove in 1899 and by 1901 the workings consisted of a 120-foot shaft with drifts and crosscuts from it. A 2-stamp mill was set in operation and produced a small amount of gold. Beginning in 1912, there were several companies active in the area but chiefly the Alaska Venture Syndicate and an Australian affiliate that controlled the operations, largely with capital raised on the London Stock Exchange. By 1914, there was about 1,500 feet of underground workings, a powerhouse had been constructed, and a compressor was in operation. In 1916, the Alaska Ventures Syndicate disbanded after spending more than about $150,000 on the property, and the deposits were largely dormant until the the late 1930s. A new company, the Alaska Gold Mountain Mines, Ltd., was formed then and began work financed by the sale of stock. They did considerable work underground, built a camp, cleared a road to the mine, and built a mill building to house the mill machinery which supposedly had been purchased. However the mill equipment never reached Alaska. The Security and Exchange Commission was soon investigating the company, and it was liquidated by 1940. After spending several hundred thousand dollars on the property from 1912 to 1940, the only production above the head of Smuggler Cove was the small amount of gold that was produced at the original 2-stamp mill in 1901. Figure 48 in Maas and others (1995) is a detailed map of the underground workings of the Old Glory Mine.

The country rocks in the area are andesitic and basaltic metavolcanic rocks that gradationally intertongue with subordinate pelitic metasedimentary rocks (Berg and others, 1988, p. 17-19). The strata were regionally metamorphosed to greenschist-grade phyllite and semischist in Late Cretaceous time (Brew, 1996, p. 27).

Their pre-metamorphic age is uncertain. Berg and others (1988, p. 17) state that they closely resemble Upper Jurassic to mid-Cretaceous marine flysch and volcanic rocks nearby on Gravina Island.

The Old Glory and Last Chance deposits consist of quartz fissure veins and stringer lodes in massive to schistose metavolcanic rocks (greenstone) (Maas and others, 1995, p. 183-184). Brooks (1902, p. 57) described two systems of quartz veins on the Last Chance claim: one strikes N-S, parallel to the foliation of the schist; the other strikes N60E. The veins contain pyrite and free gold, and the schistose country rocks adjacent to some of the veins are bleached and pyritic for a distance of up to 4.5 feet from the veins. Brooks also reported small amounts of chalcopyrite and bornite in the Last Chance veins, in addition to the pyrite and gold.

Maas and others (1995, table 25) report the following average metal contents in their samples from the main workings of the Old Glory mine: 2.29 parts per million gold, 0.30 ppm silver, 143 ppm copper, 14.0 ppm lead, and 83 ppm zinc. Samples from the Last Chance prospect contain: 6.73 ppm gold, 1.26 ppm silver, 1,338 ppm copper, 13.5 ppm lead, and 43 ppm zinc. The high copper content in the Last Chance deposit supports the early reports of copper minerals in the veins there. Maas and others (1995, table 24) also compare average gold values of the quartz veins with those of the pyritic schist at the Old Glory mine. Their results show 1.7 ppm gold in the quartz and 17.6 ppm gold in the altered schist next to the veins.

Fluid inclusion studies of quartz vein material from several of the Helm Bay lodes suggest that the veins formed at temperatures and pressures consistent with conditions during Late Cretaceous greenschist-grade regional metamorphism (Maas and others, 1995, p. 184).

Alteration:

The wallrocks adjacent to some of the veins are bleached and pyritic.

Age of mineralization:

Late Cretaceous.

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

The mines and prospects at the head of Smuggler Cove are an almost bewildering succession of companies, names for the mines, personalities, and financial plans if not schemes to fund the work on the deposits. Roppel (1905) has sorted out much of the detail but it is still unclear exactly what deposits were being controlled by which company at any given time in the area. Much of the knowledge of the mines she deciphered is centered on the companies rather than individual mines and prospects and it is not unlikely that the companies controlled different mines, claims, and prospects at various times. The Old Glory mine is probably the centerpiece of most of what Roppel has described in her chapter on 'Smuggler Cove Mines'.

Gold was discovered beyond the head of Smuggler Cove in 1899 and by 1901 the workings consisted of a 120-foot shaft with drifts and crosscuts from it. A 2-stamp mill was set in operation and produced a small amount of gold. Beginning in 1912, there were several companies active in the area but chiefly the Alaska Venture Syndicate and an Australian affiliate that controlled the operations, largely with capital raised on the London Stock Exchange. By 1914, there was about 1,500 feet of underground workings, a powerhouse had been constructed, and a compressor was in operation. In 1916, the Alaska Ventures Syndicate disbanded after spending more than about $150,000 on the property, and the deposits were largely dormant until the the late 1930s. A new company, the Alaska Gold Mountain Mines, Ltd., was formed then and

began work financed by the sale of stock. They did considerable work underground, built a camp, cleared a road to the mine, and built a mill building to house the mill machinery which supposedly had been purchased. However the mill equipment never reached Alaska. The Security and Exchange Commission was soon investigating the company, and it was liquidated by 1940. After spending several hundred thousand dollars on the property from 1912 to 1940, the only production above the head of Smuggler Cove was the small amount of gold that was produced at the original 2-stamp mill in 1901.Figure 48 in Maas and others (1995) is a detailed map of the underground workings of the Old Glory Mine.

Production notes:

Maas and others (1995, table 26) report production of 0.3 kilograms of gold and 0.8 kilograms of silver from the Old Glory mine.

Reserves:

None.

Additional comments:

The locations of the Old Glory and Last Chance sites in Elliott and others (1978, locations 34 and 35) have been revised in this report to agree with the locations of the sites in Maas and others (1995, figures 46 and 48). However, there is much uncertainty about the names and locations of the mines northwest of the head of Smuggler Cover.

Last report date: 2008-03-04

Site name(s): Shoenbar; Laskawanda; Schoenbar;

Site type: Prospects

ARDF no.: KC068

Latitude: 55.3493 **Quadrangle:** KC B-5

Longitude: 131.6419

Location description and accuracy:

This site includes several prospects or occurrences in about a square-mile area in and near the city of Ketchikan. They are at elevations ranging from near sea level to about 300 feet, and are from 0.1 to 0.7 mile northwest of the mouth of Ketchikan Creek in sections 19, 24, and 30, T. 75 S., R. 91 E., of the Copper River Meridian. The location is accurate. The site is locality 65 in Elliott and others (1978), and localities 276-280 in Maas and others (1995). The old workings on several of the prospects are concealed by housing and other city development, or are on private lots and have been filled in or covered by the owners (Maas and others, 1995, p. 194).

Commodities:

Main: Ag, Au

Other: Cu

Ore minerals: Chalcopyrite, pyrite

Gangue minerals: Quartz

Geologic description:

This part of Revillagigedo Island is underlain mainly by marine, andesitic or basaltic volcanic rocks and pelitic sedimentary rocks that are intruded by Cretaceous stocks, sills, and dikes of feldspar-porphyritic granodiorite, and by a stock and probably related plugs of Tertiary gabbro (Berg and others, 1988). The strata were regionally metamorphosed to greenschist-grade phyllite and semischist in Late Cretaceous time. They subsequently were contact metamorphosed to hornblende hornfels near some of the Cretaceous granodiorite contacts, and, more widely, peripheral to the Tertiary gabbro. The pre-metamorphic age range of the strata is uncertain. Berg and others (1988) note that they closely resemble Upper Jurassic to mid-Cretaceous flysch and volcanic rocks nearby on Gravina Island. The country rocks are cut by a high-angle fault along Tongass Narrows that displays about 4 miles of right-lateral offset.

The Laskawa or Shoenbar 'Mine' consists of a N 50 W, 50 NE sulfide-bearing band of phyllite and greenschist, cut by sulfide-bearing quartz fissure veinlets. The sulfide minerals are pyrite and chalcopyrite, and there were early reports of gold and silver (Wright and Wright, 1908, p. 152; Cobb and Elliott, 1980, p. 69). Roppel (2005) did considerable historic research on the 'Mine' and concluded that it was 'more business on paper than on what proved to be worthless ground'. The deposit was discovered in 1899 when John Shoenbar arrived in Ketchikan and purchased several claims along Ketchikan Creek. By 1904, the deposit was explored by two shafts, 125 and 85 feet deep, a short tunnel, and surface stripping. Shoenbar spend much time in the East trying to attract capital to develop the property but most of the work on the consisted of acquiring additional claims, constructing buildings and tramways, developing water rights, trying to develop power, and filing papers for patent to the claims. Little was done on the property by Shoenbar after 1904 although his claims were patented by 1920. In the 1930s, there was a brief attempt to cyanide the dump of the shafts; the results were disappointing although what little gold that may have been produced would have been the only gold produced from the property. In later years, the claims were developed and became part of the city of Ketchikan. A middle school, street, and bypass are named for Shoenbar, but all are misspelled 'Schoenbar' (Allen, 2002).

The following five occurrences were examined in the early 1990s by Maas and others (1995, locs. 276-280), who named them either from U.S. Bureau of Mines claim records, or, informally, for local landmarks.

Loc. 276: Forest Avenue quarry. Samples of silicified(?) volcanic rocks contained up to 222 parts per billion (ppb) gold, 2970 parts per million (ppm) copper, and 111 ppm molybdenum.

Loc. 277: Prison parking lot. A 2-foot sample of silicified(?) volcanic rock contained 2.1 ppm gold.

Loc. 278: Nevada lode. A 7-foot sample of silicified(?) greenstone contained 1282 ppb gold and 5,705 ppm copper. A shaft on this property was plugged.

Loc. 279: American Legion quarry. Samples of unidentified material contained up to 2,235 ppm zinc.

Loc. 280: Cape Fox. Samples of unidentified material contained up to 20 ppb gold. This property was explored in the early 1900s by a 24-foot adit and a shaft, which have been plugged.

Alteration:

Age of mineralization:

The quartz fissure veins that crosscut the metamorphic foliation probably are Late Cretaceous or younger.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Inactive

Workings/exploration:

Workings in the early 1900s included surface cuts and several short adits, shafts, and tunnels most of which have been covered by housing or commercial development, or filled in.

Production notes:

Probably none or very small.

Reserves:

None.

Commodities:

Main: Ag, Au

Other: Pb, Zn

Ore minerals: Galena, gold, pyrite, sphalerite

Gangue minerals: Muscovite, quartz

Geologic description:

The history of the Sea Level Mine has been researched in some detail by Roppel (2005). The deposit was found in 1897 and by 1898 a 35-foot tunnel was driven along a vein from which $10,000 in rich ore was recovered. Following considerable interest in the property, I.B. Hammond began developing the property in 1901 as the Sealevel Mining and Milling Company. Soon it was the most active mine in southern southeastern Alaska and about 800 feet of workings were driven on the vein, a large camp had been erected, and a 30-stamp mill was built. The mill began operation in May of 1902 and ran for 3 weeks before shutting down. After more underground exploration, the mill ran intermittently but ceased operation in July of 1903 for lack of ore, and the assets of the Sealevel Mining and Milling Company were foreclosed on in 1906. There were several attempts to put the property back in operation from 1906 to 1925, but by 1913 the buildings were already deteriorating. From 1926 to 1929, there was considerable activity by the Peerless Consolidated Mining Company to put the mine back in operation, including the construction of a new camp and power plant and the construction of a new 50-ton mill. About 300 tons of ore went through the mill in 1929 and 47 ounces of gold was produced. But the Peerless Company was reorganized soon after and what followed was mainly management changes and legal actions through the rest of the 1930s. There was little if any mining or milling beyond 1929 and eventually the patented claims were sold for their timber.

The total length of the workings was more than 1200 feet. A short tunnel with winze was also driven on the (main) vein at a point 350 feet N60E of the shaft house. The vein was exposed at several other points by opencuts and prospect tunnels, and it appears to continue northeastward for at least 2000 feet, onto the adjoining Sea Breeze claim (KC094).

The rocks in the area of the Sea Level Mine are mainly phyllite and semischist derived from pelitic sedimentary rocks and andesitic or basaltic volcanic rocks, intruded by Cretaceous granodiorite (Berg and others, 1988). The premetamorphic age of the strata is speculative. On the basis of various criteria, the rocks have been interpreted as Mesozoic or late Paleozoic (Berg and others, 1988) and Permo-Triassic or Jurassic-Cretaceous (Crawford and others, 2000). The bedded rocks and some of the granodiorite were regionally metamorphosed to greenschist grade in Late Cretaceous time and subsequently remetamorphosed

to hornblende hornfels near contacts of Cretaceous granodiorite plutons emplaced after the regional metamorphism. The metamorphic and intrusive rocks are overlain by Quaternary or Tertiary andesite and basalt.

The Sea Level deposit consists of sulfide-bearing quartz fissure veins. The veins cut hydrothermally altered mafic metavolcanic (greenstone schist) country rocks, and a 25-foot-thick body that either is an intrusive dike of altered porphyry ('blue porphyry' of Brooks, 1902, p. 65-67; and Wright and Wright, 1908, p. 144-146), or a zone of hydrothermally altered mafic metavolcanic rock (Maas and others, 1995, p. 210-218). The principal workings were on two parallel veins 15 feet apart. One is 5 feet thick and one 1-2 feet thick; both strike NE and dip steeply SE, at an acute angle to the NW strike of the foliation of the metamorphic country rocks. The veins consist of coarsely crystalline, milky quartz and minor muscovite, and contain (auriferous) pyrite, galena, and sphalerite, and sparse flakes of native gold. Pyrite cubes also are common in the altered wallrocks of the veins. Included in the veins are large breccia fragments of altered country rocks that reportedly carried as high values in precious metals as the quartz. Locally conspicuous, open-space-filling textures indicate quartz deposition at shallow crustal levels. In addition to the faulting that preceded vein formation; some of the veins in turn are sheared and offset by small faults. The quartz in the veins, however, is not recrystallized, and they thus are probably younger than most or all of the Late Cretaceous regional metamorphism (Maas and others, 1995, p. 215).

Most of the quartz veins are bordered by a hydrothermally altered zone up to three feet thick, characterized by fine-grain, light-gray to bluish-gray, massive, carbonate- and sericite-bearing rock that commonly contains cubic pyrite crystals up to an inch across (Maas and others, 1995, p. 215). Maas and others (1995) interpret this zone as hydrothermally altered mafic metavolcanic rock. Early miners called this altered rock 'blue porphyry,' which they interpreted as crosscutting altered dikes that predate the quartz veins, but are closely associated with some of the orebodies (Brooks, 1902, p. 65; Wright and Wright, 1908, p. 143). Gold content of these pyritic altered zones is high adjacent to the quartz veins and diminishes away from them. Weathered altered rocks have a reddish-brown, oxidized rind up to three inches thick.

An unknown amount of gold and silver was produced from the Sea Level mine in the early 1900s, when the ore reportedly averaged $5.35 of gold per ton (at $20.67 per ounce of gold) (Brooks, 1902, p. 66-67). Forty-seven ounces of gold was produced in 1929 from 300 tons of ore.

Alteration:

Most of the quartz veins are bordered by a hydrothermally altered zone up to three feet thick, characterized by fine-grain, light-gray to bluish-gray, massive, carbonate- and sericite-bearing rock that commonly contains cubic pyrite crystals up to an inch across (Maas and others, 1995, p. 215). Maas and others (1995) interpret this zone as hydrothermally altered mafic metavolcanic rock. Reserves:

None.

Additional comments:

Throughout its history, the name of the property has varied from 'Sea Level' to 'Sealevel.'

In the 1930s, the management of the Sea Level Mine was frequently combined with that of the the nearby Goo Goo Mine (KC096) and they shared their many legal and operational problems.

Geologic description:

The Goo Goo Mine and Goo Goo Extension (KC097) combined soon after their discovery and they share a common history. In addition, in the 1930s, both of them were sometimes linked with the Sea Level Mine (KC095). Roppel (2005) provides extensive details of the complex history of these properties. The Goo Goo vein was located in 1904 and the Goo Goo Extension in 1907, and they soon were developed by a 20-foot shaft and 15-foot tunnel. Brooks (1902, p. 67) reported gold values up to $4.00 in gold per ton (at $20.67 per ounce). About $1000 in gold (at $20.67 per ounce) was produced in 1907 from rich hand-picked samples processed with a mortar and pestle. Work continued through the 1920s and increased markedly in the 1930s with some underground exploration and considerable legal and other activity by the numerous people involved or investing in the property. Perhaps the most notable mining in the later history of the mining was the recovery in 1933 of $40,000 in gold (at $35 per ounce?) by a leaser from a rich pocket. The workings, dating back to the early 1900s, include 2 adits, one 1,800 feet long and one caved, a shaft, and several surface trenches and pits.

The rocks in the area of the Sea Level Mine are mainly phyllite and semischist derived from pelitic sedimentary rocks and andesitic or basaltic volcanic rocks, intruded by Cretaceous granodiorite (Berg and others, 1988). The premetamorphic age of the strata is speculative. On the basis of various criteria, the rocks have been interpreted as Mesozoic or late Paleozoic (Berg and others, 1988) and Permo-Triassic or Jurassic-Cretaceous (Crawford and others, 2000). The bedded rocks and some of the granodiorite were regionally metamorphosed to greenschist grade in Late Cretaceous time and subsequently remetamorphosed to hornblende hornfels near contacts of Cretaceous granodiorite plutons emplaced after the regional metamorphism. The metamorphic and intrusive rocks are overlain by Quaternary or Tertiary andesite and basalt.

According to Wright and Wright (1908, p. 147), the Goo Goo deposit is a quartz fissure vein that contains pyrite, sphalerite, galena, and free gold. The vein reportedly included pockets of ore containing considerable free gold. The Wrights do not describe the country rocks or the geologic setting of the vein.

Maas and others (1995, p. 216) provide the following combined description of an auriferous quartz fissure vein more than 4900 feet long on the Goo Goo claim and its continuation southwestward onto the adjoining Goo Goo Extension claim (KC097). The vein, which strikes NE and dips steeply SE, is in mafic metavolcanic rocks and contains, in addition to free gold, pyrite, sphalerite, and galena. Hydrothermally altered metavolcanic rock adjacent to the vein contains disseminated pyrite and accompanying gold values (see Alteration). The best results of sampling in 1946 (Maas and others, 1995, p. 217) included: 5.8 parts per million (ppm) gold in a section of vein 7.5 feet thick and 79 feet long; and 7.1 ppm gold in a section of vein 4.6 feet thick and 25 feet long. Thirty-one samples of the vein collected by Maas and others (1995) contained an average of 1.1 ppm gold. Maas and others' (1995) description of the Goo Goo and Goo Goo Extension vein indicates that its character and setting are virtually identical to the main vein on the Sea Level claim (KC095).

Combined recorded production from the claims, probably much in the early 1900s, was 1.4 kg of gold. Notably, however, $40,000 in gold (at $35 per ounce?) was produced by a leaser in 1935 from a rich pocket (Roppel, 2005).

Alteration:

The Goo Goo vein, like most of the other principal veins in the Sea Level mine area, is bordered by a hydrothermally altered zone up to three feet thick, characterized by generally fine-grain, light-gray to bluish-gray, massive, carbonate- and sericite-bearing rock that commonly contains cubic pyrite crystals up to an inch across (Maas and others, 1995, p. 215). Maas and others (1995) interpret this zone as hydrothermally altered mafic metavolcanic rock. Early miners called this altered rock 'blue porphyry,' which they interpreted as crosscutting altered dikes that predate the quartz veins, but are closely associated with some of the orebodies (Brooks, 1902, p. 65; Wright and Wright, 1908, p. 143). Gold content of these pyritic altered zones is high adjacent to the quartz veins and diminishes away from them. Weathered altered rocks have a reddish-brown, oxidized rind up to three inches thick.

Age of mineralization:

Maas and others (1995, p. 215) note that the quartz in the veins in the Sea Level mine area is not recrystallized; the veins thus are probably younger than most or all of the Late Cretaceous regional metamorphism.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

The Goo Goo Mine and Goo Goo Extension (KC097) combined soon after their discovery and they share a common history. In addition, in the 1930s, both of them were sometimes linked with the Sea Level Mine (KC095). Roppel (2005) provides extensive details of the complex history of these properties. The Goo Goo vein was located in 1904 and the Goo Goo Extension in 1907, and they soon were developed by a 20-foot shaft and 15-foot tunnel. Brooks (1902, p. 67) reported gold values up to $4.00 in gold per ton (at $20.67 per ounce). About $1000 in gold (at $20.67 per ounce) was produced in 1907 from rich hand-picked samples processed with a mortar and pestle. Work continued through the 1920s and increased markedly in the 1930s with some underground exploration and considerable legal and other activity by the numerous people involved or investing in the property.Perhaps the most notable mining in the later history of the mining was the recovery in 1933 of $40,000 in gold (at $35 per ounce?) by a leaser from a rich pocket. The

workings, dating back to the early 1900s, include 2 adits, one 1,800 feet long and one caved, a shaft, and several surface trenches and pits.

Production notes:

Combined recorded production from the Goo Goo and Goo Goo Extension claims, probably most in the early 1900s, was 1.4 kg of gold (Maas and others, 1995, p. 218). Notably, however, $40,000 in gold (at $35 per ounce?) was produced by a leaser in 1935 from a rich pocket (Roppel, 2005).

Reserves:

None.

Additional comments:

Some early reports apparently refer to this property as the Golden Dream claim, or Mountain claim (Cobb and Elliott, 1980, p. 145).

Site name(s): Goo Goo Extension; Majestic; Mother Lode

Site type: Prospect

ARDF no.: KC097

Latitude: 55.3687 **Quadrangle:** KC B-4

Longitude: 131.1907

Location description and accuracy:

The Goo Goo Extension claim is in section 18, T. 75 S., R. 94 E., of the Copper River Meridian. It adjoins the Goo Goo claim (KC096) on the southwest. It is about 0.15 mile north of, and parallel to, Gokachin Creek, and extends from the shoreline of Thorne Arm northeastward to an elevation of about 150 feet. The coordinates at about the center of the claim. The site corresponds to loc. 94 in Elliott and others (1978), and to loc. 303 (1-16) in Maas and others (1995). The location is accurate.

Commodities:

Main: Au

Other: Pb, Zn

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The Goo Goo Extension and the Goo Goo Mine (KC096) combined soon after their discovery and they share a common history. In addition, in the 1930s, both of them were sometimes linked with the Sea Level Mine (KC095). Roppel (2005) provides extensive details of the complex history of these properties. The Goo Goo vein was located in 1904 and the Goo Goo Extension in 1907, and they soon were developed by a 20-foot shaft and 15-foot tunnel. Brooks (1902, p. 67) reported gold values up to $4.00 in gold per ton (at $20.67 per ounce). About $1000 in gold (at $20.67 per ounce) was produced in 1907 from rich hand-picked samples processed with a mortar and pestle. Work continued through the 1920s and increased markedly in the 1930s with some underground exploration and considerable legal and other activity by the numerous people involved or investing in the property. Perhaps the most notable mining in the later history of the mining was the recovery in 1933 of $40,000 in gold (at $35 per ounce?) by a leaser from a rich pocket. The workings, dating back to the early 1900s, include 2 adits, one 1,800 feet long and one caved, a shaft, and several surface trenches and pits.

The rocks in the area of the Sea Level Mine are mainly phyllite and semischist derived from pelitic sedimentary rocks and andesitic or basaltic volcanic rocks, intruded by Cretaceous granodiorite (Berg and others, 1988). The premetamorphic age of the strata is speculative. On the basis of various criteria, the rocks have been interpreted as Mesozoic or late Paleozoic (Berg and others, 1988) and Permo-Triassic or Jurassic-Cretaceous (Crawford and others, 2000). The bedded rocks and some of the granodiorite were regionally metamorphosed to greenschist grade in Late Cretaceous time and subsequently remetamorphosed to hornblende hornfels near contacts of Cretaceous granodiorite plutons emplaced after the regional metamorphism. The metamorphic and intrusive rocks are overlain by Quaternary or Tertiary andesite and basalt.

Wright and Wright (1908, p. 147) describe this deposit as a 20-foot-thick quartz vein in altered schists. The vein, which they suggest is a continuation of the Goo Goo vein (KC096), strikes N63E, and contains pyrite, sphalerite, and galena. Workings in the early 1900s consisted of an open pit 10 feet deep and a tunnel 10 feet long. At that time, a picked sample assayed $30 in gold per ton (at $20.67 per ounce) (Brooks, 1902,

p. 67). Maas and others (1995, p. 217) report a mean value of 959 parts per billion gold in 24 samples of the Goo Goo Extension vein. Private examination in the early-mid-1980s of an 1,837-foot adit on the Goo Goo Extension claim outlined five zones of elevated gold values, mainly along the margins of the vein(s) (Maas and others, 1995, p. 215).

Maas and others (1995, p. 216) provide the following combined description of an auriferous quartz fissure vein more than 4900 feet long on the Goo Goo claim (KC096) and its continuation southwestward onto the adjoining Goo Goo Extension claim. The vein, which strikes NE and dips steeply SE, is in mafic metavolcanic rocks and contains, in addition to free gold, pyrite, sphalerite, and galena. Hydrothermally altered metavolcanic rock adjacent to the vein contains disseminated pyrite and accompanying gold values (see Alteration). The best results of sampling in 1946 (Maas and others, 1995, p. 217) included: 5.8 parts per million (ppm) gold in a section of vein 7.5 feet thick and 79 feet long; and 7.1 ppm gold in a section of vein 4.6 feet thick and 25 feet long. Thirty-one samples of the vein collected by Maas and others (1995) contained an average of 1.1 ppm gold. Maas and others' (1995) description of the Goo Goo (KC096) and Goo Goo Extension vein indicates that its character and setting are virtually identical to the main vein on the Sea Level claim (KC095).

Combined recorded production from the claims, probably much in the early 1900s, was 1.4 kg of gold. Notably, however, $40,000 in gold (at $35 per ounce?) was produced by a leaser in 1935 from a rich pocket (Roppel, 2005).

Alteration:

The Goo Goo Extension vein, like most of the other principal veins in the Sea Level mine area, is bordered by a hydrothermally altered zone up to three feet thick, characterized by generally fine-grain, light-gray to bluish-gray, massive, carbonate- and sericite-bearing rock that commonly contains cubic pyrite crystals up to an inch across (Maas and others, 1995, p. 215). Maas and others (1995) interpret this zone as hydrothermally altered mafic metavolcanic rock. Early miners called this altered rock 'blue porphyry,' which they interpreted as crosscutting altered dikes that predate the quartz veins, but are closely associated with some of the orebodies (Brooks, 1902, p. 65; Wright and Wright, 1908, p. 143). Gold content of these pyritic altered zones is high adjacent to the quartz veins and diminishes away from them. Weathered altered rocks have a reddish-brown, oxidized rind up to three inches thick.

Age of mineralization:

Maas and others (1995, p. 215) note that the quartz in the veins in the Sea Level Mine area is not recrystallized; the veins thus are probably younger than most or all of the Late Cretaceous regional metamorphism.

Longitude: 154.7257

Location description and accuracy:
This occurrence is about 9.8 miles south-south west of the center of Kurupa Lake and about 0.5 mile west of the center of section 28, T. 33 N., R. 18 E. The location is accurate to within one mile.

Commodities:

Main: Cu

Other:

Ore minerals: Azurite, chalcopyrite, malachite

Gangue minerals: Quartz

Geologic description:
The rocks in the area are black shale, siltstone, sandstone, quartzite, and conglomerate of the Upper Devonian, Ear Peak Member of the Kanayut Conglomerate (Kurtak and others, 1995). Anastomosing, chalcopyrite-quartz veins stained with malachite and azurite cut sandstone. The veins trend north, dip east, and are exposed for about 60 meters. Select samples contain up to 0.56 percent copper; a 2-meter chip sample across a zone of mixed sandstone and quartz veins contained 0.01 percent copper.

Alteration:
Not noted.

Age of mineralization:
Late Devonian or later based on the age of the host rock.

Generic deposit model:

Deposit model:
Chalcopyrite-quartz veins in sandstone.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:
Only limited sampling by the U.S. Bureau of Mines and the U.S. Geological Survey.

Production notes:

None.

Reserves:

None.

Site type: Occurrence

ARDF no.: KL002

Latitude: 68.1303 **Quadrangle:** KL A-4

Longitude: 154.9944

Location description and accuracy:

This occurrence is about 4.5 miles north-northeast of the small lake at the divide between a tributary to Kakivilak Creek and the head of Itilyiargiok Creek; it is about 0.6 mile west-northwest of the center of section 33, T. 32 N., R. 17 E. The location is known to within about a mile.

Commodities:

Main: Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena

Gangue minerals: Quartz

Geologic description:

The rocks in the area are mainly shale of the Upper Devonian, Hunt Fork Shale. One sample of a quartz vein found in float contained 15.37 percent lead, 0.07 percent zinc, and 0.64 percent copper. Little is known about this occurrence.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Pb-Zn quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling by the U.S. Bureau of Mines.

Production notes:

None.

Reserves:

None.

Additional comments:

The occurrence is in the Gates of the Arctic National Park which is closed to prospecting and mining.

Site name(s): Unnamed (near head of Kakivilik Creek)

Site type: Occurrence

ARDF no.: KL003

Latitude: 68.16 **Quadrangle:** KL A-4

Longitude: 154.965

Location description and accuracy:

This occurrence is about 6.8 miles north-northeast of the pass between the small lake at the divide between a small tributary of Kakivilak Creek and the head of Itilyiargiok Creek. It is about 0.4 mile northwest of the center of section 22, T. 32 N., R. 17 E. The location is accurate to within about a mile.

Commodities:

Main: Pb, Zn

Other: Ag, Cu

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area consist of shale with minor interbedded graywacke, quartzite, and conglomerate of the Upper Devonian Hunt Fork Shale. The U.S. Bureau of Mines (Kurtak and others, 1995) resampled anomalous samples collected by the U.S. Geological Survey (Sutley and others, 1984). The Bureau of Mines collected several samples of quartz veins with galena, chalcopyrite, and sphalerite. One vein was 1.5 meters thick but its extent is unknown. The samples contained 0.25 to 3.6 percent lead and 1.1 to 7.7 percent zinc; one sample contained 2,729 parts per million copper and another 2.8 grams of silver per tonne.

Alteration:

Not noted.

Age of mineralization:

Upper Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Lead-zinc-quartz veins.

Site type: Occurrence

ARDF no.: KL005

Latitude: 68.1526 **Quadrangle:** KL A-4

Longitude: 155.2492

Location description and accuracy:

This occurrence is about 6.5 miles northwest of the small lake at the divide between a tributary to Kakivilak Creek and head of Itilyiargiok Creek. It is about 0.6 mile southeast of the center of section 20, T. 32 N., R. 16 E. The location is accurate to within about a half mile.

Commodities:

Main: Pb, Zn

Other:

Ore minerals: Galena, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area are shale and minor graywacke sandstone of the Upper Devonian, Hunt Fork Shale. The occurrence consists of rubblecrop of silicified sandstone and conglomerate with sphalerite, galena and pyrite. Samples contained up to 2.8 percent zinc and 0.62 percent lead (Kurtak and others, 1995). The extent of the mineralization was not determined.

Alteration:

The sandstone host rock is silicified.

Age of mineralization:

Late Devonian or younger based on the age of the host rock. Possibly Late Jurassic to Cretaceous based on analogy with other deposits in the western Brooks Range.

Generic deposit model:

Deposit model:

Disseminated lead-zinc mineralization in sandstone.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling and mapping by the U.S. Geological Survey and U.S. Bureau of Mines.

Production notes:

None.

Reserves:

None.

Additional comments:

The occurrence is in the Gates of the Arctic National Park which is closed to prospecting and mining.

Longitude: 155.2624

Location description and accuracy:

This occurrence is about 7.4 miles northwest of the small lake at the divide between a tributary to Kakivilak Creek and the head of Itilyiargiok Creek; it is about 0.4 mile south of the center of section 17, T. 32 N., R. 16 E. The location is accurate to within about a half mile.

Commodities:

Main: Ag, Pb, Zn

Other: Cu

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area consist of quartz and sandstone of the Upper Devonian, Hunt Fork Shale in thrust contact with the Upper Devonian or Lower Mississippian, Kanayut Conglomerate (Kurtak and others, 1995). The rocks are cut by silicified fault zones and quartz veins with sphalerite, galena, and pyrite, mostly found only as rubblecrop. A random chip sample from an outcrop of a quartz vein of unknown extent contained 7.1 percent zinc, 1.95 percent lead, and 0.2 percent copper. A series of selected samples of quartz veins contained up to 24 percent zinc, 1.6 percent lead, and 171 grams of silver per tonne. The extent of the mineralization was not determined.

Alteration:

Not mentioned.

Age of mineralization:

Late Devonian or younger based on the age of the host rock. Possibly Late Jurassic to Cretaceous based on analogy with other deposits in the western Brooks Range.

Generic deposit model:

Deposit model:

Silver-lead-zinc-quartz veins and quartz breccia.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling by government agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Kady

Site type: Occurrence

ARDF no.: KL007

Latitude: 68.1989 **Quadrangle:** KL A-4

Longitude: 154.9866

Location description and accuracy:

The Kady deposit is about 1.6 miles northwest of the end of Kakivilik Creek near the center of section 4, T. 32., R. 17 E. Kurtak and others (1995) have several maps of the occurrence.

Commodities:

Main: Ag, Pb, Zn

Other: As, Au, Cu, Sn

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Kady deposit was found by the U.S. Geological Survey in about 1986 as a result of stream-sediment sampling (Duttweiler,1987). It was subsequently mapped and sampled by the U.S. Bureau of Mines (Kurtak and others, 1995).

The rocks at this occurrence are sandstone and minor conglomerate of the Shainin Lake Member of the Upper Devonian to Lower Mississippian Kanayut Conglomerate, that are thrust over the Ear Peak Member of the Kanayut (Kurtak and others, 1995). The rocks are intensely deformed into a series of generally east-trending folds. The fold axes trend N65E and plunge south.

The mineralization consists of a series of swarms of quartz veins and quartz-cemented breccia zones that crosscut the bedding and fold axes (Kurtak and others, 1995). There are two distinct types of veins: 1) barren quartz veins, and 2) sulfide-quartz veins with major sphalerite and galena, and lesser chalcopyrite and pyrite. The two types are spatially separated. The best concentration of sulfide veins and breccia is about 800 feet long and up to 150 feet wide, and trends north-northwest. It is bordered on the east by a zone up to 500 feet wide of barren quartz veins. Individual veins vary from a few centimeters to 30 meters wide and can be traced for up to 229 meters along strike. Most of the sulfide-bearing veins strike N40E and dip vertically. Another set which contains higher metal values strikes N40W and dips steeply south. At least 9 separate veins or mineralized zones have been identified in an area about 5,000 feet by 3,000 feet in size. Some notable sample included: 1) samples of galena from a breccia contained up to 59.8 percent lead, 0.7 percent zinc, and 745 grams of silver per tonne; 2) a chip sample across a 3-meter-wide vein contained 10 percent zinc, 0.10 percent lead, 10.8 grams of silver per tonne, and 53 parts per billion gold; 3) a continuous chip sample across a 1.7-meter-wide quartz vein contained 1.06 percent zinc, and 3.4 grams of silver per tonne; and 4) a grab sample across 6 meters of rubblecrop contained 14,560 parts per million copper, 0.24 percent lead, 2.3 percent zinc, and 5.8 grams of silver per tonne. Tin and arsenic are also reported.

Alteration:

Not specifically noted but associated with the introduction of much quartz in the veins and breccia.

Age of mineralization:

Late Devonian or younger based on the age of the host rock. Possibly Late Jurassic to Cretaceous by analogy with other deposits in the western Brooks Range.

Generic deposit model:

Deposit model:
Silver-lead-zinc-quartz veins and vein-breccias.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:
Only sampling and mapping by the U.S. Geological Survey and U.S. Bureau of Mines.

Production notes:
None.

Reserves:
None.

Additional comments:
The occurrence is in the Gates of the Arctic National Park which is closed to prospecting and mining.

Geologic description:

This occurrence is near the contact of shale and sandstone of the Upper Devonian, Hunt Fort Shale and the Upper Devonian or Lower Mississippian, Kanayut Conglomerate. As originally identified by the U.S. Geological Survey (Kelly and Mull, 1995), the occurrence is a single 5-meter-wide outcrop exposed along strike for about 25 meters. The mineralization is in shale and sandstone and consists of galena, sphalerite, chalcopyrite, and pyrite in quartz veins and in quartz-cemented breccia. The veins trend N40E with a shallow northwest dip. There is noticeable banding in the sulfides. Samples collected by the U.S. Geological Survey contained up to 25 percent zinc, 1 percent copper, 1.5 to 2 percent lead, 300 parts per million (ppm) silver, 1,000 ppm arsenic, and 0.75 ppm gold. Three continuous chip samples averaging 2.6 meters in length were collected by the U.S. Bureau of Mines (Kurtak and others, 1995). They averaged 2.0 percent zinc, 1.1 percent lead, 1,103 ppm copper, and 130 grams of silver per tonne. A select sample from an outcrop contained 56.9 percent zinc, 9.8 percent lead, 1,287 grams of silver per tonne, and 1,056 ppm copper.

Kurtak and others (1995) found similar mineralization nearby, about 0.8 mile north of the discovery outcrop. There, galena and sphalerite are in quartz veinlets and veins 6 millimeters to 15 centimeters thick that cut sandstone. Two select samples contained up to 1.4 percent lead, 12.1 percent zinc, and 432.4 ppm silver. About 0.6 mile northwest of the discovery outcrop, a grab sample of vein quartz in float contained 3.5 percent lead and 32 ppm silver.

Alteration:

Not mentioned.

Age of mineralization:

Late Devonian or younger based on the age of the host rock. Possibly Late Jurassic to Cretaceous based on analogy with other deposits in the western Brooks Range.

Site name(s): Bonanza Hills; Main Saddle

Site type: Prospect

ARDF no.: LC016

Latitude: 60.7061 **Quadrangle:** LC C-5

Longitude: 154.5956

Location description and accuracy:

The Bonanza Hills prospect extends about 1.5 km along a ridge, between peak 3,860 and peak 3,966, in the Bonanza Hills. It is approximately 3.5 km east-southeast of Little (Upper) Bonanza Creek in the SW1/4SW1/4 sec. 6, T. 7 N., R. 30 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Cu, Pb

Other: Au

Ore minerals: Arsenopyrite, chalcopyrite, galena, tetrahedrite

Gangue minerals: Quartz

Geologic description:

A quartz-sulfide vein system containing tetrahedrite, arsenopyrite, galena, and chalcopyrite cuts sedimentary rocks and dacite hornfels (Eakins and others, 1978). The mineralization consists of a 3-meter-wide zone of quartz sulfide 'splatter' veinlets that extends at least 150 meters along strike to a depth of 50 meters. Channel samples contain an average of 103 grams of silver per tonne and 0.5 percent combined Cu and Pb. Samples contain up to 2.24 parts per million (ppm) gold.

The contact-metamorphosed dacite flows and sedimentary rocks are part of a Jurassic to Cretaceous unit (KJs) that consists of interbedded lithic graywacke, silty sandstone, black shale , and local conglomerate (Nelson and others, 1983). Irregular quartz segregations and veinlets are locally present. Scattered stocks and locally abundant dikes of intermediate to felsic composition intrude these sedimentary rocks. Contact aureoles of hornfels ring some of the larger igneous bodies which include rhyolite dikes and a Late Cretaceous, two-mica, hypabyssal, granite pluton (Nokleberg and others, 1997).

Liberty Star Uranium and Metals Corporation (2007) has 54 State of Alaska claims covering about 13.5 square miles around this prospect. Twenty samples were collected in their preliminary work; 5 contained 0.001 to 0.006 ounce of gold per ton, 2 contained 0.02 ounce of gold per ton, 1 contained 0.267 ounce of gold per ton, one contained 0.403 ounce of gold per ton, and one contained 3.11 ounces of gold per ton.

Alteration:

Unknown.

Age of mineralization:

Cretaceous or younger.

Generic deposit model:

Deposit model:

Gold vein system or disseminated gold deposit associated with a composite intrusive center?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 2008 within a large block of claims held by Liberty Star Uranium and Metals Corporation who did preliminary sampling.

Production notes:

No production.

Reserves:

Nokleberg and others (1987; 1997) estimate that the deposit contains 45,000 tonnes of material with a grade of 81 grams of silver per tonne, 0.15 grams of gold per tonne, 0.15 percent copper, and 0.067 percent lead.

Site name(s): Kody

Site type: Prospect

ARDF no.: LC055

Latitude: 60.3968 **Quadrangle:** LC B-6

Longitude: 154.9043

Location description and accuracy:

The Kody prospect is located in the hills between the Koksetna and Chilikadrotna Rivers approximately 20 miles northwest of Lake Clark. It lies in a saddle northwest of hill 3084 at the headwaters of a tributary of the Koksetna River. The northwest 1/4 of section 31 in T. 4 N., R. 32 W. of the Seward Meridian is the approximate center of a 4 square mile prospect area. The location is accurate within 200 meters.

Commodities:

Main: Ag, Cu, Sn

Other: As, Au

Ore minerals: Arsenopyrite, chalcopyrite, pyrite, pyrrhotite

Gangue minerals: Quartz, sericite, tourmaline

Geologic description:

The area between the Koksetna and Chilikadrotna Rivers is underlain by undivided Kuskokwim Group sedimentary rocks and the Koksetna River sequence of Wallace and others (1989) that have been intruded by Cretaceous to Tertiary quartz monzonite plutons and rhyolite to dacite plugs, sills, dikes and flows (Wilson and others, 2006).

The Kody prospect is a 1 square kilometer intrusive/subvolcanic complex that has been pervasively greisenized. An exposed, steep-sided, late Cretaceous quartz monzonite plug has intruded and hornfelsed siliceous clastic sedimentary rocks that strike northeast and dip to the northwest (Ellis and others, 1985) correlating with the Jurassic-Cretaceous Koksetna River sequence of Wallice and others (1989). The quartz monzonite and adjacent hornfelsed sedimentary rocks form a 4 square kilometer topographic knob which rises greater than 1,100 feet above the surrounding lowlands. The eastern edge of the quartz monzonite and the hornfelsed sedimentary rocks has been cut by numerous rhyolite apophyses of Tertiary (?) age (Scott and Ellis, 1982).

Greisenization of the quartz monzonite is widespread. Smaller non-greisenized areas exist adjacent to the faulted northwestern hornfels contact, and these areas are chloritized and locally sericitized. The greisen varies from a white to tan to gray, fine- to medium-grained, granular, quartz-white mica rock with abundant voids. The white mica occurs as tiny 1 to 3 millimeter sprays that appear interstitial to the fine-grained secondary quartz. Incipient tourmalinization is associated with the white mica (Ellis and others, 1985).

Sulfide mineralization is distinctly localized in greisenized areas implying a genetic relationship between greisenization and introduction of the sulfides. Locally abundant sulfides were deposited in open spaces in the greisens, in fractures, in quartz-flooded zones, and in hornfelsed zones (Scott and Ellis, 1982). The greisen locally grades into a banded, fine-grained, and white to black tourmaline-quartz rock. In these flooded zones, the rock is extremely fine-grained, and open-space filling by arsenopyrite and chalcopyrite is locally common. The rock is very hard, forming irregulary shaped cobbles with a patina of intense iron-oxide stain. Where this 'flooding' occurs in the hornfels, the sedimentary rocks are also iron-stained (Ellis and others, 1985).

Pyrrhotite (up to 30 percent), arsenopyrite (up to 10 percent), chalcopyrite (up to 3 percent) and silver from 0.5 to 11 ounces per ton is present in scattered zones within the altered intrusive. A 100 by 300 meter

zone near the eastern margin of the of the greisenized quartz monzonite averaged over 1 ounce per ton silver and exceeded 100 parts per million (ppm) tin (Ellis and others, 1985).

Alteration:

A quartz-white mica-tourmaline greisen has replaced the majority of the exposed quartz monzonite at the Kody prospect. Ungreisenized areas in the quartz monzonite show local chloritization of biotite and hornblende and clay alteration of feldspars. The rhyolite which intrudes both the quartz monzonite and hornfelsed sediments is locally tourmalinized. Relict feldspar phenocrysts in the rhyolite are intensely sericitized (Ellis and others, 1985).

Age of mineralization:

Mineralization is probably related to 60.5 to 61.6 Ma intrusions dated in the area (Eakins and others, 1978).

Generic deposit model:

Deposit model:

Porphyry Sn (Cox and Singer, 1986; model 20a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20a

Production Status: None

Site Status: Inactive

Workings/exploration:

The Kody prospect was discovered by Anaconda Minerals Company in 1982. Exploration work included geologic mapping, grid rock sampling, a one kilometer induced polarization (IP)-resistivity line and a 10 square kilometer gravity survey. A Bouguer gravity map based on 39 surveyed stations and a gravity profile show an 8 milligal low that is best depicted as a 2.5 kilometer northwest dipping slab that broadens slightly with depth. The top of this anomaly is coincident with mapped quartz monzonite, greisen, and rhyolite intrusive rock (Scott and Ellis, 1982). Pyrrhotite (up to 30 percent), arsenopyrite (up to 10 percent), chalcopyrite (up to 3 percent), silver from 0.5 to 11 ounces per ton, and gold from 100 to 800 parts per billion is present in scattered zones within the altered intrusive. A 100 by 300 meter zone near the eastern margin of the of the greisenized quartz monzonite averaged over 1 ounce per ton silver and from 100 to 400 parts per million tin (Ellis and others, 1985).

ARDF no.: LC056

Latitude: 60.4713 **Quadrangle:** LC B-5

Longitude: 154.8076

Location description and accuracy:

The Koksetna prospect is located in the hills between the Koksetna and Chilikadrotna Rivers approximately 20 miles northwest of Lake Clark. The center of the prospect is on the northeast side of the valley above 2500 foot elevation at the headwaters of a tributary of the Koksetna River in the northeast 1/4 of section 3, T. 4 N., R. 32 W. of the Seward Meridian. The location is accurate within 200 meters.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: As, F, Sb, Sn

Ore minerals: Arsenopyrite, chalcopyrite, galena, pyrite, tetrahedrite

Gangue minerals: Kaolinite, quartz, sericite, tourmaline

Geologic description:

The area between the Koksetna and Chilikadrotna Rivers is underlain by undivided Kuskokwim Group sedimentary rocks and the Koksetna River sequence of Wallace and others (1989) that have been intruded by Cretaceous to Tertiary quartz monzonite plutons and rhyolite to dacite plugs, sills, dikes and flows (Wilson and others, 2006).

The Koksetna prospect is an altered and mineralized pipe-like breccia zone approximately 750 meters diameter cutting siltstones of the Koksetna River sequence. Several siliceous breccia units and a quartz-eye rhyolite porphyry along with wall rock clasts have been noted in the breccia pipe (Scott and Ellis, 1982).

Hydrothermal alteration at Koksetna is related to the intrusive rocks as well as a final stage of supergene leaching (Scott and Ellis, 1982). Prospect alteration is laterally restricted to the composite pipe and a 200 foot peripheral zone of spotty propylitiztion in the wall rock. This is due to the non-reactive nature of the siltstones, and their low permeability. The first alteration event accompanied the intrusion of quartz-eye rhyolite porphyry which has a plug-like geometry. The vast majority of the exposed porphyry is argillically altered to kaolinite with minor sericite and montmorillonite. Argillization is generally restricted to the porphyry groundmass with occasional replacement of sanidine phenocrysts by kaolinite. Small zones of quartz-sericite alteration were observed in central portions of the porphyry. Here the porphyry texture is totally obliterated and replaced by a hard, silica-rich skeleton. Crystal vugs are commonly lined with orange-yellow jarosite, probably from the weathering of sulfide. Intrusion of the rhyolite porphyry also propylitized the wall rock siltstone, andesite, and greywacke, creating localized conversion to chlorite, epidote, illite, and secondary biotite (Ellis and others, 1985).

At least two and possibly three separate pulses of mineralization have been identified at Koksetna. An early pulse of 1 to 5 percent sulfide with a high silver to copper ratio is believed to have been originally disseminated in the quartz-eye rhyolite porphyry. A possible second pulse of minor sulfide mineralization accompanied the intrusion of silica breccia. The third and final pulse of sulfide mineralization is represented by fracture-filling veins that average 2 to 5 millimeters in thickness and appear to cut all lithologies visible within the near periphery of the Koksetna breccia pipe. The quartz veins contain iron oxides, rare chalcopyrite and tetrahedrite. Local stockwork fracture zones, frequently healed by quartz, tourmaline, or sulfide veinlets, occur within the wall rock along a 100 meter margin of the intrusive contact (Ellis and

others, 1985).

Alteration:

Hydrothermal alteration at Koksetna is related to the intrusive rocks as well as a final stage of supergene leaching (Scott and Ellis, 1982). Prospect alteration is laterally restricted to the composite pipe and a 200 foot peripheral zone of spotty propylitiztion in the wall rock. This is due to the non-reactive nature of the siltstones and to their low permeability.

The first alteration event accompanied the intrusion of quartz-eye rhyolite porphyry in a plug-like geometry. The vast majority of the exposed porphyry is argillicaly altered to kaolinite with minor sericite and montmorillonite. Argillization is generally restricted to the porphyry groundmass with occasional replacement of sanidine phenocrysts by kaolinite. Small zones of quartz-sericite alteration were observed in central portions of the porphyry where the porphyry texture is totally obliterated and replaced by a hard, silica-rich skeleton. Crystal vugs are commonly lined with orange-yellow jarosite, probably from the weathering of sulfide. Intrusion of the rhyolite porphyry also propylitized the wall rock siltstone, andesite, and greywacke, creating localized conversion to chlorite, epidote, illite, and secondary biotite (Ellis and others, 1985).

Age of mineralization:

Mineralization is probably related to 60.5 to 61.6 Ma intrusions dated in the area (Eakins and others, 1978).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Workings/exploration:

In 1982 the geophysical crew of Anaconda Minerals Company (Anaconda) conducted a induced polarization (IP)-resistivity survey over the center of the rhyolite breccia pipe. The objectives of this survey were to evaluate the quality of the IP-resistivity data gathered in 1975 by Von Blaricom Geophysical Services, and to test below 1,000 feet depth for a hypothetical supergene enrichment zone (Scott and Ellis, 1982). Three-hundred rock samples were collected from a grid over the Koksetna prospect with each sample representing a 50 foot composite zone along the grid lines. Select samples of mineralized veins and breccias contained anomalous geochemistry as follows: copper 0.15 to 4 percent, silver 0.5 to 16 ounces per ton (oz/ton), lead 100 to 4100 parts per million (ppm), zinc 200 to 2700 ppm, antimony 20 to 480 ppm, tin 20 to 550 ppm, arsenic 300 to 17300 ppm, and 5 samples had anomalous gold from 50 to 1250 parts per billion (ppb) (Scott and Ellis, 1982).

In 1983 Anaconda collected 10 check samples and 7 vein samples at the Koksetna prospect. The geochemistry from these samples verified that anomalous mineralization in the periphery of the feeder pipe was strongest in the northern contact zone. Geochemical values were the following: silver 1 ppm to 4.05 oz/ton, copper 125 to 3000 ppm, lead 100 to 3500 ppm, zinc 300 to 4080 ppm, fluorine 300 to 1350 ppm, arsenic 200 to over 1000 ppm, tin 30 to 340 ppm, and gold 30 to 565 ppb (Ellis and others, 1985).

In 2007 Andover Ventures Inc. conducted a ridge and spur rock and soil sampling survey peripheral to the multiphase intrusive pipe. An IP-resisivity survey was attempted but was unable to get sufficient current into the poorly developed soils to get meaningful results (Ellis and Hoffman, 2008).

Ore minerals: Arsenopyrite, cassiterite, chalcopyrite, covellite, molybdenum, pyrite, scorodite

Gangue minerals: Muscovite, quartz, sericite, tourmaline

Geologic description:

The area between the Koksetna and Chilikadrotna Rivers is underlain by undivided Kuskokwim Group sedimentary rocks and the Koksetna River sequence of Wallace and others (1989) that have been intruded by Cretaceous to Tertiary quartz monzonite plutons and rhyolite to dacite plugs, sills, dikes and flows (Wilson and others, 2006). The Kosmic prospect lies within the Kuskokwim Group.

Quartz monzonite porphyry occurs as a small stock approximately one kilometer in diameter and is the dominant intrusive rock at Kosmic. Quartz monzonite porphyry is characterized by abundant phenocrysts of smoky quartz 3 to 5 millimeters in diameter and plagioclase with less abundant potassium feldspar phenocrysts (Scott and Ellis, 1982).

Rhyolite porphyry occurs as dikes emanating outward from the quartz monzonite porphyry. Intrusive contacts between rhyolite and quartz monzonite porphyry were not observed and at one location quartz monzonite porphyry appears to grade into rhyolite porphyry. Moderate fracturing and contact metamorphism extends outward roughly 100 meters from the intrusive-sedimentary rock contact and dies out rapidly between 100 and 200 meters from the contact (Ellis and others, 1985).

The strongest alteration occurs in rhyolite porphyry although the majority of the rocks at Kosmic are unaltered. Alteration of rhyolite porphyry is primarily sericitic and includes localized patches of silicified, tourmalinized rock where black tourmaline occurs in fractures and as rosettes throughout the rock (Ellis and others, 1985).

The rhyolite and quartz monzonite are locally cross-cut by veins; however, veining is more common in the hornfelsed sedimentary rocks. Four types of veins were observed. Type 1 veins occur in the hornfels and are 0.5 centimeter wide fractures filled with quartz, minor muscovite, and rare traces of arsenopyrite. Type 1 veins have no alteration envelopes. Some of these veins carry anomalous silver and gold. Type 2 veins are 1.0 to 5.0 millimeters wide fractures in quartz monzonite and rhyolite porphyry. These fractures are filled with quartz and minor arsenopyrite with scorodite. Muscovite envelopes extend outward approximately 1.0 to 5.0 centimeters from these veins. Grab samples from these veins carry anomalous silver and tin. Type 3 veins occur in hornfels near intrusive contacts as coarsely crystalline veins and pods up to 10 centimeters in diameter. These pegmatic veins contain glassy quartz, muscovite, biotite, and potassium feldspar. Dark green or black tourmaline crystals and very rare cassiterite occur in these veins. Type 3 veins are probably

late pegmatic phases of quartz monzonite porphyry. Type 4 veins occur in hornfels as sinuous veins and pods of milky white metamorphic quartz with clots of biotite and muscovite. These veins are common in the area and are produced by contact metamorphism. At the Kosmic prospect type 4 veins frequently contain coarse splays of pale green tourmaline (Ellis and others, 1985).

In addition to vein-type mineralization described above, three patches (approximately 10 meters in diameter each) of mineralized rhyolite porphyry were mapped on the east flank of the Kosmic prospect. The mineralization occurs in a narrow (20 meter) east-west rhyolite porphyry dike that extends onto the adjacent ridge. The mineralized rock contains 1 to 3 percent disseminated arsenopyrite and includes minor amounts of chalcopyrite, covellite, and molybdenite(?). Covellite coats chalcopyrite and arsenopyrite and has copper values to 695 ppm (Ellis and others, 1985).

Alteration:

The strongest alteration occurs in rhyolite porphyry although the majority of the rocks at Kosmic are unaltered. Alteration of rhyolite porphyry is primarily sericitic and includes localized patches of silicified, tourmalinized rock where black tourmaline occurs in fractures and as rosettes throughout the rock (Ellis and others, 1985).

Workings/exploration:

Anaconda Minerals Company (Anaconda) discovered the Kosmic prospect during a regional exploration in 1982 (Scott and Ellis, 1982). In 1983 Anaconda mapped and sampled Kosmic identifying four types of veins, three of which were mineralized. Type 1 veins in hornfels sometimes carried elevated silver up to 27 parts per million (ppm) and gold up to 4430 parts per billion (ppb). Grab samples from type 2 veins in the quartz monzonite and rhyolite porphyry carried elevated silver up to 17 ppm and tin up to 1450 ppm. Type 3 veins contained rare cassiterite, identified in hand specimen and in thin section. Eleven grab samples from mineralized rhyolite porphyry with 1 to 3 percent disseminated arsenopyrite and minor chalcopyrite, covellite and molybdenite (?) contained anomalous silver (1.3 to 30 ppm), arsenic (over 1000 ppm), and fluorine (over 5000 ppm). Five out of 22 samples had anomalous tungston values from 100 to 475 ppm. Three samples of greisenized rhyolite contained 395, 440, and 565 ppm tin (Ellis and others, 1985).

An induced polarization (IP) and resistivity anomaly at the north end of Kosmic was discovered in 2007 when Andover Ventures Inc. completed a 2.7 kilometer long geophysical survey along the crescent ridge. Rock and soil sampling along the IP line detected anomalous arsenic, copper, and zinc (Ellis and Hoffman, 2008).

Latitude: 60.2827 **Quadrangle:** LC B-6

Longitude: 155.2481

Location description and accuracy:

Located near the headwaters of Black Creek, a tributary of the Koksetna River about 25 miles west of Lake Clark. The prospect lies on the northeast flank of VABM Black in the northeast 1/4 of section 7, T. 2 N., R. 34 W. of the Seward Meridian.

Commodities:

Main: Ag, Au, Cu

Other: As, F

Ore minerals: Arsenopyrite, chalcopyrite, pyrite, pyrrhotite, scorodite

Gangue minerals: Calcite, fluorite, quartz, sericite, tourmaline

Geologic description:

The Kolossal prospect is underlain by sedimentary rocks of the Koksetna River sequence of Wallace and others (1989) that have been intruded by Cretaceous to Tertiary quartz monozonite plutons and rhyolite to dacite plugs, sills, dikes and flows. The Koksetna sequence at the prospect consists of dominantly fine grained silty sandstones and sandy siltstones. Local zones of thin bedded to laminated siltstones and poorly sorted medium-grained greywacke are interbedded on the eastern portion of the prospect area (Wilson and others, 2006).

At Kolossal the sedimentary rocks have been extensively hornfelsed, becoming pinkish-gray in color and commonly having a conchoidal fracture (Scott and Ellis, 1982). Locally the rocks have been highly tourmalinized and tourmaline veins with radiating crystals and quartz with tourmaline cores are common. The hornfelsed sedimentary rocks commonly contain from 1 to 2 percent finely disseminated pyrrhotite.

A leucocratic fine-grained equigranular, locally porphyritic, granite occurs in the northwest portion of the Kolossal prospect. Ten to twenty percent potassium feldspar phenocrysts 2 to 3 millimeters in diameter occur in portions of the intrusive. One to three percent chloritized mafics (after hornblende and biotite) are generally present except where leaching has left iron-oxide stained vugs. Locally miarolitic cavities 1 to 3 millimeters in diameter occur and are commonly lined with euhedral quartz and feldspar crystals (Ellis and others, 1985). The equigranular groundmass is composed of approximately 70 percent potassium feldspar plus plagioclase along with about 30 percent quartz and 1 to 3 percent chloritized mafics (biotite and hornblende). This granite was emplaced as a high level hypabyssal intrusion.

Greisen occurs sporadically in float in a 200 meter by 100 meter zone approximately 300 meters due north of VABM Black (Scott and Ellis, 1982). It consists of 65 to 90 percent granular quartz, 5 to 15 percent white mica (sericite) which is commonly in fractures and along boundaries of quartz grains, and 5 to 10 percent hornblende pseudomorphs which contain traces of unidentified opaques. Local zones of 1 to 3 percent purple fluorite occur. The greisens are locally mineralized with 1 to 3 percent arsenopyrite or its oxidation product, scorodite. Two occurrences of tourmaline quartz breccia have been located as float in the greisen area. The breccia consists of 1 to 10 centimeter fragments of greisenized granite and fine-grained 40 percent tourmaline and 60 percent quartz matrix (Ellis and others, 1985).

Five to ten meter wide aplite dikes occur sporadically in the prospect area. They are typically fine-grained (locally porphyritic) and are composed dominantly of quartz and feldspar. Near Black Creek the aplite dikes

contain 1 to 2 percent pyrite and quartz carbonate veins also located along the creek contain limonite stains and replacements, possibly after pyrite and chalcopyrite. On the northeast side of VABM Black a quartz latite dike is spatially associated with fracture controlled pyrite and chalcopyrite and local tourmalinization (Ellis and others, 1985).

Alteration:

At Black Hill the sedimentary rocks have been extensively hornfelsed, becoming pinkish-gray in color and commonly having a conchoidal fracture (Scott and Ellis, 1982). Locally the rocks are highly tourmalinized and tourmaline veins with radiating crystals and quartz with tourmaline cores are common.

Greisen occurs sporadically in float in a 200 meter by 100 meter zone approximately 300 meters due north of VABM Black (Scott and Ellis, 1982). It consists of 65 to 90 percent granular quartz, 5 to 15 percent white mica (sericite) which is commonly in fracture 1 to 3 percent purple fluorite occur. The greisens are locally mineralized with 1 to 3 percent arsenopyrite or its oxidation product, scorodite.

Age of mineralization:

Mineralization is probably related to 59.5 intrusions dated in the area (Eakins and others, 1978).

Generic deposit model:

Deposit model:

Polymetallic veins? (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Inactive

Workings/exploration:

The Kolossal prospect was discovered by Anaconda Minerals Company (Anaconda) following up on aeromagnetic anomalies in 1982. In 1983 Anaconda conducted geologic mapping, grid rock sampling, and gravity and ground magnetic surveys (Ellis and others, 1985).

During the 1982-1983 Anaconda programs five types of mineralization were identified at Kolossal: 1) arsenopyrite-bearing greisen, 2) quartz latite dike spatially associated with fracture controlled pyrite and chalcopyrite, 3) disseminated pyrrhotite in horfelsed sediments, 4) aplite dikes with pyrite, and 5)quartz carbonate veins with limonite stain and replacement. Rock samples from the mineralized quartz latite dike on Black Hill had fracture controlled pyrite and chalcopyrite which returned gold values from 0.3 to 1.7 parts per million (ppm) and silver values from 2 to 28 ppm. The most anomalous grab sample taken adjacent to an aplite dike contained 0.15 percent copper, 28 ppm silver, and 1 ppm gold (Ellis and others, 1985). The most anomalous tin value in a rock sample was 225 ppm.

Site name(s): Kody West

Site type: Prospect

ARDF no.: LC059

Latitude: 60.4007 **Quadrangle:** LC B-6

Longitude: 154.9423

Location description and accuracy:

The Kody West prospect is located in the Koksetna Hills approximately 20 miles northwest of Lake Clark. The prospect is on the hill southeast of hill 3017 at the headwaters of a tributary of the Koksetna River. Along the section line of the southwest 1/4 of section 25 and the northwest 1/4 of section 36 in T. 4 N., R. 33 W. of the Seward Meridian is the approximate center of the 1/2 kilometer prospect area.

Commodities:

Main: Ag, Pb, Sn, Zn

Other: As

Ore minerals: Arsenopyrite, cassiterite

Gangue minerals: Pyrite, quartz, sericite, tourmaline

Geologic description:

The area between the Koksetna and Chilikadrotna Rivers is underlain by undivided Kuskokwim Group sedimentary rocks and the Koksetna River sequence of Wallace and others (1989) that have been intruded by Cretaceous to Tertiary quartz monzonite plutons and rhyolite to dacite plugs, sills, dikes and flows (Wilson and others, 2006). The Kody West prospect lies within the Koksetna River sequence.

Hornfelsed greywacke float over a 500 by 400 meter area was found to contain abundant 0.5 to 5 centimeter wide quartz and iron oxide veins with one sample containing visible cassiterite mineralization (Scott and Ellis, 1982). The veins commonly contain gossan in void spaces and are associated with intense quartz-sericite alteration of the wall rocks with local traces of tourmaline. These veins are anomalously high in lead, zinc, silver, arsenic and tin (Ellis and others, 1985).

The observed veining and an aeromagnetic anomaly at Kody West indicate the likely presence of a shallow buried intrusive which could be related to the nearby (3 kilometers east-southeast) Kody (LC055) Sn-porphyry system (Ellis and others, 1985).

Alteration:

Abundant limonite stained quartz veins are seen cutting hornfelsed greywacke. The veins are associated with intense quartz-sericite alteration of the wall rocks with local traces of tourmaline (Ellis and others, 1985).

Age of mineralization:

Mineralization is probably related to 60.5 to 61.6 Ma intrusions dated in the Koksetna Hills (Eakins and others, 1978).

Generic deposit model:

Deposit model:

Sn-Polymetallic veins (Cox and Singer, 1986; model 20b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
20b

Production Status: None

Site Status: Inactive

Workings/exploration:

Anaconda Minerals Company (Anaconda) discovered the Kody West prospect in 1982 while following up on aeromagnetic and color anomalies. Mapping and grid rock sampling were completed. Grab samples from Kody West veins were anomalous in silver (2.3 parts per million (ppm) to 28.5 ounces per ton), lead (339 ppm to 8.55 percent), and zinc (710 to 2160 ppm). Several samples were also anomalous in arsenic, and two samples had tin values of 1150 and 3070 ppm (Scott and Ellis, 1982).

In 1983 Anaconda completed a ground magnetic survey and grid rock sampling of vein material. The quartz veins with gossan in void spaces were anomalously high in lead (100 ppm to 8.55 percent), zinc (300 to 3300 ppm), silver (1 to 912 ppm), arsenic (100 to over 1000 ppm), and tin (50 to 3070 ppm). The 21 line kilometer magnetic survey detected a shallow (less than 250 meter) 600 gamma anomaly under the topographic peaks at Kody West (Ellis and others, 1985).

Production notes:

None.

Reserves:

None.

Site name(s): Sawtooth Mountain

Site type: Mine

ARDF no.: LG006

Latitude: 65.376 **Quadrangle:** LG B-6

Longitude: 149.524

Location description and accuracy:

Cobb (1972, MF-413), loc. 2; NW1/4SW1/4 sec. 1, T. 6 N., R. 10 W., of the Fairbanks Meridian. This deposit is on Sawtooth Mountain. It is marked on the Livengood (B-6) quadrangle by a prospect symbol at the end of a trail up Buckeye Creek from the landing strip to the saddle on Sawtooth Mountain. The location is commonly believed to be accurate within about 50 meters.

Commodities:

Main: Sb

Other: Ag, Au

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Quartz

Geologic description:

Massive stibnite occurs as a vertical cylinder about 3 m wide; it is hosted in argillite of Jurassic or Cretaceous flysch near a contact with Cretaceous granitic rock (Nokleberg and others, 1987; R. M. Chapman, written communication, 1985). The quartz monzonite has been K-Ar dated at 91.0+/-0.9 Ma (Weber and others, 1992). Grab samples from the dump have up to 46.2 percent Sb, 0.7 g/ton Au and 15.1 g/ton Ag (Nokleberg and others, 1987). The vein produced 590 tonnes of ore with 58 percent stibnite through 1970, with minor production in 1984 and 1985.

Alteration:

Age of mineralization:

The granitic rock has been K-Ar dated at 91.0+/-0.9 Ma (Weber and others, 1992).

Generic deposit model:

Deposit model:

Stibnite vein (Cox and Singer, 1986; model 27d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

27d

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

A shaft reached a depth of 83 feet (Saunders, 1958; ATDM PE 49-14).

Production notes:

The vein produced 590 tonnes of ore with 58 percent stibnite through 1970, with minor production in 1984 and 1985 (Nokleberg and others, 1987).

Reserves:

None.

Geologic description:

This small old prospect is now part of the large International Tower Hills, Livengood prospect (LD202) that has been intensely studied and drilled since 2006. The Ruth Creek prospect has largely now lost its identity and the data in this record has been integrated into the Livengood record. This record has not been updated since the exploration stated on the Livengood prospect and the pre-Livengood information here is retained in its original form for historical reference.

Gold is found in numerous, nearly vertical quartz veinlets striking S. 20-60 E.; they contain pyrite and arsenopyrite (Mertie, 1918). Some of these veins contain up to 0.58 ounces of gold per ton (Mertie, 1918). The quartz veinlets are cut by calcite veins carrying some gold and sulfides (Mertie, 1918). Contiguous mineralized zones are up to 36 inches wide in altered dolomite-calcite-quartz-sulfide rock (Foster and Chapman, 1967). Small pits expose chromite in serpentinite, and a stibnite vein was uncovered in a placer cut (Joesting, 1942 [ATDM Pamph. 1]; Mertie, 1918).

Geologic description:

This small old prospect is now part of the large International Tower Hills, Livengood prospect (LD202) that has been intensely studied and drilled since 2006. The Griffin prospect has largely now lost its identity and the data in this record has been integrated into the Livengood record. This record has not been updated since the exploration stated on the Livengood prospect and the pre-Livengood information here is retained in its original form for historical reference.

The Griffin prospect consists of a massive, sulfide-bearing, green-stained silica-carbonate-talc rock veined by quartz ; samples contain as much as 3.9 ppm Au, 1,000 ppm Ni, and 1,000 ppm Cr (Foster, 1968, p. 2, 10-11). A fire assay of one sample showed 5.6 ppm Au (Foster, 1968, p. 10-11). The nature of the contact between pyritiferous metasedimentary country rock and silica-carbonate-talc rock is not known (Foster, 1968.) Small pits expose chromite in serpentinite, and a stibnite vein was uncovered in a placer cut (Joesting, 1942 [ATDM Pamph. 1]; Mertie, 1918).

Alteration:

Deposit stained green by weathering of disseminated sulfides.

Age of mineralization:

Generic deposit model:

Deposit model:

Quartz veins associated with silica-carbonate-talc rock.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

In 1955, the workings on the property included a shaft filled with water, an adit and several pits and trenches (Saunders, 1955).

Geologic description:

This small old prospect is now part of the large International Tower Hills, Livengood prospect (LD202) that has been intensely studied and drilled since 2006. The Old Smoky prospect has largely now lost its identity and the data in this record has been integrated into the Livengood record. This Smoky Hill record has not been updated since the exploration stated on the Livengood prospect and the pre-Livengood information here is retained in its original form for historical reference.

Trenching near the head of Olive Creek has exposed narrow, northwest-trending auriferous arsenopyrite-quartz veins in ferruginous quartzite near the intersection of an altered, porphyritic, biotite-monzonite dike, and a potassium feldspar-porphyry dike (Foster, 1968). Mineralization at the Old Smoky prospect is in Devonian sedimentary rocks composed of shale, argillite, fine-grained sandstone, and pebbly conglomerate (Allegro, 1984, p. 3). Narrow zones of thermal metamorphism occur along sheared contacts between these sedimentary rocks and hypabyssal igneous intrusive rocks (Allegro, 1984, p. 3). Similar felsic intrusive rocks throughout the Livengood Quadrangle have been potassium-argon dated at 58.0 to 88.8 m.y. (Turner and others, 1975).

Most of the intrusive rocks and some of the sedimentary host rocks have experienced variable degrees of metasomatic hydrothermal alteration followed by lower temperature supergene alteration (Allegro, 1984, p. 4). Allegro (1984) described four types of hydrothermal alteration: 1) silicification, as partial to complete replacement of the host rock by a dense network of quartz veinlets generally localized along contacts between the intrusive and sedimentary rocks; 2) sericitization, as fine- to medium-grained white mica in selvages along quartz veins, as anastomosing sericite-opaque mineral veinlets, and as patchy to massive sericitic replacement of feldspar, ferromagnesium minerals and quartz; 3) deposition of trigonal nets of needle-like rutile often associated with secondary quartz and minor feldspar; and 4) epidote +/- sericite as a replacement of calcic plagioclase and ferromagnesian minerals resulting in massive aggregates, pseudomorphs, veins, and vug fillings of epidote commonly associated with sericite, opaque minerals, and quartz.

Allegro's (1984) investigation and sample data reveal that the mineralization in the southern portion of the cut is localized along the contact zones between the biotite monzonite and the surrounding sedimentary rocks, and along a contact between biotite monzonite and feldspar porphyry. Channel and chip samples of arsenopyrite-stibnite quartz veins from these zones contained 1.0 to 29.8 ppm gold. Selected samples from

the prospect contain 3 to 13 ppm gold as determined by atomic absorption, and 1.6 to 7.0 ppm gold as determined by fire assay-atomic absorption (Foster, 1968, p. 2).

Adjacent to the sheared contact zone, the intrusive rocks are either highly silicified with abundant rutile and some epidote, sericite, arsenopyrite, and monor stibnite, or contain epidote with sericite, rutilated quartz and arsenopyrite (Allegro, 1984, p. 6). Other rocks from the contact zone show intense supergene effects such as clay alteration, covellite and iron-oxides. In some cases these zones contain gold. Green scorodite is present throughout the mineralized areas.

In the northern section of the prospect, the most abundant mineralization is located along the contact area between the feldspar porphyry and a roof pendant of sandstone and shale (Allegro, 1984). A massive 1-meter-wide stibnite lens surrounded by a bleached sericite zone occurs along the northern contact of the roof pendant. Channel samples along this contact zone range from 0.5 to 4.3 ppm gold (Allegro, 1984, p. 6). Some gold is also associated with saprolitic zones in all the intrusive phases but these zones are not limited to shear zones or contacts (Allegro, 1984, p. 6).

Alteration:

Most of the intrusive rocks and some of the sedimentary host rocks have experienced variable degrees of metasomatic hydrothermal alteration followed by lower temperature supergene alteration (Allegro, 1984, p. 4). Allegro (1984) described four types of hydrothermal alteration: 1) silicification, as partial to complete replacement of the host rock by a dense network of quartz veinlets generally localized along contacts between the intrusive and sedimentary rocks; 2) sericitization, as fine- to medium-grained white mica in selvages along quartz veins, as anastomosing sericite-opaque mineral veinlets, and as patchy to massive sericitic replacement of feldspar, ferromagnesium minerals and quartz; 3) deposition of trigonal nets of needle-like rutile often associated with secondary quartz and minor feldspar; and 4) epidote ± sericite as a replacement of calcic plagioclase and ferromagnesian minerals resulting in massive aggregates, pseudomorphs, veins, and vug fillings of epidote commonly associated with sericite, opaque minerals, and quartz.

Age of mineralization:

Felsic intrusive rocks throughout the Livengood Quadrangle, similar to those at the mineralized contact zone of the Old Smoky prospect, have been potassium-argon dated at 58.0 to 88.8 m.y. (Turner and others, 1975).

Generic deposit model:

Deposit model:

Gold-bearing shear zone at contact of hypabyssal intrusions into sediments.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Some trenching and prospect pits that have been channel and chip sampled.

Production notes:

None.

Reserves:

Workings/exploration:

Workings consisted of an 85-foot inclined shaft and a 60-foot tunnel (Hill, 1933, p. 157).

In 2016, the Treasure Creek Partnership consolidated three, separately owned properties, including numerous prospects and occurrences (LG038; LG039; FB074; FB075; FB076; FB077; FB078; FB079; FB080; FB081) in the Treasure and Any Creek watersheds that potentially host plutonic-related, lode-gold mineralization contained in shear zones north of Fairbanks. Exploration activity in 2016 included conducting field work and reviewing and updating 1990s-era exploration information (Athey and Werdon, 2017).

Production notes:

Hill (1933, p. 157) reported that ore was mined and shipped in 1916, but the amount is not known. Mulligan (1974, p. 12) reported development and an unknown amount of production in 1968-69.

Reserves:

None.

Site name(s): True North

Site type: Mine

ARDF no.: LG055

Latitude: 65.0459 **Quadrangle:** LG A-2

Longitude: 147.562

Location description and accuracy:

The True North Mine is about 2 miles northwest of Pedro Dome. The coordinates are near the center of several open pits which are spread over an area about 2 kilometers in diameter. The mine is near the center of section 33, T. 3 N., R. 1 E of the Fairbanks Meridian. The old Hindenburg/Markovich Mine (LG054) became part of the True North Mine.

Commodities:

Main: Au, Sb

Other:

Ore minerals: Gold, stibnite

Gangue minerals: Carbonates, quartz

Geologic description:

The True North gold mine is a structurally controlled, disseminated gold deposit on the northwest flank of Pedro Dome (Masterman, 1998). Gold was recognized on the property as early as 1913, but early production was limited to stibnite ore from the Hindenburg/Markovich Mine (ARDF site LG054), which became part of the True North Mine.

The mineralization at True North consists of thin quartz-carbonate veins, often with stibnite, in a heterogeneous, high-grade metamorphic package of calcareous eclogite, carbonaceous schist and quartzite (Swainbank and others, 1998). Gold occurs in a northeast-trending zone, 2,500 feet wide and 5.000 feet long, west of the northeast-trending Eldorado Fault. Gold-bearing ore bodies are typically 20 to 60 feet thick in gently dipping shear zones and along faulted lithologic contacts (Masterman, 1998). Alteration is characterized by quartz, manganese-oxides, ankerite, mariposite, sericite, and carbon. The gold grade averages 0.05 to 0.10 ounce of gold per ton (Masterman, 1998). The mineralization is probably 90 Ma, the same age of many deposits in the vicinity.

Exploration activities at the True North from 1991 to 1997 consisted of 9,832 top-of-bedrock soil samples, 15,621 feet of trenching, 40,133 feet of core drilling, and 153,914 feet of reverse-circulation drilling (Masterman, 1998). Soils were auger sampled in 1998 (Szumigala and Swainbank, 1999, p. 10).

In 1999, Kinross Gold Corporation acquired the True North property (Quandt and others, 2008). By 2008, the prospect consisted of a large block of State of Alaska claims that Kinross Gold Corporation had leased from several private individuals. Open-pit mining began at True North in April, 2001, and the mine eventually consisted of several large open pits spread over an area about 2 kilometers in diameter; the ore was trucked to the Fort Knox mill (FB115). In 2004, mining was suspended. From 2001 to 2004, the True North Mine had shipped 11,026,722 tons of ore to the mill. By 2009, permits had been submitted to close the mine, all the mine buildings had been removed, and revegetation of the mine workings had begun.

Quandt and others (2008) estimated that the True North deposit had an indicated resource of 3.464 million tons with a grade of 1.49 grams of gold per tonne. This estimate was done to modern industry standards. These figures were published after the mine had ceased production and was in the process of being closed.

Alteration:

Alteration is characterized by quartz, manganese-oxides, ankerite, mariposite, sericite, and carbon.

Age of mineralization:

About 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Disseminated carbonate-replacement gold mineralization associated with intrusion- and schist-hosted crushed veins and low-angle shears.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The following history of exploration is based on an abstract presented by Steve Masterman, Newmont Exploration Limited, at the 1998 Alaska Miners Association Meeting. In 1990, Dick Swainbank brought the property to the attention of AMAX Gold, Inc. (AGI). AGI acquired the claims and conducted soil sampling, trenching, and 6,332 feet of reverse-circulation (RC) drilling. In 1994, after drilling 14 more RC holes under an exploration agreement, LaTeko acquired the property from AGI. During the summer of 1994, LaTeko expanded the soil grid, excavated additional trenches, drilled 52,000 feet of RC and 2,040 feet of HQ core. In 1995, Newmont Exploration Ltd. began exploration on the property,after entering into a joint venture with LaTeko. Exploration activities on the True North property from 1991 to 1997 consisted of 9,832 top-of-bedrock soil samples, 15,621 feet of trenching, 40,133 feet of core drilling, and 153,914 feet of RC drilling (Masterman, 1998). In 1998, most exploration work consisted of soil sampling by auger (Szumigala and Swainbank, 1999, p. 10).

In 1999, Kinross Gold Corporation acquired the True North property (Quandt and others, 2008). By 2008, it consisted of a large block of State of Alaska claims that Kinross Gold Corporation had leased from several private individuals. Mining began at True North in April, 2001 and the ore was trucked to the Fort Knox mill (FB115). Mining was suspended in 2004.

In 2009, final reclamation at True North began (Szumigala and others, 2010).

Production notes:

From 2001 to 2004, the last year of production, the True North Mine had shipped 11,026,772 tons of ore to the mill.

In 2009, Fairbanks Gold Mining, Inc., the operator of True North Mine, made the decision to forego further mining and exploration at the site, and began final reclamation (Fairbanks Gold Mining, Inc, 2012, and Alaska Department of Natural Resources, 2014).

Reserves:

Quandt and others (2008) estimated that the True North deposit had an indicated resource of 3.464 million tons with a grade of 1.49 grams of gold per tonne. This estimate was done to modern industry standards. These figures were published after the mine had ceased production and was in the process of being closed.

Additional comments:

In 2009, Fairbanks Gold Mining, Inc., the operator of True North Mine, made the decision to forego further mining and exploration at the site, and began final reclamation. In 2010, 149 acres of the site were graded, growth media was placed on 52 acres, and 270 acres were scarified, seeded, and fertilized. By 2011, the major earthwork was completed leaving a small area of materials to be salvaged. As of summer 2014 the site was essentially fully revegetated and will be monitored for several more years to assure long-term

stability (Fairbanks Gold Mining, Inc, 2012, and Alaska Department of Natural Resources, 2014).

Site name(s): Fox Creek

Site type: Mine

ARDF no.: LG061

Latitude: 64.9999 **Quadrangle:** LG A-2

Longitude: 147.61716

Location description and accuracy:

At least two miles of Fox Creek has been mined; part is in the Fairbanks quadrangle, part is in the Livengood quadrangle. Most of the mining or at least the mining since WWII, has been in the Livengood quadrangle. But much of the information of record about placer mining on Fox creek cannot be assigned to one of the quadrangles, For convenience, all of the information on Fox Creek has been consolidated into this record. This site is about 3.0 miles north of Fox in section 18, T. 2 N., R. 1 E. The location is accurate.

Commodities:

Main: Au

Other: W

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

Placer gold was being mined from Fox Creek by 1908 (Prindle, 1908; Prindle and Katz, 1913). There is little record of the early mining but it is likely that prior to WWI, much if not all of Fox Creek was prospected and staked and mining took place at various places along it. In 1914, Mr. Ardvino located the Vino Bench and Vino claims near the head of Fox Creek and mined there until 1935 (Cornelius and Madonna, 1988). In 1985, Tillicum Mining acquired the property and in 1987 mined at the head of Fox Creek on what they considered an eluvial or residual placer (Cornelius and Madonna, 1988). Much of the gold was angular and intergrown with rusty quartz. In subsequent years, the upper mile or more of upper Fox Creek was mined and reclaimed (Janet Schaefer, field observation, 1999). Szumigala and others (2011) report that Tillicum Mining and three other operations had produced gold from open pit mines on Fox Creek in 2010. Satellite imagery available on the internet suggests that a bare area on lower Fox Creek in about the middle of section 30, T. 2 N., R. 1 E. (in the Fairbanks quadrangle) may be one of those mines.

Early studies report that the depth to bedrock on Fox Creek was 10 to 19 feet, and that granite is exposed near the head of the creek (Prindle and Katz, 1909; Prindle and Katz, 1913). Bedrock in the Fox Creek drainage is mainly quartz-muscovite schist, quartzite, and chlorite-quartz schist, which is intruded by Cretaceous granite, tonalite, and quartz diorite at the head of the creek (Newberry and others, 1996). Placer concentrates near the head of the creek contained an estimated 90 percent scheelite (Joesting, 1943; Byers, 1957.

About 1,500 ounces of gold was produced from Fox Creek from 1905 to 1910 (Prindle and Katz, 1913). Production figures for more recent mining are not available in the public record.

Alteration:

Age of mineralization:

Quaternary.

Site name(s): Newsboy

Site type: Mine

ARDF no.: LG100

Latitude: 65.0561 **Quadrangle:** LG A-1

Longitude: 147.4737

Location description and accuracy:

The Newsboy Mine is just south of the saddle between Cleary Creek and Last Chance Creek. It is at an elevation of about 1,750 feet, approximately two miles north-northeast of Pedro Dome in the SE1/4 section 26, T. 3 N., R. 1 E., of the Fairbanks Meridian. It is located with within the Golden Summit Project area. The location is accurate within 500 feet.

Commodities:

Main: Ag, Au

Other: Cu, Pb, Sb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, sphalerite, stibnite

Gangue minerals: Quartz

Geologic description:

The Newsboy mine was one of the major producers in the Cleary Hill area. Production began in 1911 and continued intermittently until World War II. The Newsboy mine was first staked June 25, 1909 (Times Publishing Company, 1912). The Newsboy shear zone was traced for several hundred feet on the surface and additional claims were staked. In October, 1911, a 5-stamp Joshua Hendy Mill was erected (Brooks, 1912; Smith, 1913a and 1913b). The mill operated for only a few months due to lack of water. Brooks (1912) indicated that by mid-1911 the Newsboy Mine shaft had reached the 200-foot level and working drifts had been driven on the 60-foot and 115-foot levels. By the end of 1911 the bottom of the shaft was at the 315-foot level and drifting was being conducted on a 4-foot-wide shear zone on the 215-foot and 315-foot levels.

By May 12, 1912, the mill had been moved to placer claim #11 above Discovery on Cleary Creek, about 4,000 feet northeast of and 600 feet lower than the Newsboy Mine. Water for the mill was taken from a 100-foot-deep 6-inch well, located near the mill (Smith, 1913a).

By 1913, the Newsboy Mine was being developed on the 60-, 115-, 168-, 215- and 315-foot levels. The 115-foot level extended 140 feet southwest and 100 feet northeast of the shaft and much of the ore between this level and the 168-foot level had been mined (Chapin, 1914). A few feet east of the shaft on the 115-foot level the shear zone was mined over a 14 foot width. The 315-foot level was accessed by 250 feet of drifts, but this level of the mine was flooded in 1913 (Chapin, 1914).

Surface trenching was conducted along the shear zone in 1923 but the mine was idle (Stewart, 1923). During 1931, renovation was completed on the mine and the old mill on upper Cleary Creek (Pilgrim, 1932; Smith, 1933a and 1933b), and the shaft was opened to the 160-foot level (Hill, 1933). In October, the nearly retrofitted mill burned to the ground. Development work continued in the mine and de-watering was begun in the lower mine levels (Pilgrim, 1932; Stewart, 1933; Hill, 1933).

In 1932, a diesel-powered 180-cubic-foot-capacity Sullivan compressor was installed at the mine. One-hundred and fifty tons of ore from above the 215-foot level was shipped seven miles to the Tom Gilmore Mill on Fairbanks Creek. The 215-foot level was reopened in 1932 and minor exploratory work was conducted in 1933 (Smith, 1934). The Newsboy mill was rebuilt in 1933. New grinding and flotation equipment was added to the mill in 1935 and mining resumed underground (Smith, 1938). In 1938, the

mine was de-watered at the 215-foot level (Reed, 1939). A 1200-foot-long surface trench was emplaced and drifting on the 165-foot level took place in 1938; no ore was produced in 1938 (Stewart, 1939). In December, 1940, the prospect was idle (Stewart, 1941).

In 1995, Placer Dome drilled a 1,113-foot core hole that intersected a 20-foot zone that contained 0.066 ounces of gold per ton (Freeman, 2008). The bottom of the hole contained lead-zinc mineralization associated with a stratabound(?) massive sulfide lenses in black chloritic schist. In 1998, Freegold Ventures Ltd., drilled a core hole about 900 feet west of the Newsboy shaft; it cut a 10-foot section that contained 0.096 ounce gold per ton and a 10-foot section that contained 0.065 ounce of gold per ton. Freeman suggests that the Newsboy vein and other nearby prospects are part of a northeast-trending 'vein swarm'. As of 2008, the Newsboy Mine was part of the Golden Summit project of Freegold Ventures Ltd.

The mine is in dark green, massive to tightly foliated chlorite-actinolite schist of basaltic origin. The country rocks trend N60-80E and dip 0 to 30NW (Robinson and others, 1990). The mine dumps indicate much of the mining was in quartz-biotite-mica schist and quartz-sericite schist with abundant white to granular, quartz stockwork and pervasive flood silica (Freeman, 1992). The deposit is on the Newsboy shear zone which features several generations of mainly strike-slip faulting with some dip-slip displacement. However, the dip-slip displacement is difficult to unravel due to the intensity and complexity of the movements (Freeman, 1992). The Newsboy shear zone is on the northwest limb of the Cleary antiform and is cut by a series of poorly understood, east-trending faults which predominantly dip 57-80N. These structures truncate the mineralization and despite several hundred feet of drilling and exploratory drifting, the continuation of the shear zone could not be located (Freeman, 1992).

Mineralization at the Newsboy Mine consists primarily of native gold plus arsenopyrite, some of it auriferous, with lesser amounts of stibnite, chalcopyrite, sphalerite and ubiquitous pyrite (Fairbanks Exploration Inc., unpublished report, 1986). The ore is similar to that at the nearby Tolovana Mine (LG110), about one mile east and 650 feet lower in elevation than the Newsboy shaft. Shear zones and stockworks with abundant white quartz are from 2 to 14 feet wide; they average about 4 to 5 feet wide in the upper 200 feet of workings (Hill, 1933; Stewart, 1931). The mineralization is probably mid-Cretaceous based on similarities to other deposits in the area (McCoy and others, 1997).

Samples collected in 1986 from the Newsboy Mine dumps contain high arsenic and gold coupled with erratic but generally low antimony and silver (Fairbanks Exploration Inc., unpublished report, 1986). Samples contain from 260 parts per billion (ppb) gold to 4.180 ounces of gold per ton. Sulfide-rich samples from mill concentrates and tailings near the old Newsboy mill contain much gold with abundant arsenopyrite and pyrite. Sulfide-rich mill concentrates contained from 1.433 to 3.377 ounces of gold per ton. The mill tailings contained 0.087 to 0.163 ounce of gold per ton (Fairbanks Exploration Inc., unpublished report, 1986). A significant amount of gold (810 to 5,700 ppb) was detected in quartz-sericite schist derived from rhyolite tuff and exhalite (Fairbanks Exploration Inc., unpublished report, 1986).

Alteration:

Quartz, sericite, and ankerite (Freeman, 1992).

Age of mineralization:

Probably mid-Cretaceous based on similarities with other deposits in the area (McCoy and others, 1997).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Newsboy mine was first staked June 25, 1909 (Times Publishing Company, 1912). The Newsboy shear zone was traced for several hundred feet on the surface and additional claims were staked. In October, 1911, a 5-stamp Joshua Hendy Mill was erected (Brooks, 1912; Smith, 1913a and 1913b). The mill operated for only a few months due to lack of water. Brooks (1912) indicated that by mid-1911 the Newsboy Mine shaft had reached the 200-foot level and working drifts had been driven on the 60-foot and 115-foot levels. By the end of 1911 the bottom of the shaft was at the 315-foot level and drifting was being conducted on a 4-foot-wide shear zone on the 215-foot and 315-foot levels.

By May 12, 1912, the mill had been moved to placer claim #11 above Discovery on Cleary Creek, about 4,000 feet northeast of and 600 feet lower than the Newsboy Mine. Water for the mill was taken from a 100-foot-deep 6-inch well, located near the mill (Smith, 1913a and 1913b).

By 1913, the Newsboy Mine was being developed on the 60-, 115-, 168-, 215- and 315-foot levels. The 115-foot level extended 140 feet southwest and 100 feet northeast of the shaft and much of the ore between this level and the 168-foot level had been mined (Chapin, 1914). A few feet east of the shaft on the 115-foot level the shear zone was mined over a 14 foot width. The 315-foot level was accessed by 250 feet of drifts, but this level of the mine was flooded in 1913 (Chapin, 1914).

Surface trenching was conducted along the shear zone in 1923 but the mine was idle (Stewart, 1923). During 1931, renovation was completed on the mine and the old mill on upper Cleary Creek (Pilgrim, 1932; Smith, 1933a and 1933b), and the shaft was opened to the 160-foot level (Hill, 1933). In October, the nearly retrofitted mill burned to the ground. Development work continued in the mine and de-watering was begun in the lower mine levels (Pilgrim, 1932; Stewart, 1933; Hill, 1933).

In 1932, a diesel-powered 180-cubic-foot-capacity Sullivan compressor was installed at the mine. One-hundred and fifty tons of ore from above the 215-foot level was shipped seven miles to the Tom Gilmore Mill on Fairbanks Creek. The 215-foot level was reopened in 1932 and minor exploratory work was conducted in 1933 (Smith, 1934). The Newsboy mill was rebuilt in 1933. New grinding and flotation equipment was added to the mill in 1935 and mining resumed underground (Smith, 1938). In 1938, the mine was de-watered at the 215-foot level (Reed, 1939). A 1200-foot-long surface trench was emplaced and drifting on the 165-foot level took place in 1938; no ore was produced in 1938 (Stewart, 1939). In December, 1940, the prospect was idle (Stewart, 1941).

In 1995, Placer Dome drilled a 1,113-foot core hole (Freeman, 2008). In 1998, Freegold Ventures Ltd., drilled a core hole about 900 feet west of the Newsboy shaft;. As of 2008, the Newsboy Mine is part of the Golden Summit project of Freegold Ventures Ltd.

In 2012, Freegold collected 218 soil samples (Abrams and Giroux, 2013).

Production notes:

In May of 1911, the Newsboy Mine produced a 66 ton ore shipment which yielded $5008.20 in gold, or about 244 ounces of gold. An additional 7.5 tons of ore was shipped in 1911 to the Garden Island Mill in Fairbanks and was reported to contain $104 gold per ton (5 ounces of gold per ton) in free milling gold (Brooks, 1913; Smith, 1913). Drifting and mining continued at the Newsboy Mine in 1913 although no production figures for the year are available (Chapin, 1914). Despite production of nearly $150,000 worth of gold (7250 troy ounces), the mine was shut down in 1915. In 1932, 150 tons of ore from above the 215-foot level was shipped 7 miles to the Tom Gilmore Mill on Fairbanks Creek. The total estimated production from 175 feet to the surface is 35,937 tons of ore and 8,125 tons of waste from which 35,937 troy ounces of gold were recovered (Freeman, 1992).

Reserves:

The following discussion of reserves is taken from Freeman (1992) and is based on analysis of old mine maps. Ore reserves blocked out between the 350-foot and 175-foot levels are estimated at 21,875 tons of ore and 10,937 tons of waste rock, with a resource of 21,875 ounces of gold in place. The estimated reserves along the Newsboy shear zone system are considerably larger. Based on the past production figures, an estimated 75 percent of the reserves will consist of 4 feet of shear zone in a 6 foot heading; the remaining 25 percent of the reserves are figured on a 14-feet -wide shear zone on 14 feet of heading. The reserves are based on free gold at a grade of 0.5 ounce of gold per ton. Sulfide-encapsulated fine gold is expected to contribute a significant amount to the total gold; however, since reliable figures on the average amount of sulfide-encapsulated gold are not available, no value is given to this form of gold in the geologic reserves.

The adjusted total geologic reserves takes into account the 44,062 tons of ore and waste estimated to have been mined from the Newsboy shaft. Based on the above assumptions, the total geologic reserve of the Newsboy shear zone system to the 1200 level is 813,938 tons at a grade of 0.5 ounce of gold per ton. It should be noted that the reserves are hypothetical reserves and as such no dilution or recovery factors have been included in the calculations.

Last report date: 2014-12-23

Site name(s): Stibnite

Site type: Prospect

ARDF no.: LG105

Latitude: 65.0625 **Quadrangle:** LG A-1

Longitude: 147.4574

Location description and accuracy:

The Stibnite prospect is located just above the junction of Willow Creek and Cleary Creek in the NE1/4NW1/4 sec. 25, T. 3 N., R. 1 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, Pb, Sb

Other: Au

Ore minerals: Argentiferous galena, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG207).

By 1916, the Stibnite prospect was being explored by the Eldorado Mining and Milling Company and it consisted of an open cut and a 40-foot shaft (Mertie, 1918). A 3- to 12-inch-thick shear zone contained 'commercial grade' lead and silver with minor gold. The principal ore minerals are argentiferous galena, stibnite and pyrite. The ore is in quartzite and is parallel to the schistosity of the country rock.

Alteration:

Not stated.

Age of mineralization:

About 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Lead, silver, antimony and gold mineralization in quartzite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

By 1916, the Stibnite prospect was being explored by the Eldorado Mining and Milling Company and it consisted of an open cut and a 40-foot shaft (Mertie, 1918).

Production notes:

None.

Reserves:

None.

Site name(s): Johnson; Johnson and Martin

Site type: Prospect

ARDF no.: LG106

Latitude: 65.0637 **Quadrangle:** LG A-1

Longitude: 147.4577

Location description and accuracy:

The Johnson prospect is near the mouth of Willow Creek, a headwater tributary of Cleary Creek. It is in the NW1/4NE1/4 sec. 25, T. 3 N., R. 1 E., of the Fairbanks Meridian. The location is accurate to within 1,000 feet.

Commodities:

Main: Sb

Other: W

Ore minerals: Arsenopyrite, pyrite, scheelite, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this prospect is part of a larger mineralized system that is described as a separate ARDF site (LG207).

In 1942, a placer cut on Willow Creek exposed high-grade stibnite in several parts of a shear zone (Joesting, 1943). The stibnite is in a vertical vein with occasional quartz and other sulfides; it is 6 to 8 inches wide and was traced N40E for 75 feet (Killeen and Mertie, 1951). Nearby in 1912, a shaft was sunk 16 feet on a narrow quartz stringer carrying stibnite (Killeen and Mertie, 1951). Massive stibnite and coarse grained scheelite were identified on the dumps at the Johnson and Martin prospect (Byers, 1957). The prospect was examined by Metz and Robinson (1980) who noted that massive stibnite and scheelite were in quartz muscovite schist that strikes N60E and dips 25NW. Ore exposed in a 28-inch-thick horizon in a small pit contained abundant coarse- to fine-grained stibnite, discrete bands of coarse scheelite grains to 0.8 inch across, and minor pyrite and arsenopyrite. By volume, stibnite constitutes 95 percent of the lens, scheelite 4 percent, and arsenopyrite and pyrite about 1 each.

In 1986 the prospect was examined by Fairbanks Exploration Inc. (Fairbanks Exploration Inc., unpublished report, 1986). They reported disseminated to massive coarse-bladed stibnite with scheelite crystals disseminated in the stibnite. Gold values ranged from 420 parts per billion (ppb) to 2,450 ppb; silver values ranged from a trace to 2.21 ounces of silver per ton, antimony values were greater than 10,000 parts per million (ppm), and arsenic values ranged from 600 to 800 parts per million. Extensive trenching was conducted by the Yukon Tanana Mining Company in the vicinity of the Johnson and Martin prospect in 1988 but the results of this work are not known (Freeman, 1992).

(Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG207).

The only published information on this prospect states that some rich gold ore was extracted prior to 1910 (Brooks, 1911). The prospect was clearly distinct from the nearby Tolovana mine (ARDF no. LG110) at that time, but may have been developed with the Tolovana mine later. No information is available on the character of mineralization.

Longitude: 147.4552

Location description and accuracy:

This prospect is in the bed of Willow Creek, a tributary of Cleary Creek about 100 yards from its mouth. It is in the NE1/4 sec. 25, T. 3 N., R. 1 E., of the Fairbanks Meridian. The location is accurate

Commodities:

Main: Sb

Other: As, Au, Zn

Ore minerals: Arsenopyrite, gold, pyrite, sphalerite, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG207).

This antimony prospect was uncovered during placer mining operations and was described by Henry Joesting in a report to the Alaska Territorial Department of Mines in 1942. The antimony ore occurs as stibnite in a zone of white quartz and gouge that strikes east-west across the valley of Willow Creek (Joesting, 1942; ATDM PE 49-7). In the hydraulic cut where the overburden and gravel had been removed, high-grade ore could be traced continuously from the west side of the cut to the creek, a distance of about 75 feet. Ore is also found on the east side of the cut, about 100 feet from the creek. Between these two showings of ore, the zone consists mainly of quartz and gouge, with minor amounts of stibnite and pyrite, and occasionally arsenopyrite. Some pieces of high-grade stibnite found on the surface measured about a foot across. Most of the ore is fine-grained and massive with a minor portion made up of coarse-bladed crystals of stibnite. The higher grade portions contained 56 percent antimony. Small amounts of pyrite and arsenopyrite occur in the lower grade material.

The bedrock is mainly a soft, badly weathered biotite schist, with considerable clay. The schist strikes east and dips steeply north. Several thin limestone beds were noted. A few of these beds about 100 feet upstream from the stibnite prospect contain sphalerite and pyrite. Numerous small veins and lenses of glassy quartz were also noted in the bedrock. Some contain small amounts of pyrite, arsenopyrite, and sphalerite.

Alteration:

Not stated.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:
Stibnite-quartz vein (Cox and Singer, 1986; model 27d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
27d

Production Status: None

Site Status: Active

Workings/exploration:
The vein was exposed by a hydraulic cut during placer mining operations.

Production notes:
No record of production.

Reserves:
None.

Site name(s): Tolovana

Site type: Mine

ARDF no.: LG110

Latitude: 65.0626 **Quadrangle:** LG A-1

Longitude: 147.4518

Location description and accuracy:

The Tolovana Mine is about 25 feet above Willow Creek at an elevation of 1,300 feet. It is approximately 1/8 of a mile upstream from the junction of Willow Creek and Cleary Creek, in the NW1/4NE1/4 sec. 25, T. 3 N., R. 1 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Pb, Sb, W

Ore minerals: Arsenopyrite, galena, gold, pyrite, scheelite, stibnite, tetrahedrite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG207).

The Tolovana Mine is an old property that was discovered before 1910. It operated intermittently until at least 1949, and was the site of considerable work in the 1980s. By 1910, an 85 foot adit had been driven at the Tolovana Mine. In July, 1911 a Huntington disc mill was installed and began operation on the prospect. The mill ran continuously through mid-November when lack of water forced it to close. The mill began operating again in March, 1912 after a well and pump had been installed on Willow Creek (Times Publishing Company, 1912). In July, 1912 a two-stamp Nissen mill was erected and began crushing ore on August 23, 1912.

In 1912, the mine consisted of a 400-foot adit from which several short drifts were driven; small stopes were also developed (Smith, 1913). The adit extends along the main shear zone for 130 feet where it intersects a vertical fault. (Note by compiler: In much of the early literature on this mine, the term 'shear zone' usually referred to a fault zone with parallel mineralized quartz veins, stringers, or pods, i.e., in other words what others here and elsewhere might have referred to as a sheared quartz vein or lode. The description that follows generally reflects the old 'shear zone' terminology.) The workings turned north for 30 feet and then turn east again, along the offset extension of the shear zone. Approximately 100 feet from the portal of the adit, a winze was sunk to a depth of 50 feet and drifts were driven to the east and west. A second winze, inclined 60 degrees to the south, was driven from the east end of the drift but was flooded in 1912. A third winze, located 330 feet from the portal, was sunk from the adit level to a depth of 100 feet (Loftus, 1927). A shaft near the portal of the adit had been sunk to a depth of 100 feet and a drift driven on the 50-foot level connects with the winze in the adit. Due to the flooding of the shaft near the Tolovana adit in late 1912, work was shifted to the Willow Creek-Bedrock Creek divide where a 55-foot shaft, the Scheuyemere #1 shaft, was sunk on a 12- to 14-inch-thick shear zone (Times Publishing Company, 1912). This shaft is sometimes referred to as the Tolovana Stibnite prospect (Chapin, 1914).

By 1913, the shaft and the winze had been connected by a drift on the 100-foot level and the ore between the adit and the 100 foot level was mined (Chapin, 1914). Additional stoping took place above the adit level. By 1913, the Scheuyemere #1 shaft had been sunk to a depth of 100 feet and drifts were driven 50

feet to the east and 30 feet to the west on the 50-foot level (Chapin, 1914). A raise, 24 feet west of the shaft, connected with the surface and the block of ground between the shaft and the raise had been stoped from the 50-foot level to the surface.

In 1913, a new shear zone was discovered and shaft sinking was in progress (Chapin, 1914). This shaft, the South shaft, was connected to the Tolovana adit by a crosscut.

In 1922, the Tolovana adit was 530 feet long. A drift had also been driven from the 50-foot level of the winze for 30 feet to the east where it intersected a fault which offsets the shear zone (Stewart, 1922; Davis, 1922). In the South shaft, drifting at the 50-foot level went out 15 feet to the west and 20 feet to the east along the shear zone. A total of 150 feet of new drifting was completed on the Tolovana Mine in 1923 and 8 to 10 tons of ore were milled on site (Stewart, 1923).

The Tolovana mine was inactive until 1930 when exploration was renewed (Smith, 1933). The western extension of the Tolovana shear zone, on the west side of Willow Creek, was discovered in 1930 and was explored through the Parenteau adit (Stewart, 1931). This adit was driven 160 feet to the west ; 50 tons of ore was treated in the mill in 1930. The Parenteau adit was caved about 75 feet from the portal when visited in 1931 (Hill, 1933).

Antimony and gold were mined from the prospect in 1949 (Saarela, 1950). In August 1984, the Mine was explored by dozer and backhoe. A small gravity mill was constructed near the old portal of the Tolovana adit and several large open cuts were excavated in the vicinity of the Scheuyemere #1 shaft (Freeman, 1992). Surface samples from the Upper Pit area and the dump were also collected in 1986 (Fairbanks Exploration Inc., unpublished report, 1986).

Three types of metamorphic rocks are present at the Tolovana Mine (LeLacheur, 1991). The dominant rock unit is micaceous quartzite. Subordinate crenulated biotite-schist and a thin layer of amphibole-biotite schist are interlayered in the quartzite. Strongly altered plutonic rock is exposed in several trenches at the south end of the property (LeLacheur, 1991). The dominant process of ore deposition seems to have been replacement of the country rock and fault zones by quartz, sericite and sulfides, rather than quartz deposition in veins (LeLacheur, 1991, p. 50).

Initial development began on a series of 1- to 3-inch quartz veinlets with visible gold which trend N75E (Prindle, 1910). Ore in the Tolovana Mine varies from ribbon-texture quartz stringers to massive quartz veins which vary from a few inches to 3 feet in width. The mineralization had been traced for over 1,500 feet along strike. The 1- to 3-inch quartz stringers are separated by calcareous schist with disseminated pyrite. The gold-bearing quartz stringers contain euhedral stibnite but do not normally contain pyrite (Smith, 1913a). The gold through 1912, varied from 792 to 824 fine; the highest silver content was 180 parts per thousand from a sample with a gold fineness of 792 (Smith, 1913, B 525; Smith, 1913, B 542). Several generations of quartz have been noted; most of the gold occurs in the glassy quartz which postdates the more abundant milky-white quartz (Smith, 1913b).

A sheared vein was discovered in 1913, about 100 feet south of the portal of the adit; it strikes east and dips 50S (Chapin, 1914). The sheared vein is 18 inches to 36 inches wide and consists of massive white quartz with gouge along each contact. This vein is parallel to the shear exposed in the Tolovana adit. Shaft sinking was in progress in 1913. This shaft, referred to as the South shaft was later connected to the Tolovana adit by a crosscut.

The Tolovana vein (called a shear zone in the early literature) strikes N30-65E and dips 30-60SE (Smith, 1913, B 525, Smith, 1913, B 542). The western extension of the Tolovana vein was discovered in 1930 and was developed by the 160-foot Parenteau adit. The mineralization is in 1- to 12-inch-wide stringer zones similar to that mined from the Tolovana adit. The ore contained gold associated with arsenopyrite, stibnite, pyrite, galena and tetrahedrite (Stewart, 1933; Pilgrim, 1933).

The prospect was sampled by Fairbanks Exploration Inc. in 1986 (Fairbanks Exploration Inc., unpublished report, 1986). Backhoe and dozer trenches on the Tolovana prospect exposed a large section of metarhyolite tuff, exhalite, and volcaniclastic metaquartzite of the upper Cleary Sequence. These rocks contain disseminated and shear-zone-controlled arsenopyrite, pyrite, stibnite and native gold. The structures which hosted the high grade gold-quartz shear zones in the old Tolovana Mine trend predominantly N60-80E and dip steeply southeast; they transect the flat-lying, northeast-trending Cleary Sequence. Chip samples were collected in the Upper Pit across exposures of sulfide-bearing metarhyolite, cut by numerous 1-6 inch thick white quartz veins. Samples contained 520 to 3,600 parts per billion (ppb) gold. Samples from high-grade dump material at the small mill set up near the old Tolovana shaft contained 0.27 to 0.52 ounces of gold per ton. The samples consisted of white, massive, quartz vein material with 1-3 percent arsenopyrite and minor

stibnite. The country rock welded to the sheared selvages is metarhyolite similar to that seen in the Upper Pit. As a check on the efficiency of the old gravity circuit in the Tolovana mill, a sample was collected from the tailings pond below the mill. This sample consisted of coarse sand-size material, 20-30 mesh in size; it was mainly quartz, arsenopyrite, pyrite and stibnite. A sample assayed 0.458 ounce of gold per ton. This suggested that the mill did a poor job of recovering the fine gold in the ore (Fairbanks Exploration Inc., unpublished report, 1986). In 1988 and 1989, Yukon Tanana Mining conducted extensive surface trenching on the Tolovana Mine and the adjoining Chechako prospects; the work outlined an estimated 150,000 ounces of gold that could be mined from the surface pit (R. Blakestad, oral communication, 1991).

Alteration:

Pods and disseminations of jamesonite occur in an amorphous, green vuggy matrix in the walls surrounding the gouge zone (LeLacheur, 1991). Quartz, sericite, ankerite and carbon alteration also present.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Disseminated gold in quartz veins along shear zones.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Tolovana Mine is an old property that was discovered before 1910. It operated intermittently until at least 1949, and was the site of considerable work in the 1980s. By 1910, an 85-foot adit had been driven at the Tolovana Mine. In July, 1911 a Huntington disc mill was installed and began operation. The mill ran continuously through mid-November when lack of water forced it to close. The mill began operating again in March, 1912 after a well and pump had been installed on Willow Creek (Times Publishing Company, 1912). In July, 1912 a two-stamp Nissen mill was erected and began crushing ore on August 23, 1912.

In 1912, the mine consisted of a 400-foot adit from which several short drifts were driven; small stopes were also developed (Smith, 1913). The adit extends along the main shear zone for 130 feet where it intersects a vertical fault. (Note by compiler: In much of the early literature on this mine, the term 'shear zone' usually referred to a fault zone with parallel mineralized quartz veins, stringers, or pods, i.e., in other words what others here and elsewhere might have referred to as a sheared quartz vein or lode. The description that follows generally reflects the old 'shear zone' terminology.) The workings turned north for 30 feet and then turn east again, along the offset extension of the shear zone. Approximately 100 feet from the portal of the adit, a winze was sunk to a depth of 50 feet and drifts were driven to the east and west. A second winze, inclined 60 degrees to the south, was driven from the east end of the drift but was flooded in 1912. A third winze, located 330 feet from the portal, was sunk from the adit level to a depth of 100 feet (Loftus, 1927). A shaft near the portal of the adit had been sunk to a depth of 100 feet and a drift driven on the 50-foot level connects with the winze in the adit. Due to the flooding of the shaft near the Tolovana adit in late 1912, work was shifted to the Willow Creek-Bedrock Creek divide where a 55-foot shaft, the Scheuyemere #1 shaft, was sunk on a 12- to 14-inch-thick shear zone (Times Publishing Company, 1912). This shaft is sometimes referred to as the Tolovana Stibnite prospect (Chapin, 1914).

By 1913, the shaft and the winze had been connected by a drift on the 100-foot level and the ore between the adit and the 100 foot level was mined (Chapin, 1914). Additional stoping took place above the adit level. By 1913, the Scheuyemere #1 shaft had been sunk to a depth of 100 feet and drifts were driven 50 feet to the east and 30 feet to the west on the 50-foot level (Chapin, 1914). A raise, 24 feet west of the shaft,

connected with the surface and the block of ground between the shaft and the raise had been stoped from the 50-foot level to the surface.

In 1913, a new shear zone was discovered and shaft sinking was in progress (Chapin, 1914). This shaft, the South shaft, was connected to the Tolovana adit by a crosscut.

In 1922, the Tolovana adit was 530 feet long. A drift had also been driven from the 50-foot level of the winze for 30 feet to the east where it intersected a fault which offsets the shear zone (Stewart, 1922; Davis, 1922). In the South shaft, drifting at the 50-foot level went out 15 feet to the west and 20 feet to the east along the shear zone. A total of 150 feet of new drifting was completed on the Tolovana Mine in 1923 and 8 to 10 tons of ore were milled on site (Stewart, 1923).

The Tolovana mine was inactive until 1930 when exploration was renewed (Smith, 1933). The western extension of the Tolovana shear zone, on the west side of Willow Creek, was discovered in 1930 and was explored through the Parenteau adit (Stewart, 1931). This adit was driven 160 feet to the west; 50 tons of ore was treated in the mill in 1930. The Parenteau adit was caved about 75 feet from the portal when visited in 1931 (Hill, 1933).

Antimony and gold were mined from the prospect in 1949 (Saarela, 1950). In August 1984, the Mine was explored by dozer and backhoe. A small gravity mill was constructed near the old portal of the Tolovana adit and several large open cuts were excavated in the vicinity of the Scheuyemere #1 shaft (Freeman, 1992).

The prospect was sampled by Fairbanks Exploration Inc. in 1986 (Fairbanks Exploration Inc., unpublished report, 1986). Backhoe and dozer trenches on the Tolovana prospect exposed a large section of metarhyolite tuff, exhalite, and volcaniclastic metaquartzite of the upper Cleary Sequence. In 1988 and 1989, Yukon Tanana Mining conducted extensive surface trenching on the Tolovana Mine and the adjoining Chechako prospects; the work outlined an estimated 150,000 ounces of gold that could be mined from the surface pit (R. Blakestad, oral communication, 1991).

Production notes:

Ore was shipped from the prospect as early as 1909 (Times Publishing Company, 1912). Production through 1912 averaged $20 to $105 per ton (1 to 5 ounces of gold per ton (Smith, 1913, B 525; Smith, 1913, B 542). In 1923, 8 to 10 tons of ore were milled on site, averaging $16 gold per ton (0.8 ounces of gold per ton) (Stewart, 1923). A small amount of ore was milled in 1924 and in 1931 (Stewart, 1923; Pilgrim, 1932; Smith, 1933, B 844). A little antimony and gold were mined in 1949 (Saarela, 1950).

Reserves:

In 1988 and 1989 Yukon Tanana Mining conducted extensive surface trenching on the Tolovana and adjoining Chechako prospects and outlined a reserve of about 150,000 ounces of gold that could be mined from a surface pit (R. Blakestad, oral commun., 1991).

Site name(s): Dolphin; Golden Summit

Site type: Prospect

ARDF no.: LG112

Latitude: 65.0617

Quadrangle: LG A-1

Longitude: 147.4466

Location description and accuracy:

The Dolphin intrusive body is an elongate northeast-trending stock, about 2,000 feet by 1,200 feet in plan view on the ridge between Willow Creek and Bedrock Creek. It is centered about 0.4 mile south of the junction of Bedrock and Cleary Creeks and about 0.5 mile northeast of the center of section 25, T. 3 N., R. 1 E., of the Fairbanks Meridian. The location is accurate within 1/4 mile. It is located within the Golden Summit Project area.

Commodities:

Main: Au

Other: Ag, Bi, Pb, Sb, Te, Zn

Ore minerals: Arsenopyrite, bismuthinite, boulangerite, chalcopyrite, galena, gold, jamesonite, maldonite, marcasite, native bismuth, pentlandite, pyrite, pyrrhotite, sphalerite, stibnite, tetradymite, tetrahedrite

Gangue minerals: Calcite, feldspar, sericite

Geologic description:

Note: As of early 2012, this site and several others nearby were being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008). Considerable mineralization has been discovered that indicates this prospect is part of a larger mineralized system that is described separately as ARDF site (LG207).

In 1995, Freegold discovered significant disseminated gold mineralization in granodiorite and tonalite of the Dolphin stock (Freeman and others, 1998). Soil sampling in 1995 and 1996 delineated a large northeast trending gold anomaly with gold values over 100 parts per billion (ppb). The anomaly coincides with the south contact of the Dolphin stock and is aligned with the Dolphin shear zone. The gold anomaly is also highly anomalous in silver, arsenic, lead, antimony and zinc. It is the southeast part of a broad gold-in-soil anomaly which extends from the west bank of Willow Creek to Bedrock Creek.

As recognized in early 2012 (Adams and Giroux, 2011, 2012), the Dolphin stock is roughly elliptical in plan view, trends northeast, and is about 2,000 feet long and up to 1,200 feet wide. At least five intrusive phases have been identified: 1) equigranular to weakly porphyritic, biotite granodiorite; 2) equigranular to weakly porphyritic, hornblende-biotite tonalite; 3) fine-grained biotite-granite porphyry; 4) fine-grained biotite rhyolite to rhyodacite porphyry, and 5) fine-grained mafic dikes. Drilling along the northern edge of the stock encountered calc-silicate skarn at a depth of 400 feet, suggesting that the north contact of the stock dips steeply north. The southern contact of the stock dips shallowly to the south. Drilling at the northeast end of the stock suggests that it branches into a dike swarm there and that the main stock may be faulted at depth. The deposit is open to the west toward Willow Creek, and is at least 1,000 feet deep, the bottom of the deepest hole. Three Ar40/Ar39 age determinations on sericite from the mineralization and from a shear zone vary from 88.3 to 90.1 Ma.

During 1995-96, Freegold completed 15,559 feet of reverse circulation drilling in 46 drill holes. In 1998, a single vertical core hole was drilled to a depth of 1,033 feet. Seven holes were drilled in 2004 and 26 more were drilled in 2011 when the Dolphin prospect was the center of exploration by Freegold in the Cleary area. Over the years, the prospect has also been covered by numerous geochemical and geophysical surveys

and has been trenched and sampled as part of Freegold extensive work in the Cleary Hill area since 1991.
Adams and Giroux (2011, 2012) classify the Dolphin deposit as an intrusion- hosted sulfide-quartz stockwork. Four distinct assemblages of ore minerals have been identified that mark the transition from early, high temperature mineralization to late low-temperature mineralization: 1) high-temperature arsenopyrite, maldonite, gold, native bismuth, bismuthinite, pyrite, and pyrrhotite; 2) low-temperature arsenopyrite and marcasite; 3) chalcopyrite, sphalerite, and galena; and 4) tetrahedrite, and jamesonite. There are also zones with more than 50 percent sulfides that include galena, tetrahedrite, and sphalerite. Up to 2 percent disseminated scheelite is locally present. Electron microprobe analyses and polished section microscopy indicate that native gold and bismuthinite occur as inclusions in arsenopyrite. Visible gold is rare and is hosted in white, quartz stockwork veins. Preliminary metallic sieve analyses suggest little or no nugget effect (Adams, 1997). Bottle roll analyses from granodiorite from the oxide zone recovered 82 percent to 92 percent of the gold; less than 10 percent of the gold was recovered in the sulfide-rich altered granodiorite.
The gold content of the Dolphin prospect is chiefly in quartz veinlets, typically less than 1 mm wide, that cut the stock (Freeman, 2008; Adams and Giroux, 2011, 2012). Vein orientations vary with no apparent preferred orientation. At least three separate hydrothermal events can be identified in the Dolphin core as seen in multiple, flooded zones of alternating silicification and sericitization, local scheelite-bearing carbonate zones, and sulfide-rich zones containing elevated base metals. Scheelite-bearing carbonate-alteration zones generally contain lower gold values and tend to form halos around the higher-grade gold mineralization. Silica flooding occurs throughout the intrusive and the rocks locally may contain up to 90 percent silica. The silica-flooded zones often contain chalcedonic green, brown, or black quartz. In some drill holes the silicification of the granodiorite almost completely obliterates the original igneous textures. Chloritic alteration is rare.
As estimated by Adams and Giroux (2012), based on drilling through 2011 and a cut-off grade of 0.3 gram of gold per ton, the Dolphin stock has an indicated resource of 17.270 million tonnes with an average grade of 0.62 grams of gold per tonne (or 341,000 ounces of gold) and an inferred resource of 64.440 million tonnes with an average grade of 0.55 gram of gold per tonne (or 1,135,000 ounces of gold).
A total of 87 holes, totaling 24,156 m, have been drilled within the resource area since 2011 (as of Dec. 2016). In 2016, 717 soil samples were collected; they delineate a gold-in-soil geochemical anomaly west of the current Dolphin deposit. Previously completed shallow rotary air blast drilling was composited and indicates better-grade oxide material may be present to the north (Athey and Werdon, 2017).

Alteration:

The Dolphin deposit is marked by multiple flooded zones of alternating silicification and sericitization, with local scheelite-bearing carbonate zones (Freeman and others, 1998). In some drill holes the silicification of the granodiorite almost completely obliterates the original igneous textures. Chloritic alteration is rare.

Age of mineralization:

Three Ar40/Ar39 age determinations on sericite from the mineralization and from a shear zone that cut the stock vary from 88.3 to 90.1 Ma.

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

During 1995-96, Freegold completed 15,559 feet of reverse circulation drilling in the Dolphin prospect in 46 drill holes. In 1998, a single vertical core hole was drilled to a depth of 1,033 feet. Seven holes were drilled in 2004 and 26 more were drilled in 2011 when the Dolphin prospect was the center of exploration by Freegold in the Cleary area. Over the years, the prospect has also been covered by numerous geochemical and geophysical surveys and has been trenched and sampled as part of Freegold's extensive work in the Cleary Hill area since 1991.

In 2012, 47 drill holes representing 48,937 feet were completed in the Dolphin/Cleary Hill area by Freegold. A revised NI 43-101 compliant gold resource was calculated (Abrams and Giroux, 2013).

In 2013, ten drill holes representing 11,392 feet were completed in the Dolphin/Cleary Hill area. A subsequent revised NI 43-101 compliant gold resource ensued (Abrams and Giroux, 2013).

A total of 87 holes, totaling 24,156 m, have been drilled within the resource area since 2011 (as of Dec. 2016). In 2016, 717 soil samples were collected; they delineate a gold-in-soil geochemical anomaly west of the current Dolphin deposit. Previously completed shallow rotary air blast drilling was composited and indicates better-grade oxide material may be present to the north (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

As estimated by Abrams and Giroux (2013), based on drilling through 2013 and a cut-off grade of 0.3 gram of gold per ton, the Dolphin stock has an indicated resource of 79.800 million tonnes with an average grade of 0.66 gram of gold per tonne (or 1.683 million ounces of gold) and an inferred resource of 248.060 million tonnes with an average grade of 0.61 gram of gold per tonne (or 4.841 million ounces of gold). Included within this new resource is an oxide component.

In January 2016, Freegold Ventures Ltd. released a preliminary economic assessment (PEA) for their Golden Summit gold property near Fort Knox mine north of Fairbanks, followed by a March 2016 technical report, which was amended and restated in May 2016 (Abrams and others, 2016). Freegold’s initial development scenario for Golden Summit includes a proposed heap-leach operation focused on the existing oxide portion of the resource, with a staged approach to a larger milling scenario. Only blocks falling within the conceptual open pit are reported as a mineral resource, and using a 0.3 gram of gold per tonne cut-off, this results in an indicated resource of 61,460,000 tonnes at 0.69 gram of gold per tonne (1,363,000 contained ounces of gold) and an inferred resource of 71,500,000 tonnes at 0.69 gram of gold per tonne (1,584,000 contained ounces of gold). Using $1,300 per ounce of gold, the PEA evaluated a two-phase, 24-year, open pit mine generating two gold streams, each operating at 10,000 tonnes per day for 2,358,000 ounces of doré produced over the life of the mine; processing operations for the oxide and sulfide mineralized materials are heap leach and bi-oxidation, respectively (Abrams and others, 2016).

Site name(s): Crosscut

Site type: Prospect

ARDF no.: LG114

Latitude: 65.0647 **Quadrangle:** LG A-1

Longitude: 147.4486

Location description and accuracy:

The Crosscut prospect is just east of the junction of Willow Creek and Cleary Creek; it is in the NW1/4NE1/4 sec. 25, T. 3 N., R. 1 E., of the Fairbanks Meridian.

Commodities:

Main: Sb

Other: As, Sb

Ore minerals: Pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG207).

Mineralization found in prospect pits consisted of bladed stibnite and pyrite with abundant antimony, arsenic and iron oxides (Smith, 1913). A 100-foot adit was driven below the prospect pits but did not intersect the mineralization seen in the pits.

Alteration:

Age of mineralization:

Mid-Cretaceous by analogy with other mineralization in the area.

Generic deposit model:

Deposit model:

Stibnite vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The workings consisted of prospect pits and a 100-foot adit (Smith, 1913).

Production notes:

No record of production and unlikely.

Reserves:

None.

Site name(s): Wyoming

Site type: Mine

ARDF no.: LG118

Latitude: 65.0635 **Quadrangle:** LG A-1

Longitude: 147.4376

Location description and accuracy:

The Wyoming Mine is about 400 yards south of the Cleary Hill Mine (ARDF no. LG119) on the east side of Bedrock Creek. It is in the NW1/4NW1/4 section 31, T. 3 N., R. 2 E., of the Fairbanks Meridian.

Commodities:

Main: Ag, Au

Other: As, Pb, Sb, W, Zn

Ore minerals: Arsenopyrite, boulangerite, jamesonite, gold, scheelite, stibnite

Gangue minerals: Calcite, quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG205).

The Wyoming Mine is along a shear zone with quartz veins up to 2 feet thick that contain gold, stibnite and scheelite. Scheelite was particularly abundant in the wall rocks and along the margins of the shear zone (Moffit, 1927). The shear zone strikes N 80 E and dips 50 S (Hill, 1933). Ore in the main stope averaged about $6.00 of gold per ton (0.3 ounces of gold per ton) and consisted of 12 to 14 inches of hard white quartz and brecciated schist with minor iron-oxide staining (Hill, 1933).

The Wyoming prospect was investigated in 1943 as a possible source of tungsten (Byers, 1957). Scheelite is present in limestone lenses found east of the north-trending fault in both the Wyoming and Lower adits. By 1943, the Wyoming adit consisted of 350 feet of drift west of the north-trending fault, a 100-foot crosscut to the south on the east side of the north-south fault, and 200 feet of drift along the Wyoming shear zone from the end of the 100-foot crosscut (Byers, 1957). A 70-foot section of the 200-foot drift east of the fault averaged 0.3 percent tungsten oxide over 6 inches. In a sublevel stope above the same zone, a 1-foot by 3-foot area averaged 20 percent tungsten oxide in a limestone replacement body (Byers, 1957). Samples found on the Lower adit dump, and samples collected in place from the Wyoming shear zone in the Lower adit contained 0.28 to 1.64 percent tungsten oxide with trace molybdenum, manganese, antimony and arsenic.

Fairbanks Exploration Inc. conducted 11 man-days of field work on the Wyoming prospect in 1987. Nineteen rock samples were collected and the alteration zones were mapped. Several samples were collected from bedrock exposures and dumps in and around the mine (Fairbanks Exploration Inc., unpublished report, 1987). These samples contained low gold, antimony, and silver, and elevated arsenic. Gold values were higher where jamesonite and/or boulangerite are visible in the shear zone. Most of the dump material on the Wyoming dump is sulfide-free, white quartz, attesting to close grade control during mining. Stratiform arsenopyrite lenses up to 4 inches thick were discovered on bedrock exposures in a placer cut below the dump of the Lower adit. These occurrences are associated with rhyolitic tuff beds; samples had unexpectedly low gold values (Fairbanks Exploration Inc., unpublished report, 1987).

In 1989, Fairbanks Exploration Inc. conducted 10 man-days of field work on the prospect and collected eighteen rock samples (Fairbanks Exploration Inc., unpublished report, 1989). Exposures in the old placer

cut on lower Bedrock Creek consist of pale-yellow to gray, thinly bedded, felsic volcanic tuff and siliceous exhalite containing quartz, sericite, minor chlorite, and disseminated pyrite and lesser arsenopyrite. These units are correlative with the upper third of the Cleary Sequence. Foliation in this area trends N60-80E and dips 10 to 20SE. The rocks are heavily jointed and appear to have undergone minor dip-slip deformation along sericite-rich bedding planes. Sulfide mineralization is concentrated along stratiform horizons which vary from one inch to over six inches in thickness. Visible gold was found in one of these horizons early in 1989 after heavy rains exposed new outcrops in this area. The sulfide contents of the exhalite are from 5 to 25 percent of the rock; the ground mass consists of fine-grained quartz, and clay after feldspar.

Sample results from the 1989 program indicate that highly anomalous gold and arsenic, and weakly anomalous antimony, lead and zinc are associated with felsic tuff and exhalite over the entire area exposed along the creek bottom and the banks of lower Bedrock Creek (Fairbanks Exploration Inc., unpublished report, 1989).

Alteration:

The rocks in the old placer cut on lower Bedrock Creek are heavily jointed and appear to have undergone minor dip-slip deformation along sericite rich bedding planes.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

By 1909, development work had begun on the Wyoming shear zone (Prindle, 1910). By the end of 1910, 300 feet of adit had been driven on the Wyoming shear and 50 feet of shaft had been sunk on the Carlisle Fraction claim which was adjacent to the Cleary Hill mine (Brooks, 1911). At the 80-foot station of the Wyoming adit, a 50-foot winze was sunk at an angle of 60 degrees south, but was flattened to 49 degrees south near the bottom of the winze (Smith, 1913b). An unknown amount of material from the winze was custom milled and reportedly returned high values in gold.

In 1913, the Wyoming prospect. was being mined at the surface. Four tons of ore were custom milled at the Blue Moon Mazeppa Mine on Chatham Creek and another 4.5 tons was stockpiled (Chapin, 1914). No production records are available for these two shipments. Limited development was carried out at the Wyoming prospect in 1914. In 1915, development activities continued on the Wyoming shear and were expanded to the Colorado shear located about 500 feet north of and parallel to the Wyoming shear (Stewart, 1915). Thirty-nine tons of ore from these two shear zones were custom milled at the Blue Moon Mazeppa mill on Chatham Creek but no production figures are available. Development of the Wyoming prospect was discontinued by 1916 (Brooks, 1918), but limited mining was conducted on the prospect in 1917 (Martin, 1919).

Development work on the Wyoming adit began again in 1921 when the adit was lengthened and a 60-foot winze sunk from the adit level (Brooks, 1921). The Wyoming shear was traced onto the adjacent Alabama claim in 1922 (Davis, 1922; Stewart, 1922). By 1923, the Wackwitz brothers erected a small, ball mill and mined a limited amount of high grade ore from the Wyoming adit. The ore averaged averaged $10-20 of gold per ton (0.5 to 1.0 ounce of gold per ton) with recovery estimated at 85 percent (Loftus, 1927). The prospect was operated by the Gustafson brothers in 1924 and produced a small amount of gold (Smith,

1926). A new ball mill was installed in 1925 and operated for one month.

By 1927, the Wyoming shear was accessible through three adits, the Lower, Wyoming (upper) and Crawford adits; these totaled 500 feet of workings over 150 vertical feet of shear zone (Loftus, 1927). Production continued in 1927, and ore was milled at the nearby Cleary Hill mill (Smith, 1930). Development work increased and surface facilities were improved in 1928 (Smith, 1930). Minor production from the prospect continued in 1929 and 1930 (Smith, 1932; Smith, 1933). By 1930, developments at the Wyoming mine consisted of the 165- foot- long Wyoming adit and a Lower adit 1,000 feet long, approximately 100 feet lower than the Wyoming adit (Pilgrim, 1931; Stewart, 1931). The Crawford adit was 75 feet long and approximately 40 feet above the Wyoming adit. By 1931, a fourth adit had been driven 60 feet on a sheared gold-quartz parallel to the Wyoming shear zone (Pilgrim, 1931; Stewart, 1933).

In 1931, the Wyoming adit was caved and inaccessible. The Lower adit followed the Wyoming shear zone for 300 feet where the shear was faulted about 100 feet to the south (Hill, 1933). A raise connected the Lower and Wyoming adits. A stope that extended for about 70 feet along strike connected the Lower adit to the Wyoming adit and appears to rake about 45 degrees to the west (Hill, 1933). Development work in the Crawford adit followed a north-dipping shear zone which is separate from the Wyoming shear.

Reed (1939) reported that in 1938 Fred and Ernest Wackwitz completed 30 feet of drifting, 20 feet of crosscuts, 125 feet of adit, and milled 56 tons of ore with an average grade of $47 of gold per ton (1.34 ounces of gold per ton). The ore was milled on site in a 20-ton Herman ball mill. By 1943, the Wyoming adit consisted of 350 feet of drift west of the north-south fault, a 100 foot crosscut to the south on the east side of the north-trending fault, and 200 feet of drift along the Wyoming shear from the end of the 100-foot crosscut (Byers, 1957).

In 1987, Fairbanks Exploration Inc. conducted eleven man-days of field work on the Wyoming prospect. Nineteen rock samples were collected and an alteration map prepared. Several samples were collected from bedrock exposures and dumps in and around the Wyoming mine site (Fairbanks Exploration Inc., unpublished report, 1987). In 1989, Fairbanks Exploration Inc. conducted ten man-days of field work on the prospect and collected eighteen rock samples (Fairbanks Exploration Inc., unpublished report, 1989). The alteration in the old placer cut on lower Bedrock Creek was also studied and mapped.

Production notes:

Smith (1913b) reported that an unknown amount of ore was custom milled in 1913 from the Wyoming adit. In 1913, the Wyoming was mined at the surface. In 1913, four tons of ore were custom milled at the Blue Moon Mazeppa mine on Chatham Creek and another 4.5 tons was stockpiled (Chapin, 1914). In 1915, thirty-nine tons of ore were custom milled at the Blue Moon Mazeppa mill on Chatham Creek but no production figures are available.

By 1923, the Wackwitz brothers erected a small, ball mill and mined a limited amount of high grade ore from the Wyoming adit. Ore grades averaged $10-20 of gold per ton (0.5 to 1.0 ounces of gold per ton) with recovery estimated at 85 percent (Loftus, 1927). Production continued in 1927, and ore was milled at the nearby Cleary Hill mill (Smith, 1930). Minor production from the prospect continued in 1929 and 1930 (Smith, 1932; Smith, 1933). Reed (1939) reported that 56 tons of ore were milled with an average grade of $47 of gold per ton (1.34 ounces of gold per ton).

Reserves:

None.

Site name(s): Cleary Hill; Summit; Cleary; Freegold

Site type: Mine

ARDF no.: LG119

Latitude: 65.0666 **Quadrangle:** LG A-1

Longitude: 147.4386

Location description and accuracy:

The coordinates are near the main portal of the Cleary Hill Mine, which is labeled on the Livengood (A-1) quadrangle. The mine is north of Bedrock Creek, a tributary of Cleary Creek, in section 19, T. 3 N., R. 2 E., of the Fairbanks Meridian. The underground workings extend east-southeast from the portal for at least 2,000 feet. It is located with within the Golden Summit Project area. The location is accurate within 100 feet.

Commodities:

Main: Au

Other: Ag, Cu, Pb, Sb, W, Zn

Ore minerals: Arsenopyrite, boulangerite, chalcopyrite, covellite, galena, gold, jamesonite, pyrite, scheelite, silver, sphalerite, stibnite, tetrahedrite

Gangue minerals: Quartz

Geologic description:

As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008). Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG205).

In the early 1900s, visible gold was reported in quartz veins within schist at what would become the Cleary Hill Mine (Prindle, 1910). The Cleary Hill Mine operated intermittently from 1911 to 1950. The Cleary Hill mine was the largest lode-gold producer in the Fairbanks Mining District, prior to the development of the Fort Knox mine.

The Cleary Hill Mine is in mafic volcanics, quartzites and quartz muscovite schists on the north flank of the Cleary antiform (Freeman and others, 1998). Mineralization style is characterized as schist-hosted shear zones with discrete and/or crushed gold-arsenic-antimony- quartz vein. The Cleary Hill vein strikes N70-80W and dips 45 to 70S. The dip of the vein varies according to the host rock, with steeper dips in more competent rocks and shallow dips in less competent rocks (Freeman and others, 1998). The mine consisted of over six levels that produced ore from quartz veins that contained coarse free gold, and minor arsenopyrite, pyrite, boulangerite, and tetrahedrite. Higher grade intervals have gold values from the hundreds to the thousands of ounces of gold per ton. These intervals are commonly associated with acicular needles and felted masses of boulangerite and jamesonite that occur in white to gray quartz veins that are 1 to 5 feet thick (Freeman and others, 1998).

During the 1986 field season, the waste dumps of the Cleary Hill Mine were examined and grab samples were collected by Fairbanks Exploration Inc. (Fairbanks Exploration Inc., unpublished report, 1986). Quartz vein samples on the Penrose and Upper adit dumps are associated with chlorite-actinolite schist of mafic volcanic origin, that are typical of the the lower third of the Cleary Sequence. Dump samples contained arsenopyrite, pyrite, stibnite, jamesonite, native gold, and minor scheelite from quartz-bearing shear zones and stockworks with thin argillized selvages. Significant ankerite occurs in some shear zones and weathers to a bright ocherous, red color. Visible gold is usually associated with jamesonite needles and rosettes similar to mineralization in the Christina adit (LG146) and the Nordale adit of the Homestake mine

(LG157). Along the shear zones, up to one-half percent scheelite is finely disseminated in chlorite-actinolite schist and less commonly forms coarse-grained aggregates in sulfide-free quartz. Gold values vary up to 0.558 ounce of gold per ton and appear to be higher in samples of siliceous exhalite, metarhyolite tuff and carbonaceous quartzite from the lower dumps at the mine. Reserve estimates of the waste dump made by Fairbanks Exploration Inc. in 1988 indicated the Cleary Hill mine dumps contain 71,176 tons of rock with an average grade of 0.159 ounce of gold per ton and 0.099 ounce of silver per ton (Fairbanks Exploration Inc., unpublished report, 1987; Fairbanks Exploration Inc., unpublished report, 1988).

Complete production records are not available for the Cleary Hill mine, however, existing published and private records indicate the Cleary Hill mine produced more than 100,000 fine ounces of gold from approximately 77,000 tons of material with an average grade of 1.3 ounces of gold per ton (Porterfield and Croff, 1986; Metz and others, 1987). This ranks the Cleary Hill mine as the largest lode-gold producer in the Fairbanks Mining District, prior to the development of the Fort Knox mine.

Alteration:

Deposition of quartz, sericite and ankerite in alteration zones (Freeman and others, 1998).

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby (Freeman, 2008).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

Mineralization was first discovered on the Freegold claim prior to 1910, near the junction of Cleary and Bedrock Creeks. Shortly after, rich surface outcrops were discovered at the surface at what would become the Cleary Hill Mine; selected samples assayed up to 5,950 ounces of gold per ton.

By the summer of 1910, the Main adit had been driven 630 feet on the Freegold claim and a 50-foot shaft with 90 feet of drift was also driven on the main shear zone approximately 800 feet uphill from the portal of the main adit (Brooks, 1911). In 1911, a five stamp Joshua Hendy mill, the first private mill in the Fairbanks Mining District, was put into operation on the Freegold claim. By the end of 1911, there were about 1,200 feet of underground workings (Brooks, 1912). By 1912, the Main adit had been driven over 1,050 feet and a second adit, the 215-foot-long Penrose adit, had been driven from a portal 140 feet higher than the Main adit (Cunningham, 1912). The two adits were connected by a 170-foot raise driven 900 feet from the portal of the Main adit. Twenty stopes were developed on the Main-adit level. A 30-foot winze was sunk 650 feet from the portal of the Main adit but water hampered sinking it. By the end of 1912, the winze exposed ore 300 feet below the surface (Cunningham, 1912). By the end of 1913, Brooks and others (1914) stated that the Main adit was 1,280 feet long, the Penrose adit was 280 feet long, and the Upper adit was 200 feet long. A total of 1,000 feet of workings were accessible from the main winze with working drifts at the 70- and 112-foot levels.

Funding allowed only 200 feet of new drifting in 1915 and the mine closed in September, 1915 (Brooks, 1916; Smith, 1917). The Cleary Hill mine remained closed until 1924 when it was amalgamated with the neighboring Wyoming mine (Stewart, 1923).

Efforts to reopen the Cleary Hill mine began in the fall of 1923 and continued through 1929 (Smith, 1926; Moffit and others, 1927; Smith, 1930, B 813). This work included a 400-foot adit to reach the ore bodies at the 70-foot level of the Main winze. This Lower adit was collared at the elevation of Bedrock Creek near

the mill site (Moffit and others, 1927). In addition, the Upper adit was extended to a length of 900 feet; 538 feet of crosscuts and a 40-foot raise extended from this adit (Stewart, 1931). The Penrose adit was extended 45 feet to a total length of 325 feet, and three crosscuts totaling 595 feet were driven from it. A 89-foot raise was driven to connect the Penrose and Upper adits. The Main adit was extended 192 feet to a total length of 1,472 feet , 51 feet of drift was driven on the Powder House shear zone, and 154 feet of drift was driven on the Doget shear zone. Near the mill a shaft was sunk 185 feet and a crosscut was driven from the bottom of the shaft for 280 feet. A shaft was also sunk on the ridge above the Upper adit. This shaft, known as the Deep shaft, was 50 feet deep; it had a 80-foot crosscut at the bottom (Stewart, 1931).

The mine resumed production in 1929 and rapidly became one of the largest operations in the district (Smith, 1930, B 810; Smith, 1932). In 1930, mining was concentrated in the Penrose adit (Stewart, 1931) and the Cleary Hill mine was again the largest producer in the Fairbanks Mining District (Pilgrim, 1931). The mill operated for 7 months during 1932 and development was concentrated below the Main adit level (Pilgrim, 1933). In 1938 the Cleary Hill mine drove 250 feet of new drifts and crosscuts, sank 100 feet of winze, and drilled 4,200 feet of AX diamond core.

No other work was conducted at the Cleary Hill mine until 1969 when International Minerals and Chemicals excavated two bull dozer trenches on the surface projection of the Cleary Hill shear zone (Pilkington, 1970). Samples were only weakly anomalous in gold and silver.

The dumps of the mine were sampled by Fairbanks Exploration Inc. in 1986 (Fairbanks Exploration Inc., unpublished report, 1986). In 1988, Tri-Con Mining bulk sampled the upper and lower dumps to determine if this material could be processing economically.

Freegold Ventures Ltd. conducted drilling at Clear Hill mine area from 2011 to 2013. Cleary Hill area was included in with Dolphin zone for revised NI 43-101 compliant resource estimates created each year following drilling (Abrams and Giroux, 2013).

Production notes:

Waste dump reserve estimates made by Fairbanks Exploration Inc. in 1988 indicated the Cleary Hill mine dumps contained 71,176 tons of rock that averaged 0.159 ounce of gold per ton and 0.099 ounce of silver per ton (Freeman and others, 1987; Freeman and others, 1988).

Prior to World War II, 280,000 ounces of gold were mined from Cleary Hill (Abrams and Giroux, 2013).

Reserves:

As estimated by Abrams and Giroux (2013), based on drilling through 2013 and a cut-off grade of 0.3 gram of gold per ton, the Dolphin stock has an indicated resource of 79.800 million tonnes with an average grade of 0.66 gram of gold per tonne (or 1.683 million ounces of gold) and an inferred resource of 248.060 million tonnes with an average grade of 0.61 gram of gold per tonne (or 4.841 million ounces of gold). Included within this new resource is an oxide component.

Last report date: 2014-12-23

Site name(s): Paupers Dream

Site type: Prospect

ARDF no.: LG120

Latitude: 65.0645

Quadrangle: LG A-1

Longitude: 147.4296

Location description and accuracy:

The Paupers Dream prospect is on the divide between Bedrock Creek and Chatham Creek, approximately one-quarter mile southeast of the Cleary Hill mine; it is in the NE1/4NW1/4 sec. 30, T. 3 N., R. 2 E., of the Fairbanks Meridian.

Commodities:

Main: Au

Other: As

Ore minerals: Arsenopyrite, gold

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG205).

The date of discovery of this prospect is not known however Anthony Goessman began prospecting in the area in 1905. In December of 1908, Mr. Goessman transferred his interest in the Wyoming, Paupers Dream, Texas, Alabama, California, New Year's Fraction, Idaho, Colorado and Apex Fraction claims to the Tanana Quartz and Hydraulic Mining Company (Times Publishing Company, 1912).

The Paupers Dream prospect is a north-trending shear zone which extends from the Paupers Dream claim (MS1639) on the south, through the California claim (MS1639), and onto the Texas claim. Where exposed on the Paupers Dream claim, the shear zone dips steeply west and has a high sulfide content, primarily arsenopyrite (Smith, 1913; B 525). Free gold was particularly abundant in weathered portions of the shear zone. This shear trends across the California prospect to the east of the eastern-most shaft on the California prospect (LG121).

Alteration:

Not noted.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Undetermined

Site Status: Active

Workings/exploration:

Smith (1913) describes the shear zone of the Paupers Dream prospect as extending through the California and Texas claims, but there is no detailed description of the workings.

Production notes:

None.

Reserves:

None.

Site type: Prospect

ARDF no.: LG121

Latitude: 65.0677 **Quadrangle:** LG A-1

Longitude: 147.4298

Location description and accuracy:

The California prospect is on the divide between Bedrock Creek and Chatham Creek, approximately one-quarter mile east of the Cleary Hill mine. It is in the SE1/4SW1/4 sec. 19, T. 3 N., R. 2 E., of the Fairbanks Meridian.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG205).

A shaft was sunk on the California prospect on what was believed to be the extension of the Cleary Hill shear zone which was mined extensively on the adjacent Free Gold claim (LG119). The shaft was sunk along the shear zone for 20 feet at a 60S inclination; it then flattened to 40S. for an additional 40 feet (Smith, 1913). A 1- to 3-foot-wide quartz-bearing zone extends nearly to the bottom of the shaft where it is cut off by a flat-lying fault. The ore was reportedly of lower grade than other shear zones in the area; production records are not available. A second shaft was sunk to an unknown depth east of the first shaft but was not accessible in 1912 when visited by Smith (1913). Dump material at this shaft included quartz-feldspar granite which was reportedly associated with a gold-bearing shear zone in the shaft.

Geologic description:

In the 1950s through the 1970s, almost 20,000 ounces of gold was mined from surface and underground workings on the Christina prospect. Exploration continued throughout the 1980s, when several holes were drilled to explore the extent of mineralization in the Christina system. Based on the drilling conducted in the 1980s, reserves have been estimated at over 68,000 ounces of gold. Mineralization is characterized as schist-hosted auriferous shear systems with discrete and/or crushed veins and skarn.

The following geologic description is based on mapping conducted by Fairbanks Exploration Inc. (unpublished report, 1988): The Christina prospect consists of a N 70-80 W, 75 S shear zone. The Christina shear separates Cleary sequence rocks to the north from Fairbanks Schist to the south. The Cleary sequence forms the footwall and consists of interbedded rhyolite metatuff, laminated graphitic quartzite, black graphitic schist and chloritic calc-schist. The hanging wall is composed of biotite-quartz-mica schist, and micaceous quartzite. Both the hanging wall and foot wall are gently folded into east-west trending open folds whose axes plunge 10 to 20 degrees to the west. Amplitudes of the open folds range from 4 to 8 feet and wavelengths range from approximately 10 to 40 feet.

On an outcrop scale, the Christina structure contains a series of parallel quartz veinlets which pinch and swell and form a sinuous outcrop pattern along strike (Freeman and others, 1998). For example, the Christina shear on the west end consists of two discrete, quartz-rich zones with a total thickness of approximately 2 feet. Within 60 feet of strike length to the east, the quartz-rich zones merge and pinch down to a thickness of a few inches. In general, the Christina shear contains less massive quartz and more stockwork quartz to the east.

Hypogene and supergene alteration of the shear and adjacent wallrock has produced reddish hematite after pyrite, greenish scorodite after arsenopyrite, and yellow to white antimony oxides after stibnite, jamesonite and boulangerite. Sulfide and oxide alteration typically form envelopes paralleling the shear. Alteration in the footwall reaches at least 40 feet from the shear in the lower sample area near the Vetter shaft while alteration in the hanging wall is minor. Scorodite and hematite alteration were most prevalent in the western portion of sample area. Antimony oxide alteration becomes pervasive in the central portion of the vein where quartz-free pods of massive, striated stibnite occur.

In 1981, Placid Oil Company completed 4661 feet of diamond drilling in 16 holes on the Christina and Orange Free shear zones. The Orange Free shear zone has a northeast strike nearly perpendicular to the

Christina shear zone. In 1985, Placid Oil utilized reverse circulation rotary drilling techniques to complete 4623 feet of drilling in 18 holes on the Christina shear zone. At a 5-foot mining width, the Christina system had drill indicated reserves of 39,600 tons grading 0.660 ounces of gold per ton and 1.74 ounces of silver per ton in one block; another block containing 73,900 tons grading 0.370 ounce of gold per ton and 0.71 ounce of silver per ton. The Spirit shear zone, located in the hanging wall of the Christina shear zone, contained an estimated reserve of 36,900 tons grading 0.411 ounce of gold per ton and 0.40 ounce of silver per ton over a five-foot mining width (Porterfield and Croff, 1986). The average grade of the Christina shear zone was 0.551 ounce of gold per ton and 0.61 ounce of silver per ton while the Orange Free shear zone averaged 0.167 ounce of gold per ton and 15.4 ounces of silver per ton (Bentzen, 1982).

Alteration:

Hypogene and supergene alteration of the shear and adjacent wallrock has produced reddish hematite after pyrite, greenish scorodite after arsenopyrite, and yellow to white antimony oxides after stibnite, jamesonite and boulangerite. Sulfide and oxide alteration typically form envelopes paralleling the shear. Alteration in the footwall reaches at least 40 feet from the shear near the Vetter shaft while alteration in the hanging wall is minor. Scorodite and hematite alteration were most prevalent in the western portion of the deposit. Antimony oxide alteration becomes pervasive in the central portion where quartz-free pods of massive, striated stibnite occur (Fairbanks Exploration Inc., unpublished report, 1988).

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby (Freeman, 2008).

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

Mineralization on the Kawalita claim, which adjoins the Christina prospect to the south and east, was discovered in 1908 (Smith, 1913). Between 1961 and 1963, Ed Ebbert sank an inclined shaft to a depth of 50 feet on the western end of the Kawalita claim. In 1963, this shaft was deepened to 147 feet and the haulage levels moved into the footwall to better control the heavy ground and water. The underground portion of the mine was closed in 1965, but surface mining on the Kawalita claim continued through 1966.

In late 1977, Tri-Con Mining and Mohawk Oil Company extracted shear zone material from surface cuts on the Christina claim over a strike length of 450 feet to a depth of 15 feet. In early 1978, Placid Oil Company leased the Christina prospect and began an extensive exploration and development program. Geological mapping, VLF and magnetics geophysical surveys, and soil and rock geochemical sampling surveys were followed up in 1978 with dozer trenching and completion of 5174 feet of diamond core drilling in 23 holes. Approximately 2314 feet of diamond core drilling in nine holes as well as extensive soil grid geochemical surveys were completed in 1980 on the Christina shear zone system. In 1981, approximately 1489 feet of trackless underground drifting was driven to and on the Christina shear zone system. The Christina adit was constructed at a design size of 8 feet by 8 feet, however, timbering in some areas reduced the finished dimensions of the workings. During construction of the adit a previously undiscovered shear zone, the Orange Free shear zone, was intersected approximately 300 feet from the portal. In addition to the underground workings, Placid Oil completed 4661 feet of diamond drilling in 16 holes on the Christina and Orange Free shear zone.

Activities on the Christina in 1982 consisted of 13,045 feet of diamond core drilling in 25 holes designed

to test the down-dip extension of the Christina system. In addition, 600 pound bulk samples were collected by Placid Oil Company from the Christina shear zone and the Orange Free shear zone where these shears were exposed in underground workings (Bentzen, 1982). Activities on the Christina prospect in 1983 consisted of 8512 feet of diamond core drilling in 23 holes to further outline ore shoots on the Christina shear zone (Porterfield and Croff, 1986). In 1985 Placid Oil utilized reverse circulation rotary drilling techniques to complete 4623 feet of drilling in 18 holes on the Christina shear zone. In 1986, Fairbanks Exploration Inc. conducted preliminary grab sampling of the Christina adit and Nordale adit dumps (Fairbanks Exploration Inc., unpublished report, 1986).

During July, 1988, Fairbanks Exploration Inc. extracted a bulk sample from a high grade portion of the Christina shear zone in the same area as the 1986 bulk sample and the Mohawk open cut. Initial work on the program entailed stripping overburden to prepare a 12 foot wide pad along the length of the shear zone. Ore was extracted with a backhoe by digging a trough approximately 3 feet wide and 3 feet deep. After each three-foot lift was mined, the footwall and hangingwall were stripped to expose the next lower bench for mining. Two separate areas on the Christina prospect were mined to obtain the 1988 bulk sample. Most of the tonnage (approximately 85 percent) was excavated from the upper sample area; the remaining 15 percent of the ore was extracted from the lower sample area.

During the summer and fall of 1990, Polar Mining conducted bulk sampling of the Christina shear zone near the Kawalita shaft. Unlike the Christina shear in the 1988 bulk sample area, the Polar Mining sample area contains mineralization in both the foot wall and hanging wall of the Christina shear. Polar Mining exposed this shear zone for approximately 500 strike feet. Approximately 1,000 to 1,200 tons of material were extracted from this area and treated in a one stage wet jig. This method of sampling proved unsatisfactory since tailings ponds averaged 0.14 ounce of gold per ton (P. Metz, oral communication, 1991) while the recovered grades averaged 0.030 to 0.033 ounce of gold per ton (D. May, oral communication, 1990).

From 2011 to 2012, Freegold Ventures Ltd. undertook its first drilling in the Christina area, completing 12 holes. In 2011, an induced polarization (IP) and resistivity survey was executed. In 2012, ground based geophysics and shovel soil sampling was conducted. (Abrams and Giroux, 2013).

Production notes:

Between 1957 and 1961, approximately 4900 troy ounces of gold was extracted from 500 feet of surface strike on the Kawalita claim (R. Vetter, oral commun., 1991; Saunders, 1960, ATDM MR 49-4). The shear zone material averaged one troy ounce per ton (Brown, 1962; R. Vetter, 1986, oral commun.). Between 1961 and 1966, an estimated 10,000 ounces of gold was extracted from surface and underground workings on the Christina prospect on the Kawalita claim (R. Vetter, oral commun.1986). In 1963 and 1964, Scott Haskins extracted 962 troy ounces of gold from shear zone material which averaged 1.96 ounces per ton over 350 feet of strike to a depth of 10 feet (S. Haskins, 1986, oral commun.). Mr. Haskins also sunk a 90 foot shaft on the shear zone but production from this shaft was insignificant. In 1967 and 1968 approximately 250 troy ounces of gold was extracted from a 35-foot-deep shaft and 110 feet of surface workings (R. Vetter, oral commun., 1986). In late 1977, Tri-Con Mining and Mohawk Oil Company leased the Christina claim and extracted shear zone material from surface cuts over a strike length of 450 feet to a depth of 15 feet. Material from this open cut averaged approximately 3 troy ounces of gold per ton (R. Vetter, oral commun., 1986). Total production by Tri-Con-Mohawk is estimated at 3375 troy ounces of gold.

Prior to World War II, 20,000 ounces of gold were mined from Christina (Abrams and Giroux, 2013).

Reserves:

None.

Other:

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG206).

The vein exposed at the McCarty shaft varies from a few inches to five feet wide; it strikes N70W and dips 65SW. It has been traced for 1,200 feet and samples from the surface pits along the whole distance carry gold. There has been considerable shearing along the vein walls and several small faults have been noted. The vein filling is a milky quartz that often contains arsenopyrite (W.J. McCarty, unpublished report, 1932).

By 1930, the McCarty shaft was sunk 60 feet on the south-dipping McCarty shear zone (Stewart, 1931). A drift from the 60-foot level of the shaft extended 135 feet east and 369 feet west. Two raises had been driven to the surface from the 60-foot level, one at the 135-foot station in the east drift and one at the 284-foot station of the west drift. The shaft was being deepened in 1930. Work continued in 1932 to deepen the shaft from 80 to 150 feet and drive production drifts at that level (Pilgrim, 1933). Stopes above the 60-foot level produced a little more than 1,000 tons of ore by 1930. This ore was processed at the nearby McCarty mill northeast of the McCarty shaft. There was at least some production through the 1930s but the details are unknown.

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG206).

Prior to 1969, the divide between Fairbanks and Wolf Creeks was host to several producing mines and numerous prospects. The mineralization sought in all of these mines and prospects was high grade gold mineralization that occurred in several veins along several large northwest- and northeast-trending shear zones. Low grade mineralization was known to be present at the McCarty (LG152), Pioneer (LG155) and Pennsylvania (LG156) mines nearby, along the margins of higher grade portions of the shear zones. However, these lower grade zones could not be profitably worked using the existing technology of the 1980s (W. McCarty, oral communication, 1988). In 1969, International Minerals and Chemicals (IMC) began an exploration program designed to test the possibility of surface mining the lower grade material in this area. IMC conducted trenching and rotary drilling targeted at low-grade zones adjacent to previously mined high grade shear zones. hese activities resulted in discovery of the Saddle prospect (Pilkington, 1970).

IMC's initial exploration efforts on the Saddle prospect consisted of geological mapping and sampling of four, previously excavated trenches and open cuts. IMC also excavated 5 new trenches totaling 4,299 feet. Initial sampling was conducted in three trenches previously excavated by Keystone Mines Inc. One of these trenches was located in the footwall of the Pennsylvania shear zone, approximately 1,300 feet northeast of the Pioneer shaft (LG155). This trench exposed a schist-hosted quartz-bearing shear zone oriented N 35 E, 65NW. One-foot channel samples collected in the hanging wall of this shear included 9 feet that with 0.9 part per million (ppm) gold and 58.3 ppm silver. The rocks in the trench consisted of iron-, arsenic- and antimony-oxide-stained silver-gray schist.

IMC also sampled two trenches previously excavated by Keystone Mines approximately 500 feet west of the Pioneer shaft. These trenches cut the Pioneer shear zone which trends N 70 W and dips 50 S. The first trench had 17 feet that assayed 0.54 ppm gold and 75.6 ppm silver; the rocks in the trench consisted of brecciated and silicified quartz-mica schist with minor iron- and antimony-oxide staining. The second trench had 25 feet that assayed 5.68 ppm gold and 142.6 ppm silver in silicified and brecciated quartz-mica schist with weak iron-oxide staining.

To test the down-dip extent of the northeast-trending mineralization identified in the trenches, IMC drilled

using a 5-inch rotary drilling rig (Pilkington, 1970). Two vertical holes totaling 485 feet were drilled.
Based on the results from their trenching and drilling, IMC inferred reserves of 2,111,000 tons with a grade of 0.037 ounces of gold per ton and 0.46 ounces of silver per ton (Pilkington, 1970). These reserves were considered subeconomic at then-current price of gold and silver and IMC terminated its lease with Keystone Mines Inc. in 1970.
In 1987, Keystone Mines leased their holdings to Fairbanks Exploration Inc. In 1988, BP Minerals, acting as operator of a joint venture with Fairbanks Exploration Inc. drilled 7 holes totaling 3,465 feet to confirm the earlier IMC work (Klessig, 1988).

Primary Reference: Pilkington, 1970; Freeman, 2008

Reporter(s): C.J. Freeman, J.R. Guidetti Schaefer (Avalon Development Corporation); D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-06-05

Site name(s): McCarty; American Eagle

Site type: Mine

ARDF no.: LG152

Latitude: 65.0646 **Quadrangle:** LG A-1

Longitude: 147.3536

Location description and accuracy:

The McCarty Mine is labeled on the Livengood A-1 quadrangle; it is in the headwaters of Fairbanks Creek at an elevation of about 1970 feet; it is in the NW1/4NE1/4 section 28, T. 3 N., R. 2 E., of the Fairbanks Meridian.

Commodities:

Main: Au, Sb

Other: Ag, As, Pb, Zn

Ore minerals: Arsenopyrite, gold, jamesonite, pyrite, sphalerite, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG206).

The McCarty Mine, also known as the American Eagle Mine, was one of the most productive gold mines in the district. The American Eagle shear zone was mined through the American Eagle adit and American Eagle shaft. Although the old stamp mill and head-frame of the McCarty Mine were still standing in 1992, the underground workings of the mine were inaccessible (Freeman, 1992).

The rocks in the area are mainly quartz-mica schist, but quartzite and calcareous schist also are present locally. The wall rocks adjacent to the vein are sericitized (Joesting, 1941).

Most ore came from the American Eagle vein, which is from one to three feet thick, strikes N60W and dips 55-60SW; it consists of coarsely crystalline quartz with free gold and small amounts jamesonite, stibnite, arsenopyrite and sphalerite (Joesting, 1941, p. 3). Large kidneys of high-grade stibnite with up to 61 percent antimony, occur in segments of the vein (Joesting, 1941, p. 3).

During the winter of 1914-1915, a 450-foot adit was driven on the American Eagle claim and significant of ore were mined during the summer of 1915 (Stewart, 1915). By 1915, the American Eagle shaft had been sunk to a depth of 107 feet (Brooks, 1915). In 1936, United States Smelting Refining and Mining Company (USSR&M) began drifting along the 135-foot level through the American Eagle shaft (Smith, 1939). Extensive development continued in 1938 but the results of sampling were not encouraging (Smith, 1939). In 1938, USSR&M sank 120 feet of shaft in the American Eagle vein, shaft, put in 625 feet of raise, and drove 1,816 feet of drift, crosscuts and adit (Reed, 1939). Mining continued in 1939 when USSR&M completed 465 feet of drifts and crosscuts and nearly 400 feet of raises. The ore was treated in a 2-stamp Nissen mill and the tailings were impounded for later upgrading (Smith, 1941). Mining continued in 1940 when 639 feet of drifts and crosscuts were driven as well as 545 feet of raises. The American Eagle shaft was deepened to 250 feet giving access to over a mile of drifts and 1,750 feet of raises, with workings on the 28-, 135-and 235-foot levels (Smith, 1942). Mining continued in 1941 when USSR&M sank a 65-foot winze from the east end of the 235 level. USSR&M maintained the properties until 1958 but no further mining was reported (Porterfield and Croff, 1986). The stamp mill at the McCarty Mine also processed ore from the Henry Ford group of claims which included ore from both the McCarty vein (LG150) and the

Henry Ford vein (LG153).

In 1984, Placid Oil Company drilled 6,137 feet in 23 diamond core holes. Based on this work, the deposit was estimated to have 15,000 tons of reserves with an average grade of 0.80 ounces of gold per ton. During this period Alaska Mineral Services also constructed a small carbon-in-pulp leach plant (the Haskins mill) at the McCarty Mine to treat mill tailings from the McCarty mine and the Hi Yu mine.

In 1986, Fairbanks Exploration Inc. collected bulk samples from the mill tailings and waste dump. The average gold grades of the mill tailings was 0.091 to 0.168 ounces of gold per ton. However, a portion of the samples was taken from mill tailings which had been re-treated in a cyanide mill erected on the prospect in the early 1980s. Therefore, the results are not an accurate estimate of gold grades for the bulk of the American Eagle mill tailings. Channel sampling of American Eagle mill tailings in 1987 indicated an average grade of 0.123 ounces of gold per ton and 0.74 ounces of silver per ton (Fairbanks Exploration Inc., unpublished report, 1987). The mill tailings were estimated to contain about 3,000 tons of material in 1987. At least some of these mill tailings were processed by Tri-Con Mining after mid-August 1988. The average gold grade of the mine dumps of the McCarty Mine range from 0.132 to 0.158 ounces of gold per ton (Fairbanks Exploration Inc., unpublished report, 1988).

Through 1917, the American Eagle vein produced approximately 967 ounces of gold with an average grade of about one ounce of gold per ton (J. McCarty, unpublished report, 1932). Rock mined during development in 1929 and 1930 produced 1,274 ounces of gold from 1,225 tons of ore (J. McCarty, unpublished report, 1932; Hill, 1931). During 1931, approximately 34 ounces of gold was recovered from 27 tons of material excavated from a surface cut on the American Eagle shear zone (J. McCarty, unpublished report, 1932). Smith (1933b) reported that the McCarty mine was the largest producer in the Fairbanks Creek basin in 1931. A total of 600 tons of ore was milled in 1938 at a rate of 240 tons per month (Reed, 1939). The McCarty mine ceased operations in 1942 due to War Production Board Limitation Order L208. However, about 15 tons of high-grade stibnite ore was shipped from the prospect in 1942. This ore contained 60.66 percent antimony (Joesting, 1942). An additional 5 tons of stibnite ore with 45 percent antimony was shipped from the mine in 1942 (Joesting, 1943; Killeen and Mertie, 1951).

Estimates of the total mine production vary from 26,800 ounces of gold from 16,750 tons of ore (Porterfield and Croff, 1986), to 60,000 ounces of gold (Metz and others ,1987).

Alteration:

Sericitization of country rock.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold-stibnite vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The McCarty Mine, also known as the American Eagle Mine, was one of the most productive gold mines in the district. The American Eagle shear zone was mined through the American Eagle adit and American Eagle shaft. Although the old stamp mill and head-frame of the McCarty Mine were still standing in 1992, the underground workings of the mine were inaccessible (Freeman, 1992).

During the winter of 1914-1915, a 450-foot adit was driven on the American Eagle claim and significant of ore were mined during the summer of 1915 (Stewart, 1915). By 1915, the American Eagle shaft had

been sunk to a depth of 107 feet (Brooks, 1915). In 1936, United States Smelting Refining and Mining Company (USSR&M) began drifting along the 135-foot level through the American Eagle shaft (Smith, 1939). Extensive development continued in 1938 but the results of sampling were not encouraging (Smith, 1939). In 1938, USSR&M sank 120 feet of shaft in the American Eagle vein, shaft, put in 625 feet of raise, and drove 1,816 feet of drift, crosscuts and adit (Reed, 1939). Mining continued in 1939 when USSR&M completed 465 feet of drifts and crosscuts and nearly 400 feet of raises. The ore was treated in a 2-stamp Nissen mill and the tailings were impounded for later upgrading (Smith, 1941). Mining continued in 1940 when 639 feet of drifts and crosscuts were driven as well as 545 feet of raises. The American Eagle shaft was deepened to 250 feet giving access to over a mile of drifts and 1,750 feet of raises, with workings on the 28-, 135-and 235-foot levels (Smith, 1942). Mining continued in 1941 when USSR&M sank a 65-foot winze from the east end of the 235 level. USSR&M maintained the properties until 1958 but no further mining was reported (Porterfield and Croff, 1986). The stamp mill at the McCarty Mine also processed ore from the Henry Ford group of claims which included ore from both the McCarty vein (LG150) and the Henry Ford vein (LG153).

In 1984, Placid Oil Company drilled 6,137 feet in 23 diamond core holes. During this period Alaska Mineral Services also constructed a small carbon-in-pulp leach plant (the Haskins mill) at the McCarty Mine to treat mill tailings from the McCarty mine and the Hi Yu mine.

In 1986, Fairbanks Exploration Inc. collected bulk samples from the mill tailings and waste dump. At least some of these mill tailings were processed by Tri-Con Mining after mid-August 1988.

Production notes:

Total production from the American Eagle shear through 1917 was approximately 967 ounces of gold with an average grade of about one ounce of gold per ton (J. McCarty, unpublished report, 1932). Milling of development material in 1929 and 1930 produced 1,274 ounces of gold from 1,225 tons of ore, averaging 1.04 ounces of gold per ton (J. McCarty, unpublished report, 1932; Hill, 1931). During 1931, approximately 34 ounces of gold was recovered from 27 tons of material excavated from a surface cut on the American Eagle shear zone (J. McCarty, unpublished report, 1932). Smith (1933, B 844) reported that the McCarty mine was the largest producer in the Fairbanks Creek basin in 1931. A total of 600 tons of ore from the American Eagle workings was milled in 1938 at a rate of 240 tons per month (Reed, 1939).

The McCarty mine ceased operations in 1942 due to War Production Board Limitation Order L208. However, about 15 tons of high-grade stibnite ore was shipped from the prospect in 1942. This ore graded 60.66 percent antimony (Joesting, 1942). In addition, about 5 tons of stibnite ore grading 45 percent antimony was also shipped from the American Eagle mine in 1942 (Joesting, 1943; Killeen and Mertie, 1943).

Total production from the McCarty mine workings (American Eagle, Henry Ford and McCarty shear zones) is estimated at 26,800 ounces from 16,750 tons of ore, averaging 1.6 ounces of gold per ton (Porterfield and Croff, 1986). However, Metz and others (1987) estimate production from the McCarty mine was approximately 60,000 ounces of gold.

Reserves:

In 1984, Placid Oil Company drilled 6,137 feet in 23 diamond-core holes. Based on this work, the deposit was estimated to have 15,000 tons of reserves with an average grade of 0.80 ounces of gold per ton.

In 1986, Fairbanks Exploration Inc. collected bulk samples from the mill tailings and waste dumps. The mill tailings were estimated to contain about 3,000 tons of material in 1987. At least some of this material was processed by Tri-Con Mining after mid-August 1988.

Last report date: 2008-06-05

Site name(s): Henry Ford

Site type: Mine

ARDF no.: LG153

Latitude: 65.0656 **Quadrangle:** LG A-1

Longitude: 147.3574

Location description and accuracy:

The Henry Ford shaft is the northernmost shaft on a group of six claims of the McCarty/ American Eagle Mine (LG152). The shaft is at the head of Fairbanks Creek, just east of the Wolf Creek divide. It is in the NW1/2 sec. 28, T. 3 N., R. 2 E., of the Fairbanks Meridian.

Commodities:

Main: Ag, Au

Other: As

Ore minerals: Arsenopyrite, gold

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008). Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG206).

Although sometimes considered separately, by the 1930s, the Henry Ford deposit was part of or at least mined in conjunction with the the McCarty (American Eagle) Mine (LG152). The upper Henry Ford vein strikes N40E and dips northwest. The quartz vein carries free gold and considerable arsenopyrite. Concentrates from arsenopyrite-rich samples from one of the surface pits contain some gold and 1,600 ounces of silver per ton. The vein is cut in three places by quartz stringers, all of which carry gold (W. J. McCarty, unpublished report, 1932).

Alteration:

Not specified.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Undetermined

Site Status: Active

Workings/exploration:

Shaft on a vein.

Production notes:

Included in the production from the McCarty/American Eagle Mine (LG152).

Reserves:

None.

Site name(s): Ebbert

Site type: Mine

ARDF no.: LG154

Latitude: 65.0666 **Quadrangle:** LG A-1

Longitude: 147.3613

Location description and accuracy:

The Ebbert prospect is in upper Wolf Creek approximately 2,000 feet northwest of the McCarty mine (LG152); it is in the SE1/4SW1/4 section 21, T. 3 N., R. 2 E., of the Fairbanks Meridian.

Commodities:

Main: Au

Other: Ag, As, Pb, Sb, Sn

Ore minerals: Arsenopyrite?, galena?, gold, jamesonite, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG206).

The first work on the Ebberts Mine was done by Hugh M. Hinton, who hand trenched the prospect (Saunders, 1960). The prospect was inactive until about 1950 when it was dozer trenched by United States Smelting Refining and Mining (USSR&M). Initially the exploration was for antimony. In June 1960, Arctic Alaska Fisheries and Enterprises Inc. cut several dozer trenches on the prospect and exposed the Ebberts shear zone which is sometimes referred to as the Jamesonite shear zone (Saunders, 1960). The Ebbert deposit was mined for antimony from a shallow shaft and in open cuts from 1961 through 1964 by Ed Ebbert (R. Vetter, oral communication, 1986). The mine was idle until 1967 when Ed Ebbert reopened the shaft and trenches after finding high gold values in quartz-rich portions of the shear zone. In 1969, the Ebberts Mine was sampled by International Minerals and Chemicals (IMC) in the vicinity of the main shaft (Pilkington, 1970). IMC also excavated a dozer trench which crossed the Ebberts shear 200 feet east of the Ebberts shaft.

The deposit consists of gold-quartz-rich portions of a shear zone. The lode was sampled and mapped in 1968; it contained extremely high gold, silver, lead, antimony, arsenic and tin values (Forbes and others, 1968). The quartz veins and wall rock in old prospect trenches carry as much as 2.87 parts per million (ppm) gold (Pilkington and others, 1969). The veins predominantly trend in two directions: about N70W with a dip of 55S, and about N65E with a dip of 70S. Altered schist that extends as much as 1 foot into the footwall of the veins contain significant gold. Grab samples of the veins contained 0.05 and 2.87 ppm Au (Pilkington and others, 1969). In 1969, the Ebberts Mine was sampled by International Minerals and Chemicals (IMC) in the vicinity of the main shaft. Here the, the shear zone trends N85W and dips 60S; it consists of narrow quartz stockwork zones on the hanging wall and foot wall, separated by altered schist. Stibnite and jamesonite occur on the hanging wall and in kidney shaped masses. The mineralized zone is 13 feet wide and averaged 0.06 ounce of gold per ton and 8.4 ounces of silver per ton (Pilkington, 1970). IMC also excavated a dozer trench which crossed the Ebberts shear 200 feet east of the Ebberts shaft. Samples from the trench contained 0.046 ounce of gold per ton and 0.32 ounce of silver per ton over 25 feet.

Alteration:

Schist is altered near the veins.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold-silver(-arsenic-antimony) vein along shear zone and antimony vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The first work on the Ebberts deposit was done by Hugh M. Hinton who hand trenched the prospect (Saunders, 1960). The prospect was inactive until about 1950 when it was dozer trenched by United States Smelting Refining and Mining (USSR&M). In June 1960, Arctic Alaska Fisheries and Enterprises Inc. cut several dozer trenches on the prospect and exposed the Ebberts shear zone which is sometimes referred to as the Jamesonite shear zone (Saunders, 1960). The mine was idle until 1967 when Ed Ebbert reopened the shaft and trenches (Anderson and Johnson, 1970). In 1969, the Ebberts Mine was sampled by International Minerals and Chemicals (IMC) in the vicinity of the main shaft (Pilkington, 1970). IMC also excavated a dozer trench which crossed the Ebberts shear 200 feet east of the Ebberts shaft.

Production notes:

The Ebbert prospect was mined for antimony from a shallow shaft and open cuts from 1961 through 1964 by Ed Ebbert (R. Vetter, oral commun., 1986).

Reserves:

None.

Location description and accuracy:

The Pioneer Mine is on the divide between Fairbanks Creek and Wolf Creek along the old Circle-Fairbanks trail; it is in the SE1/4SW1/4 sec. 21, T. 3 N., R. 2 E., of the Fairbanks Meridian. The property consists of several claims: the War Eagle, Leroy, Pioneer, Iron Mask, Black Warrior and Willie. Most production came from the Pioneer claim.

Commodities:

Main: Au

Other: Sb

Ore minerals: Gold, stibnite

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG206).

In 1904, Angus McDougall was the first to prospect in the vicinity of the Pioneer Mine (Times Publishing Company, 1912). He and his partners Julius Hoffman, Mr. McGowan and Mr. Clark, eventually staked the Pioneer group which consisted of the War Eagle, Leroy, Pioneer, Iron Mask and Black Warrior claims (Times Publishing Company, 1912). The adjacent Willie claim was staked in 1909 by Lawrence J. McCarty. By 1910, the Willie claim was owned by Frank Lawson and Lawrence McCarty and an unspecified amount of ore had been custom milled from the prospect (Brooks, 1910). In the winter of 1910, shaft sinking began on the Willie claim by Lawrence McCarty's sons, Lawrence Junior, age 9 and Willie, age 7. The two boys were assisted by their older sister who acted as surface superintendent (Times Publishing Company, 1912).

By 1912, the Pioneer shaft had been sunk to a depth of 120 feet and two other shafts sunk to depths of 49 and 85 feet. Additional prospect pits exposed the shear zone along 800 feet along strike. In early 1912, a 50-foot-shaft was sunk on the Iron Mask claim. By mid-1912, the westernmost claim of the Pioneer group, the War Eagle claim was traced in several 8- to 10-foot deep pits (Smith, 1913; B 525). On the Leroy claim, two shafts were sunk on one of the lodes that was exposed on the War Eagle claim. Development work on the Pioneer claim included about 200 feet of drifts to the east and west at the 110-foot level (Smith, 1913a). Fifty feet of drift was completed from the 75-foot level in the next shaft to the east, and still further east, a 38-foot-deep shaft was sunk. The farthest east claim of the Pioneer group, the Black Warrior claim was explored by test pits, 12- to 15-feet deep every 50 feet, along 400 to 500 feet of strike. By 1916, two shafts had been sunk on the Pioneer claim on an inch-thick antimony-bearing shear zone (Mertie, 1918).

In 1951, dozer trenching at the Pioneer Group exposed the tops of the old drifts on the antimony-bearing, shear zone (Saunders, 1960). A shaft was sunk an additional 20 feet to determine if high grade stibnite mineralization was present (Saunders, 1960). In 1969, the Pioneer group of claims were examined by dozer trenching and rotary drilling. Placid Oil Company was active in 1984 and 1985 they drilled 2,154.7 feet of core hole at 13 sites near the Pioneer and Pennsylvania mines (Porterfield and Croff, 1986). In 1988, BP

Minerals did some reverse-circulation drilling in the Pioneer mine area (Freeman, 1992).

The Pioneer shafts and prospect pits exposed a shear zone that extends for over 800 feet along strike. By 1912, $22,000 worth of gold (1,064 ounces) had been mined; the average width of the vein was 34 inches, and the average grade was 2.2 ounces of gold per ton. The highest value was obtained from a 22 ton shipment to the Chena mill which returned an average of $180 gold per ton (8.7 ounces of gold per ton) (Times Publishing Company, 1912). By 1916, two shafts had been sunk on the Pioneer claim on an 18-inch-thick antimony-bearing shear zone oriented N85E, 80 N. (Mertie, 1918). Five hundred feet west of the antimony-bearing zone, three gold-bearing quartz stockworks along shear zones were exposed. Two of these zones were from 12- to 14-inches-thick and were oriented N35-45E, 60-80NW. The third zone had an east strike and a dip of 45S. These exposures averaged about $10 gold per ton or 0.5 ounces of gold per ton (Mertie, 1918).

The Willie claim had a 4- to 5-foot-wide iron-oxide-stained quartz stockwork zone oriented N50E, 80SE (Prindle, 1910). Free gold could be panned for 1,000 feet along its strike. Shaft sinking in 1910 revealed a 10-inch-thick high-grade portion of the shear zone.

The Iron Mask claim contained an eight-foot-wide mineralized shear zone oriented east that dipped 65S. A 50-foot shaft was sunk on this claim by late 1912 and the ore averaged $25 gold per ton (about 1.2 ounces of gold per ton) (Times Publishing Company, 1912). A three-foot-wide, high-grade zone was also exposed on the Iron Mask claim. This zone has a hanging wall of bleached, white, decomposed rock believed to be a fine-grained intrusive (Smith, 1913, B 525, Smith, 1913, B 542). The gold-bearing portion of the lode is in fault contact with the decomposed intrusive rock. On the Iron Mask claim, an 8-inch-thick stibnite-bearing shear zone was exposed which strikes N80W and dips 75SW. Farther to the east but still on the Iron Mask claim, a 4-foot-thick shear zone carrying low grade gold and stibnite mineralization was exposed and traced into Fairbanks Creek. At the War Eagle claim, visible gold was found in two separate zones which averaged 1 to 2 feet wide (Smith, 1913, B 525). In the Leroy claim, the high grade portion of the shear zone averaged 1 foot wide (Smith, 1913, B 525). The farthest east claim, the Black Warrior, had test pits that exposed high grade. gold-quartz shear zones which averaged 8 to 10 inches wide.

The average fineness of the Pioneer group gold through 1912 was 814.5 (Smith, 1913, B 525).

Alteration:

Yellowish oxidation products of stibnite common in quartz.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold and stibnite in quartz shear zones.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

In 1904, Angus McDougall was the first to prospect in the vicinity of the Pioneer mine (Times Publishing Company, 1912). He and his partners Julius Hoffman, Mr. McGowan and Mr. Clark, eventually staked the Pioneer group, which consisted of the War Eagle, Leroy, Pioneer, Iron Mask and Black Warrior claims (Times Publishing Company, 1912). The adjacent Willie claim was staked in 1909 by Lawrence J. McCarty. By 1910, the Willie claim was owned by Frank Lawson and Lawrence McCarty and an unspecified amount of ore had been custom milled from the prospect (Brooks, 1910). In the winter of 1910, shaft sinking was begun on the Willie claim by Lawrence McCarty's sons, Lawrence Junior, age 9 and

Willie, age 7. The two boys were assisted by their older sister who acted as surface superintendent (Times Publishing Company, 1912).

By 1912, the Pioneer shaft had been sunk to a depth of 120 feet and two other shafts sunk to depths of 49 and 85 feet. Additional prospect pits exposed the shear zone along 800 feet along strike. In early 1912, a 50-foot-shaft was sunk on the Iron Mask claim. By mid-1912, the western-most claim of the Pioneer group, the War Eagle claim was traced in several 8- to 10-foot deep pits (Smith, 1913, B 525). On the Leroy claim, two shafts were sunk on one of the lodes that was exposed on the War Eagle claim. Development work on the Pioneer claim included about 200 feet of drifts to the east and west at the 110-foot level (Smith, 1913, B 525). Fifty feet of drift was completed from the 75-foot level in the next shaft to the east, and still further east, a 38-foot-deep shaft was sunk. The farthest east claim of the Pioneer group, the Black Warrior claim was explored by test pits, 12- to 15-feet deep, every 50 feet along 400 to 500 feet of strike. By 1916, two shafts had been sunk on the Pioneer claim on an inch-thick antimony-bearing shear zone (Mertie, 1918).

In 1951, dozer trenching at the Pioneer Group exposed the tops of the old drifts on the antimony-bearing, shear zone (Saunders, 1960). A shaft was sunk an additional 20 feet to determine if high grade stibnite mineralization was present (Saunders, 1960). In 1969, the Pioneer group of claims were examined by dozer trenching and rotary drilling. In 1984 and 1985, Placid Oil Comp was active in the area and drilled 13 holes near the Pioneer and Pennsylvania Mines that totaled 2,145.7 feet of core. In 1988, BP Minerals did some reverse-circulation drilling in the Pioneer mine area (Freeman, 1992).

Production notes:

Production from the Pioneer mine through 1931 was estimated at $14,000 (677 ounces). This production was primarily from above the 50-foot level of the main shaft (Hill, 1933).

Reserves:

None.

Site name(s): Pennsylvania

Site type: Mine

ARDF no.: LG156

Latitude: 65.0686 **Quadrangle:** LG A-1

Longitude: 147.3575

Location description and accuracy:

The Pennsylvania Mine is on the ridge east of the head of Wolf Creek; it is in the SE1/4SW1/4 sec. 21, T. 3 N., R. 2 E., of the Fairbanks Meridian. The location is for the northwest shaft which is on the divide between the head of Wolf Creek and Fairbanks Creek.

Commodities:

Main: Au

Other: Sb

Ore minerals:

Gangue minerals: Quartz

Geologic description:

Note: As of 2008, this site and several others in the vicinity are being explored as a single entity by Freegold Ventures Inc. (Freeman, 2008) Considerable new mineralization has been discovered that indicates this is part of a larger mineralized system that is described as a separate ARDF site (LG206).

Free gold occurs at the Pennsylvania Mine associated with antimony oxides in white quartz. The mineralization is along a shear zone that strikes N76W and dips 56SW (Smith, 1913). The high grade portion of the shear zone average 12 to 15 inches thick.

The Pennsylvania claim was staked in October 1911 by Lawrence J. McCarty and soon became part of the McCarty group of claims which included the Pennsylvania, Willie, Dorothy, Marie, Kentucky and Freegold claims (Times Publishing Company, 1912).

In late 1911, an 8.5-ton sample of material from the Pennsylvania Mine averaged $100 gold per ton (4.8 ounces of gold per ton). A second lot of ore was custom milled in early 1912 and averaged $52 gold per ton (2.5 ounces of gold per ton). By 1913, the Pennsylvania shaft was 146 feet deep, and between 1922 and 1931, the west drift on the 50-foot level was 70 feet long and stoped to the surface. This work produced approximately $10,000 worth of gold (484 ounces) (Hill, 1933).

The Pennsylvania mine was examined in 1942 as a possible source of antimony. Samples from a one-half ton stockpile of oxidized stibnite near the shaft had an average grade of 57.01 percent antimony but the mine did not possess sufficient quantity of this material to warrant additional exploration or development (Killeen and Mertie, 1951).

Alteration:

Stibnite altered to antimony oxides.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold-stibnite-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

By late 1912, the Pennsylvania shaft was 140 feet. deep. Drifts were driven 20 feet to the northwest and southeast on the 140-foot level. At the 50- foot level, drifts extended 50 feet northwest and 50 feet southeast with a raise connected to the surface from the southeast drift (Times Publishing Company, 1912). The ore was hoisted using a Little Giant steam hoist and was shipped to the company mill constructed on upper Fairbanks Creek by L.J. McCarty and Emil C. Fursteneau. This mill began operation in September, 1912 and consisted of a Little Giant #3 roll mill which fed minus-40-mesh pulp over amalgamation plates (Times Publishing Company, 1912). The tailings were not impounded. The mill had a capacity of 8 to 20 tons of ore per day (Smith, 1913). By mid-1913, the Pennsylvania shaft was 146 feet deep (Chapin, 1914). Some time between 1922 and 1931, the western drift on the 50-foot-level was extended to a length of 70 feet and stoped to the surface. The shaft and workings were flooded in 1931.

Production notes:

In late 1911, an 8.5 ton sample of material from the Pennsylvania Mine averaged $100 per ton in gold (4.8 ounces of gold per ton). A second lot of Pennsylvania ore was custom milled in early 1912 and averaged $52 per ton (2.5 ounces of gold per ton). The mine was not in production in 1913. The mine was examined in 1922 by Stewart (1922) and Davis (1922) but was not in production at that time. Some time between 1922 and 1931, the western drift on the 50-foot level was extended to a length of 70 feet and stoped to the surface; this work produced about $10,000 in of gold (484 ounces) (Hill, 1933).

Reserves:

None.

Site name(s): Goose Creek

Site type: Prospect

ARDF no.: LG161

Latitude: 65.077 **Quadrangle:** LG A-1

Longitude: 147.36

Location description and accuracy:

The location given is the approximate center of the Goose Creek soil anomaly; it is on an unnamed creek between Goose Creek and upper Wolf Creek in the NW1/4 section 21, T. 3 N., R. 2 E., of the Fairbanks Meridian. The location is accurate within 500 feet.

Commodities:

Main: Au

Other: Ag, As, Bi, Pb, Sb, Zn

Ore minerals: Arsenopyrite, pyrite, sphalerite, stibnite, tetrahedrite

Gangue minerals: Sericite

Geologic description:

In 1996, Freegold Recovery Inc. outlined a +5,000 foot long multi-element soil anomaly on the Goose Creek prospect (Freeman and others, 1998). The core of the grid, covering an area approximately 2,000 feet by 1,000 feet, averaged over 100 parts per billion (ppb) gold, three times the mean gold value over the project area. This anomaly trends N 80 W and was extended to a length of 10,000+ feet in 1997. The anomaly is located in lower plate rocks of the Fairbanks Schist and appears to have secondary anomalies associated with district scale northeast trending structures similar to those on the Cleary Hill (ARDF no. LG119), Dolphin (ARDF no. LG112) and Wolf Creek (ARDF no. LG138) prospects. Mineralization is characterized as intrusion and schist-hosted, gold bearing stockwork veins, shears and disseminations. Initial drilling in late 1997 consisted of 5,038 feet of reverse circulation drilling in 11 holes. Preliminary assay results from one hole returned intercepts averaging up to 0.118 ounce of gold per ton over 160 feet in highly sericitized chlorite schist cut by 10 to 20 percent white quartz veins. Anomalous gold is associated with anomalous arsenic, antimony, lead, silver, and zinc. Pyrite is relatively abundant in the sericitic alteration envelope but does not appear to be correlative with gold values.

In 1998, 10 reverse circulation holes totaling 5,017 feet were drilled in the Goose Creek prospect to determine the extent and geometry of the higher grade intercepts encountered in the 1997 drill program. Results indicate that mineralization is controlled by an 85 degree south dipping structure. The gold-bearing alteration envelope around this structure is restricted in size indicating limited potential for bulk tonnage mineralization in this area (Freeman and others, 1998).

Alteration:

Sericitic alteration (Freeman and others, 1998).

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby (Freeman and others, 1998).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Soil sampling in 1996 lead to the discovery of a multi-element soil anomaly more than 5,000 feet long. Initial drilling in late 1997 consisted of 5,038 feet of reverse circulation drilling in 11 holes. In 1998, 10 reverse circulation holes totaling 5,017 feet were drilled (Freeman and others, 1998).

In 2011, an induced polarity (IP) and resistivity survey was completed by Freegold Ventures Ltd., indicating potential areas of mineralization. Freegold executed soil sampling between 2011 and 2012 (Abrams and Giroux, 2013).

Production notes:

None.

Reserves:

None.

Site name(s): Too Much Gold Creek

Site type: Mine

ARDF no.: LG169

Latitude: 65.067

Quadrangle: LG A-1

Longitude: 147.297

Location description and accuracy:

Too Much Gold Creek is a tributary of Fairbanks Creek, located approximately 4 miles from Cleary Summit, and accessible via the Fairbanks Creek road. The location given is near the confluence with Fairbanks Creek on the north side of the road. The location is accurate within 1,000 feet.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Evidence of recent placer mining (1980's?) near the confluence of Too Much Gold Creek and Fairbanks Creek was observed in 1999 (J. Schaefer, field observation, 1999). Bedrock in the area is quartz muscovite schist, quartzite and chlorite quartzose schist (Newberry and others, 1996). Too Much Gold Creek drains an area that includes several prospects and mines that have been worked for their gold in quartz veins (Too Much Gold Creek Divide, ARDF no. LG176; Basham, ARDF no. LG177; Excelsior, ARDF no. LG179; Plumbum, ARDF no. LG168; Governor, ARDF no. LG172; and Whitehorse, ARDF no. LG170).

The original record from 1999 reported this site as a mine. It is currently reported as a prospect. Gold mineralization on the property occurs in three main forms, including intrusive-hosted sulfide-quartz stockwork veinlets (such as the Dolphin gold deposit), auriferous sulfide-quartz veins (exploited by historic underground mines), and shear-hosted gold-bearing veinlets. All three types are considered to be part of a large-scale intrusive-related gold system (or 'IRGS') on the property. (Abrams and Giroux, 2013).

This prospect is part of the Golden Summit property (Abrams and Giroux, 2013; Walcott, 2013).

Alteration:

Not reported.

Age of mineralization:

Not reported.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au-PGE (Cox and Singer, 1986; model 39a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Inactive

Workings/exploration:

The ground near the mouth of the creek, just north of Fairbanks Creek road appears to have been placer mined. The amount of vegetation suggests that this mining probably took place in the 1980s (J. Schaefer, field observation, 1999).

British Petroleum/Fairbanks Exploration performed trenching and reverse circulation drilling from 1987-1988 (Abrams and Giroux, 2013).

The original record from 1999 reported this site as a mine. It is currently reported as a prospect. Gold mineralization on the property occurs in three main forms, including intrusive-hosted sulfide-quartz stockwork veinlets (such as the Dolphin gold deposit), auriferous sulfide-quartz veins (exploited by historic underground mines), and shear-hosted gold-bearing veinlets. All three types are considered to be part of a large-scale intrusive-related gold system (or 'IRGS') on the property. (Abrams and Giroux, 2013).

Production notes:

No record of production.

Reserves:

None.

Longitude: 147.2818

Location description and accuracy:

The coordinates given here for the Hi Yu Mine are at the main portal of the mine on the west side of Moose Creek, about 0.5 miles above its mouth on Fairbanks Creek. The underground workings extend west-northwest for more than 5,000 feet. The portal is about 0.5 mile east-northeast of the center of section 23, T. 3 N., R. 2 E., of the Fairbanks Meridian.

Commodities:

Main: Au

Other: Ag, Pb, Sb, Zn

Ore minerals: Argentiferous galena, arsenopyrite, boulangerite, gold, pyrite, sphalerite, stibnite

Gangue minerals: Quartz

Geologic description:

The Hi Yu Mine was one of the major producers in the Fairbanks district prior to WWII. This mine consists of several quartz veins along a prominent shear zone, and most offset by faults. The veins contain free gold and sulfides including stibnite, argentiferous galena, arsenopyrite, boulangerite, pyrite, and sphalerite. The mineralization is probably mid-Cretaceous based on its similarities to other deposits in the area (McCoy and others, 1997).

By 1913, the Hi Yu vein and shear zone had been traced for over 900 feet along strike and 625 feet down dip, and the Main adit had been driven 450 feet from the south side of Moose Creek (Prindle, 1913; Smith, 1913a). A second adit known as the Lower adit, was collared in 1913. By 1914, the northwest-trending, south-dipping shear zone and associated veins was known to be over 3,000 feet long on the surface and contained several ore shoots (Chapin, 1914). A twenty-three-ton lot of ore from the first 150 feet of the Main adit assayed 6.29 ounces of gold per ton. This gold had a fineness of 850 to 857 and contained 13 to 14 percent silver (Chapman, 1914). By 1916, the Lower adit had been abandoned and a new adit, the Hi Yu adit, was collared on the Hi Yu claim approximately 500 feet above the level of Moose Creek (Stewart, 1922). At the 350 foot station of the Hi Yu adit, the lode bifurcated. The northern branch, trends N75W and dips steeply south; underground it extended 125 feet from the split and could be followed on the surface for over 2,000 feet from the portal of the Upper adit (Mertie, 1918). By 1920, the Hi-Yu adit had been driven 1,300 feet. The average grade of the ore in 1922 was $25 to $30 gold per ton (1.21 to 1.45 ounces of gold per ton). Tailings from the stamp mill were being collected in a settling pond since they contained approximately $4.00 in gold per ton (0.20 ounce of gold per ton) (Stewart, 1922).

Production records indicate that by 1933, the Hi-Yu Mine had produced 13,560 ounces of gold from 8,200 tons of ore with an average grade of 1.65 ounces of gold per ton (Hill, 1933). In August of 1933, a rich ore shoot was discovered in the Upper adit on the Helen S claim. Between August 1933 and June, 1934, this shoot produced 3,010 ounces of gold from ore that averaged 2.1 ounces of gold per ton (Joralemon, 1934).

In the fall of 1941, a 2-foot-wide stibnite pod was relocated on the Antimony shear zone approximately 600 feet north of the portal of the Main adit. This material contained 60 to 66 percent antimony, 0.01 ounce of gold per ton, and 1 ounce of silver per ton (Joesting, 1942). Approximately 15 tons of this material was

identified in surface pits by 1942 (Joesting, 1943).
Fairbanks Exploration Inc. conducted limited sampling of the Hi-Yu mine waste dumps and stamp sand tailings ponds in 1986 (Fairbanks Exploration Inc., unpublished report, 1986). Samples of the waste dumps from both levels of the mine indicate that the mineralization is hosted by siliceous exhalite, metarhyolite tuff, and black carbonaceous quartzite of the Cleary Sequence. The mineralization in these rocks consists of fine-grained, stratiform arsenopyrite and pyrite in metavolcanic lenses and stibnite-pyrite mineralization in pelitic host rock. Intense argillic alteration is all but destroyed by the nearly complete oxidation of most samples. Samples from the dump of the Main adit dump contained 260 to 3,200 parts per billion (ppb) gold, associated with highly anomalous arsenic, antimony and silver (Fairbanks Exploration Inc., unpublished report, 1986).
Samples of mill tailings collected from the tailings pond below the mill contained up to 1.701 ounces of gold per ton, up to 6.14 ounces of silver per ton, and anomalous arsenic and antimony (Fairbanks Exploration Inc., unpublished report, 1986). A significant proportion of the gold in the mill tailings is in -30-mesh material and much of the sulfides are concentrated in lenses in the tailings. In 1988, Tri-Con Mining mined 14,600 tons of material from the mill tailings of the Hi-Yu Mine and the McCafty Mine (LG152), the material averaged 0.10 ounce of gold per ton (Freeman, 1992). During this work, Ti-Con re-milled all of the Hi Yu mill tailings.
In 1998, Freegold drilled two holes near the Hi Yu vein. One tested a zone of alteration exposed in a series of shafts and prospects along the northwest projection of the Hi-Yu vein; the other tested the projection of low-grade mineralization in the footwall of the Hi Yu vein. Neither hole went through the Hi Yu vein. As of early 2008, the Hi Yu Mine was part of Freegold Venture LImited's, Golden Summit project (Freeman, 2008).

Alteration:

Quartz, sericite and ankerite; intense argillic alteration is all but destroyed by the nearly complete supergene alteration present on most samples.

Age of mineralization:

Probably about 90 Ma based on analogy with similar gold deposits nearby.

Generic deposit model:

Deposit model:

Gold (-arsenic-antimony) vein (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; large

Site Status: Active

Workings/exploration:

The HiYu lode was discovered in 1912 (Times Publishing Company, 1912). Initial development began on the Helen S claim, and by 1913 the Main adit was 450 feet long , with a 65-foot raise connected to the surface approximately 250 feet from the portal. A second adit, 50 feet below the Main adit, known as the Lower adit, was collared in 1913. In 1914, the Main adit was lengthened to 550 feet and the Lower adit driven 450 feet (Stewart, 1922). By the end of 1915, the Main adit was 700 feet long and the Lower adit remained 450 feet long. By 1916, the Lower adit had been abandoned and a new adit, the Hi Yu adit, was collared on the Hi Yu claim approximately 500 feet above the level of Moose Creek (Stewart, 1922). By 1920 the Hi Yu adit was 1,300 feet long and a raise connected the Hi Yu adit with the surface at the 800 foot station of the adit (Stewart, 1922).
By the end of 1922, the Hi Yu Mine had stoped out all of the ore on the Helen S claim between the Lower and Main adits for about 400 feet from the portal. Similarly, all of the ore had been stoped out between the

Main and Upper adits for a distance of 800 feet from the portals. The Main adit was extended to a length of 1,000 feet. On the Hi Yu claim, all of the ore had been stoped out between the Hi Yu adit and the surface for a distance of 1,100 feet from the portal, except for a block 150 feet long near the middle of the adit (Stewart, 1922). Mill tailings were being collected in a settling pond since they contained approximately $4.00 per ton in gold (0.20 ounce of gold per ton) (Stewart, 1922).

Stewart (1923) reported the Upper adit on the Helen S claim had been extended to a length of 600 feet by 1923. This adit level is approximately 125 feet below the level of the Hi Yu adit on the Hi Yu claim. In addition, the Lower adit on the Helen S claim was extended to a length of 500 feet. In 1931 a raise was being driven between the Main adit and Upper adit (Smith, 1933, B 836; Smith, 1933, B 844; Stewart, 1933). In 1932, the Upper adit was 1,200 feet long and the Main adit was 1,525 feet long (Pilgrim, 1933). Patty (1933) indicated the Upper adit on the Helen S claim was 1600 feet long in early 1933. The Upper adit was 1,875 feet long in 1934 and a crosscut was being driven from the Upper adit to intersect the Antimony shear zone, a 4-foot-wide shear zone that was reported to average 0.5 ounce of gold per ton. In 1938, the Hi-Yu mine drove 300 feet of drifts and 250 feet of raises on the Lower adit level and in sublevels between the Lower and Main adits.

In 1984, Placid Oil Company dug several trenches and drilled a total of 8,205 feet in 19 core holes (Porterfield and Croff, 1986). Two holes totaling 515 feet were drilled in 1985 on the Hi Yu shear zone. Fairbanks Exploration Inc. conducted limited sampling of the Hi Yu waste dumps and tailings in the mill ponds in 1986 (Fairbanks Exploration Inc., unpublished report, 1986). In July, 1988, 27 samples were collected from the Hi Yu mine tailings (Fairbanks Exploration Inc., unpublished report, 1988).

Production notes:

The Hi Yu Mine, also known as the Crites and Feldman mine, was the second largest lode gold producer in the Fairbanks District prior to WWII. By September 1914, the mine was in full production, milling an average of 7 tons of ore per day, primarily from the Lower adit (Stewart, 1915; Brooks, 1916). By 1916, the Hi Yu Mine had replaced the Cleary Hill mine as the largest producer in the Fairbanks Mining District. The mine continued to be the largest producer in the district from 1924 to 1926 (Brooks and Capps, 1924; Brooks, 1924; Moffit, 1927). Smith (1930) reported only development work in 1927, but significant production was again reported in 1928 and 1929 (Smith, 1930; Smith, 1932). There was no production in 1930 and the mine was not in operation for most of 1931. During the winter of 1932-33 over $100,000 worth of gold (4,837 ounces) was produced from stopes above the Upper adit. Records from the Hi Yu and Helen S shear zones provided by the owners in 1933, indicate production of 13,560 troy ounces of gold from 8,200 tons of ore, with an average grade of 1.65 ounces of gold per ton (Hill, 1933). In August of 1933, a rich ore shoot was discovered in the Upper adit on the Helen S claim. Between August 1933 and June, 1934, this shoot produced 3,010 ounces of gold from material that averaged 2.1 ounces of gold per ton (Joralemon, 1934). The Hi Yu Mine remained the second largest producer in the Fairbanks Mining District during 1936, 1937 and 1938 (Smith, 1938; Smith, 1939, B 910; Smith, 1939, B 917). In 1938, the mine produced 2,500 tons of ore which averaged $24 in gold per ton (0.68 ounce of gold per ton) (Reed, 1939). The mine recorded continuous production in 1939 and 1940 (Smith, 1941; Smith, 1942). Killeen and Mertie (1943) reported that the Hi Yu Mine was shut down in 1942 by the War Production Board Order L208, and like most other mines in the district, the Hi Yu Mine did not reopen after World War II.

Existing records indicate the Hi-Yu mine produced approximately 22,161 ounces of gold between 1933 and 1941 (E. Brandell, written commun., 1949). In 1988, Tri-Con Mining mined 14,600 tons of material from the mill tailings of the Hi-Yu Mine and the McCafty Mine (LG152), the material averaged 0.10 ounce of gold per ton (Freeman, 1992). During this work, Ti-Con re-milled all of the Hi Yu mill tailings.

Reserves:

Ore reserve estimates of the Hi Yu Mine are limited to the dump at the Main adit where sampling in 1986 indicated 34,530 tons of material with an average grade of 0.397 ounce of gold per ton and 1.60 ounce of silver per ton. However, these estimates are not representative of the true grades in the dumps since the 1986 sampling was restricted to material with visible sulfides or quartz. The true grade of the Hi Yu waste dumps is probably 0.05 to 0.10 ounce of gold per ton (Freeman, 1992).

Last report date: 2008-06-05

Site name(s): Gil

Site type: Prospect

ARDF no.: LG200

Latitude: 65.0258 **Quadrangle:** LG A-1

Longitude: 147.1084

Location description and accuracy:

The Gil prospect is on a large block of claims with several areas of mineralization, but most of the the work has been concentrated in a small area targeted as two potential open pit mines. The coordinates are centered there, about 0.9 mile southeast of the mouth of All Gold Creek on Fish Creek. The prospect is about 0.3 mile southeast of the center of section 3, T. 2 N., R. 3 E. of the Fairbanks Meridian.

Commodities:

Main: Au, Bi, Te

Other: Ag, Mo, W

Ore minerals: Arsenopyrite, pyrite

Gangue minerals: Calcite, quartz

Geologic description:

The rocks in the area are mainly quartz-mica schist and micaceous quartzite of the lower Paleozoic, Fairbanks Schist. The mineralization at Gil is mostly in the Cleary Sequence, which consists of calc-silicate hornfels, amphibolite, actinolite-white mica schist, felsic schist, and biotite-chlorite schist (Avalon Development Corp., 2005). The Cleary Sequence strikes northeast and dips steeply north. The metamorphic rocks are intruded by several nearby mid-Cretaceous granitic plutons.

Three phases of deformation are recognized at Gil resulting in large-scale asymmetric folds and faults trending northeast with variable dip. The oldest of these faults are low angle reverse faults. Conjugate to the northeast-striking faults are northwest-striking strike-slip faults that dip to the southwest or are vertical. Distinct, close-spaced northwest-striking near vertical joint sets cross cut nearly all lithologies and foliation. These joints are important controls to mineralization (Sims, 2015).

The mineralization at the Main Gil locality is stratabound in calc-silicate hornfels; it consists mainly of auriferous quartz and quartz-calcite veins in shear zones and in limonite-stained fractures. The veins contain 1 to 3 percent sulfides, mainly arsenopyrite. Samples show a strong bismuth-tellurium association, with some molybdenum, arsenic, and tungsten (Avalon Development Corp., 2005). Alteration is seen as an intense retrograde assemblage of calc-silicate minerals (Sims, 2015).

The North Gil locality consists of auriferous quartz veins less then 2 inches thick. The veins are in quartz-white mica schist interlayered with calcareous biotite-white mica schist, felsic schist, and marble. The veins contain less than 1 percent sulfides, mainly pyrite and arsenopyrite (Avalon Development Corp., 2005). Alteration is vein-controlled and consist of sericitc to potassic (secondary biotite) alteration along vein margins (Sims, 2015).

Alteration:

At the Main Gil alteration is seen as an intense retrograde assemblage of calc-silicate minerals. At North Gil alteration is vein-controlled and consist of sericitc to potassic (secondary biotite) alteration along vein margins (Sims, 2015).

Age of mineralization:

Probably around 92 Ma based on age of mineralization and intrusion of the nearby Fort Knox deposit (Selby and others, 2002).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins in skarns (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

The Gil prospect was acquired by Teryl Resources Corp. (Teryl) in 1989 and in 2008 was being explored as a joint venture between Teryl and Kinross Gold Corp. (Kinross) until Kinross acquired Teryl's remaining interest in Gil in 2011 (Teryl Resources Corp., 2008; Sims, 2015).

Since the early 1990s exploration work on the Gil prospect has included soil sampling, geologic mapping, rock sampling, ground magnetic and resistivity surveys, trenching, reverse circulation (RC) drilling, core drilling, airborne magnetic and electromagnetic (EM) surveys, and metallurgical testing (Avalon Development Corp., 2005). Kinross drilled 581 RC holes totaling 52,180 meters and 154 core holes totaling 21,582 meters between 1993 and 2014 (Sims, 2015).

Production notes:

None.

Reserves:

Quandt and others (2008) indicate that the Gil deposit has an indicated mineral resource to modern industry standards of 3.548 million tonnes of material with a grade of 1.03 grams of gold per tonne.

The Gil mineral resource was updated in 2015 with an indicated resource of 29,515.8 million tonnes with a grade of 0.56 grams per tonne (g/t) gold and an inferred resource at 4,026 million tonnes of material with a grade of 0.49 g/t gold. This resource was estimated using a cutoff grade of 0.21 g/t gold based on a gold price of US$1,400 per ounce (Sims, 2015).

Site name(s): Livengood; Old Smoky; Ruth Creek; Lillian Creek

Site type: Prospect

ARDF no.: LG202

Latitude: 65.5091 **Quadrangle:** LG C-4

Longitude: 148.5335

Location description and accuracy:

Since 2006, International Tower Hill Mines Ltd. has extensively studied and drilled the Livengood prospect which covers a northeast trending area at least 2 by 3 kilometers in size. The center of the area is about 0.5 mile north of Money Knob and about 0.6 mile west-northwest of the center of section 23, T. 8 N., R. 5 W.

Commodities:

Main: As, Au, Fe, Sb

Other:

Ore minerals: Arsenopyrite, cinnabar, gold, pyrite, scorodite, stibnite

Gangue minerals: Calcite, quartz

Geologic description:

In 2006, International Tower Hill Mines Ltd., began work at the Livengood prospect (Klipfel, Carew, and Pennstrom, 2009). The prospect covers a northeast-trending area at least 2 by 3 kilometers in size near Money Knob and includes several smaller and older prospects including the Griffin, Lillian Creek, Ruth Creek, and Old Smoky. Individually these older prospects are now mainly of interest for their geological relevance to the large body of mineralization that International Tower Hill has defined and was studying and drilling in 2011 (Brechtel and others, 2011).

The Lillian Creek prospect (about 0.7 mile northwest of Money Knob) consists of narrow auriferous arsenopyrite-quartz-scorodite veins in and near a limonite-stained dike in altered and contorted graywacke-argillite country rocks. Samples of the veins contained 0.5 to 48 parts per million (ppm) gold (Foster, 1968). Joesting (1942), reported a mineralized zone in a cut bank that contains stibnite and traces of cinnabar and gold. The Ruth Creek prospect (about 0.4 mile northwest of Money Knob) consists of numerous, nearly vertical quartz veinlets striking S 20-60 E, that contain pyrite and arsenopyrite (Mertie, 1918). Some of these veins assayed up to 0.58 ounce of gold per ton. The veinlets are cut by calcite veins carrying some gold and sulfides (Mertie, 1918). Contiguous mineralized zones up to 36 inches wide are in altered dolomite-calcite-quartz-sulfide rock (Foster and Chapman, 1967).

The best known of the old prospects near Money Knob is the Old Smoky prospect, about 0.3 mile north of Money Knob. Trenching near the head of Olive Creek exposed narrow, northwest-trending auriferous arsenopyrite-quartz veins near the intersection of an altered, porphyritic, biotite-monzonite dike, with a potassium feldspar-porphyry dike (Foster, 1968). The mineralization is in shale, argillite, fine-grained sandstone, and pebbly conglomerate (Allegro, 1984; Athey, Szumigala, and others, 2004; Athey, Werdon, Newberry, and others, 2004; Athey, Werdon, Szumigala, and others, 2004; Athey and Craw, 2004). Narrow zones of thermal metamorphism are along sheared contacts between the sedimentary rocks and hypabyssal intrusive rocks.

Most of the intrusive rocks and some of the sedimentary host rocks at the Old Smoky prospect have experienced variable degrees of metasomatic hydrothermal alteration followed by lower-temperature supergene alteration (Allegro, 1984). Allegro described four types of hydrothermal alteration: 1) silicification, as partial to complete replacement of the host rock by a dense network of quartz veinlets

generally localized along contacts between the intrusive and sedimentary rocks; 2) sericitization, as fine- to medium-grained white mica in selvages along quartz veins, as anastomosing sericite-opaque mineral veinlets, and as patchy to massive sericitic replacement of feldspar, ferromagnesian minerals and quartz; 3) deposition of trigonal nets of needle-like rutile often associated with secondary quartz and minor feldspar; and 4) epidote +/- sericite as a replacement of calcic plagioclase and ferromagnesian minerals resulting in massive aggregates, pseudomorphs, veins, and vug fillings of epidote commonly associated with sericite, opaque minerals, and quartz.

Since the mid-1970s a succession of companies have explored the area around Money Knob (Brechtel and others, 2011). Homestake Mining Company drilled 6 holes in 1976; Occidental Petroleum drilled 6 holes in 1981; Amax Exploration drilled 3 holes in 1991 and did surface geochemistry and sampling; Placer Dome drilled 9 holes in 1995 and 1996; and Cambior Inc. explored in 2001-2002.

In 2003, AngloGold Ashanti (USA) Exploration began work and drilled 12 holes. In 2006, International Tower Hill Mines Ltd. (ITH) acquired the property from AngloGold and began an aggressive exploration program that was ongoing as of August 2011. By late 2011, ITH had drilled 550 reverse-circulation holes and 94 core holes, covered the property with several geochemical surveys as well as by aerial and ground geophysical surveys, and collected and analyzed a multitude of samples. They have also commissioned a series of twelve, detailed, increasingly sophisticated 43-101 reports that describes the geology in detail, lays out development scenarios for the property, and for some years has quantified the resources of the property. The latest of these is by Brechtel and others (2011); the earlier ITH 43-101 reports that are largely superseded by it are included in the reference list. Almost all of the description that follows comes from those reports. As of late 2011, ITH had outlined a deposit that they propose to mine from a large open pit about 3,000 feet long and 1,500 feet wide.

The oldest rocks at the prospect are late Proterozoic to early Paleozoic basalt, mudstone, chert, dolomite, and limestone of the Amy Creek sequence. A Cambrian ophiolite sequence of mafic and ultramafic rocks is in thrust contact above the Amy Creek sequence. The ophiolitic rocks are overlain by Devonian shale, siltstone, conglomerate, and volcanic and volcaniclastic rocks; the Devonian rocks are the main host for the mineralization. The Devonian rocks are overthrust by more Cambrian ophiolitic rocks. All are intruded by 92 to 93 Ma (Cretaceous) monzonite, diorite, and syenite stocks, dikes, and sills that are considered to be genetically related to the mineralization. The host rocks are part of fold-thrust belt of Paleozoic and/or Cretaceous age and the complex thrust-fold architecture is apparently the key to the emplacement of the Cretaceous stocks, sills, and dikes, and forms the pathways for the mineralizing hydrothermal fluids.

The mineralization occurs in two styles: as multiphase quartz veins spread through the ore body, and as disseminated ore minerals. The disseminated low-grade mineralization is pervasive; many of the drill holes are mineralized for 50 percent or more of their length. The stages of mineralization from early to late are: 1) intrusion of feldspar porphyry dikes and sills; 2) arsenopyrite-pyrite-gold mineralization accompanied by biotite alteration; 3) arsenopyrite-pyrite-gold mineralization accompanied by albite-quartz alteration; 4) arsenopyrite-pyrite-gold mineralization accompanied by sericitic alteration; and 5) late stibnite-gold mineralization accompanied by propylitic alteration and the intrusion of late, biotite porphyry dikes and sills.

As of August, 2011, at a cutoff grade of 0.22 gram of gold per tonne, the Livengood deposit has a measured and indicated resource of 933 million tonnes with an average grade of 0.55 gram of gold per tonne (or 16.5 million ounces of gold). At the same cutoff, there is an additional inferred resource of 257 million tonnes with an average grade of 0.50 gram of gold per tonne. The estimation of a reserve was not possible at that time.

In October 24, 2016, International Tower Hill Mines Ltd. (ITH) released a prefeasibility study for its advanced-exploration-stage, Livengood gold project (Hardie and others, 2016). ITH’s initial, proposed optimized project configuration includes a conventional surface mine utilizing large-scale mining equipment in a blast/load/haul operation. Mill feed would be processed in an estimated 47,700 tonne-per-day comminution circuit consisting of primary and secondary crushing, wet grinding in a single semi-autogenous (SAG) mill and single ball mill, and followed by a gravity gold circuit and a conventional carbon-in-leach circuit. The prefeasibility study’s mine plan is estimated to provide sufficient ore (life-of-mine gold head grade of 0.71 gram of gold per tonne) to support an average annual production rate during years 1-5 of 378,300 ounces of gold per year, and an annual production rate of approximately 294,100 ounces of gold per year over an estimated 23-year mine life, producing a total of approximately 6.8 million ounces of gold.

On December 28, 2016, International Tower Hill Mines Ltd. announced the closing of a non-brokered, private-placement financing of $22.0 million, with Paulson & Co. Inc., Tocqueville Asset Management, L.P., and AngloGold Ashanti (U.S.A.) Exploration Inc. owning 34.2, 19.7, and 9.5 percent of ITH shares, respectively. ITH intends to use the net proceeds of the private placement for full satisfaction of the final payment due in January 2017 for acquisition of certain mining claims and related rights in the vicinity of the Livengood gold project (approximately $14.7 million), continuation of optimization studies to further improve and de-risk the project, required environmental baseline studies, and for general working capital purposes. ITH's 2017 work program is designed to follow up on improvements outlined in their prefeasibility study (Athey and Werdon, 2017).

Alteration:

From early to late in the mineralization process, it is associated with a sequence of biotite alteration, albite-quartz alteration, sericitic alteration, and porphyritic alteration.

Age of mineralization:

Associated with and probably genetically tied to 92-93 Ma porphyry dikes, sills, and plugs.

Generic deposit model:

Deposit model:

Intrusion-related gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Since well before WWII, several small prospects were known in the area that would become this prospect; these include the Griffin, Lillian Creek, Ruth Creek, and Old Smoky prospects. Beginning in the mid-1970s, a succession of companies have explored the area around Money Knob by mapping, and geochemical and geophysical surveys in the search for a large, bulk-mineable gold deposit (Brechtel and others, 2011). Homestake Mining Company drilled 6 holes in 1976; Occidental Petroleum drilled 6 holes in 1981; Amax Exploration drilled 3 holes in 1991; Placer Dome drilled 9 holes in 1995 and 1996; and Cambior Inc. explored in 2001 and 2002.

In 2003, AngloGold Ashanti (USA) Exploration began work and drilled 12 holes. In 2006, International Tower Hill Mines Ltd. (ITH) acquired the property from AngloGold and began an aggressive exploration program that was ongoing as of August 2011. By late 2011, ITH had drilled 550 reverse-circulation holes and drilled 94 core holes; covered the property with several geochemical surveys as well as by aerial and ground geophysical surveys; and collected and analyzed a multitude of samples. They have also commissioned a series of twelve, detailed, increasingly sophisticated 43-101 reports that among other things discuss the geology in detail, lay out development scenarios for the property, and quantify the resources of the prospect.

Production notes:

None.

Reserves:

As of August, 2011, at a cutoff grade of 0.22 gram of gold per tonne, the Livengood deposit has a measured and indicated resource of 933 million tonnes with an average grade of 0.55 gram of gold per tonne (or 16.5 million ounces of gold). At the same cutoff, there is an additional inferred resource of 257 million tonnes with an average grade of 0.50 gram of gold per tonne. The estimation of a reserve was not possible

at that time.

As of August 2016, the Livengood gold project's mineral resource, based on 783 drill holes totaling 218,674 m, is estimated at 497.3 million measured tonnes at an average grade of 0.68 gram of gold per tonne (10.84 million ounces), and 28.0 million indicated tonnes at an average grade of 0.69 gram of gold per tonne (0.62 million ounces), for a total measured and indicated resource of 525.4 million tonnes at an average grade of 0.68 gram of gold per tonne (11.5 million ounces). Inferred resources include 52.8 million tonnes at an average grade of 0.66 gram of gold per tonne (1.1 million ounces). A portion of these mineral resources have been converted into proven reserves (measured mineral resources contained within the pit shape, above cut-off grades) of 377.7 million tonnes at an average grade of 0.71 gram of gold per tonne (8.62 million ounces) and probable reserves (indicated mineral resources contained within pit designs, above cut-off grades) of 14.0 million tonnes at an average grade of 0.72 gram of gold per tonne (0.353 million ounces), for total proven and probable reserves of 391.7 million tonnes at an average grade of 0.71 gram of gold per tonne (8.97 million ounces) (Hardie and others, 2016).

Reporter(s): D.J. Grybeck (Contractor, USGS); M.B. Werdon (DGGS)

Last report date: 2017-08-26

Site name(s): Shorty Creek; Hill 1710

Site type: Prospect

ARDF no.: LG203

Latitude: 65.4516 **Quadrangle:** LG B-4

Longitude: 148.5448

Location description and accuracy:

This is the original Shorty Creek prospect that was drilled in 1972 (Freeman, 2010). Since 2005, it is one of several prospects often referred to as part of the Shorty Creek project which covers a large area and several other prospects. Conversely, in discussing the Shorty Creek project, this prospect is often referred to as the Hill 1710 prospect (e.g., in Freeman, 2010). The prospect is about 4.9 mile south of Livengood on a north-south ridge at the hill 1710 at the headwaters of Shorty Creek and Ranney Hollow 0.4 mile northeast of the center of section 10, T. 7 N., R. 5 W. of the Fairbanks Meridian.

Commodities:

Main: Ag, Cu, Mo

Other: As, Bi, Pb, Sb, Sn, W, Zn

Ore minerals: Arsenopyrite, bornite, chalcopyrite, molybdenite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The rocks in the Shorty Creek area are mainly the Lower Cretaceous Wilber Creek sequence of folded black carbonaceous siltstone, gray feldspathic sandstone and silty sandstone, black shale, and polymictic conglomerate (Albanese, 1983a; Weber and others, 1992). The sequence disconformably overlies Lower Paleozoic carbonate, volcanic, and pelitic rocks. Several small plutons, mostly of granodiorite composition, are in the Shorty Creek area. Biotite hornfels and lesser diopside hornfels is widespread. Although outcrops of the plutonic rocks crop are sparse, the widespread hornfels suggests large intrusions nearby or at depth. The structure of the area is dominated by northwest-directed, northeast-trending thrust faults and northeast-trending, open to recumbent isoclinal folds (Freeman, 2010).

The Shorty Creek prospect is in a strong geochemical soil anomaly marked by the association of silver, arsenic, bismuth, molybdenum, antimony, tungsten, copper, lead, zinc, and tin. This anomaly continues to the northeast for at least 1.4 miles to peak 1890. Operators drilling at the prospect in the 1970s concluded that the mineralization was associated with felsic dikes and sills that intrude the Cretaceous Wilber Creek sequence (Freeman, 2010).

Hill 1710 is associated with a curvilinear magnetic high that is offset by the Ranney Hollow fault in an apparent left lateral sense (Abrams, 2015). The cause of this magnetic anomaly may be related to contact metamorphism around a buried intrusive which has undergone magnetite destructive alteration or the anomaly may be from copper-gold magnetite skarn mineralization hosted in Lower Paleozoic carbonate units dipping to the south beneath the Wilber Creek sequence.

Alteration:

Alteration observed is biotite to lesser diopside hornfels related to contact metamorphism from the intrusion of several plutons (Freeman, 2010).

Age of mineralization:

Probably related to intermediate plutons, one of which has been dated at 63 Ma (Albanese, 1983a).

Generic deposit model:

Deposit model:

Copper-molybdenum porphyry system (Cox and Singer, 1986; model 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

21a

Production Status: None

Site Status: Active

Workings/exploration:

The Shorty Creek prospect was first staked for antimony in 1972 (Freeman, 2010). Some additional sampling soon led to the concept that it was a copper-molybdenum deposit in a large aeromagnetic anomaly. Earth Resources Inc. staked the property and drilled 10 holes in 1972 on the south slope of Hill 1710, possibly in a joint venture with BP Minerals. Eakins (1974) collected four grab samples from drill cuttings left at the Earth Resources drill pads. The samples contained 170 to 1,050 parts per million (ppm) copper, 20 to 60 ppm lead, 105 to 640 ppm zinc, less than 0.2 to 1.1 ppm silver, and less than 100 parts per billion (ppb) gold.

There has been no further drilling on this Shorty Creek prospect. However, there is a long history of geologic mapping, geochemical sampling, aerial and ground geophysical surveys by industry and government, including drilling at one nearby prospect (Freeman, 2010). After the discovery of mineralization in 1979 along the Alyeska Pipeline service road about 2.5 miles south of the Hill 1710 prospect (Robinson and Metz, 1979), there was considerable interest and drilling at the Hill 1835 prospect (LG209) about 1.7 miles southeast of the Hill 1710 prospect. The area was largely dormant from 1990 to 2005.

In 2005, Select Resources leased a large block of claims, staked more, and in 2010 they held several large blocks that totaled more than 300 claims and included several other prospects (Freeman, 2010). In 2005, they did considerable rock and soil sampling on their claims which they collectively call the Shorty Creek project or just Shorty Creek.

Freegold Ventures Limited (Freegold) completed 28.6 kilometers of induced polarization (IP) surveying and collected 354 soil samples in 2014 covering the prospect areas of Hill 1710 and Hill 1835 (LG209). Soil samples with anomalous copper and molybdenum were associated with lower chargeabilities over Hill 1710 (Abrams, 2015).

Freegold Ventures Limited’s 2016 drilling program at their intrusion-related Shorty Creek property included 7 holes totaling 3,038 m; 2 holes were drilled in the 'Hill 1835' area, and 5 holes were drilled in the '1710' area to test copper-molybdenum targets. ‘Hill 1835’ mineralization is spatially associated with a magnetic high defined by airborne- (Burns and others, 2015) and ground-based surveys, as well as magnetic highs in inverted profiles. Drilling highlights include 434.5 meters averaging 0.57 percent copper-equivalent, and 409.6 meters averaging 0.41 percent copper-equivalent. In the ‘1710’ area, 5 drill holes totaling 2,019.8 m, tested a copper-molybdenum soil anomaly and magnetic high. Drill hole SC 16-07 intersected 0.11 percent copper and 0.011 percent molybdenum from 0-159 m, including 0.15 percent copper and 0.009 percent molybdenum from 0-70.8 meters within quartz-feldspar porphyry. The entire 396-meter-long drill hole averaged 0.08 percent copper and 0.006 percent molybdenum. Additionally, Freegold conducted new ground-based geochemical sampling, geophysical surveys, and claim staking in 2016, and identified the new Quarry and Steel Creek target areas (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Additional comments:

The new Steel Creek geophysically defined target does not correspond to ARDF description LG027 (Steel Creek).

Site name(s): Coffee Dome

Site type: Prospect

ARDF no.: LG204

Latitude: 65.0957 **Quadrangle:** LG A-1

Longitude: 147.0827

Location description and accuracy:

The Coffee Dome prospect is on a large block of claims that cover about 16 square miles. However, most of the known mineralization is in an elongate north-trending area about 0.8 mile long and 0.3 mile wide near the center of section 11, T. 2 N., R. 3 E. The coordinates are at about the center of this area, about 2 miles east of Coffee Dome. The location is accurate.

Commodities:

Main: Au, Bi, Te

Other: Cu, Pb, Sb, Zn

Ore minerals: Arsenopyrite

Gangue minerals: Quartz

Geologic description:

In early 2010, the Coffee Dome prospect was being explored by International Tower Hill Mines, Ltd. (2008) who staked the property from 2004 to 2006. Through 2006, the work on the property was mainly stream sediment and soil geochemical surveys and some sampling of surface mineralization. The property was first identified from anomalous gold, tellurium, and bismuth geochemical anomalies and mineralized samples collected at the surface. The mineralized samples consist of banded quartz veins 10 to 30 cm thick with scorodite and occasionally arsenopyrite. During 2007, International Tower Hill (2007) dug several trenches over the main target area that exposed veins with grades of up to 168 grams of gold per tonne and high silver, arsenic, antimony, bismuth, and tellurium. Soil surveys defined two large areas anomalous in gold that are thought to reflect a large gold system over 3 kilometers long and 1 kilometer wide. They consider the deposit analogous to the Pogo mine (BD033) and probably close to an intrusive source. The rocks in the area consist mainly of middle to early Paleozoic and(or) Late? Proterozoic quartz and pelitic schist of the Yukon-Tanana Upland (Wilson and others, 1998).

In 2009, International Tower Hill Mines (2009) drilled 5 holes on the Coffee Dome project. The holes targeted a northeast-trending structural zone that is marked at the surface by resistivity and soil-geochemistry anomalies. Multiple thick zones of low-grade gold mineralization were cut. Notable intercepts were 17 meters with 0.3 gram of gold per tonne and 22 meters with 0.21 gram of gold per tonne. Few sulfides were seen in the holes.

Alteration:

No data.

Age of mineralization:

Generic deposit model:

Deposit model:

Arsenopyrite-gold-quartz veins with tellurium and bismuth.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In early 2010, the Coffee Dome prospect was being explored by International Tower Hill Mines, Ltd. (2008) who staked the property from 2004 to 2006. Through 2006, the work on the property was mainly stream sediment and soil geochemical surveys and some sampling of surface mineralization. During 2007, International Tower Hill (2007) dug several trenches that exposed mineralization and they extended their soil surveys. They drilled 5 holes in 2009.

Production notes:

None.

Reserves:

None.

Additional comments:

The claims that cover the Coffee Dome prospect are both State of Alaska mining claims and land leased from the University of Alaska; as of 2007, most of the known mineralization is on the University of Alaska lands.

Site name(s): Cleary Hill (Freegold)

Site type: Mine

ARDF no.: LG205

Latitude: 65.065 **Quadrangle:** LG A-1

Longitude: 147.4387

Location description and accuracy:

This record covers an area about 3,000 feet long and several thousand feet wide, centered about 0.2 mile south of the Cleary Hill Mine buildings near the mouth of Bedrock Creek. The site represents a major exploration program by Freegold Ventures Ltd. that began in 1996 and was ongoing in 2008 (Freeman, 2008). The area includes several old prospects and the Cleary Hill Mine (LG114-116 and LG118-121) that were previously described individually in ARDF. These individual records are retained in ARDF for their geologic detail and history. The work by Freegold, however, has revealed much new mineralization in the area and the company now interprets the deposits in the area as a single system of veins, what they call the 'Cleary Hill vein swarm'.

Commodities:

Main: Ag, Au

Other: Ag, As, Au, Cu, Sb, Pb, Zn

Ore minerals: Arsenopyrite, boulangerite, jamesonite, pyrite, stibnite, tetrahedrite

Gangue minerals: Quartz

Geologic description:

The ARDF record for the Cleary Hill Mine (LG119) gives many of the details of the mining and geology of the best known and most productive of the deposits within this site. To summarize from Freeman (2008), the Cleary Hill Mine produced about 281,000 ounces of gold from 1908 to 1942 at an average grade of about 1.3 ounces of gold per ton. The mineralization consists of quartz veins with varying amounts of arsenopyrite, pyrite, boulangerite, jamesonite, tetrahedrite, and stibnite. The veins cut interbedded Paleozoic volcanic rocks, quartzite, and quartz mica schists on the north flank of the Cleary antiform. Most of the production was from the Cleary Hill vein system that strikes about N70-80W and dips about 45-70 degrees south. The system consists of a set of subparallel veins that were exposed on 6 levels. Regionally, the deposit is part of a east-northeast-trending mineral belt at least six miles long that is related to a series of parallel, northeast-trending fault zones spaced about 8,000 feet apart. The mineralization is middle Cretaceous (McCoy and others, 1997).

Although it was examined intermittently by several generations of geologists, there was little exploration in the area from 1942 to 1996. In 1996, Freegold Ventures Ltd., drilled 7 reverse-circulation holes that totaled 2,080 feet. The drilling confirmed that the mineralization at the Cleary Hill Mine persisted below the lowest underground workings. In 1997 and 1998, they core drilled another 9 holes. Geochemical soil sampling indicated that the mineralization was much more extensive than just in the old mine workings. In 2000, one hole cut a previously unknown, mineralized shear zone, the Currey Zone. The Currey mineralization is marked by pervasive quartz veining and sericitic alteration and consists of coarse-grained pyrite and fine-grained sulfides and sulfosalts in the quartz. Several intercepts are characterized by a strong arsenic and antimony signature. In 2002, Freegold did 4.5 line miles of ground geophysical surveys. From 2002 to 2006, Freegold drilled at least 6 more core holes and dug several thousand feet of trenches over the Cleary Hill Mine workings and adjacent areas; this revealed many new veins and mineralized shear zones. In 2006, they collected 9,900 tons of bulk samples from surface exposures of 8 separate auriferous shear

zones, to analyze and characterize the ore. They also collected 3,000 tons of material from the old mine dumps. Encouraging results from these samples led to a major drilling program beginning in December, 2006; it included 504 rotary-air-blast holes that totaled 28,602 feet along 14 fences of holes. The detailed results of this drilling and other Freegold exploration since 1996 is available in Freeman (2008).

As a result of this work, Freeman (2008) has outlined a system of pervasive mineralization and veins-many previously unrecognized -that extend for over 3,000 feet along strike to a depth of 1,000 feet. The mineralization is open at both ends and at depth. The mining before WWII was mainly on a few structurally continuous, high-grade quartz veins in a master shear zone. The newly revealed mineralization is much more extensive and structurally complex, featuring both pre- and post-mineralization faulting and several stages of deposition. Consequently, it is difficult to correlate the veins mined underground at the Cleary Hill Mine with those those newly discovered in the recent surface workings and drill holes.

Alteration:

Sericitic alteration adjacent to the quartz veins.

Age of mineralization:

Middle Cretaceous by analogy with other mineralization in the area.

Generic deposit model:

Deposit model:

Gold-arsenic-antimony quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; medium

Site Status: Active

Site name(s): Saddle (Freegold)

Site type: Prospect

ARDF no.: LG206

Latitude: 65.0659

Quadrangle: LG A-1

Longitude: 147.3613

Location description and accuracy:

The Saddle prospect as defined by Freegold Ventures Ltd. in 2008 includes a number of prospects and the McCarty Mine (LG150-156) that were previously described individually in ARDF and these records have been retained for their geologic details and history. The center of the prospect is on the ridge at the head of Fairbanks Creek about 0.2 mile west-northwest of the McCarty Mine as shown on the U.S. Geological Survey, Livengood A-1, 1:63,360-scale topographic map.

Commodities:

Main: Ag, As, Au, Pb, Sb

Other:

Ore minerals: Arsenopyrite, boulangerite, gold, jamesonite, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

The Saddle prospect as defined by Freegold Ventures Ltd. in 2008 (Freeman, 2008) includes several old prospects and the McCarty Mine (LG150-156). These were previously described individually in ARDF and these records are retained for their geologic detail and history. The older ARDF record for the Saddle prospect (LG151) is particularly informative.

Placid Oil explored the property from 1978 to 1994 and drilled at least 23 core holes, but the results were more generally indicative of mineralization than defining ore reserves (see LG152). As of early 2008, Freegold has mainly conducted reconnaissance, surface sampling, and has examined the numerous old records in anticipation of future drilling and trenching.

Freeman (2008) redefines the Saddle prospect is a 'vein swarm' that includes several prospect and small mines (LG150-151 and LG153-156) and the McCarty (American Eagle) Mine (LG152), which produced about 60,000 ounces of gold prior to WWII from ore that contained about 1.6 ounces of gold per ton. The vein swarm at Saddle has the highest density of parallel veins along the Cleary Hill mineral belt; it extends for about 3,500 feet along strike and has a minimum width of 2,500 feet. The Saddle prospect is at the intersection of the swarm of northwest-trending, high-grade gold-quartz veins and a district-scale northeast-trending fault structure. The veins are in altered Paleozoic quartz-sericite schist; they contain variable amounts of arsenopyrite, pyrite, stibnite, native gold, boulangerite, and jamesonite. The sulfides in the veins are oxidized to a depth of at least 310 feet. Drilling has verified that the mineralization persists to a depth of at least 650 feet and remains open in all directions.

Alteration:

Age of mineralization:

Mid-Cretaceous by analogy with other mineralization in the area.

Generic deposit model:

Deposit model:

Quartz veins with arsenopyrite, As-Sb sulfosalts, and stibnite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Saddle prospect as defined by Freegold Ventures Ltd. in 2008 (Freeman, 2008) includes several old prospects and the McCarty Mine (LG150-156). These were previously described individually in ARDF and these records are retained for their geologic detail and history. The older ARDF record for the Saddle prospect (LG151) is particularly informative.

Placid Oil explored the property from 1978 to 1994 and drilled at least 23 core holes, but the results were more generally indicative of mineralization than defining ore reserves (see LG152). As of early 2008, Freegold has mainly conducted reconnaissance, surface sampling, and has examined the numerous old records in anticipation of future drilling and trenching.

Production notes:

The McCarty/American Eagle Mine in the Freegold prospect area produced about 60,000 ounces of gold prior to WWII; several of the other deposits produced small amounts of ore that was processed through the McCarty mill. There has been no production since 1942.

Reserves:

None by modern reserve standards.

Site name(s): Tolovana (Freegold)

Site type: Mine

ARDF no.: LG207

Latitude: 65.0634 **Quadrangle:** LG A-1

Longitude: 147.4504

Location description and accuracy:

The Tolovana prospect is an area of extensive exploration by Freegold Ventures Ltd. that began in 1996 within the Golden Summit Project. The area includes several old prospects and the Tolovana Mine (LG105-106, LG109-110, and LG112) that were previously described individually in ARDF. The location is accurate to within 100 feet.

Commodities:

Main: Ag, Au, Sb

Other: Cu, Pb

Ore minerals: Arsenopyrite, boulangerite, galena, gold, jamesonite, sphalerite, stibnite, tetrahedrite

Gangue minerals: Quartz

Geologic description:

The ARDF record for the Tolovana Mine (LG100) gives the details of the mining and geology of the best known and most productive of the deposits in this site. To summarize (from Freeman, 2008), the Tolovana Mine produced about 5,000 ounces of gold prior to 1942. The mineralization consists of quartz veins and stockworks with varying amounts of arsenopyrite, pyrite, boulangerite, jamesonite, tetrahedrite, and stibnite. The country rocks are Paleozoic volcanic rocks, quartzite, and garnet-biotite schist on the north flank of the Cleary antiform. The middle Cretaceous Dolphin granodiorite pluton outcrops over an area about 2,000 feet long and 1,000 feet wide on the south side of the prospect. Regionally, the deposit is part of a east-northeast-trending mineral belt at least six miles long that is related to a series of parallel, northeast-trending fault zones, spaced about 8,000 feet apart. It is also probably continuous with the mineralization at the adjacent Cleary Hill (Freegold) deposit (LG205) to the north. The mineralization is middle Cretaceous (McCoy and others, 1997).

Although the Dolphin intrusive was drilled from 1994 to 1996 and in 1998, there was little exploration of the quartz veins on the prospect from 1941 to 2004. In 2004, Freegold Ventures Ltd., dug 1,790 feet of trenches and drilled 7 core holes that totaled 3,584 feet. The 2004 drilling indicated that the mineralization is a stockwork deposit. In the eastern part of the prospect it is in metamorphic rocks; in the central and western parts it is in the Dolphin intrusive. In 2007, Freegold contracted an extensive drilling program using rotary-air-blast equipment; 170 holes were drilled, totaling 11,449 feet. Numerous samples had significant gold values. The detailed results of this drilling are available in Freeman (2008).

On the basis of their work, Freegold has defined at least two subparallel mineralized structures, the Tolovana Mine structure and the Scheuyemere vein structure, that extend east-northeast more than 1,900 feet from the old Tolovana Mine (LG110). The mineralization is open at both ends and at depth. The mining before World War II was mainly on a few structurally continuous, high-grade quartz veins in a master shear zone. Recent work indicates that the mineralization is much more extensive and structurally complex, complicated by multiple generations of folding, faulting, and mineralization. The extent of the stockwork-type mineralization in the Dolphin intrusive is unknown.

Alteration:

Chloritization, kaolinitization, silicification and sericitization. Carbonate alteration, as calcite or less commonly dolomite or iron carbonate, is found locally (Abrams and Giroux, 2013).

Age of mineralization:

Unknown, but perhaps 88.3-90.1 Ma inferred from Ar40/Ar39 radiometric age dates of two sericite samples representing two distinctly different styles of gold mineralization (Abrams and Giroux, 2013).

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Although the Dolphin intrusive was drilled from 1994 to 1996 and in 1998, there was little exploration of the quartz veins on the prospect from 1941 to 2004. In 2004, Freegold Ventures Ltd., dug 1,790 feet of trenches and drilled 7 core holes that totaled 3,584 feet. In 2007, Freegold contracted an extensive drilling program using rotary-air-blast equipment; 170 holes were drilled, totaling 11,449 feet. Numerous samples had significant gold values.

In 2010 a ground based geophysical survey was conducted (Abrams and Giroux, 2013).

In 2011, Freegold completed its first NI-43 101 compliant resource calculation using previous drilling completed in the Dolphin/Tolovana area. Ground-based induced polarization (IP) geophysics and shovel soil sampling was also performed in 2011 (Abrams and Giroux, 2013).

In 2012, the NI-43 101 compliant resource was updated; the zone used in the calculation was deepened and extended to the northeast to include the Clearly Hill area (Abrams and Giroux, 2013).

In 2013, Freegold drilled 10 holes of 11,392 feet and updated the NI-43 101 compliant resource again (Abrams and Giroux, 2013).

Production notes:

None.

Reserves:

The 2013 resource estimate at the Dolphin/Cleary Zone is as follows: Indicated resource (total): With a gold cut-off of 0.30 gram per tonne, 79,800,000 tonnes of 0.66 gram of gold per tonne; contained 1,683,000 ounces gold. Inferred resource (total): With a gold cut-off of 0.30 gram per tonne, 248,060,000 tonnes of 0.61 gram of gold per tonne; contained 4,841,000 ounces gold. (Abrams and Giroux, 2013).

Additional comments:

The Tolovana prospect is an area of extensive exploration by Freegold Ventures Ltd. that began in 1996 within the Golden Summit Project. The area includes several old prospects and the Tolovana Mine (LG105-106, LG109-110, and LG112) that were previously described individually in ARDF. These individual records are retained in ARDF for their geologic detail and history. The work by Freegold, however, has revealed much new mineralization in the area and the company now interprets the deposits in the area as a single system of veins, that they call the 'Cleary Hill vein swarm'.

Site name(s): Hill 1870; Shorty Creek

Site type: Prospect

ARDF no.: LG208

Latitude: 65.4169 **Quadrangle:** LG B-4

Longitude: 148.5326

Location description and accuracy:

The Hill 1870 prospect is on hill 1870 about 0.5 mile southwest of the head of Shorty Creek. It is about 7.3 miles south of Livengood, about 0.5 mile west-southwest of the center of section 23, T. 7 N., R. 5 W., and about 0.2 miles west of the Alyeska Pipeline service road.

Commodities:

Main: Ag, As, Au, Cu, Mo

Other: Bi, Pb, Sb, Sn, W, Zn

Ore minerals: Arsenopyrite, bornite, chalcopyrite, gold, molybdenite, pyrite, pyrrhotite, stibnite

Gangue minerals: Quartz

Geologic description:

There is a long history of exploration by industry and government at and around this prospect on large blocks of claims that cover much of the area south of the Tolovana River in the Shorty Creek-Ranney Hollow-Steel Creek- Wilbur Creek area. Freeman (2010) describes the extensive mapping, sampling, and geophysical and geochemical surveys in this area. The exact chronology of this prospect is unclear but it known by 1985 and probably was discovered, mapped and sampled in conjunction with work at the Hill 1835 prospect (LG209) (Freeman, 2010). At the Hill 1870 prospect, hornfelsed flysch of the Wilbur unit, iron-oxide cemented breccia, and strongly altered crackle breccia were found on the flanks of hill 1870. Samples contain less than 69 to 1,063 parts per billion gold, 0.7 to 5.8 parts per million (ppm) silver, and 160 to more than 1,000 ppm arsenic. The mineralization is probably the same as that at the better known Hill 1835 prospect (LG209) prospect about a mile to the northeast. The Hill 1835 prospect was drilled in 1989 and 1990. The core from that drilling shows disseminated and fracture controlled pyrite, pyrrhotite, chalcopyrite, arsenopyrite, and bornite. The most intense hydrothermal alteration in this area is at the nearby Hill 1835 prospect (LG209). In addition to widespread biotite-diopside hornfels, late vein and flood silicification is accompanied by variable crackled to matrix supported brecciation. Widespread pervasive sericite (?) or clay (?) alteration overprints all other alteration and mineralization, giving the rocks a pale yellow to tan bleached appearance.

The area was largely dormant from 1990 to 2005. In 2005, Select Resources leased a large block of claims, staked more, and as of 2010 they held several large blocks that totaled more than 300 claims and include several other prospects including this, the original Shorty Creek prospect (Freeman, 2010). In 2005, they did considerable rock and soil sampling on their claims which they collectively call the Shorty Creek project or just Shorty Creek.

The hills south of the Tolovana River in this area are covered with sub-Arctic forest and loess; outcrop is sparse. The rocks in the area are mainly the Lower Cretaceous Wilbur Creek sequence of folded black carbonaceous siltstone, gray feldspathic sandstone and silty sandstone, black shale, and polymictic conglomerate (Albanese, 1983 [Bedrock geology]; Weber and others, 1992). The sequence disconformably overlies Lower Paleozoic carbonate, volcanic, and pelitic rocks. Several small plutons, mostly of granodiorite composition, are in the Shorty Creek area. Biotite hornfels and lesser diopside hornfels is widespread. Although outcrops of the plutonic rocks crop are sparse, the widespread hornfels suggests large

intrusions nearby or at depth. The structure of the area is dominated by northwest-directed, northeast-trending thrust faults and northeast-trending, open to recumbent isoclinal folds.

Freeman (2010) notes that others consider the prospects in the Shorty Creek area to be intrusive-related gold (IRG) deposits. However, he concludes that the Shorty Creek mineralization is more likely a large copper-gold-molybdenum porphyry system about 8 miles in diameter. This system is manifested in three main types of deposits: 1) proximal copper-gold-molybdenum mineralization as seen in the old Shorty Creek deposit (HG203); 2) high-sulfidation epithermal gold-arsenic-bismuth-tungsten+/-copper+/-silver mineralization as seen at the Hill 1835 prospect (HG209); and 3) intermediate sulfidation epithermal gold-silver-lead-zinc+/-arsenic+/-antimony+/-manganese mineralization as seen on the ridge south of Wilbur Creek.

Alteration:

The most intense hydrothermal alteration in the area occurs at the nearby Hill 1835 prospect (HG New H1004). In addition to widespread biotite-diopside hornfels, late vein and flood silicification is accompanied by variable crackled to matrix-supported brecciation. Widespread pervasive sericite (?) or clay (?) alteration overprints all other alteration and mineralization giving the rocks a pale yellow to tan bleached appearance.

Age of mineralization:

Probably related to intermediate plutons, one of which has been dated at 63 Ma. A white mica from a drill hole at the nearby Hill 1835 prospect (HG New H1004) gave a Ar40/Ar39 age of 65-70 Ma.

Generic deposit model:

Deposit model:

Part of a copper-gold-molybdenum porphyry system (Cox and Singer, 1986; model 20c or 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c or 21a

Production Status: None

Site Status: Active

Site name(s): Hill 1835; Shorty Creek

Site type: Prospect

ARDF no.: LG209

Latitude: 65.4309 **Quadrangle:** LG

Longitude: 148.5136

Location description and accuracy:

This prospect is on hill 1835 about 0.5 mile northeast of the head of Shorty Creek and about 7 miles south-southeast of Livengood. Since 2005, it is one of several prospects often referred to as part of the Shorty Creek project which covers a large area and several other prospects. It is southeast quarter of section 14, T. 7 N., R. 5 W of the Fairbanks Meridian. The location is accurate with a quarter mile.

Commodities:

Main: Au, Cu

Other: As, Bi, Pb, Sb, Sn, W, Zn

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The hills south of the Tolovana River in this area are covered with sub-Arctic forest and loess; outcrop is sparse; however at the Hill 1835 prospect there is an absence of vegetation which is attributed to acidic soils and metal toxicity (Abrams, 2015). The rocks in the area are mainly the Lower Cretaceous Wilber Creek sequence of folded black carbonaceous siltstone, gray feldspathic sandstone and silty sandstone, black shale, and polymictic conglomerate (Albanese, 1983a; Weber and others, 1992). The sequence disconformably overlies Lower Paleozoic carbonate, volcanic, and pelitic rocks. Several small plutons, mostly of granodiorite composition, are in the Shorty Creek area. Biotite hornfels and lesser diopside hornfels is widespread. Although outcrops of the plutonic rocks are sparse, the widespread hornfels suggests large intrusions nearby or at depth.

The most intense hydrothermal alteration occurs at the Hill 1835 prospect. In addition to widespread biotite-diopside hornfels, late vein and silica flooding is accompanied by variable crackled to matrix-supported brecciation. Widespread pervasive sericite (?) or clay (?) alteration overprints all other alteration and mineralization giving the rocks a pale yellow to tan bleached appearance. The area is dominated by northwest-directed, northeast-trending thrust faults and northeast-trending, open to recumbent isoclinal folds (Freeman, 2010). Mineralization at the Hill 1835 prospect appears to be bound by northeast striking faults and part of the same structural zone exposed over one mile to the southwest on the Alyeska Pipeline access road where a shear zone several hundred feet wide contains intense brecciation, silicification, and gold-sulfide mineralization, including arsenopyrite, stibnite, galena, and chalcopyrite. Rubble and outcrop at Hill 1835 contain hornfels with large (1 centimeter) cubic molds of pyrite, often partially filled with limonite. Drill chips contain disseminated and fracture-controlled pyrite, pyrrhotite, chalcopyrite, arsenopyrite, and bornite. Vuggy, barren, stockwork quartz veins cut grain-supported and matrix-supported breccias and appear to be the last phase of silicification (Abrams, 2015). Gold values from drill holes at Hill 1835 drilled in 1989 were higher in the hornfels in the upper 100 to 150 feet of drilling while copper values were higher outside the hornfels particularly near the bottom of some holes.

Alteration:

The most intense hydrothermal alteration in the area occurs at this prospect. In addition to widespread

biotite-diopside hornfels, late vein and silica flooding is accompanied by variable crackled to matrix-supported brecciation. Widespread pervasive sericite (?) or clay (?) alteration overprints all other alteration and mineralization giving the rocks a pale yellow to tan bleached appearance (Freeman, 2010).

Age of mineralization:

Probably related to intermediate plutons, one of which has been dated at 63 Ma. A white mica from a drill hole gave a 40Ar/39Ar age of 65 to 70 Ma (Albanese, 1983a).

Generic deposit model:

Deposit model:

Copper-gold porphyry system (Cox and Singer, 1986; model 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

There is a long history of exploration by industry and government at and around this prospect. Freeman (2010) describes the extensive mapping, sampling, and geophysical and geochemical surveys in this area. In 1979, massive sulfide as much as 5 inches thick were found in roadcuts along the Alyeska Pipeline service road about a half mile southwest of Hill 1835 (Robinson and Metz, 1979). This led to extensive soil and rock sampling in the area by Fairbanks Exploration Inc. (FEI).

In 1989 and 1990, FEI and Asarco Ltd. drilled 20 reverse-circulation holes that totaled 6,843 feet at this prospect. Numerous intercepts of up to 500 feet were cut that contained more than 0.1 part per million (ppm) gold; some notable intercepts were 125 feet that contained 1.776 ppm gold and 25 feet that contained 4.577 ppm gold (Freeman, 2010). The core from the 1989 to 1990 drilling shows disseminated and fracture controlled pyrite, pyrrhotite, chalcopyrite, arsenopyrite, and bornite.

The area was largely dormant from 1990 to 2005. In 2005, Select Resources leased a large block of claims, staked more, and as of 2010 they held several large blocks that totaled more than 300 claims and included several other prospects (Freeman, 2010). In 2005, they did considerable rock and soil sampling on their claims which they collectively call the Shorty Creek project or just Shorty Creek.

Freegold Ventures Limited (Freegold) completed 28.6 kilometers of induced polarization (IP) surveying and collected 354 soil samples in 2014 covering the prospect areas of Hill 1835 and Hill 1710 (LG203). A resistivity high at Hill 1835 represents the silicified hornfels and is associated with a gold-arsenic-bismuth-copper soil anomaly (Abrams, 2015).

Freegold Ventures Limited’s 2016 drilling program at their intrusion-related Shorty Creek property included 7 holes totaling 3,038 m; 2 holes were drilled in the ‘Hill 1835’ area, and 5 holes were drilled in the ‘1710’ area to test copper-molybdenum targets. ‘Hill 1835’ mineralization is spatially associated with a magnetic high defined by airborne- (Burns and others, 2015) and ground-based surveys, as well as magnetic highs in inverted profiles. Drilling highlights include 434.5 meters averaging 0.57 percent copper-equivalent, and 409.6 meters averaging 0.41 percent copper-equivalent. In the ‘1710’ area, 5 drill holes totaling 2,019.8 m, tested a copper-molybdenum soil anomaly and magnetic high. Drill hole SC 16-07 intersected 0.11 percent copper and 0.011 percent molybdenum from 0-159 m, including 0.15 percent copper and 0.009 percent molybdenum from 0-70.8 meters within quartz-feldspar porphyry. The entire 396-meter-long drill hole averaged 0.08 percent copper and 0.006 percent molybdenum. Additionally, Freegold conducted new ground-based geochemical sampling, geophysical surveys, and claim staking in 2016, and identified the new Quarry and Steel Creek target areas (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Additional comments:

The new Steel Creek geophysically defined target does not correspond to ARDF description LG027 (Steel Creek).

Other:

Ore minerals:

Gangue minerals:

Geologic description:

There is a long history of exploration by industry and government at and around this prospect on large blocks of claims that cover much of the area south of the Tolovana River in the Shorty Creek-Ranney Hollow-Steel Creek- Wilbur Creek area. Freeman (2010) describes the extensive mapping, sampling, and geophysical and geochemical surveys in this area. The only direct evidence of lode mineralization at this site are shafts and pits reported by placer miners west of the mouth of Wilbur Creek (Freeman, 2010). However, the Wilbur Creek ridge east of the creek roughly coincides with a strong geochemical anomaly in arsenic, silver, lead, zinc, and manganese.

In 2005, Select Resources leased a large block of claims, staked more, and as of 2010 they held several large blocks that totaled more than 300 claims and include several other prospects including this, the original Shorty Creek prospect (Freeman, 2010). In 2005, they did considerable rock and soil sampling on their claims which they collectively call the Shorty Creek project or just Shorty Creek.

The hills south of the Tolovana River in this area are covered with sub-Arctic forest and loess; outcrop is sparse. The rocks in the area are mainly the Lower Cretaceous Wilbur Creek sequence of folded black carbonaceous siltstone, gray feldspathic sandstone and silty sandstone, black shale, and polymictic conglomerate (Albanese, 1983 [Bedrock geology]; Weber and others, 1992). The sequence disconformably overlies Lower Paleozoic carbonate, volcanic, and pelitic rocks. Several small plutons, mostly of granodiorite composition, are in the Shorty Creek area. Biotite hornfels and lesser diopside hornfels is widespread. Although outcrops of the plutonic rocks crop are sparse, the widespread hornfels suggests large intrusions nearby or at depth. The structure of the area is dominated by northwest-directed, northeast-trending thrust faults and northeast-trending, open to recumbent isoclinal folds.

Freeman (2010) notes that others consider the prospects in the Shorty Creek area to be intrusive-related gold (IRG) deposits. However, he concludes that the Shorty Creek mineralization is more likely a large copper-gold-molybdenum porphyry system about 8 miles in diameter. This system is manifested in three main types of deposits: 1) proximal copper-gold-molybdenum mineralization as seen in the old Shorty Creek deposit (HG203); 2) high-sulfidation epithermal gold-arsenic-bismuth-tungsten+/-copper+/-silver mineralization as seen at the Hill 1835 prospect (HG New H1004); and 3) intermediate sulfidation epithermal gold-silver-lead-zinc+/-arsenic+/-antimony+/-manganese mineralization as seen on the ridge south of Wilbur Creek.

Alteration:

The most intense hydrothermal alteration in the area occurs at the nearby Hill 1835 prospect (HG New H1004). In addition to widespread biotite-diopside hornfels, late vein and flood silicification is accompanied by variable crackled to matrix-supported brecciation. Widespread pervasive sericite(?) or clay(?) alteration overprints all other alteration and mineralization giving the rocks a pale yellow to tan bleached appearance.

Age of mineralization:

Probably related to intermediate plutons, one of which has been dated at 63 Ma. A white mica from a drill hole at the nearby Hill 1835 prospect (HG New H1004) gave a Ar40/Ar39 age of 65-70 Ma.

Generic deposit model:

Deposit model:

Part of a copper-gold-molybdenum porphyry system (Cox and Singer, 1986; model 20c or 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c or 21a

Production Status: None

Site Status: Active

Workings/exploration:

There is a long history of exploration by industry and government at and around this prospect on large blocks of claims that that have and still do cover much of the area south of the Tolovana River in the Shorty Creek-Ranney Hollow-Steel Creek- Wilbur Creek area. See Freeman (2010) for the details and the many references to the extensive mapping, sampling, and geophysical and geochemical surveys in this area. Aside from reports of old pits and shafts west of the mouth of Wilbur Creek, the only work that has been done in vicinity of this prospect is mapping, sampling, and geochemical surveys.

Site name(s): Saddle

Site type: Occurrence

ARDF no.: LG211

Latitude: 65.406 **Quadrangle:** LG B-6

Longitude: 149.546

Location description and accuracy:

The Saddle occurrence is located on a north-northwest trending ridge of the Sawtooth Mountains, 1.6 miles north-northwest from the peak VAMB 4494 'Tooth'; NE1/4, and about 0.2 mile east-northeast from the center of section 26, T. 7 N., R. 10 W., of the Fairbanks Meridian. The Saddle occurrence location is accurate within 300 meters.

Commodities:

Main: Au

Other: As, Sb

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

The Saddle occurrence lies near the halfway point of known mineralization on the gold mineralized trend Tooth Trend (J.R. Woodman, Senior Natural Resource Manager, Doyon Limited, written communication, 2014). The Peak and Huron prospects are located on the Tooth trend, which coincides with projection of southwest-northeast trending thrust fault contact, in Devonian sedimentary rocks (Wilson and others, 1998).

Sixty-four soil samples were collected in 1994 by ASA-Montague over a 1/4 mile square area. Three widely spaced soil samples yielded assay results greater than 0.5 part per million (ppm) gold with some anomalous arsenic and antimony. More than 80 rock grab samples were also collected in the soil grid area. (ASA-Montague, 1994).

Saddle surface sample gold mineralization is hosted in quartz monozonite,adjacent hornfels and silicified Devonian sedimentary rocks (ASA, Inc., 1992).

Alteration:

Silicification (ASA, Inc., 1992).

Age of mineralization:

Cretaceous or later based on age of the quartz monzonite (Wilson and others, 1998).

Generic deposit model:

Deposit model:

Intrusive-related gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Site type: Prospect

ARDF no.: LG212

Latitude: 65.425 **Quadrangle:** LG B-5

Longitude: 149.48

Location description and accuracy:

The Huron prospect is located on a northeast-trending ridge of the Sawtooth Mountains between Huron Creek and Mud Fork, 2.8 miles north-northeast from the peak VAMB 4494 'Tooth'; NW1/4NE1/4 and 0.4 mile north-northeast from the center of section 19, T. 7 N., R. 9 W., of the Fairbanks Meridian. The Huron Prospect location is accurate within 300 meters.

Commodities:

Main: Au

Other: Ag, Cu, Hg, Mo, Pb, Sb, U, W, Zn

Ore minerals: Arsenopyrite, gold, pyrrhotite

Gangue minerals: Quartz, sericite

Geologic description:

The Huron Prospect is the northeastern most prospect on a gold mineralized trend known at the Tooth Trend (J.R. Woodman, Senior Natural Resource Manager, Doyon Limited, written communication, 2014). The Huron prospect, Peak prospect, and Saddle occurrence are located on the Tooth trend, which coincides with projection of a southwest-northeast trending thrust fault contact, in Devonian sedimentary rocks (Wilson and others, 1998).

Huron gold mineralization is associated with (a) narrow quartz-sulfide veins within quartz monozonite sills and in sedimentary rocks adjacent to the sills; (b) semi-massive pyrrhotite-rich sulfide plus silica replacement bodies in calcareous sedimentary rocks adjacent to the sills. Quartz-sulfide veins contain up to 15 percent arsenopyrite and assays up to 1.4 grams of gold per tonne for a 5 foot interval (sample HC9603, 25 to 30 feet) with sericitic alteration selvages hosted in two quartz monzonite/granite dikes and adjacent sedimentary rock (ASA -Montague, 1997).

Sixty-one soil samples were collected on and near two quartz monozonite sills by ASA-Montague in 1994. Nineteen of the soil samples yielded assays of greater than 0.5 part per million (ppm) gold, with the highest containing 1.57 ppm gold (ASA-Montague, 1994a, 1994b). In 1996 and 1997, eleven core holes totaling 2,368 feet were drilled in sedimentary hornfels adjacent to the sills. A total of 10 drill intercepts ranging from 0.1 foot to 5.0 feet thick yielded assays of greater than 1.0 ppm gold (ASA-Montague,1997).

Alteration:

One type of alteration associated with gold mineralization is semi-massive pyrrhotite-rich sulfide plus silica replacement bodies in calcareous sedimentary rocks adjacent to the sills. Another type of alteration also associated with gold mineralization is sericitic alteration in which sericitic selvages are hosted in two quartz monzonite/granite dikes and adjacent sedimentary rock (ASA -Montague, 1997).

Age of mineralization:

Cretaceous or later based on age of the quartz monzonite (Wilson and others, 1998).

Generic deposit model:

Deposit model:

Intrusive-related gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Site name(s): Rampart Copper

Site type: Occurrence

ARDF no.: LG213

Latitude: 65.6647 **Quadrangle:** LG C-5

Longitude: 149.0513

Location description and accuracy:

The copper occurrences were exposed during excavation for the Trans-Alaska Pipeline and are situated on the right-of-way located in SE¼NE¼, SE¼SE¼, and NW¼SE¼ Section 29, T. 10 N., R. 7 W., Fairbanks Meridian. The site is along the pipeline service pad on the north-facing hillslope to the Hess Creek valley.

Commodities:

Main: Cu

Other:

Ore minerals: Chalcopyrite, malachite, pyrite

Gangue minerals:

Geologic description:

The Rampart Group is mapped by Weber, and others (1992) as Triassic and Permian extrusive and intrusive mafic rocks with some undifferentiated sedimentary rocks. Brosge and others (1969) noted that diabase dikes and larger bodies of gabbro and augite diorite are common within the mapped boundaries of the Rampart Group'. A dike of hornblende diorite in the Rampart Group south of Hess Creek in the Livengood Quadrangle was found to locally contain as much as 10 percent sulfide.

Alteration:

No significant alteration.

Age of mineralization:

Host rock diorite is Permian; age of mineralization is unknown.

Generic deposit model:

Deposit model:

Porphyry copper (Cox and Singer, 1986; model 17).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17

Production Status: None

Site Status: Inactive

Workings/exploration:

In the 1970s the Bureau of Mines made mineral evaluation studies of the Trans-Alaska Pipeline Corridor

for the Bureau of Land Management. A dike of hornblende diorite south of Hess Creek in the Livengood Quadrangle was found to locally contain as much as 10 percent sulfide. Copper minerals occur in chert and diorite float at several sites locally; the best assay value was 1.56 percent copper in a select hand sample. Further examination found copper mineralization to be limited and discontinuous, and associated with diorite dikes and sills. Copper minerals were seen in hand specimen. A few blebs of chalcopyrite were noted in the diorite (?) and malachite coated fractures in the chert over a small area near one of the diorite (?) dikes and meta-siltstone. Investigation included several ground magnetic surveys, soil sampling, and general reconnaissance of the area (McDermott and others, 1981). Analytical results for soil and rock samples are reported in Averett and Barker, 1981.

Due to the low concentrations and low tonnages implied by a dike or sill-like occurrence of disseminated copper in diorite, and the lack of significant copper mineralization, alteration, mineral zoning and alteration zoning typical of copper-porphyry deposits, no further work was recommended.

Production notes:

None.

Reserves:

None.

Additional comments:

Access to the pipeline pad requires a temporary use permit from Alyeska Pipeline Service Co. Splits of most samples collected by the U.S. Bureau of Mines and referenced in this report have been archived at the Alaska Geologic Materials Center, Anchorage, Alaska and are available for review.

Site name(s): Mount Schwatka; East Fork Flat Creek

Site type: Occurrence

ARDF no.: LG214

Latitude: 65.9172 **Quadrangle:** LG D-1

Longitude: 147.061

Location description and accuracy:

This site represents closely-spaced multiple mineral occurrences and anomalies at the headwater divide between the upper East Fork of Flat Creek and an unnamed east tributary of Jefferson Creek located about 6 miles northeast of Mt. Schwatka. The site is at elevations of 2,000 to 3,000 feet and involves all of Sections 26 and 35, T. 13 N., R. 3 E., of the Fairbanks Meridian. The location is accurate within 0.5 mile and denotes the center point of these two sections.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Mo, Pb

Ore minerals: Smithsonite, unknown zinc mineral(s)

Gangue minerals:

Geologic description:

The Mount Schwatka area is a fault-bounded block about 35 to 40 miles east-west and composed of marine sedimentary and volcanic rocks (Chapman and others, 1971). Like the Crazy Mountains to the east, it is one of several fragmented geologic blocks termed klippen-like features (Payne, 1959) comprised of North American plate geology that are tectonically emplaced along the Tintina Fault (Payne, 1959). The Tintina Fault is a major feature of northwest North America and in central Alaska it has resulted in conspicuous fault-lineated valleys and elongate but discontinuous hills and ridges composed of sedimentary rock that abut the Yukon River basin. It is generally believed these rocks are correlative to the Selwyn Basin in the Yukon Territory (Tempelman-Kluit, 1977). This implies that there has been as much as 280 miles of right lateral displacement along the Tintina Fault.

In the Mt. Schwatka area a Cambrian black shale unit is overlain by Ordovician-Silurian volcanic rocks including the Fossil Creek Volcanics (Blodgett and others, 1987). In the local area of this occurrence the shale unit also includes intermediate tuffaceous limestone, andesite, and locally pyroclastics, gray shale, and chert (Barker, 1980). Stratigraphically overlying the volcanic rocks is the Tolovana Limestone (Chapman and others, 1971), which prominently caps some of the higher terrain.

Similar to the Selwyn Basin, the Mt. Schwatka area features a number of lead-zinc occurrences, some with minor copper, and mostly localized in early- to mid-Paleozoic marine sediments and volcanics including intermediate tuffaceous. Most mineral occurrences are hosted in, or near, fault zones and breccia.

Sulfides of copper, lead, zinc and their associated oxides occur in quartz veins that cut outcropping sequences of calcarenite (?), tuffaceous limestone, and commonly iron-stained argillite rocks within a complex structural setting (Barker, 1980). A few subcrops of dense iron-rich tuff, chert and shale were noted. This host sequence is bounded on the north and east by the Tolovana Limestone, which caps the higher ridges. At a few locations specks of galena were noted in the limestone near contacts with underlying argillaceous rocks.

Alteration:

Most original mineralization has been destroyed by oxidation and gossan development. Smithsonite is

generally a carbonate-altered sphalerite (Barker, 1980).

Age of mineralization:

Generic deposit model:

Deposit model:

Zinc replacement body? (Cox and Singer, 1986; model 19a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

19a?

Production Status: None

Site Status: Inactive

Workings/exploration:

Sulfides of copper, lead, zinc and their associated oxides occur in quartz veins that cut outcropping sequences of calcarenite (?), tuffaceous limestone, and commonly iron-stained argillite rocks within a complex structural setting (Barker, 1980). A few subcrops of dense iron-rich tuff, chert and shale were noted. This host sequence is bounded on the north and east by the Tolovana Limestone, which caps the higher ridges. At a few locations specks of galena were noted in the limestone near contacts with underlying argillaceous rocks.

On a west-facing ridge slope a boulder train of smithsonite occurs; samples contained 30 to 46.5 percent zinc, up to 0.175 percent lead, and 0.18 percent copper. Near the head of this slope an argillite sample was anomalous with lead, zinc, and also reported 6 ppm silver and 195 ppm molybdenum. The source was not found exposed. Isolated patches and pods of sulfides with malachite staining occur in the host sequence. Peripheral to the area, about 7 of 15 widely spaced soil samples and 9 of 10 stream sediment samples contained anomalous values of one or several of these metals.

The evaluation of this site was one visit with no follow-up.

Production notes:

None.

Reserves:

None.

Additional comments:

This site is on land now included in the Yukon Flats National Wildlife Refuge, which excludes mineral exploration activities.

Site name(s): Roy Creek

Site type: Prospect

ARDF no.: LG215

Latitude: 65.4847

Quadrangle: LG B-1

Longitude: 147.0773

Location description and accuracy:

The prospect is located 42 miles northwest of Chena Hot Springs, 7.2 miles east-southeast from VABM 4772 'Cache Mountain', and 0.5 miles south of the center of section 26, T. 8 N., R 3 E., Fairbanks Meridian. It lies on the ridge between Roy and O'brian creeks. The location is accurate to within approximately 100 feet (Susan Karl, USGS, oral commun., 2014).

Commodities:

Main: U

Other: F, REE

Ore minerals: Allanite, bastnaesite, monazite, thorianite, thorite, uraninite, xenotime

Gangue minerals: Fluorite, hematite, topaz, tourmaline

Geologic description:

This area contains significant uranium-rare earth mineralization. There are numerous uranium prospects, uraniferous springs and stream-sediments in the area (Barker and Clautice, 1977). Mt. Prindle pluton is a tourmaline- and topaz-bearing porphyritic biotite granite that crops out over a 50-square-km area. Country rock is quartzite and micaceous quartzite with subordinate quartz-mica schist, phyllitic schist and calcareous schist, thermally metamorphosed to upper hornblende facies near the pluton contact. The pluton is cut by three major NE-trending faults, and several quartz porphyry, aplite and pegmatite dikes.

Lithologies of the Roy Creek prospect consist of a Late Precambrian-Cambrian low grade metasedimentary asseblege intruded by a Cretaceous age alkaline complex (Burton, 1981). The intrusive complex consists of aegirine augite syenite and biotite augite porphric syenite.

Fissure veins containing allanite, bastnaesite, monazite, thorianite, thorite, uraninite, and xenotime occur in Cretaceous porphyritic biotite syenite and alkali granite (Burton, 1981). The deposit contains significant La, Cd, Nd, Pr, Yb, and fluorite. Hematitic alteration of wall rock and leaching of magnetite occurs in host rocks. Samples contain up to 0.1 percent U-238 and 15 percent rare-earth elements (Burton, 1981).

Alteration:

There is hematitic alteration of wall rock and leaching of magnetite in host rocks (Burton, 1981).

Age of mineralization:

K-Ar dates of 85.4 - 86.7 Ma on augite syenite from the Roy Creek Pluton (Burton, 1981) when corrected with appropriate decay constants are 87.5+/-6.4 and 88.9+/-3.6 Ma.

Generic deposit model:

Deposit model:

U-REE deposit associated with a monzogranite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Exploration in the Mt Prindle area has focused on radioactive mineral occurrences within the syenite and surrounding altered quartzites. Fissure veins contain anomalous U, Th, and REEs. Some exploration prospect pits and limited drilling was carried out at Roy Creek by MAPCO in the late 1970s but no further development has taken place. Claims were active from 1977 through at least 1981 (Menzie and others, 1983, p. 56).

Production notes:

None.

Reserves:

None.

Additional comments:

The 9/9/1998 version of this record combined the Roy Creek and Little Creek records and listed the coordinates for Little Champion Creek in the Circle quadrangle. The ARDF number for Little Champion Creek remains CI051.

Site name(s): Peak

Site type: Prospect

ARDF no.: LG216

Latitude: 65.386 **Quadrangle:** LG B-6

Longitude: 149.609

Location description and accuracy:

The Peak prospect is located on a peak on the western side of Sawtooth Mountain, 2.6 miles west of VANM 4494 'Tooth'. It is in the SW1/4 SW1/4 of section 33, 0.4 mile southwest from the center of section 33, T. 7 N., R. 10 W., of the Fairbanks Meridian. This location is accurate within 300 meters (J.R. Woodman, Natural Resource Manger, Doyon Limited, written commun., 2014).

Commodities:

Main: Au

Other: As

Ore minerals: Arsenopyrite, gold

Gangue minerals: Quartz, sericite

Geologic description:

American Scotland Australia found that gold mineralization is associated with quartz veins and sericitic alteration selvages hosted in two quartz monzonite / granite dikes and adjacent sedimentary rock (ASA-Montague,1997). Country rock is the Devonian Quail unit of Weber and others (1992) consisting of phyllite, siltstone, quartzose sandstone, graywacke, and conglomerate. Unit may be correlated with Nation River Formation of the Charley River quadrangle.

In 1994, ASA-Montague performed soil sampling to test for gold mineralization (ASA-Montague, 1994). In 1996 and 1997 ASA-Montague conducted core drilling to determined the extent of mineralization (ASA-Montague, 1997).

Surface samples assays show high-grade gold concentrations exhibit a poor correlation with arsenic. Drill assay results indicate gold mineralization is hosted in quartz veins and high arsenic values are commonly found in the adjacent vein selvages and sporadically in auriferous quartz veins (ASA-Montague, 1997; J.R. Woodman, Natural Resource Manager, Doyon Limited, written communication, 2014).

Alteration:

Quartz and sericite (ASA-Montague, 1997).

Age of mineralization:

Gold mineralization probably associated with Cretaceous intrusive rocks (ASA-Montague, 1997). Dikes likely similar in age to mid-Cretaceous (91 Ma) Sawtooth pluton (Weber and others, 1992).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins? (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a?

Production Status: None

Site Status: Inactive

Workings/exploration:

American Scotland Australia found that gold mineralization is associated with quartz veins and sericitic alteration selvages hosted in two quartz monzonite / granite dikes and adjacent sedimentary rock (ASA-Montague,1997). Surface samples assays show high-grade gold exhibits a poor correlation with arsenic. Drill assay results indicate gold mineralization is hosted in quartz veins and high arsenic values are commonly found in the adjacent vein selvages and sporadically in auriferous quartz veins. Thirty-three soil samples were collected in a 150 X 150 meter grid covering the dikes. Seven of the soil samples yielded assays of greater than 1.0 ppm gold (ASA-Montague, 1994; and J.R. Woodman, Natural Resource Manager, Doyon Limited, written communication, 2014).

In 1996 and 1997, eight core holes totaling 1556 feet were drilled in and adjacent to the dikes. A total of 34 drill intercepts ranging from 0.7 feet - 4.7 feet thick yielded assays of greater than 1.0 ppm gold. Surface samples assays show high-grade gold concentrations exhibit a poor correlation with arsenic. Drill assay results indicate gold mineralization is hosted in quartz veins and high arsenic values are commonly found in the adjacent vein selvages and sporadically in auriferous quartz veins (ASA-Montague,1997; J.R. Woodman, Natural Resource Manager, Doyon Limited, written communication, 2014).

Location description and accuracy:
Prospect site is a large area northwest of the Sawtooth Mountain mine (ARDF LG006; Cobb (1972, MF-413), loc. 2) and west of VABM Tooth. It apparently spans SW1/4 sec. 36, T.7 N., R. 10 W and the N1/2 sec. 2, T. 6 N., R. 10 W., of the Fairbanks Meridian on Sawtooth Mountain. Latitude and longitude are approximate and near the center of the prospect area and are accurate wiItin about 1/2 mile.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:
Rock samples taken from 1987 to 1993 by American Copper and Nickel Company (ACNC), WGM, Placer Dome and Australia Scotland and America (ASA) 27 yielded greater than 10 ppm gold with the highest containing 103 ppm gold, located approximately 1 mile north of the stibnite mine shaft (ARDF LG006). The drill intercepts showing gold mineralization were found in quartz veins and are strongly associated with arsenopyrite (ASA-Montague, 1995; American Copper and Nickel Company, 1989; WGM, 1989).

Alteration:
Quartz and arsenopyrite (ASA-Montague, 1995).

Age of mineralization:
The granitic rock has been K-Ar dated at 91.0+/-0.9 Ma (Weber and others, 1992).

Generic deposit model:

Deposit model:
Intrusion hosted gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

From 1987 through 1993, American Nickel and Copper Company, WGM, Placer Dome and Australia Scotland and America (ASA) collected over 200 rock samples from the Sawtooth Mountain quartz monzonite intrusion. 27 of the rock samples yielded greater than 10 ppm gold with the highest of 103 ppm gold located approximately 1 mile north of the stibnite mine shaft. In 1993 ASA collected 595 soil samples in a 400 foot X 400 foot grid over the intrusion. Three core holes were drilled in the near the surface exposure of the quartz monzonite intrusion, within 1 mile west of the stibnite mine shaft. Core holes SM93-01, SM93-02 both encountered 5 intercepts less than two feet wide with grades of over 5.0 ppm Au. Core hole SM93-03 encountered 4 intercepts less than two feet wide with grades of over 2.0 ppm Au. The gold mineralization drill intercepts were found in quartz veins and are strongly associated with arsenopyrite (ASA-Montague, 1995; American Nickel and Copper Company, 1989; WGM, 1989).

Site name(s): Cache Mountain

Site type: Occurrence

ARDF no.: LG218

Latitude: 65.4853 **Quadrangle:** LG B-1

Longitude: 147.3166

Location description and accuracy:

The Cache Mountain tin occurrence consists of greisen rubble located on a south-trending ridge leading from the summit of Cache Mountain at an elevation of 3,840 feet. Elevations in the prospect area range from 3,500 to 4,700 feet. The occurrence is in the SW1/4 SE1/4 sec. 27, T. 8 N., R. 2 E of the Fairbanks Meridian. Accuracy of the location is within about 1,500 feet.

Cache Mountain is a prominent 4,772-foot high mountain in the White Mountains area about 40 miles due north of Fairbanks and about two miles north of this occurrence.

Commodities:

Main: Sn

Other: W

Ore minerals: Cassiterite

Gangue minerals: Chlorite, clay, epidote, hematite, magnetite, plagioclase, pyrrhotite, quartz, sericite

Geologic description:

Cache Mountain is underlain by a biotite granite pluton of similar composition to the Lime Peak pluton to the east. Both the intrusions are composed of four apparent phases: a fine-grained to porphyritic biotite granite, a coarser grained biotite granite, lesser phases of smoky, finely crystalline quartz biotite-muscovite tourmaline granite locally quartz-rich, and a younger cross-cutting porphyritic rhyolite. Based on A-F-M and K2O-Na2O-CaO ternary plots these phases compare closely to Lime Peak (Warner, 1984).

An occurrence of tin greisen was located along the ridge south of the mountain where a chip sample of scattered mineralized rubble over an area 50 feet across assayed 0.105 percent tin (Warner, 1984). Berryhill, 1964, also reported a similar occurrence from the general area that assayed 0.22 percent tin although the exact location has been lost over the years. Petrographic examination of Berryhill’s samples by the U.S. Bureau of Mines described the samples as tourmaline-bearing greisen rather than lithium enriched (Berryhill, 1964).

Analyses of heavy mineral concentrates were weakly to moderately anomalous for tin were reported by Warner (1984) in drainages on either side of the ridge.

Alteration:

Greisen, locally argillic, limonite, goethite, hematite staining and corroded quartz, wider zones of sericite, argillic and chloritic alteration. Tourmaline is found in the greisen (Warner, 1984).

Age of mineralization:

Quartz monzonite of the Cache Mountain pluton was dated at 59.8±1.8 Ma, Paleocene (Holm, 1973; Rinehart and others, 1997).

Generic deposit model:

Deposit model:

Granite-hosted greisen tin veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The Cache Mountain area was selected for study by the U.S. Bureau of Mines in 1979 because of on-going Strategic and Critical minerals assessments in Alaska by the Bureau of Mines. Warner (1984) reports only one sample of finely crystalline granite float yielded evidence of potential mineralization; 1,050 parts per million (ppm) tin was found. Pan Concentrate samples from creeks radiating from Cache Mountain yielded between 370 to 2,390 ppm tin and 200 to 400 ppm tungsten (Warner, 1984). In comparison to tin values in pan concentrates collected elsewhere in the White Mountain upland area, none of the Cache Mountain values are highly anomalous (Warner, 1984).

Production notes:

None.

Reserves:

None.

Additional comments:

Claims (BEE block) staked in area by Mapco Minerals in 1976; no further work was performed.

Site name(s): Terra

Site type: Mine

ARDF no.: LH010

Latitude: 61.7739 **Quadrangle:** LH D-2

Longitude: 153.7027

Location description and accuracy:

The Terra prospect is at an elevation of about 5,030 feet, about 8.5 miles southwest of the junction of Fish Creek and the Hartman River. It is about 0.5 mile south of the center of section 31, T. 19 N., R. 24 W., of the Seward Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu, Mo, Pb

Other: As, Sb, W

Ore minerals: Arsenopyrite, chalcopyrite, electrum galena, jordanite, molybdenite, native gold, pyrite, pyrrhotite, sphalerite, tennantite

Gangue minerals: Carbonate, quartz, sericite

Geologic description:

In 1990, Allen reported anomalous gold in a rock at sample location 819 from a basal moraine near here. A GIS compilation and follow-up of published U.S. Geological survey mapping and sampling in the area (Allen, 1990; Allen and others 1990; Allen and Slaughter, 1990) by Kennecott Exploration led to the discovery of finely disseminated native gold and minor sulfides and sulfosalts in tectonic breccia and carbonate-quartz veins in monzonite and diorite intrusive rocks of the Hartman sequence and Jurassic or Lower Cretaceous hornfelsed sedimentary rocks of the Kahiltna terrane (Porterfield, 2000). Porterfield describes two target areas, each approximately 6,000 feet in length, that contain high-grade mineralization in quartz veins and carbonate-cemented tectonic breccia. The quartz veins contained as much as 687 parts per million (ppm) gold and 1,135 ppm silver; the breccia contained as much as 71 ppm gold and 572 ppm silver.

Rock-chip samples, talus fines, and soil samples were collected from two target areas on the Terra prospect. In samples, gold correlates with arsenic, silver, antimony, copper, and lead. Porterfield (2000) reports that bismuth and tungsten are anomalous in some samples.

In 2004, AngloGold Ashanti (USA) Exploration, Inc. began work on the Terra prospect with surface geochemistry and outcrop sampling. In 2005, they drilled 12 holes south of the terminus of the glacier at the head of Fish Creek (Klipfel and Giroux, 2010). In 2006, International Tower Hill Mines began work on the property in a joint venture with AngloGold; they drilled 12 holes in 2006 and another 15 holes in 2007 (International Tower Hill Mines, Ltd., 2008). In 2010, International Tower Hill signed a joint venture with the Terra Mining Corporation to explore the property (Terra Mining Corp., 2010). In 2010, International Tower Hill formed a new company, Corvus Gold Inc., to take over many of their prospects, including Terra; the joint venture with Terra Mining continued as before and Terra was acquired by WestMountain Gold Corporation in March of 2011.

WestMountain drilled four more holes in 2011 and extended the Ben vein an additional 200 meters; several other veins were also intersected in the drilling in the hanging wall of the Ben vein (WestMountain Gold Corp., 2011). Some notable intercepts were: 1) 0.84 meters that averaged 7.42 grams of gold per tonne and 69.39 grams of silver per tonne, this included 0.31 meter that averaged 15.60 grams of gold per tonne and 138.00 grams of silver per tonne; 2) 0.36 meters that averaged 35.70 grams of gold per tonne and 174

grams of silver per tonne; 3) 5.60 meters that averaged 8.15 grams of gold per tonne and 69.69 grams of silver per tonne; and 4) 0.53 meters that averaged 25.60 grams of gold per tonne and 4.90 grams of silver per tonne.

The mineralization at the Terra prospect consists of high-grade epithermal, quartz-carbonate veins 0.1 to 2 meters thick with visible gold. The veins are near the periphery of a Cretaceous diorite stock that intrudes a thick sequence of carbonaceous shale of the Late Jurassic Kahiltna Shale (Klipfel and Giroux, 2010). The veins typically contain gold, electrum, sulfosalts, arsenopyrite, pyrite, pyrrhotite, sphalerite, and chalcopyrite. Alteration includes silica-rich selvages near the veins and sericite-rich selvages farther away. The selvages may also contain up to 10 percent pyrite and arsenopyrite but the selvages seldom extend more than a meter from the veins. The holes on the Ben Vein indicate that it extends for at least 600 meters along strike and persists to a depth of at least 350 meters. It varies from from 0.2 to 3.0 meters wide and has an average gold value of 19.8 grams per ton. Five other vein systems have been identified on the prospect including a discovery in 2007, the Ice vein. All of the vein systems have a north-northwest to north-south strike with with variable west dips.

Early in 2008, International Tower Hill (Klipfel and Giroux, 2008 and 2010) reported an inferred resource estimate for the Ben Vein of 168,000 ounces of gold and 318,000 ounces of silver in material with an average grade of 12.2 grams of gold per ton and 23.1 grams of silver per ton. The mineralization was then open at both ends and at depth.

In 2016, WestMountain Gold Inc. conducted small-scale surface mining and milling operations at Terra but in late summer, a landslide buried the surface bulk-sampling area. By mid-September, WestMountain Gold Inc. had processed 890 tons of material from the high-grade gold vein at Terra, and had another 1,470 tons of stockpiled material that was mined prior to the landslide (Athey and Werdon, 2017).

Alteration:

Carbonates, iron-oxides, quartz, and sericite in selvages near the veins (Klipfel and Giroux, 2008).

Age of mineralization:

Cretaceous; sericite from a quartz vein in hornfels has an Ar/Ar age date of 66.4 +/- 5.7 Ma (Porterfield, 2000).

Generic deposit model:

Deposit model:

Epithermal gold-silver veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Kennecott Exploration carried out reconnaissance mapping and surface sampling in the late 1990s that first identified the Terra deposit (Porterfield, 2000). In 2004, AngloGold Ashanti (USA) Exploration, Inc. (2008) began work on the Terra prospect with surface geochemistry and outcrop sampling; in 2005 they drilled 12 holes south of the terminus of the glacier at the head of Fish Creek. In 2006, International Tower Hill Mines began work on the property in a joint venture with AngloGold; they drilled 12 holes in 2006 and another 15 holes in 2007. In 2010, International Tower Hill signed a joint venture with the Terra Mining Corporation to explore the property (Terra Mining Corp., 2010). In 2010, International Tower Hill formed a new company, Corvus Gold Inc., to take over many of their prospect, including Terra. The joint venture with Terra Mining continued as before and Terra was acquired by WestMountain Gold Corporation in March of 2011.

WestMountain Gold, Inc. (WMTN) drilled four more holes in 2011. In 2012, WMTN drilled four more

holes; in 2013, WMTN drilled five more holes (Greg Schifrin, written communication, 2014).

Production notes:

In 2016, WestMountain Gold Inc. conducted small-scale surface mining and milling operations at Terra but in late summer, a landslide buried the surface bulk-sampling area. By mid-September, WestMountain Gold Inc. had processed 890 tons of material from the high-grade gold vein at Terra, and had another 1,470 tons of stockpiled material that was mined prior to the landslide (Athey and Werdon, 2017).

Reserves:

Early in 2008, International Tower Hill (Klipfel and Giroux, 2010) announced an initial inferred resource estimate for the Ben Vein of 168,000 ounces of gold and 318,000 ounces of silver in ore with an average grade of 12.2 grams of gold per ton and 23.1 grams of silver per ton.

In 2013, the first t test run on production occurred 75 tons were run averaging 3 oz per ton (Greg Schifrin, written commun., 2014).

Additional comments:

In 2013, Gustavson and Associates completed a 43-101 report with an indicated resource of 50,000 Au and inferred 370,000 ounces of gold for a total gold resource of 420,000 grade gold and 15.5 grams per ton with a 5 year reserve (WestMountain Gold, Inc., 2014).

In 2014, WMTN acquired 100 percent ownership - buying out Corvus Gold joint venture agreement (WestMountain Gold, Inc., 2014).

Last report date: 2017-08-26

Site name(s): Copper Joe

Site type: Prospect

ARDF no.: LH020

Latitude: 61.545 **Quadrangle:** LH C-1

Longitude: 153.1777

Location description and accuracy:

This prospect is on a west tributary to the upper Styx River in the Alaska Range about 16.5 miles northeast of Snowcap Mountain in the northeast quarter of section 24, T. 17 N., R. 22 W., of the Seward Meridian. The location site is centered where potassic alteration with A-veins and chalcopyrite has been found in outcrop along the creek.

Commodities:

Main: Ag, Au, Cu, Mo, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Quartz, sericite

Geologic description:

As originally described by Reed and Elliott (1970), iron-stained and altered intrusive rocks are present along about 200 feet of a creek. The altered rocks consist dominantly of quartz and sericite with minor potassium feldspar and biotite. These rocks generally contain less than one percent sulfide minerals, including pyrite, sphalerite, and galena, which are disseminated and in quartz veins as much as 2 inches wide. Sphalerite and galena also occur as thin veinlets and disseminations in felsite. Shear zones in the altered intrusions are also mineralized with sulfides. Besides zinc and lead values, rock samples contained as much as 15 parts per million (ppm) silver and 300 ppm molybdenum. The altered intrusive rocks are probably Late Cretaceous or Tertiary components of the Alaska-Aleutian Range batholith (Reed and Lanphere, 1973).

Float boulders contained chalcopyrite. Potassic alteration with quartz-magnetite stockworks and disseminated chalcopyrite extends over an area of about 1 kilometer by 3 kilometers, and intense phyllic alteration extends outward about another 2.5 kilometers. Kennecott did a ground magnetic survey that defined a magnetic high about 1.0 by 1.9 kilometers in area that trends northeast from the mineralization. Rock samples contained up to 0.73 percent copper, 0.415 grams of gold per tonne, and 0.125 percent molybdenum (Kiska Metals Corporation, 2010).

In 2016, First Quantum Minerals funded a single, 806-meter-long, exploratory drill hole targeting the center of a 1.4-kilometer-wide magnetotelluric anomaly, which is coincident with other geological, geochemical, and geophysical anomalies, at Kiska Metals Corp.'s Copper Joe porphyry copper property in southwest Alaska. The drill hole into the Evening Star target intercepted more than 400 meters of hydrothermal breccia with strong phyllic alteration, abundant pyrite, sparse early quartz veins, magnetite-anhydrite-pyrite-chalcopyrite veins, and banded molybdenite veins. No significant copper grades were intersected but extensive brecciation and strong alteration suggests a robust hydrothermal porphyry system; additional drilling is required to determine if ore-grade mineralization exists. First Quantum Minerals withdrew from the project at the end of the season. In December 2016, AuRico Metals Inc. announced a definitive agreement to acquire Kiska Metals, subject to customary closing conditions including Kiska shareholder approval, expected in the first quarter of 2017 (Athey and Werdon, 2017).

Alteration:

A core zone of potassic and magnetite alteration associated with porphyry dikes and an extensive 4.5 by 2.5 kilometer zone of moderate to intense phyllic alteration peripheral to the core zone (Roberts, 2014).

Age of mineralization:

Probably Late Cretaceous or Tertiary based on similarities with other mineralized intrusives of the Alaska-Aleutian Range batholith (Reed and Elliott, 1970; Reed and Lanphere, 1973).

Generic deposit model:

Deposit model:

Copper-gold-molybdenum porphyry? (Cox and Singer, 1986, model 20c or 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c? or 21a?

Production Status: None

Site Status: Active

Workings/exploration:

In 2006, Kennecott Exploration staked 100 State of Alaska mining claims over this prospect, which they interpreted to have porphyry-style alteration in porphyritic monzodiorite rocks (Kiska Metals Corporation, 2010). Kennecott did a ground magnetic survey that defined a magnetic high about 1.0 by 1.9 kilometers in area that trends northeast from the mineralization. Rock samples contained up to 0.73 percent copper, 0.415 grams of gold per tonne, and 0.125 percent molybdenum.

In 2010, Kiska Metals Corp. (Kiska) signed an option agreement with Kennecott to explore the Copper Joe claims. Exploration work conducted by Kiska consisted of geological mapping, rock, soil and stream sediment geochemistry sampling, and an induced-polarization (IP) survey and ground magnetics around a prospective area defined in previous work by AMAX and Kennecott. In 2011, a short follow-up program was conducted on Copper Joe that consisted of geological mapping, rock geochemistry sampling, and prospecting. At this time, new claims were staked (Shogun Claims) to the northwest of the Copper Joe claims covering drainages with anomalous copper and gold in stream sediment samples collected in 2010 (Roberts, 2014).

Kiska and First Quantum Minerals Ltd. (First Quantum) drilled two holes totalling 885 meters at Copper Joe in 2014. Drilling did not return any significant assay results but did confirm a large porphyry-hydrothermal system. One drill hole intersected two zones of heterolithic, magnetite breccia cross-cutting a porphyritic quartz monzonite and the other drill hole intersected a moderately to strongly chlorite-epidote altered quartz monzonite breccia intruded by a weakly altered biotite-feldspar porphyry (Kiska Metals Corp., 2014). Exploration work in 2015 includes a geophysical survey and infill geologic mapping (Kiska Metals Corp., 2015).

Site name(s): Revelation

Site type: Prospect

ARDF no.: LH036

Latitude: 61.7783 **Quadrangle:** LH D-3

Longitude: 153.0635

Location description and accuracy:

The location of the Revelation prospect is ambiguous. Most recently (2011), it is reported to be about 10.6 miles south-southeast of the junction of the South Fork of the Kuskokowim River and the Styx River near the center of section 34, T. 20 N., R. 21 W. The prospect may be a mile or more from this location and an earlier report places it about 2 miles to the north-northwest.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Pyrite

Gangue minerals: Quartz

Geologic description:

Relatively little is known about the Revelation prospect. It probably is similar to other deposits in the area (TY031, TY032, TY 019) that are associated with the Cretaceous (65-66 Ma), Mount Estelle and similar plutons in the area. The Mount Estelle pluton is zoned with a granite core and marginal phases of quartz monzonite, quartz monzodiorite, augite monzodiorite, diorite, and lamprophyric mafic and ultramafic rocks (Reed and Elliott, 1970; Millholland, 1995; Crowe and others, 1991; Crowe and Millholland, 1990). The pluton intrudes Jurassic and Cretaceous sedimentary rocks that are hornfelsed adjacent to the pluton, are locally stained red, and have been altered to sericite and clay. Pyrite is disseminated along fractures.

There was considerable work in the Mount Estelle area by government and industry as far back as the 1970s that identified mineralization but most of the work was more reconnaissance than prospect specific (see TY019). From 2005 to 2008, several companies, Hidefield Gold Plc. (2008), International Tower Hill Mines Ltd. (2007) and Millrock Resources Inc. (2008), worked in the area and defined several specific prospects. As described in Hidefield (2008), the Revelation vein can be traced for 200 meters on the surface. Two samples contained 32.4 and 7.07 grams of gold per ton, 8.1 and 12.6 grams of silver per ton, and 0.10 and 0.15 percent copper.

Millrock is currently (March, 2012) exploring the area as part of their Estelle project, which covers a large block of claims north and south of Mount Estelle; the Revelation vein is in that block. Millrock describes the deposit as quartz stockwork veining that extends for 600 meters in an iron-stained zone of porphyritic diorite and hornfelsed sedimentary rocks. Their geochemical sampling suggests the area of mineralization is larger.

Alteration:

Iron staining and sericitic and clay alteration in hornfelsed rocks.

Age of mineralization:

Probably related to a nearby 65-66 Ma pluton.

Generic deposit model:

Deposit model:

Gold-copper porphyry deposit? Intrusion-related gold deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

There was considerable work in the Mount Estelle area by government and industry as far back as the 1970s that identified mineralization but most of the work was more reconnaissance than prospect specific (see TY019). From 2005 to 2008, several companies, Hidefield Gold Plc. (2008), International Tower Hill Mines Ltd. (2007) and Millrock Resources Inc. (2008), worked in the area and defined several specific prospects, including the Revelation prospect. Millrock is currently (March, 2012) exploring the area as part of their Estelle project which covers a large block of claims north and south of Mount Estelle; the Revelation prospect is in that block. Their only work in 2011 at the Revelation prospect was surface sampling.

Site name(s): Frozen Creek

Site type: Prospect

ARDF no.: MD032

Latitude: 63.532

Quadrangle: M C-4

Longitude: 154.513

Location description and accuracy:

The Frozen Creek prospect is situated on a south rim of an east-facing cirque valley on the east side of the Mystery Mountains at an elevation of 2,500 feet (762 m) in Section 6, T. 23 S., R. 22 E., of the Kateel River Meridian. Prospect is known to within 250 feet (76 m).

Commodities:

Main: Au, Cu

Other: Ag

Ore minerals: Chalcopyrite, magnetite, pyrite, pyrrhotite

Gangue minerals: Tourmaline

Geologic description:

The Frozen Creek prospect consists of a large zone of boron metasomatism in the eastern edge of the Mystery Mountains Pluton. It is the eastern-most porphyry-like prospect in a seven mile (11 km) long northeast-trending zone of similar prospects that cut across the central Mystery Mountains. The Frozen Creek prospect is inferred to be Late Cretaceous based on isotopic age of Mystery Mountains intrusive complex (Moll and others, 1981).

A strong copper-gold soil anomaly was detected at Frozen Creek (DiMarchi and others, 1997), which is part of the core of Cu-Au anomalies that are surrounded by a lead-zinc mineral zonation. Disseminated chalcopyrite and pyrrhotite are found throughout a tourmaline-enriched monzonitic plutonic rocks; little mineralization is noted in host biotite hornfels. Malachite is locally abundant in hairline fractures in small intrusive bodies. The mineralized zone at Frozen Creek is at least 1,500 feet (457 m) in diameter. Two grab samples of mineralization collected by Clautice and others (1993) averaged 585 ppm copper and 2.1 ppm silver.

Alteration:

Sericite and secondary biotite in pluton.

Age of mineralization:

The Frozen Creek prospect is inferred to be Late Cretaceous based on isotopic age of Mystery Mountains intrusive complex (Moll and others, 1981).

Generic deposit model:

Deposit model:

Porphyry Cu-Au (Cox and Singer, 1986; model 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active?

Workings/exploration:

The Frozen Creek prospect was found during regional exploration conducted by WGM Inc. in 1977 (Andrews, 1978). American Copper and Nickel Inc. (ACNC) worked on the prospect from 1988 to 1990, and ASA Inc. continued work through 1997 (DiMarchi and others, 1997). During 1989-1991, ACNC explored the area as a porphyry copper-gold target. ASA Inc. continued exploration work with the same target in mind during 1995 and 1996. Two grab samples reported by Clautice and others (1993) averaged 585 ppm copper and 2.1 ppm silver.

Newmont Mining Corporation (2012) collected soil samples on ridges and spurs with a nominal spacing of 100 meters and followed up with grid soil samples in 2010 and 2011. Soil samples having assays of greater than 100 ppb gold and 1,000 ppm copper form an elongate anomalous zone of approximately 1,100 meters long. High-grade gold and copper assays in soil samples are centered on a zone of 3 to 5 granite porphyry dikes that exhibit potassic alteration (Newmont Mining Corp, 2012).

In 2012, drilling by Newmont identified long intercepts of low grade copper and gold (164.5 meters of 0.17 ppm gold and 0.09 percent copper in hole COTT-0004 and 134.1 meters of 0.37 ppm gold and 0.1 percent copper in hole COTT-0005b), hosted in a fine grained to aphanitic andesite (Newmont Mining Corp., 2013).

Production notes:

None.

Reserves:

None.

Newmont Mining Corp., 2013, Doyon Kuskokwim Block 10, 2012 Work Summary, Doyon limited report 2013-05 (Report held by Doyon Limited, Fairbanks, Alaska).

Primary Reference: DiMarchi and others, 1997

Reporter(s): Bundtzen, T.K. (Pacific Rim Geological Consulting); V.C. Zinno (Alaska Earth Sciences, Inc.)

Last report date: 2016-03-15

Site name(s): Shepard

Site type: Occurrence

ARDF no.: MD034

Latitude: 63.592 **Quadrangle:** M C-3

Longitude: 154.225

Location description and accuracy:

The Shepard occurrence is situated on a north-facing spur of a sharp 3,160 foot high peak that overlooks Shepard Creek. The occurrence is at an elevation of 3,080 feet (939 m) in section 9, T. 22 S., R. 24 E., of the Kateel River Meridian. The site is accurate to within 500 feet (152 m).

Commodities:

Main: Au, Cu, Zn

Other: Co

Ore minerals: Arsenopyrite, chalcopyrite

Gangue minerals: Quartz

Geologic description:

The Shepard occurrence consists of quartz veins in and near a northwest trending quartz monzonite dike swarm (DiMarchi and others, 1992). The quartz veins contain disseminated arsenopyrite, chalcopyrite, and carry gold values; they are found in zones of silicic and phyllic alteration in the quartz monzonite dikes.

Surface samples collected by DiMarchi and others (1992) contain up to 500 ppb gold. Nine samples averaged 100 ppb gold. Copper, cobalt, and arsenic values were not reported.

Soil samples collected by Newmont Mining Corporation in 2011 demonstrated high-grade gold assays of up to 18 ppm gold. These samples are associated with 5 to 10 centimeter wide quartz veins hosted in intensely hornfelsed Kuskokwim metamorphic rocks (Newmont Mining Corp, 2011).

Alteration:

Silicic and phyllic in intrusion.

Age of mineralization:

The Shepard prospect is inferred to be Late Cretaceous based on isotopic age of Mystery Mountains intrusive complex (Moll and others, 1981).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model no. 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active?

Workings/exploration:

Surface samples taken by DiMarchi and others (1992) contain up to 500 ppb gold. Nine samples averaged 100 ppb gold. Copper, cobalt, and arsenic values are not reported.

Newmont Mining Corporation collected 222 soil samplings and 21 rock chip samples in conjunction with detailed geologic mapping in 2011. Soil samples were collected along ridges and spurs on a nominal spacing of 100 meters. High-grade gold assays in soil samples of up to 18 ppm gold, are associated with 5 to 10 centimeter wide quartz veins hosted in intensely hornfelsed Kuskokwim metasediments (Newmont Mining Corp, 2011).

Production notes:

None.

Reserves:

None.

Additional comments:

The Shepard occurrence is on lands selected or owned by Doyon Ltd. For further information, contact Doyon Ltd. at 210 1st Ave., Fairbanks, Alaska, 99701.

ARDF no.: MD062

Latitude: 63.2381 **Quadrangle:** M A-4

Longitude: 154.7759

Location description and accuracy:

The main portal of the Nixon Fork Mine is near the head of Crystal Gulch about 0.2 mile north of the center of section 13, T. 26 S., R. 21 E., of the Kateel River Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu

Other: Bi, Th, U, W

Ore minerals: Azurite, bismuth, bornite, chalcocite, chalcopyrite, chrysocolla, electrum, gold, malachite, scheelite, unidentified U/Th minerals

Gangue minerals: Calcite, diopside, epidote, garnet, limonite, quartz, sericite, siderite, tremolite

Geologic description:

The Nixon Fork deposit was first staked in 1917 and was mined intermittently from 1918 to 1964, notably by the Yukon-Treadwell company and by E.M. Whalen, from several shafts, open pits, and trenches (Mertie, 1936, Herreid, 1966, Wallis and Rennie, 2005, Postle and others, 2006). The total production during this period is estimated to be 42,200 ounces of gold, 11,281 ounces of silver, and 41,400 pounds of copper from ore that averaged about 1.5 ounce of gold per ton. Much of this production came from ore bodies in the vicinity of this site near the head of Crystal Gulch but at least some came from the nearby Whalen Shaft (MD071) and from the glory hole near it.

The property was explored by Battle Mountain Gold from 1984 to 1988 and by the Nixon Fork Joint Venture/Central Alaska Gold from 1989 to 1993. From 1985 to 1998, 719 surface and underground, reverse circulation and core holes were drilled that totaled 63,093 meters. The deposit was mined by Nevada Goldfields Inc. from 1995 to 1999, when they filed for bankruptcy and the property reverted to its owners. They produced 137,749 ounces of gold and 2,145,826 pounds of copper from 122,391 tons of ore with a 'reconciled' grade of 42 grams of gold per tonne.

St. Andrew Goldfields Ltd. leased the property in 2003, did extensive surface and underground drilling, drove several spiral declines on the ore bodies they defined, and built a 200-ton-per-day mill. They began mining in late 2006 and produced their first gold in January 2007 (St. Andrew Goldfields Ltd., 2009). In the first nine months of 2007, they produced 18,105 tons of ore with a grade of 17.1 grams of gold per ton. Production was suspended in October 2007 to better define the ore bodies as the production was lower than anticipated from their reserve estimates.

In February, 2009, Fire River Gold (2010) acquired the property and in early 2010 they were engaged in a major program of re-logging and reanalyzing the surface and drill samples from the previous operators, mapping, and new drilling to define the deposit.

The Nixon Fork Mine consists of several classic gold-copper, epidote-diopside-garnet skarn deposits,

generally within 10 to 150 meters of the periphery of a Cretaceous (68 to 70 Ma) quartz monzonite to granodiorite stock about 3 by 5 kilometers in outcrop area (Moll and others, 1981, Bundtzen and Miller, 1997, Wallis and Rennie, 2005). The stock intrudes the Ordovician Telsitna Formation, a 2,000-meter-thick sequence of limestone and dolomite, and Cretaceous calcareous sandstone and shale. Both the quartz monzonite and the host rocks are cut by late, quartz-feldspar and quartz porphyry dikes.

At least 6 ore bodies are known along about a mile of the west contact of the stock near Crystal Gulch and several more are suspected from surface sampling (Wallis and Rennie, 2005). Five of these were mined from 1995 to 1998. The ore bodies are irregular and complex, often with branching arms, but are roughly pipelike, dip steeply, and follow or parallel the border of the stock at depth. In plan, the ore bodies typically are about 4 meters by 20 to 30 meters in area and extend down dip as much as several hundred meters, sometimes more. They are typically associated with epidote-diopside-garnet skarn near carbonate rocks or hornfels near sandstone and shale. Both exoskarn and endoskarn are present. Most of the ore minerals and skarn are in exoskarn 10 to 30 feet into the marble front. Minor mineralized endoskarn occurs within satellite bodies of monzonite; however, most of this mineralization is not ore grade. The main ore minerals are pyrrhotite, chalcopyrite, pyrite, and native gold; minor bornite and chalcocite are known. The quartz monzonite is sericitized and argillized near the mineralization and some of the ore bodies are oxidized to a depth of 160 meters. However, two of the major ore bodies, the Crystal and Garnet Extension, show little sign of oxidization to the surface.

In 2006, Postle and others (2006) estimated the resources and reserves of the Nikon Fork Mine for St Andrew Gold Fields Ltd. These are: 1) a measured resource of 23,400 tonnes with a grade of 36.8 grams of gold per tonne; 2) an indicated resource of 126,000 tonnes with a grade of 21.6 grams of gold per tonne; 3) an inferred resource of 93,000 tonnes with a grade of 15.5 grams of gold per tonne; 4) a proven reserve of 47,000 tons with a grade of 34.05 grams of gold per tonne; and 5) a probable reserve of 137,500 tonnes with a grade of 18.6 grams of gold per tonne. However, when mining took place from late 2006 to late 2007, the production fell short of the estimates. In early 2010, Fire River Gold was engaged in a major program to better define the reserves and resources.

In Fall of 2010, Fire River released an updated mineral resource estimate (Fire River Gold Corp., 2010b). In July 2011, Fire River started up the Nixon Fork Mill (Fire River Gold, 2011). There was ongoing drilling, mining, and milling in 2012 and early 2013 (Fire River Gold Corp., 2013).

Alteration:

Extensive development of endoskarn, exoskarn, and hornfels that is genetically related to the mineralization. Quartz monzonite is sericitized and argillized near the mineralization and some of the ore bodies are oxidized up to a depth of 160 meters (Moll and others, 1981, Bundtzen and Miller, 1997). Other evidence of alteration includes weak argillic alteration around narrow sulfide quartz veins and broad zones of propylitic alteration are present in the quartz monzonite. Late felsic dikes may exhibit silicification overprinted on the argillic alteration (Wallis and Rennie, 2005).

Age of mineralization:

Late Cretaceous based on 68 to 70 Ma, isotopic age of quartz monzonite adjacent to the skarn ore bodies (Moll and others, 1981, Bundtzen and Miller, 1997, Wallis and Rennie, 2005).

Generic deposit model:

Deposit model:

Copper-gold skarn (Cox and Singer, 1986; model 18b)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: Yes; medium

Site Status: Probably inactive

Workings/exploration:

The Nixon Fork deposit was first staked in 1917 and was mined intermittently from 1918 to 1964, notably by the Yukon-Treadwell company and by E.M. Whalen, from several shafts, open pits, and trenches (Mertie, 1936, Herreid, 1966, Wallis and Rennie, 2005, Postle and others, 2006).

The property was explored by Battle Mountain Gold from 1984 to 1988 and by the Nixon Fork Joint Venture/Central Alaska Gold from 1989 to 1993. From 1985 to 1998, 719 surface and underground, reverse circulation and core holes were drilled that totaled 63,093 meters. The deposit was mined by Nevada Goldfields Inc. from 1995 to 1999, when they filed for bankruptcy and the property reverted to its owners.

St. Andrew Goldfields Ltd. leased the property in 2003, did extensive surface and underground drilling, drove several spiral declines on the ore bodies they defined, and built a 200-ton-per-day mill. They began mining in late 2006 and produced their first gold in January 2007 (St. Andrew Goldfields Ltd., 2009). Mining was suspended in October 2007 to better define the ore bodies as the production was lower than anticipated from their reserve estimates.

In February, 2009, Fire River Gold (2010) acquired the property and in early 2010, they were engaged in a major program of re-logging and reanalyzing the surface and drill samples from the previous operators, mapping, and new drilling to define the deposit.

In Fall of 2010, Fire River released an updated mineral resource estimate (Fire River Gold Corp., 2010b). In July 2011, Fire River started up the Nixon Fork Mill (Fire River Gold, 2011). There was ongoing drilling, mining, and milling in 2012 and early 2013 (Fire River Gold Corp., 2013).

Production notes:

The Nixon Fork deposit was first staked in 1917 and was mined intermittently from 1918 to 1964, notably by the Yukon-Treadwell company and E.M. Whalen, from several shafts, open pits, and trenches (Mertie, 1936, Herreid, 1966, Wallis and Rennie, 2005). The total production during this period is estimated to be 42,200 ounces of gold, 11,281 ounces of silver, and 41,400 pounds of copper, from ore that averaged about 1.5 ounce of gold per ton. Much of this production came from ore bodies in the vicinity of Crystal Gulch. But at least some came from the Whalen Shaft (MD071), about a mile south, and from the glory hole near it.

The deposit was mined by Nevada Goldfields Inc. from 1995 to 1999 when they filed for bankruptcy. They produced 137,749 ounces of gold and 2,145,826 pounds of copper from 122,391 tons of ore with a 'reconciled' grade of 42 grams of gold per ton. In the first nine months of 2007, St Andrew Goldfields produced 18,105 tons of ore with a grade of 17.1 grams of gold per ton. Production was suspended in October 2007.

Reserves:

In 2006, Postle and others (2006) estimated the resources and reserves of the Nikon Fork Mine for St Andrew Gold Fields Ltd. These are: 1) a measured resource of 23,400 tonnes with a grade of 36.8 grams of gold per tonne; 2) an indicated resource of 126,000 tonnes with a grade of 21.6 grams of gold per tonne; 3) an inferred resource of 93,000 tonnes with a grade of 15.5 grams of gold per tonne; 4) a proven reserve of 47,000 tons with a grade of 34.05 grams of gold per tonne; and 5) a probable reserve of 137,500 tonnes with a grade of 18.6 grams of gold per tonne. However, when mining took place from late 2006 to late 2007, the production fell short of the estimates. In early 2010, Fire River Gold was engaged in a major program to better define the reserves and resources.

In December 2011, Fire River released an updated resource estimate based on 2010 and 2011 drilling results. These are: 1) an indicated resource of 129,060 tonnes with a grade of 24.9 grams of gold per tonne in the mines plus 2) an indicated resource of 92,000 tonnes with a grade of 7.9 grams of gold per tonne in the tailings for 3) a total indicated resource of 3,941,067 grams of contained gold; 4) an inferred resource of 53,980 tonnes with a grade of 28.0 grams of gold per tonne in the mines plus 5) an inferred resource of 48,000 tonnes with a grade of 7.4 grams of gold per tonne in the tailings for 6) an inferred resource of 1,863,681 grams of contained gold (Fire River Gold Corp., 2011).

Additional comments:

In June 2013, Fire River announced they were suspending operations and placing the mine into care and maintenance mode (Fire River Gold Corp., 2013). In 2014, Fire River announced they defaulted on their credit agreement terms with Waterton Global Value, L.P., and that Waterton has taken full and unrestricted

ownership of the Nixon Fork Gold Mine (Fire River Gold Corp., 2014).

Site name(s): Whalen Shaft

Site type: Mine

ARDF no.: MD071

Latitude: 63.2164 **Quadrangle:** M A-4

Longitude: 154.7696

Location description and accuracy:

The Whalen Shaft is about 0.5 mile northeast of the center of section 24, T. 26 S., R. 21 E., on the ridge at the head of Rudy Creek. It is near the 'Glory Hole' shown on the 1:63,360-scale U.S. Geological Survey topographic map. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other: Bi, Th, U, W

Ore minerals:

Gangue minerals: Calcite, diopside, epidote, garnet, limonite, quartz, sericite, siderite, tremolite, zeolite

Geologic description:

Mineralization was first staked in the area in 1917 and was mined intermittently from 1918 to 1964, notable by the Yukon-Treadwell company and by E.M. Whalen from several shafts, open pits, trenches, and a glory hole (Mertie, 1936; Herreid, 1966, Wallis and Rennie, 2005). The total production during this period is estimated to be 42,200 ounces of gold, 11,281 ounces of silver, and 41,400 pounds of copper from ore that averaged about 1.5 ounce of gold per ton. During this period, most of the mining took place here and about a mile to the north in the vicinity of Crystal Gulch (MD062); together they were usually referred to as the Nixon Fork Mine and their production aggregated. Much of the production during this period probably came from the Whalen Shaft area.

There has been almost continuous exploration and considerable mining in the vicinity by several companies since 1984 but most of it has been concentrated in what is now usually called the Nixon Fork Mine (MD062) near Crystal Gulch, about a mile to the north. The several companies who have worked in the area undoubtedly have done some work in the Whalen Shaft area and it is noted in passing in several of the reports of their work. However little detail is available for the Whalen Shaft area specifically. The geology and mineralization is also similar to that at the better-known Nixon Fork Mine (MD062). The mineralization at the Nixon Fork Mine consists of several classic gold-copper, epiodote-diopside-garnet skarn deposits, generally within 10 to 150 meters of the periphery of a Cretaceous (68 to 70 Ma) quartz monzonite to granodiorite stock about 3 by 5 kilometers in size (Moll and others, 1981; Bundtzen and Miller, 1997, Wallis and Rennie, 2005). The Whalen Shaft is on the southern periphery of this stock. The stock intrudes the Ordovician Telsitna Formation, a 2,000-meter-thick sequence of limestone and dolomite, and Cretaceous calcareous sandstone and shale. Both the quartz monzonite and the host rocks are cut by late quartz-feldspar and quartz porphyry dikes. The orebodies are irregular and complex, often with branching arms, but are roughly pipelike, dip steeply, and follow or parallel the border of the intrusion at depth. In plan the orebodies typically are about 4 meters by 20 to 30 meters in area and extend down dip for several hundred meters. They are typically associated with epidote-diopside-garnet skarn near carbonate rocks or hornfels near sandstone and shale. Both exoskarn and endoskarn are present. Most of the ore minerals and skarn occur in exoskarn 10 to 30 feet into the marble front. Minor mineralized endoskarns occur within satellite bodies of quartz monzonite; however, most of this mineralization is not ore grade. The main ore minerals are pyrrhotite, chalcopyrite, pyrite, and native gold; minor bornite and chalcocite are known The

quartz monzonite is sericitized and argillized near the mineralization and some of the ore bodies are oxidized up to a depth of 160 meters.

Alteration:

Age of mineralization:

Late Cretaceous based on 68 to 70 Ma isotopic age of monzonite adjacent to the skarn ore bodies.

Generic deposit model:

Deposit model:

Cu-Au skarn (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: Yes

Site Status: Active

Workings/exploration:

The Whalen Shaft was driven to an unknown depth, but not below the water table, which was at about 400 feet. A glory hole is nearby and probably other workings. Beginning in 1984, several companies have extensively explored and drilled in the area but almost all of that work has been concentrated about a mile to the north at what is now called the Nixon Fork Mine (MD062). Some of the recent exploration undoubtedly extended to the vicinity of the Whalen Shaft as it is part of the same property. But other than mentioning it in passing, no detail is available.

Production notes:

Mineralization was first staked in the area in 1917 and was mined intermittently from 1918 to 1964, notable by the Yukon-Treadwell company and E.M. Whalen, from several shafts, open pits, trenches, and a glory hole (Mertie, 1936; Herreid, 1966, Wallis and Rennie, 2005). The total production during this period is estimated to be 42,200 ounces of gold, 11,281 ounces of silver, and 41,400 pounds of copper from ore that averaged about 1.5 ounce of gold per ton. During this period, most of the mining took place here and about a mile to the north in the vicinity of Crystal Gulch; together they were usually referred to as the Nixon Fork Mine and their production aggregated. Probably much of the production during this period came from the Whalen Shaft area.

Reserves:

None.

Site name(s): North Shepard

Site type: Occurrence

ARDF no.: MD082

Latitude: 63.6431 **Quadrangle:** M C-3

Longitude: 154.3001

Location description and accuracy:

The North Shepard occurrence is situated on the northeast-facing side of a ridge between Johns and Shepherd Creeks. The occurrence is located 0.3 mile northeast from the center of Section 30, T. 21 S., R. 24 E., of the Kateel River Meridian. The site is accurate to within 500 feet (152 m).

Commodities:

Main: Au, Cu

Other: As, Co

Ore minerals: Arsenopyrite, chalcopyrite, gold

Gangue minerals: Quartz, sericite

Geologic description:

The North Shepard occurrence consists of quartz veins contained in felsic dikes. Anomalous gold mineralization is associated with quartz-sericite alteration of the dikes (DiMarchi and others, 1992, Newmont Mining Corp., 2012). The quartz veins contain disseminated arsenopyrite, chalcopyrite, and carry gold values; they are found in zones of silicic and phyllic alteration in the quartz monzonite dikes.

Surface samples collected by DiMarchi and others (1992) contain up to 500 ppb gold. Nine samples averaged 100 ppb gold. Copper, cobalt, and arsenic values were not reported.

Newmont Mining Corporation (2012) collected soil samples and rock chip samples in conjunction with detailed geologic mapping on Doyon Land in 2011. Soil samples were collected along ridges and spurs on a nominal spacing of 100 meters resulting in the identification of a northeast trending gold and arsenic anomaly associated with the northeast trending dike swarm. Newmont follow-up soil sampling in 2012 consisted of grid soil sampling a 2 kilometer by 5 kilometer area. Anomalous gold was found to be associated with veins bearing quartz- sericite in altered rhyolite dikes (Newmont Mining Corp., 2012, 2013).

Alteration:

Quartz and sericite (Newmont Mining Corp., 2012).

Age of mineralization:

The North Shepard prospect is inferred to be Late Cretaceous or early Tertiary based on isotopic age of Mystery Mountains intrusive complex (Moll and others, 1981).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active?

Workings/exploration:

Newmont Mining Corporation (2012) collected 466 soil samples and 23 rock chip samples in conjunction with detailed geologic mapping on Doyon Land in 2011. Soil samples were collected along ridges and spurs on a nominal spacing of 100 meters resulting in the identification of a northeast trending gold and arsenic anomaly. Newmont follow-up soil sampling in 2012 consisted of grid soil sampling a 2 kilometer by 5 kilometer area. Anomalous gold was found to be associated with veins bearing quartz- sericite in altered rhyolite dikes. Selected rock chip samples of quartz veins hosted in rhyolite dikes yielded assays of up to 12 ppm gold, whereas, non-quartz veined rock chip samples collected within the northeast trend typically yielded assays of 1 to 3 ppm gold. In 2012, Newmont drilled 3 NQ size core holes totaling 486 meters designed to intersect the sericite altered rhyolite dikes. Drill intercepts of anomalous gold include 4.9 meters of 3.74 g/t gold in hole number SHEP-0002 and 2.8 meters of 8.07 g/t gold in hole number SHEP-0003 (Newmont Mining Corp., 2012 and Newmont Mining Corp., 2013).

Production notes:

None.

Reserves:

None.

Site name(s): Vinasale

Site type: Prospect

ARDF no.: MG009

Latitude: 62.7051 **Quadrangle:** M C-6

Longitude: 155.7071

Location description and accuracy:

The Vinasale prospect is near the top of Vinsale Mountain directly east of the Kuskokwim River about 18 miles south of McGrath. The location is centered on the area of a calculated resource of the Central zone near the western edge of section 8, T. 30 N., R. 34 W, of the Seward Meridian.

Commodities:

Main: Ag, Au

Other: As, Bi, Mo, Pb, Sb, Zn

Ore minerals: Arsenopyrite, galena, jamesonite, pyrargyrite, pyrite, silver, sphalerite, stibnite

Gangue minerals: Dolomite, quartz, sericite

Geologic description:

Vinasale Mountain is underlain by a nearly circular composite, intrusive complex, about 2,500 meters in diameter (Bundtzen, 1986; DiMarchi, 1993; Adams and Giroux, 2011). The intrusive complex includes peraluminous, porphyritic quartz monzonite, rhyolite porphyry, shonkinite, and monzonite breccia. The intrusive phases cut and thermally alter flysch of the Late Cretaceous, Kuskokwim Group (Bundtzen and Miller, 1997). The stock has been dated by K-Ar methods at 69 Ma (Solie and others, 1991). The intrusive is marked by a magnetic high centered over Vinasale Mountain and a ring-shaped magnetic low that coincides with hornfels at the periphery of the intrusive complex.

During industry exploration work from 1989 to 1991 (DiMarchi, 1993), large coincident soil anomalies in gold, arsenic, antimony, lead, and molybdenum were found in three distinct zones named the Central, Northeast, and South zones on the top of Vinasale Mountain. The Central zone is approximately 457 by 610 meters in size and contains up to 2,470 parts per billion (ppb) gold. The Northeast and South zones contained up to 185 ppb and 335 ppb gold, respectively. The soil anomalies resulted in drilling that discovered significant gold-polymetallic mineralization.

The most common alteration types associated with gold mineralization consist of sericite-dolomite alteration and silicification. Strong dolomite alteration is generally indicative of higher gold values. Sericite-dolomite alteration occurs primarily as replacements of feldspars either in broad zones or in centimeter-scale alteration envelopes adjacent to sulfide-quartz veins. Silicification most often occurs as stockwork zones and veins up to 4 cm wide, although irregular quartz segregations and zones of pervasive flood silica can also be found locally. Broad zones of light-green sericite alteration are found adjacent to some zones of intense silicification. Weak propylitic alteration (mostly as incipient chlorite alteration of biotite) is widespread, generally occurring distal to gold mineralization relative to sericite-dolomite alteration and silicification. Minor amounts of chlorite or tourmaline alteration are found locally, and are typically associated with late shears and thin, late stage quartz veins (Abrams and Giroux, 2013).

The mineralization consists of disseminated sulfides and sulfide-quartz veins and veinlets. Sulfide mineralization in the Central zone consists of disseminated pyrite and arsenopyrite in areas of silica flooding in quartz monzonite, sericitic alteration in monzonite breccias, and quartz-dolomite veins and segregations in all intrusive rocks. Subordinate veinlets and veins contain coarsely crystalline pyrite, galena, arsenopyrite, sphalerite, stibnite, pyrargyrite, and jamesonite, and microscopic native silver and minor gold

(DiMarchi, 1993). The Northeast and South zones contain gold mineralization similar to but weaker than that in the Central zone.

Alteration:

Sericite-dolomite alteration and silicification are the main forms of alteration observed with mineralization. Weak propylitic alteration occurs more distal to mineralization (Abrams and Giroux, 2013).

Age of mineralization:

Hydrothermal sericite from the Central zone has been dated at 68.0 +/- 1.7 Ma (DiMarchi, 1993).

Generic deposit model:

Deposit model:

Intrusion-related gold (IRG) (McCoy and others, 1997).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

In 1990, Placer Dome U.S. Inc. and Central Alaska Gold Mining Company initiated a diamond drill program, concentrating on the Central zone. They drilled 65 holes that totaled 11,260 meters through 1993 (DiMarchi, 1993). The two longest auriferous intercepts in the Central zone were 63.1 meters with 2.42 grams per tonne (g/t) gold and 71.9 meters with 2.27 g/t gold. Those intercepts averaged 338 parts per million (ppm) antimony, 108 ppm zinc, 5 ppm lead, 3 ppm bismuth, and 0.7 ppm silver. In mineralized core, the gold/silver ratio is about 2:1. Arsenic is most concentrated in the southern Central zone where it averages 0.80 percent. The Northeast zone averaged about 500 ppm barium.

ASA-Montague leased the property from Doyon, Limited in 1994, and collected 771 soil samples, 20 rock samples and drilled 26 core holes (5262.4 meters). Most of this work was focused on the Central zone to upgrade the quality of the resource but some drill holes tested the outlying geophysical and soil anomalies. In 1995 and 1996 ASA-Montague did metallurgical testing, an environmental and permitting review, pre-feasibility study, and a resource estimate (Abrams and Giroux, 2013).

In 2007, Freegold Ventures Limited (Freegold) (2007) signed an agreement with Doyon, Limited to explore the property. Their 2007 and 2008 work included staking an additional 12,000 acres northeast of the previous claims that covered about 128,000 acres, a rock and and stream sediment sampling program, an aerial geophysical survey over the property, and an induced polarization (IP) survey (Adams and Giroux, 2011).

Freegold drilled 6 holes totaling 6,396 feet in 2010 with the aim at expanding the historical resources as well as testing weaker geophysical anomalies to the northeast. Exploration by Freegold during 2011 was entirely focused on the Central zone. The program was aimed at expanding and upgrading the current NI 43-101 resource. This work included a diamond core drilling program and an IP/resistivity geophysical survey. The geophysical survey indicates that in addition to the Central zone where most of the drilling has been conducted that a significant geophysical anomaly is defined in the Northeast zone where limited drilling has indicated mineralization of similar character to the Central zone (Abrams and Giroux, 2013).

In 2012 Freegold drilled 13 holes, 5 at the Northeast zone, 6 at the Central zone, and 2 between these two zones for a total of 3,425 meters. Highlights from the drilling include 85.3 meters at 1.49 g/t gold, 29.3 meters at 1.63 g/t gold, 12.2 meters at 1.34 g/t gold, 29.3 meters at 1.19 g/t gold, 9.1 meters at 1.10 g/t gold, and 33.7 meters at 1.09 g/t gold (Abrams and Giroux, 2013).

Production notes:

None.

Reserves:

Adams and Giroux (2011) calculated the inferred resource of the Central zone at 15 levels by varying the cut-off grade from 0.10 to 2.00 grams per tonne (g/t) gold. At a cut-off grade of 0.5 g/t gold, the Central zone has an inferred resource of 37.260 million tonnes with a grade of 1.11 g/t gold (or 1,331,000 ounces of gold); at a cut-off grade of 1.0 g/t gold, it has an inferred resource of 17.070 million tonnes with a grade of 1.57 g/t gold (or 859,000 ounces of gold).

The resource at Vinasale was updated again by Abrams and Giroux (2013). At a 0.5 g/t gold cut-off there is an indicated resource of 3.41 million tonnes averaging 1.48 g/t gold (162,000 ounces of gold) and an inferred resource of 50.2 million tonnes averaging 1.06 g/t gold (1,703,000 ounces of gold).

Additional comments:

The Vinasale prospect is located within Doyon, Limited conveyed land. For more information contact Doyon, Limited, Fairbanks, Alaska.

Site name(s): Alder Gulch; Vinasale

Site type: Mine

ARDF no.: MG010

Latitude: 62.696 **Quadrangle:** M C-6

Longitude: 155.71

Location description and accuracy:

The Alder Gulch placer mine is located in Alder Gulch, a south flowing tributary that drains the south slope of Vinasale Mountain. The mine workings are at an elevation of 850 feet (259 meters) in the NE 1/4 section 18, T. 30 N., R. 34 W., of the Seward Meridian. T.K. Bundtzen investigated the mine in 1982. The accuracy is within one-quarter mile.

Commodities:

Main: Ag, Au

Other: Bi, PGE, Sb, W

Ore minerals: Bismuth, gold, ilmenorutile, monazite, scheelite

Gangue minerals:

Geologic description:

The Alder Gulch heavy mineral placer deposit consists of auriferous, semi-residual and alluvial, unconsolidated deposits of Quaternary age in a steep gulch on the south flank of Vinasale Mountain. The placer deposit lies down slope and downstream from a mineralized 69.0 Ma granitic pluton that forms most of Vinasale Mountain (Bundtzen, 1986). Alder Gulch has only intermittent water flow and is dry through much of late summer and fall.

The gold and heavy mineral bearing material ranges from 0.5 to 2 meters thick, over stream widths of 12 to 20 meters. Placer gold has been detected for about 2 kilometers below the main workings. The placer deposit begins just below the contact between quartz monzonite and sheared hornfels, which may be a mineralized source for the placer minerals. The stream gradient is very steep and averages about 100 meters/kilometer at the head of Alder Gulch.

Principal heavy minerals identified during mining activities include placer gold that exhibits a fineness of 930, abundant native bismuth and scheelite; minor hastingsite, ilmenite, magnetite, and zircon; trace amounts of monazite, and ilmenorutile; and up to 2.6 ppm PGE (Bundtzen, 1986). The mineralogical source of the PGE is unknown. Sulfide-scheelite-quartz float found in the placer cut contains up to 14.3 grams/tonne gold (Bundtzen, 1986).

In 2010, Freegold completed it's initial drilling on the Vinasale Project; a total of 1,947 meters were drilled in the Central Zone. The results of which were incorporated into Freegold's initial NI-43-101 compliant resource, which was completed in March 2011. The 2011 exploration program included a 13 hole diamond drill program the results of which were incorporated into an updated NI 43-101 compliant resource in March 2012. The addition of 13 drill holes drilled in 2011 and the expansion of the body expanded the tonnage of the resource. During the 2012 exploration season, Freegold completed 13 core drill holes for a total of 11,238 feet (3,425.7 meters). Reconnaissance level rock and soil geochemistry were also completed in the Central Zone, Northeast Zone and in outlying areas (Freegold, 2014).

In March 2013 a new updated NI 43-101 Compliant resource was completed, which incorporated the results of the 2012 drilling. The resource estimate was completed by Giroux Consultants Ltd. of Vancouver, BC. Canada. Indicated resources are 3.41 million tonnes averaging 1.48 grams of gold per tonne for 162,000 ounces, and inferred resources are 53.25 million tonnes averaging 1.05 grams of gold per tonne for

1,799,000 ounces of gold utilizing a cutoff value of 0.5 gram of gold per tonne as a possible open pit cutoff within the total blocks (Abrams and Giroux, 2013).

Alteration:

Extensive oxidation of regolith results in grussification of plutonic suite (Bundtzen, 1986).

Age of mineralization:

Quaternary, based on geomorphic character (in active stream basin) (Bundtzen, 1986).

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Gold heavy mineral placer (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Surface exploration includes samples collected and processed by mine operator Peter Snow and samples reported by Bundtzen (1986). Sulfide-scheelite-quartz float found in the mine cut contain up to 14.3 grams/tonne gold.

In 2010, Freegold completed it's initial drilling on the Vinasale Project, a total of 1,947 meters were drilled in the Central Zone. The results of which were incorporated into Freegold's initial NI-43-101 compliant resource, which was completed in March 2011. The 2011 exploration program included a 13 hole diamond drill program the results of which were incorporated into an updated NI 43-101 compliant resource in March 2012. The addition of 13 drill holes drilled in 2011 and the expansion of the geologic solid expanded the tonnage of the resource. During the 2012 exploration season, Freegold completed 13 core drill holes for a total of 11,238 feet (3,425.7 meters). Reconnaissance level rock and soil geochemistry were also completed in the Central Zone, Northeast Zone and in outlying areas (Freegold, 2014).

In March 2013, a new updated NI 43-101 Compliant resource was completed, which incorporated the results of the 2012 drilling. The resource estimate was completed by Giroux Consultants Ltd. of Vancouver, BC. Canada. Indicated resources are 3.41 million tonnes averaging 1.48 grams of gold per tonne for 162,000 ounces, and inferred resources are 53.25 million tonnes averaging 1.05 grams of gold per tonne for 1,799,000 ounces of gold utilizing a cutoff value of 0.5 gram of gold per tonne as a possible open pit cutoff within the total blocks (Abrams and Giroux, 2013).

Bundtzen (1986) collected a series of bulk concentrate samples from Peter Snow's 1982 operation, and concluded that up to 68 kilograms of scheelite could be recovered from one tonne of concentrate.

Production notes:

Between 1930 and 1932, Carl Shutler mined in shallow hand mining cuts and produced 106.5 ounces (3.3 kg) gold and 20.2 ounces (0.6 kg) of byproduct silver Bundtzen, 1986). In 1981 and 1982, Peter Snow produced 16.5 ounces (503 grams) gold and 3.5 ounces (108 grams) of silver from a series of small test pits using a small tractor.

Reserves:

Indicated resources are 3.41 million tonnes averaging 1.48 grams of gold per tonne for 162,000 ounces, and inferred resources are 53.25 million tonnes averaging 1.05 grams of gold per tonne for 1,799,000 ounces of gold utilizing a cutoff value of 0.5 grams of gold per tonne as a possible open pit cutoff within the total blocks (Abrams and Giroux, 2013).

Additional comments:

Freegold Ventures Ltd. entered into an Exploration Agreement with an Option to Lease the Vinasale Project from Doyon Limited, an Alaskan Native Regional Corporation, in 2007.

Last report date: 2016-02-25

Site name(s): Roberts (near Middle Fork of Kuskokwim River)

Site type: Prospect

ARDF no.: MG030

Latitude: 62.196 **Quadrangle:** M A-3

Longitude: 154.4487

Location description and accuracy:

The Roberts prospect is on the crest of a steep, north-sloping ridge near the head of an unnamed tributary of the Middle Fork of the Kuskokwim River. It is at an elevation of about 4,170 feet about 0.2 mile southeast of the center of section 5, T. 24 N., R. 28 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Ag, Au, Bi, Co, Cr

Ore minerals: Bravoite, chalcopyrite, galena, pentlandite, pyrite, pyrrhotite, Te-Bi sulfosalts, unidentified PGE minerals

Gangue minerals: Hematite, magnetite

Geologic description:

The Roberts prospect is in a differentiated, mafic-ultramafic sill that cuts silty limestone and shale of the Late Cambrian to Early Ordovician, Lyman Hills Formation, the oldest facies of the Dillinger subterrane (Bundtzen, Harris, and Gilbert, 1997). The sill is undated, but believed to be correlative with Late Triassic feeders in the Tatina River Volcanics, a subdivision of the Middle Devonian to Lower Jurassic Mystic subterrane (Bundtzen, Harris, and Gilbert, 1997; T.K. Bundtzen and G.M. Laird, written communication, 1998).

The mafic-ultramafic sill trends N 55 E and dips about 35SE parallel to bedding; it varies in composition from picrite to diorite but mostly is gabbro. Surface sampling and mapping indicate that the sill is differentiated with picrite-gabbro near the base and diorite near the top (T.K. Bundtzen and G.M. Laird, written communication, 1998). Another mafic sill mapped by Gilbert and others (1988) about 3 kilometers southwest is on strike with the Roberts occurrence.

The mineralization at the Roberts prospect is mainly disseminated and network-style sulfides with a notable content of platinum group elements (PGE) in the lower and middle part of the sill. The ore minerals include megascopic chalcopyrite, pyrite, magnetite, and pyrrhotite, and microscopic bravoite, galena, Bi-Te sulfosalts, and pentlandite. According to W.S. Roberts (written communication, 1984), the PGE mineral may be a palladium-bismuth telluride. T.K. Bundtzen and G.M. Laird (written communication, 1998) could not identify the PGE minerals at the prospect. Based on limited chip-channel sampling, the thickness of the mineralized zone varies from 2 to 4 meters and extends for a strike length of at least 25 meters.

Five samples taken perpendicular to the strike of the sill contained up to 0.49 parts per million (ppm) palladium, 0.35 ppm platinum, 0.8 ppm silver, 0.09 ppm gold, 1,315 ppm copper, 1,510 ppm nickel, and 1,530 ppm chromium (T.K. Bundtzen and G.M. Laird, written communication, 1998). Bench tests conducted by the Bureau of Mines showed up to 4.71 percent nickel, 0.16 percent cobalt, 4.68 percent copper, 6.2 ppm platinum, 7.7 ppm palladium, and 4.7 ppm gold (W.S. Roberts, written communication, 1984; Foley and others, 1997; Bundtzen, Harris, and Gilbert, 1997).

Brozdowski and Taylor (2009) reported on recent work by Nycon Resources Inc. They drilled the prospect and flew two airborne geophysical surveys over it covering about 195 square kilometers. Brozdowski and Taylor describe the Roberts prospect as an anastomosing dike- to sill-like body of olivine

gabbro and peridotite that extends for about 430 meters along strike and is about 50 feet thick. Its magnetic expression and drill holes indicate it dips steeply west. Several rock chip samples contained 2.27 to 2.32 percent nickel, 1.31 to 2.30 percent copper and 13.22 to 16.88 ppm platinum group elements. A drill intercept 8.4 meters long contained 0.94 ppm platinum and 1.07 ppm palladium. The geophysical data suggests the Roberts prospect is part of a belt of similar deposits that includes the nearby Chip-Loy prospect (MG032).

Alteration:

Serpentinization of ultramafic phases of sill.

Age of mineralization:

Probably correlative with Late Triassic feeders in Tatina River Volcanics (Bundtzen, Harris, and Gilbert, 1997).

Generic deposit model:

Deposit model:

Disseminated Ni-Cu-PGE in gabbro (Cox and Singer, 1986; model 5b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

5b

Production Status: None

Site Status: Active

Workings/exploration:

The Robert's prospect was discovered in 1981 by W.S. Roberts of the U.S. Bureau of Mines while working with the Alaska Division of Geological and Geophysical Surveys in the McGrath quadrangle. The prospect was sampled by the Alaska Division of Geological and Geophysical Surveys and the U.S. Bureau of Mines several times in the 80s and 90s. In 2009, Nycon Resources Inc. was active on the property; they drilled the prospect and flew two airborne geophysical surveys over it that covered about 195 square kilometers.

Production notes:

None.

Reserves:

None.

Last report date: 2010-04-02

Site name(s): Chip-Loy

Site type: Prospect

ARDF no.: MG032

Latitude: 62.1664 **Quadrangle:** M A-3

Longitude: 154.3834

Location description and accuracy:

The Chip-Loy deposit is on a steep valley wall of what is locally called Straight Creek, one of the headwater tributaries of the Middle Fork of the Kuskokwim River. It is between about 2,900 feet to 4,000 feet in elevation, about 0.3 mile southeast of the center of section 15, T. 24 N., R. 28 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Co, Cu, Ni

Other: Ag, Au, Fe

Ore minerals: Bravoite, chalcopyrite, cubanite, galena, nickelian pyrrhotite, pentlandite, sphalerite, tetradymite, violarite, undetermined Co-Ni-Fe arsenide

Gangue minerals: Ilmenite

Geologic description:

According to Herreid (1968), Foley (1987), and Foley and others (1997), the Chip-Loy deposit consists of an irregular, steeply dipping layer of massive to disseminated, nickelian pyrrhotite and other sulfides in an elongate, composite, diabase intrusion. Herreid (1968) describes the diabase, which ranges from gabbro to diorite, as a pipe in plan view, but Smith and Albanese (1985) describe it as a dike. The diabase trends in a northeast direction and varies from 40 meters to 260 meters wide; cliff walls prevent accurate investigations of the intrusion's true dimensions. The composite diabase intrusion cuts mid-Silurian Terra Cotta Mountains Sandstone, a formation of the Dillinger subterrane of Lower Paleozoic age. (Bundtzen, Harris, and Gilbert, 1997). Gilbert and others (1988) assign an early Tertiary age to the mineralized diabase intrusion.

The Chip-Loy deposit contains disseminated to massive sulfides, mainly pyrrhotite and chalcopyrite, with minor cubanite and sphalerite, and trace galena, bravoite, violarite, tetradymite ($Bi2Te2S$), and undetermined Co-Ni-Fe arsenides (Bart Cannon, written communication, 1998). The sulfides are intergrown with ilmenite and other rock-forming minerals such as plagioclase and olivine. The northeast trending, sulfide-bearing zone is in the diabase about 10 to 30 meters from the contact with sandstone and shale. The zone is about 335 meters long and 10 to 15 meters wide but is quite irregular along strike. Herreid (1968) estimated that the Chip-Loy deposit contains an inferred reserve of about 150,000 tonnes of disseminated and massive sulfide mineralization. Smith and Albanese (1985) suggested a larger reserve than Herreid; they estimate 0.15 to 1.25 million tonnes of sulfide mineralization.

Chip-channel samples from the Chip-Loy deposit contained up to 3.30 percent nickel, 0.25 percent cobalt, 2.10 percent copper, 12.1 grams of silver per tonne, and 43.2 percent iron (Smith and Albanese, 1985; Bundtzen and others, 1982). A single sample of massive sulfide mineralization contained 3.0 grams of gold per tonne (Foley, 1987; Gilbert and others, 1988). Tetradymite is in the interstices of the rock-forming silicates. A 12-meter-long chip-channel sample across the deposit contained 0.28 percent copper, 2.6 grams of silver per tonne, 444 parts per million (ppm) cobalt, 0.70 percent nickel, and 17.82 percent iron (Smith and Albanese, 1985; Gilbert and others, 1988). Pyrrhotite from selected samples averaged 0.4 percent cobalt and 1.5 percent nickel (Bart Cannon, written communication, 1998). About 50 percent of the nickel

and cobalt is in pyrrhotite; the remainder is in pentlandite and other nickel and cobalt minerals.
Brozdowski and Taylor (2009) reported on recent work by Nycon Resources Inc. as part of their exploration on a large block of claims. They drilled the prospect and flew two airborne geophysical surveys over it that covered about 195 square kilometers. Brozdowski and Taylor describe the deposit as a highly-contaminated Early Tertiary gabbro to diorite dike. Grab samples contained up to 2.7 percent nickel, 0.4 percent copper, and 20 parts per billion platinum and palladium. The aerial geophysical data suggest that the Chip-Loy prospect is part of a belt of similar deposits that includes the nearby Roberts prospect (MG030).

Alteration:

Slight oxidation of massive sulfides.

Age of mineralization:

Little evidence for age. Thought to be early Tertiary by Gilbert and others (1988) and Brozdowski and Taylor (2009); however, the nearby Roberts deposit (MG030) possibly is Late Triassic.

Generic deposit model:

Deposit model:

Gabbroic Ni-Cu (Cox and Singer, 1986; model 7a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

7a

Production Status: None

Site Status: Active

Workings/exploration:

The Chip-Loy deposit was discovered and staked by prospectors Ed Chipp and Robert Loy in the early 1960s. Since then numerous geologists from industry and government have visited and sampled it. In 2009, the prospect was explored and drilled by Nycon Resources, Inc. as part of their study of similar deposits on a large block of claims that covered this prospect.

Production notes:

None.

Reserves:

Herreid (1968), who provides the only detailed geologic map of the Chip-Loy deposit, estimated approximately 150,000 tonnes of disseminated-to- massive sulfide mineralization. Smith and Albanese (1985) estimated that that the deposit contains 0.15 and 1.25 million tonnes of disseminated to massive mineralization.

Site name(s): Little Bird; BMP

Site type: Prospect

ARDF no.: MG047

Latitude: 62.3692 **Quadrangle:** M B-2

Longitude: 153.7942

Location description and accuracy:
The Little Bird prospect is on an east-facing slope on the west side of Sheep Creek Valley at an elevation of about 3,600 feet It is in the SE1/4 section 6, T. 26 N., R. 24 W., of the Seward Meridian.

Commodities:

Main: Ag, Cu, Zn

Other: Pb, W

Ore minerals: Chalcopyrite, galena, pyrrhotite, scheelite, sphalerite

Gangue minerals: Epidote, diopside

Geologic description:
The Little Bird occurrence is a sulfide-bearing, pyroxene skarn in limestone of the Lower Devonian, Barren Ridge Limestone, a unit of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997). The skarn occurs near a weakly mineralized, granite porphyry stock (Brewer and others, 1992). Discontinuous semi-massive and disseminated pyrrhotite with chalcopyrite, sphalerite, and galena occur in a 200 meter by 700 meter skarn zone. The grades and widths of the mineralization in the skarn are variable, but samples contain up to 4.5 percent copper, 1.7 percent lead, 11.4 percent zinc, 426.1 grams of silver per ton , and 0.33 percent tungsten (Brewer and others, 1992). The deposit was explored by Anaconda Minerals Company from 1981-1983.
In 2008, this prospect was one of several in a block of claims covering more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:
Mineralization in a skarn zone.

Age of mineralization:
Cretaceous?

Generic deposit model:

Deposit model:
Polymetallic lead-zinc skarn (Cox and Singer, 1986; model 18c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
18c

Production Status: None

Site Status: Active

Workings/exploration:

The Little Bird occurrence was explored by Anaconda Minerals Company from 1981-1983 (Rob Kell, written communication, 1984). As of 2008, the prospect was in a large block of claims called the BMP project by International Tower Hill MIne, Ltd.

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Crash; Sheep Creek 2; BMP

Site type: Prospect

ARDF no.: MG049

Latitude: 62.353 **Quadrangle:** M B-2

Longitude: 153.8015

Location description and accuracy:

The Crash prospect is located in an unnamed east-flowing tributary of Sheep Creek. It is 4.0 kilometers northwest of Smith Lake at an elevation of 2,800 feet in the SW1/4 sec. 7, T. 26 N., R. 24 W., of the Seward Meridian.

Commodities:

Main: Ag, Cu, Zn

Other: Au, Pb

Ore minerals: Chalcopyrite, galena, malachite, pyrrhotite , sphalerite

Gangue minerals: Quartz

Geologic description:

The Crash prospect consists of two siliceous, cataclastic breccias similar to those that host the mineralization at the Dahl prospect (MG053). The Crash zone is in a splay structure associated with a regional fault that hosts the Dahl prospect (MG053). The mineralization in one shale-hosted breccia zone contains massive chalcopyrite and sphalerite with traces of galena. It is near the contact of the Lower Ordovician to Lower Silurian, Post River Formation and the Middle to Upper Silurian Terra Cotta Mountains Sandstone, both units of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997). The other cataclastic breccia contains abundant arsenopyrite. Both sulfide-bearing breccia zones are from 3 to 30 centimeters thick, appear stratiform or parallel to sedimentary bedding, and are isoclinally folded. This suggests the sulfides were formed prior to Lower Cretaceous compressive deformation (Bundtzen, Harris, and Gilbert, 1997). The mineralization at the Crash prospect might be related to younger plutons. Samples from the larger sulfide-bearing breccia contain up to 16.5 percent copper and 926.8 grams of silver per tonne. (Brewer and others, 1992). The smaller cataclastic zone has a pod 02 to 2.0 meters thick of massive arsenopyrite that contains 6.8 grams of gold per tonne. Three samples collected by Smith and Albanese (1985) contain up to 316 parts per million (ppm) copper, 86 ppm lead, 940 ppm zinc, and 10.5 grams of silver per tonne. The gold in the Crash is atypical of most sulfide occurrences and prospects in the Farewell Mineral Belt.

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:

Age of mineralization:

Undated; inferred to be Lower Ordovician to Lower Silurian, based on graptolites found in mineralized area (Bundtzen, Harris, and Gilbert, 1997).

Generic deposit model:

Deposit model:

Either sedimentary exhalative lead-zinc or polymetallic vein (Cox and Singer, 1986; model 31a or 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31a or 22c

Production Status: None

Site Status: Active

Workings/exploration:

Tom Smith and Mary Albanese first sampled the Sheep Creek-2 occurrence in 1982 during mineral investigations by the Alaska Division of Geological and Geophysical Surveys (Smith and Albanese, 1985). As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:

None.

Reserves:

None.

Primary Reference: International Tower Hill Mines, Ltd., 2008

Reporter(s): T.K. Bundtzen (Pacific Rim Geological Consulting); D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-06-05

Site name(s): Sheep Creek-1; BMP

Site type: Occurrence

ARDF no.: MG051

Latitude: 62.3419 **Quadrangle:** M B-2

Longitude: 153.8018

Location description and accuracy:

The Sheep Creek-1 occurrence is in the main tributary valley of Sheep Creek, about 2.0 kilometers upstream from the junction of the main tributary and the Smith Lake fork. It is at an elevation of about 2,800 feet in the SW1/4 sec. 18, T. 26 N., R. 24 W., of the Seward Meridian.

Commodities:

Main: Ag, Zn

Other: Pb, Sb, V

Ore minerals: Pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Sheep Creek-1 occurrence is a discontinuous zone of metal-bearing, sulfur-rich shale and siltstone of the Lower Ordovician to Lower Silurian Post River Formation, a unit of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997). The shale-hosted mineralization contains graptolites that correspond to the Monograptus spiralis zone of Lower Silurian age. The mineralized zones occur in distinctive areas where a bright yellow sulfur staining seeps out of pyrite-rich lamina in the black shale. Within the sulfur-rich zones, disseminated pyrite and sphalerite occur in bands 2 to 4 centimeter thick.

Bundtzen, Harris, and Gilbert (1997) regard the Sheep Creek-1 occurrence as a sedimentary-exhalative lead-zinc deposit; however, it may be an epigenetic occurrence related to nearby plutons. Random chip samples reported by Bundtzen, Kline, and Clough (1982) and Bundtzen, Harris, and Gilbert (1997) from four stratiform horizons contained an average of 600 parts per million (ppm) lead, 1,700 ppm zinc, 1,000 ppm vanadium, and 2.7 grams of silver per tonne. Smith and Albanese (1985) reported a single sample from the Sheep Creek-1 occurrence that contained 720 ppm lead, 37.1 grams of silver per tonne, and 472 ppm antimony.

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:

Strong sulfurous alteration.

Age of mineralization:

Inferred to be Lower Silurian based on graptolite collected at the prospect.

Generic deposit model:

Deposit model:

Sedimentary exhalative Pb-Zn? deposit (Cox and Singer, 1986; model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
31a?

Production Status: None

Site Status: Active

Workings/exploration:
First recognized in 1981 (Bundtzen, Kline, and Clough, 1982). The prospect was subsequently examined by industry and government. As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:
None.

Reserves:
None.

Additional comments:

Reporter(s): T.K. Bundtzen (Pacific Rim Geological Consulting); D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-06-05

Site name(s): Sheep Creek-West; BMP

Site type: Prospect

ARDF no.: MG052

Latitude: 62.3298 **Quadrangle:** M B-2

Longitude: 153.8115

Location description and accuracy:

The Sheep Creek-West prospect is on the west side of Sheep Creek Valley just downstream from the intersection of the Rat Fork and the South Fork of Sheep Creek; it is at an elevation of 3,400 feet in the SW1/4 section 13, T. 26 N., R. 24 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Au, Cd

Ore minerals: Cerussite, chalcopyrite, galena, malachite, pyrrhotite, sphalerite

Gangue minerals: Epidote, garnet, iron oxides, johannsenite

Geologic description:

The Sheep Creek-West prospect contains oxidized, sulfide mineralization. It is along a steeply dipping, northeast-striking fault(?) zone, 2 to 3 meters wide that juxtaposes silty limestone against tan arkosic sandstone. Both units belong to the Lower to Upper Silurian, Terra Cotta Mountains Sandstone, a formation within the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997). The fault zone strikes northeast for at least 135 meters and is marked by a distinctive notch along the steep side hill. Sphalerite, galena, chalcopyrite and pyrrhotite in epidote, johannsenite, and garnet skarn replace limestone as vug fillings and stringers along the shear zone (Bundtzen, Kline, and Clough, 1982). Abundant malachite staining is a conspicuous feature locally along the fault zone.

Two chip samples collected across about 3 meters of the zone contain up to 0.85 percent copper, 1.01 percent lead, 0.58 percent zinc, 30 parts per million cadmium, 86 grams of silver per tonne and 0.60 grams of gold per tonne. (Bundtzen, Kline, and Clough, 1982).

The vein is probably related to nearby polymetallic veins at the Dahl (MG053), and the Sheep Creek-South (MG057) prospects that are part of the Farewell Mineral Belt. The structurally controlled, vein-type mineralization may be related to skarn mineralization observed throughout the Farewell Mineral Belt.

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:

Sulfides are highly oxidized with the development of conspicuous cerussite, iron oxides, and malachite.

Age of mineralization:

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
22c

Production Status: None

Site Status: Active

Workings/exploration:
Surface sampling by Bundtzen and others in 1981 and 1982 was done on behalf of the Alaska Division of Geological and Geophysical Survey. As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:
None.

Reserves:
None.

Last report date: 2008-06-05

Site name(s): Dahl, BMP

Site type: Prospect

ARDF no.: MG053

Latitude: 62.3272

Quadrangle: M B-2

Longitude: 153.8118

Location description and accuracy:

The Dahl prospect is in a steep north-trending gulch, 4.0 kilometers west of the outlet of Smith Lake and one kilometer south of the junction of the headward tributaries of Sheep Creek. It is at elevation of about 3,600 feet near the middle of the boundary between sections 19 and 24, T. 26 N., R. 24 W., of the Seward Meridian.

Commodities:

Main: Ag, Cu, Zn

Other: Pb

Ore minerals: Chalcopyrite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Dahl prospect consists of several impressive zones of massive chalcopyrite-pyrite-sphalerite mineralization that replaces Lower Paleozoic carbonaceous shale in contact zones between a north-trending quartz-feldspar porphyry sill(?) and shale. The massive sulfide mineralization is exposed for over 90 meters along a narrow north-trending ravine between two unnamed tributaries of upper Sheep Creek. The quartz-feldspar porphyry sill is parallel to the contact between the Lower Ordovician to Lower Silurian Post River Formation and mid-Silurian Terra Cotta Mountains Sandstone; both are units of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997).

The mineralized horizon consists primarily of massive pyrrhotite with variable amounts of chalcopyrite, and sphalerite, and traces of tetrahedrite; it is 2.0 to 4.5 meters wide in a 4.0 meter to 7.0 meter zone of siliceous breccia. This breccia is localized in the faulted contact between the Ordovician-Lower Silurian Post River Formation and the mid to Upper Silurian Terra Cotta Sandstone. Chalcopyrite forms fine-grained masses up to 15 centimeters thick. Subordinate sphalerite, pyrrhotite, and pyrite accompany the chalcopyrite and form separate masses up to 5 centimeters thick. Minor quartz gangue occurs in the sulfide zones, which range from 1 to 5 meters thick.

The genesis of the Dahl prospect is controversial. The Anaconda Minerals Company, which explored the deposit in 1982 with a diamond drill, regarded the Dahl prospect as a shale hosted, sedimentary exhalative, massive-sulfide deposit in lower Silurian tuffaceous(?) shale (Reed, 1982; Brewer and others, 1992). They based this interpretation on: (1) the stratigraphic section of the Dillinger sub-terrane is similar to that in the Selwyn Basin in Yukon Territory, Canada, which hosts significant 'sedex' mineralization of the same age; (2) the wallrocks at the Dahl prospect contain framboidal pyrite with high lead, zinc and copper contents, (3) pyrite has been altered to pyrrhotite and 'buckshot' textures similar to that observed at Faro orebody, in Yukon; and (4) the whitish(?) layer interlayered with the sulfides was believed to be a syndepositional, submarine tuff. Sulfide-rich shale sections in drill core that were examined by T.P. Bundtzen (personal observation) in 1983 contained the graptolite Monograptus spiralis which confirms that the host rock is Lower Silurian in age.

However, Smith and Albanese (1985) observed crosscutting relationships of sulfides and host sediments, and sulfide replacements in the younger(?) quartz-feldspar porphyry sill(?). The quartz-feldspar porphyry

was also observed to cut bedding in host sediments. Isotopic S34 values from pyrrhotite average -0.2, which suggests derivation from plutonic sources (T.K. Bundtzen, written communication, 1989). Hence, Smith and Albanese (1985) and Bundtzen, Harris, and Gilbert (1997) classified the Dahl prospect as an epigenetic, sulfide replacement deposit.

Two holes were drilled on the Dahl prospect. Drill hole DP-W01 intersected 5.5 meters of massive sulfide mineralization that averaged 0.9 percent copper, 1.0 percent lead, 6.0 percent zinc, and 177.3 grams of silver per tonne. Diamond drill hole DP-D01 intersected 3.5 meters of semi-massive sulfides that averaged 4.0 percent copper, 0.3 percent lead, 1.0 percent zinc, and 370.1 grams of silver per tonne (Brewer and others, 1992). Bundtzen, Kline, and Clough (1982), Smith and Albanese (1985) and Bundtzen, Harris, and Gilbert (1997) reported that chip samples contained up to 5.40 percent copper, 3.48 percent zinc, and 165.0 grams of silver per tonne. A down hole geophysical survey showed that the DP-D01 drill-hole intercept is electrically continuous with the surface outcrops, suggesting that surface mineralization continues down dip for at least 150 meters. Additional surface conductivity surveys also suggest that the massive sulfide horizon extends to the north an additional 150 meters. No estimates of size and grade have been made (Reed, 1982; Brewer and others, 1992).

In 2008, the Dahl prospect was one of the prominent deposits in a block of claims that covered more than 70 square miles and known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008). Their mapping in 2007 suggests that the mineralization occurs along a fault developed in a north-trending anticlinal hinge that extends 5 km to the south through several prospects (MG057 and MG061) to the 6120 prospect (MG062) and about 3 kilometers to the north through several other prospects (MG049-051).

Alteration:

Age of mineralization:

Unknown; believed to be either Tertiary, based on presumed age of the associated quartz-feldspar porphyry sill or Silurian, based on fossil identification (Bundtzen, Harris, and Gilbert, 1997).

Generic deposit model:

Deposit model:

Either polymetallic replacement or sedimentary exhalative lead-zinc (Cox and Singer, 1986; model 19a or 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

19a or 31a

Production Status: None

Site Status: Active

Workings/exploration:

The Dahl prospect was discovered by Anaconda Minerals Company in 1980 or 1981 and two holes were drilled in 1982. In 2008, the Dahl prospect was one of the prominent deposits in a block of claims that covered more than 70 square miles and known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Production notes:

None.

Reserves:

None.

Site name(s): Smith Lake; BMP

Site type: Prospect

ARDF no.: MG055

Latitude: 62.3279

Quadrangle: M B-2

Longitude: 153.7404

Location description and accuracy:

The Smith Lake prospect is about 150 meters west of the outlet of Smith Lake and 120 meters upstream from the junction of a small unnamed tributary and the Smith Lake fork of Sheep Creek. It is at an elevation of 3,000 feet in the SW1/4 sec. 21, T. 26 N., R. 24 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Bi, Co

Ore minerals: Chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Clinopyroxene, siderite

Geologic description:

The mineralization at the Smith Lake prospect consists of a high angle, sulfide-rich fault zone in mid-Silurian clastic rocks of the Terra Cotta Sandstone, a unit of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997). The fault zone trends N45E, dips steeply to vertically, and is from 0.5 to one meter wide. An adit driven into the mineralized zone exposed about 8 meters of the sulfide vein along its strike.

The main ore mineral is pyrrhotite which makes up 75 percent of the sulfides; minor amounts of pyrite, chalcopyrite, galena, and sphalerite are associated with the pyrrhotite. The gangue material includes significant secondary siderite and highly deformed clinopyroxene. Selected chip samples contained up to 1.05 percent copper, 1.74 percent lead, 5.22 percent zinc, 42.0 grams of silver per tonne, 100 parts per million (ppm) cobalt, and 100 ppm bismuth (Bundtzen, Kline, and Clough, 1982; Smith and Albanese, 1985). A 0.3-meter-long channel sample collected by Brewer and others (1992) contained 14.8 percent lead, 10.6 percent zinc, 0.6 percent copper, and 90.2 grams of silver per tonne. The Smith Lake mineralization is typical of other silver-polymetallic prospects in Farewell Mineral Belt.

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:

Siderite alteration.

Age of mineralization:

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Some time prior to 1980, an 8-meter-long adit was driven into this sulfide-rich fault zone. It has been sampled several times by government and industry geologists from the early 80s into the 1990s. As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:

None.

Reserves:

None.

Site name(s): Clough; BMP

Site type: Occurrence

ARDF no.: MG056

Latitude: 62.3258 **Quadrangle:** M B-2

Longitude: 153.7712

Location description and accuracy:

The Clough occurrence is in a saddle that separates two northwest-trending ridge lines, about 2.0 kilometers west of the north end of Smith Lake. It is at an elevation of about 4,500 feet in the SW1/4 sec. 20, T. 26 N., R. 24 W., of the Seward Meridian. (The occurrence as shown in Bundtzen, Harris, and Gilbert (1997; map no. 10) is mislocated.)

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Co

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals: Epidote, quartz

Geologic description:

The Clough occurrence is a small but rich deposit in skarn adjacent to an altered, east-west-trending felsic (?) dike. The skarn is in argillaceous limestone of the mid-Silurian Terra Cotta Mountains Sandstone, a unit of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997).

The principle sulfides are massive pyrite and sphalerite in veins up to 8 centimeters thick; they and a trace of chalcopyrite occur in an epidote-quartz skarn. One grab sample of mineralization contained 13.0 percent zinc, 0.11 percent lead, 0.50 percent copper, 26 grams of silver per tonne, and 300 parts per million cobalt. (Bundtzen, Kline, and Clough, 1982; Bundtzen, Harris, and Gilbert, 1997).

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:

None.

Age of mineralization:

Generic deposit model:

Deposit model:

Low temperature lead-zinc skarn (Cox and Singer, 1986; model 18c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18c

Production Status: None

Site Status: Active

Workings/exploration:

The Clough occurrence was found by Jim Clough of Alaska Division of Geological and Geophysical Surveys during a geologic mapping program in 1981 (Bundtzen, Kline, and Clough, 1982). As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:

None.

Reserves:

None.

Additional comments:

Similar to Rat Fork-Headwall (MG059) and Rat Fork-Base (MG058) prospects.

Site name(s): Rat Fork-Base; BMP

Site type: Prospect

ARDF no.: MG058

Latitude: 62.3189 **Quadrangle:** M B-2

Longitude: 153.8727

Location description and accuracy:

The Rat Fork-Base prospect is near the base of the cirque that defines the head of the Rat Fork of Sheep Creek. It is at an elevation of 4,175 feet in the NW1/4 sec. 26, T. 26 N., R. 25 W., of the Seward Meridian. An active rock glacier forms the southern boundary of the prospect area. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Cd, Co, Fe

Ore minerals: Chalcopyrite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Clinopyroxene (johannsenite), epidote, garnet

Geologic description:

The Rat Fork-Base prospect consists of disseminated sulfides in calc-silicate hornfels and marble adjacent to an extensive, east-trending, granodiorite sill and dike swarm. (The same plutonic complex is exposed at the Rat Fork-Headwall (MG059) prospect.) At the Rat Fork-Base prospect, the calc-silicate zone, which consists of garnet, epidote, and clinopyroxene in arkosic, metaclastic rocks, has been intruded by several mafic sills that parallel bedding. The plutonic rocks intrude Lower Paleozoic rocks that are part of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997).

The zone of disseminated mineralization trends about east, varies from 1 to 10 meters thick , and can be traced along the strike for about 40 meters. The ore minerals include abundant pyrite and pyrrhotite, with minor chalcopyrite and sphalerite. (The mineralization is similar to that at the Rat Fork-Headwall (MG059), Tin Creek North (MG041), Tin Creek Midway (MG043), Smith Lake (MG055), and Bowser Creek Main (MG068) skarn deposits in the Farewell Mineral belt.)

Sometime in the late 1960s or early 1970s, a single hole was drilled by Falconbridge Minerals through their subsidiary St. Eugene Mining Company but there is little record of their activities. Sulfide-bearing, talus samples collected below the drill station contained 0.31 percent copper, 1.85 percent zinc, 6.5 grams of silver per tonne, 158 parts per million (ppm) cobalt, 161 ppm cadmium, and 41.4 percent iron (Smith and Albanese, 1985).

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:

Surface oxidation of massive pyrite and pyrrhotite forms a pronounced ferricrete gossan.

Age of mineralization:

Unknown; possibly 25 to 35 Ma, based on the age of similar dike swarm in the Tin Creek area (Solie and others, 1991).

Generic deposit model:

Deposit model:

Lead-zinc (copper) skarn (Cox and Singer, 1986; model 18c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18c

Production Status: None

Site Status: Active

Workings/exploration:

Sometime in the late 1960s or early 1970s, a single hole was drilled by Falconbridge Minerals through their subsidiary St. Eugene Mining Company but there is little record of their activities. The prospect was later sampled by the Alaska Division of Geology and Geophysical Surveys. As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:

None.

Reserves:

None.

Site name(s): Rat Fork-Headwall; BMP

Site type: Prospect

ARDF no.: MG059

Latitude: 62.3194 **Quadrangle:** M B-2

Longitude: 153.8909

Location description and accuracy:

The Rat Fork-Headwall prospect is just below the crest of a steep ridge that forms the headwall of a glacial cirque at the head of the Rat Fork of Sheep Creek; it is at an elevation of about about 5,500 feet in the NW1/4 sec. 27, T. 26 N., R. 25 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: As, Cd

Ore minerals: Chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Clinopyroxene, epidote, garnet

Geologic description:

The Rat Fork-Headwall prospect consists of disseminated sulfides and a sulfide vein in calc-silicate skarn in a east-trending, granodiorite dike swarm more than 1.5 kilometers wide (Bundtzen Kline, and Clough, 1982). The dike swarm cuts lower Paleozoic clastic rocks and carbonates of the Dillinger sub-terrane (Bundtzen, Harris, and Gilbert, 1997). The dikes are not dated at this prospect but are similar to dikes that have dated as 25 to 35 Ma at the nearby Tin Creek-Midway prospect (MG043) to the northeast (Solie and others, 1991; Bundtzen, Harris, and Gilbert, 1997).

The calc-silicate skarns, which are composed of garnet, epidote, and clinopyroxene (johannsenite) occur mainly in arenaceous, recrystallized limestone. The sulfide-bearing vein parallels a pervasive joint set which cuts various calc-silicate rocks and limestone (Smith and Albanese, 1985). The sulfide vein trends N85W, dips 85S, varies from 0.5 to 3 meters thick, and can be traced for about 22 meters along strike. The main ore minerals in the vein are pyrite, sphalerite (marmatite), galena, and chalcopyrite. The sulfides locally make up to 45 percent of the vein. Chip samples taken across the vein at three places contained up to 0.56 percent copper, 11.10 percent lead, 14.10 percent zinc, 301 grams of silver per tonne, 3.80 percent arsenic, 0.12 percent cadmium, and 42.40 percent iron (Smith and Albanese, 1985).

The Rat Fork-Headwall prospect is part of a widespread polymetallic mineral belt, the Farewell Mineral belt, that includes the Tin Creek North (MG041), Tin Creek South (MG044), Bowser Creek-Main (MG068), Bowser Creek Northeast (MG067), and Smith Lake (MG055) prospects.

In the late 1960s and early 1970s, Falconbridge Minerals through their exploration operator St. Eugene Mining Company, diamond drilled from two stations near the sulfide vein but there is little information on the results of this work. In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., 2008).

Alteration:

Extensive oxidation of pyrite-rich areas to ferricrete gossan.

Age of mineralization:

Inferred to be 25 to 35 Ma, based on K-Ar dating of similar granodiorite dike swarms nearby.

Generic deposit model:

Deposit model:

Lead-zinc (copper) skarns (Cox and Singer, 1986; model 18c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18c

Production Status: None

Site Status: Active

Workings/exploration:

In the late 1960s and early 1970s, Falconbridge Minerals through their exploration subsidiary St. Eugene Mining Company, diamond drilled from two stations near the sulfide vein but there is little information on the results of this work. Subsequently, the prospect was examined and sampled by several government agencies. As of 2008, the prospect is within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:

None.

Reserves:

None.

Site name(s): Ozzna Creek; BMP

Site type: Prospect

ARDF no.: MG060

Latitude: 62.2948 **Quadrangle:** M B-2

Longitude: 153.9485

Location description and accuracy:

The Ozzna Creek prospect is on the north facing slopes of Ozzna Creek, a west-flowing tributary of the Windy Fork of the Kuskokwim River; it is at an elevation of about 4,750 feet in the SE1/4 sec. 32, T. 26 N., R. 25 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Mo

Ore minerals: Chalcopyrite, galena, molybdenite, pyrite, sphalerite

Gangue minerals: Carbonate, epidote, quartz, sericite

Geologic description:

The Ozzna Creek prospect consists of base metal sulfide veins and replacement deposits in an extensive quartz-sericite-pyrite halo rimming a 450-meter-wide, quartz-monzonite breccia pipe,. The pipe forms the core of a distinctive, precipitous, 7,205-foot -high peak. A biotite separate from the quartz monzonite pipe gave a K-Ar age of 58 Ma. (Solie and others, 1991). A pronounced magnetic high rims the edge of the breccia pipe (Rob Kell, written communication, 1983). (The magnetic anomaly that rims the quartz monzonite breccia pipe is similar to geophysical features found in porphyry copper systems throughout the North American Cordillera.)

The vein and replacement deposits consist of small pods and lenses of pyrrhotite, sphalerite, argentiferous galena, and pyrite in a gangue of carbonate, epidote, and quartz along shear zones in felsic dikes and igneous breccia. Most of the sulfide pods are from 0.2 to 1.5 meters wide and 0.5 to 6.0 meters long. Selected samples contained 1,623 to 2,189 grams of silver per tonne (Reed and Elliott, 1968).

The quartz-sericite-pyrite halo that surrounds the quartz-monzonite breccia pipe is from 15 to 60 meters wide and can be traced along strike for about 450 meters. Disseminated chalcopyrite and traces of molybdenite occur in pyrite-rich igneous breccia. Selected samples from the quartz-sericite-pyrite halo contain up to 0.08 percent copper, 150 parts per million molybdenum, 1.50 percent lead, 1.00 percent zinc, 14.6 grams of silver per tonne, and 2.48 grams of gold per tonne. (Bundtzen, Kline, and Clough, 1982; Bundtzen, Harris, and Gilbert, 1997).

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., (2008).

Alteration:

Pyritic and sericitic alteration in breccia pipe.

Age of mineralization:

Early Tertiary (58 Ma), based on K-Ar biotite age of intrusion.

Generic deposit model:

Deposit model:

Porphyry copper molybdenum deposit? (Cox and Singer, 1986; model 21a?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

21a?

Production Status: None

Site Status: Active

Workings/exploration:

Surface sampling by several government agencies. As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Badnews; BMP

Site type: Prospect

ARDF no.: MG061

Latitude: 62.2965 **Quadrangle:** M B-2

Longitude: 153.7684

Location description and accuracy:

The Badnews Prospect is on a steep, precipitous, north-facing slope of Peak 6,920; it is at an elevation of about 5,700 feet in the SW1/4 sec. 32, T. 26 N., R. 24 W., of the Seward Meridian. The location is from Foley (1987).

Commodities:

Main: Ag, Au, Cu, Zn

Other: Cd, Co, Pb

Ore minerals: Chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, epidote, garnet, quartz

Geologic description:

The deposit at the Badnews prospect is a Cu-Pb-Zn-Ag-Au (Co-Pb) skarn in tightly folded limestone, siltstone, and argillite of the mid-Silurian Terra Cotta Mountains Sandstone, a unit of the Dillinger subterrane (Bundtzen, Harris, and Gilbert, 1997). The limestone layers have been preferentially replaced by skarn minerals and locally sulfides; clastic rocks have been transformed into purple-green hornfels. The center of the prospect is a granodiorite porphyry stock with apophyses and numerous dikes that intrude a large aureole of hornfelsed sedimentary rocks (Bundtzen, Harris, and Gilbert, 1997). Several east-trending, high-angle, granodiorite dikes cut the limestone; the dikes are apparently pathways for the fluids that deposited the mineralization and formed the skarn. A post-skarn breccia occurs at the contact of one granodiorite dike.

The main ore minerals are chalcopyrite, pyrrhotite, sphalerite, and a trace of galena. Pyrrhotite is the dominant sulfide in practically all the mineralized skarn zones. The skarn consists of abundant recrystallized calcite and red garnet, with minor epidote and quartz. Massive sulfide pods and mantos up to 10 meters thick can be traced laterally for several hundred meters (Brewer and others, 1992). Individual sulfide zones reach a maximum thickness of 0.7 meters in skarn zones that are up to 2 meters wide. Sphalerite is most abundant in epidote-garnet-rich skarn, whereas chalcopyrite and pyrrhotite are most abundant in calcite-garnet skarn (Foley, 1987).

Twenty-three grab samples from skarns where chalcopyrite and sphalerite dominate contained an average of 3.7 percent zinc and 0.4 percent copper (Brewer and others, 1992). Selected samples from zinc-rich areas also contain up to 1,740 parts per million (ppm) cadmium. The gold content of the Badnews skarn is higher than in any other deposit of the Farewell Mineral Belt; select samples contain up to 11.2 grams of gold per tonne and 143.1 grams of silver per tonne (Brewer and others, 1992). The average gold content of numerous grab samples of the mineralized skarn was 490 parts per billion. Two grab samples of sulfide-bearing skarn collected by Foley (1987) contained up to 9.20 percent zinc, 93 ppm lead, 0.44 percent copper, 290 ppm cobalt, and 16.6 grams of silver per tonne.

In 2008, this prospect was one of several in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., (2008).

Alteration:

Strong secondary biotite (potassic) alteration in skarn.

Age of mineralization:

Generic deposit model:

Deposit model:

Low temperature lead-zinc skarn (Cox and Singer, 1986; model 18c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18c

Production Status: None

Site Status: Active

Workings/exploration:

The Badnews polymetallic prospect was named by Roger Burleigh during mineral investigations conducted in 1979 by Placid Oil Company. Only surface sampling has taken place at the site, mainly by Anaconda Minerals and the U.S. Bureau of Mines. As of 2008, the prospect was within a large block of claims called the BMP project by International Tower Hill MIne, Ltd. (2008).

Production notes:

None.

Reserves:

None.

Site name(s): 6120; Pyrrhotite; BMP

Site type: Prospect

ARDF no.: MG062

Latitude: 62.2872 **Quadrangle:** M B-2

Longitude: 153.7804

Location description and accuracy:

The 6120 prospect is on the steep, precipitous southern flank of Peak 6,920 at the head of Sheep Creek. It is at an elevation of 5,750 feet in the NW1/4 sec. 5, T. 25 N., R. 24 W., of the Seward Meridian.

Commodities:

Main: Au,Cu

Other: Co, Fe, Ni, Zn

Ore minerals: Pyrite, pyrrhotite

Gangue minerals: Calcite

Geologic description:

The Pyrrhotite occurrence consists of several pods of pyrrhotite with minor pyrite, enclosed in banded hornfels and marble adjacent to a small stock of highly altered granodiorite porphyry. The host rocks are thermally altered marble and clastic sediments of the mid-Silurian Terra Cotta Mountains Sandstone, a unit of the Dillinger sub-terrane (Bundtzen and others, 1997).

Pyrrhotite occurs as disseminated grains in veinlets up to 8 centimeters thick, as semi-massive to massive sulfide pods up to 30 centimeters thick, and as clots and crystals up to three centimeters across. Grab samples of pyrrhotite-rich mineralization collected by Anaconda Minerals Company contained up to 0.44 percent nickel and 460 parts per million (ppm) cobalt (Brewer and others, 1992). Selected samples reported by Foley (1987) contain up to 180 ppm nickel, 180 ppm copper, and 180 ppm zinc. Massive pyrrhotite-bearing samples contained 58.00 percent iron.

In 2008, the 6120 prospect was one of the prominent deposits in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., (ITH) (2008). Their mapping in 2007 suggests that the mineralization occurs along a fault developed associated with a north-trending anticlinal hinge that extends 8 to the north through several deposits (MG061, MG057, MG052-049), and notable the Dahl prospect (MG053). Twenty samples of skarn collected in outcrop by ITH in 2008 contained an average of 2.3 percent copper, 3.4 grams of gold per ton, 33 grams of silver per ton, 0.16 percent nickel and 0.07 percent cobalt.

Alteration:

None.

Age of mineralization:

Generic deposit model:

Deposit model:

Polymetallic replacement? (Cox and Singer, 1986; model 19a?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

19a?

Production Status: None

Site Status: Active

Workings/exploration:

The 6120 occurrence (initially called the Pyrrhotite prospect) was discovered during geologic mapping in 1981 by the Alaska Division of Geological and Geophysical Surveys (Bundtzen, Kline, and Clough, 1982). The prospect was examined by several companies and government agencies through the 1980s and 1990s. In 2008, the 6120 prospect was one of the prominent deposits in a block of claims that covered more than 70 square miles, known collectively as the BMP project (International Tower Hill Mines, Ltd., (2008). They mapped and sampled the deposit in 2007.

Site name(s): Miyaoka; Miyaoka West

Site type: Prospect

ARDF no.: MH006

Latitude: 63.7127 **Quadrangle:** M C-6

Longitude: 146.7414

Location description and accuracy:

The Miyaoka prospect is at an elevation of about 5,000 feet on the ridge east of the terminus of the east lobe of Hayes Glacier. The mineralized area is about 1,000 feet long and 200 feet wide. The center of the mineralization is about 0.3 mile southwest of elevation 5110 and about 0.6 mile west-southwest of the center of section 11, T. 14 S., R. 5 E.

Commodities:

Main: Cu, Zn

Other: As, Au

Ore minerals: Arsenopyrite, chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

The rocks in the area are derived from Devonian felsic to intermediate volcanic rocks, mainly andesite, dacite, and quartz keratophyre flows and tuffs, and from Devonian or older shale, marl, and marble (Nokleberg and others, 1992 [MF]; 1992 [Open-File]). The rocks have been penetratively deformed, dismembered, and metamorphosed to chlorite-mica-quartz schist with marble and greenstone, first to lower-amphibolite-grade rocks in the Early Cretaceous and then retrograded to lower-greenschist-grade rocks in the mid-Cretaceous. Detailed mapping of the prospect by American Copper and Nickel Company in 1993 indicated that a felsic intrusion is infolded with mineralized schist and part of the mineralization may be a pyrrhotite-rich skarn (W.T. Ellis, unpublished data, 1993).

The Miyaoka prospect was discovered and sampled by the U.S. Geological Survey in the mid-1980s. American Copper and Nickel Company mapped and sampled the prospect in 1993 and it was examined and sampled by the Bureau of Land Management in the early 2000s.

The Miyaoka prospects consists of lenses, disseminations, and stringers of massive sulfides in the iron-stained metamorphic host rocks (Nokleberg and Aleinikoff 1985; Aleinikoff and Nokleberg, 1985; Nokleberg and others, 1991; Bittenbender and others, 1991). The massive sulfides are generally structureless but in places have a crude banding that parallels the layering in the metamorphic rocks. The sulfide minerals are predominantly pyrrhotite and pyrite with minor chalcopyrite; sphalerite, galena, and arsenopyrite are reported.

The mineralization occurs in two horizons that can be traced north-northwest for about 0.8 mile but the main zone of mineralization is about 1,000 feet long and 200 feet wide. Bittenbender and others (2007) collected 17 measured samples across the main zone of mineralization. The samples averaged 0.096 parts per million (ppm) gold, 0.2 ppm silver, 784 ppm copper, 8.3 ppm lead, 54 ppm zinc, and 3.4 ppm arsenic. The highest-grade sample were: 27 feet that averaged 1.2 ppm gold; 6.2 feet that averaged 0.50 ppm silver; 4.9 feet that averaged 2,750 ppm copper; and 11 feet that averaged 14 ppm arsenic. A high-grade sample collected nearby had the highest metal content of the samples they collected: 7.1 ppm silver, 985 ppm lead, and 2,290 ppm zinc.

Alteration:

Age of mineralization:

Probably Devonian, the pre-metamorphic age of the host rocks.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a); related base-metal skarn.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Workings/exploration:

The Miyaoka prospect was discovered and sampled by the U.S. Geological Survey in the mid-1980s. American Copper and Nickel Company mapped and sampled the prospect in 1993. Examined and sampled by the Bureau of Land Management in the early 2000s.

Commodities:

Main: Ag, As, Au, Cu, Pb, Sn, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

The rocks in the area are derived from Devonian felsic to intermediate volcanic rocks, mainly andesite, dacite, and quartz keratophyre flows and tuffs, and from Devonian or older shale, marl, and marble (Nokleberg and others, 1992 [MF-1996-D]; Nokleberg and others, 1992 [OFR 92-594]; Bittenbender and others, 2007). The rocks were metamorphosed and intensely deformed into chlorite schist, limestone, and greenstone that were first metamorphosed to lower amphibolite facies in the Early Cretaceous and then retrograded to lower greenschist grade in the mid-Cretaceous.

Resource Associates of Alaska was active in the area in 1970s but they deeded their claims to Cook Inlet Region Incorporated in 1980 (Bittenbender and others, 2007). The prospect was examined and sampled by the U.S. Geological Survey in about 1990 (Nokleberg and others, 1991), by the American Copper and Nickel Company in 1993, and by the Bureau of Land Management in the early 2000s. There are no workings on the prospect.

This prospect is part of a belt of massive sulfide deposits that is about 8 miles long and as much as one-third of a mile wide (Nokleberg and others, 1991; Lange and others, 1993).. Deposits in the belt consist of massive sulfide lenses, pods, and disseminations of pyrrhotite and pyrite, and less abundant galena, sphalerite, and chalcopyrite. Individual lenses and pods are as much as 3 feet thick.

Samples collected here during reconnaissance sampling by the U.S. Geological Survey in the 1980s contained as much as 0.72 percent lead, 0.69 percent zinc, 0.5 percent arsenic, and 0.11 percent copper (Nokleberg and others, 1991). Bittenbender and others (2007) identified zones of thin, massive sulfide pods, lenses, and stringers in tightly folded quartz-mica and quartz-chlorite schist from about 4,900 to 5,300 feet elevation. The zones generally are less than 1 foot thick, may structurally thicken to 2 feet, and are 3 to 4 feet in length. The sulfides are mainly pyrrhotite with small amounts of chalcopyrite, pyrite, and galena. Their samples contained up to 685 parts per billion gold, 13.7 parts per million (ppm) silver, 4,660 ppm copper, 1,350 ppm lead, and 1,035 ppm zinc.

Alteration:

Not specifically noted.

Age of mineralization:

Probably Devonian, the pre-metamorphic age of the host rocks.

Generic deposit model:

Deposit model:
Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
28a

Production Status: None

Site Status: Undetermined

Workings/exploration:
Resource Associates of Alaska was active in the area in 1970s but they deeded their claims to Cook Inlet Region Incorporated (Bittenbender and others, 2007). The prospect was examined and sampled by the U.S. Geological Survey in about 1990 (Nokleberg and others, 1991), by the American Copper and Nickel Company in 1993, and by the Bureau of Land Management in the early 2000s. There are no workings on the prospect.

Production notes:
None.

Reserves:
None.

Last report date: 2012-05-13

Site name(s): Hayes Glacier East

Site type: Prospect

ARDF no.: MH008

Latitude: 63.6858 **Quadrangle:** M C-6

Longitude: 146.5556

Location description and accuracy:

This prospect is at an elevation of about 4,900 feet, south of the end of the Hayes Glacier. It is about 2.6 miles west of VABM 4862 'Glacier' and about 0.2 mile east-southeast of the center of section 22, T. 14 S., R. 6 E.

Commodities:

Main: Cu, Zn

Other: Ag, Pb

Ore minerals:

Gangue minerals:

Geologic description:

The rocks in the area are derived from Devonian felsic to intermediate volcanic rocks, mainly andesite, dacite, and quartz keratophyre flows and tuffs, and from Devonian or older shale, marl, and marble (Nokleberg and others, 1992 [MF]; 2002 [\Open-File]; Bittenbender and others, 2007). The rocks were intensely deformed into chlorite schist, limestone, and greenstone that were first metamorphosed to lower amphibolite facies in the Early Cretaceous and then retrograded to lower greenschist facies in the mid-Cretaceous.

Resource Associated of Alaska was active in the area in 1970s but they deeded their claims to the Cook Inlet Region Incorporated in 1980 (Bittenbender and others, 2007). The prospect was examined and sampled by the U.S. Geological Survey in about 1990 (Nokleberg and others, 1991), by the American Copper and Nickel Company in 1993, and by the Bureau of Land Management in the early 2000s. There are no workings on the prospect.

Samples taken during a U.S. Geological Survey reconnaissance in the 1980s consisted of disseminated to semi-massive pyrite, chalcopyrite, galena, sphalerite, and pyrrhotite in chlorite-epidote-carbonate schist (Nokleberg and others, 1991). A grab sample of chalcopyrite-bearing schist contained 0.92 percent copper, 0.22 percent zinc, 0.06 percent lead, and 10 parts per million (ppm) silver.

Bittenbender and others (2007) identified thin, massive-sulfide lenses and stringers in several horizons from 4,700 to 4,950 feet in elevation. The mineralization can be traced for about 0.8 mile along strike in zones that trend east and dip about 60 degrees south. The massive sulfides lenses and stringers are generally less than 1.5 feet thick and consist mainly of pyrrhotite with minor chalcopyrite, pyrite, and galena. Samples contained up to 29.4 ppm silver, 2.4 ppm gold, 3,470 ppm lead, 1.94 percent copper, and 1,140 ppm zinc.

Alteration:

Not specifically noted. The mineralization and host rocks have been subject to regional amphibolite- and greenschist-facies metamorphism in the Cretaceous.

Age of mineralization:

Probably Devonian, the pre-metamorphic age of the host rocks.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Site name(s): Roberts No. 1

Site type: Occurrence

ARDF no.: MH009

Latitude: 63.5971

Quadrangle: M C-5

Longitude: 146.2664

Location description and accuracy:

The Roberts No. 1 occurrence is about 3.8 miles north-northeast of McGinnis Peak at an elevation of about 7,500 feet. It is about 0.2 mile south-southeast of the center of section 19, T. 15 S., R. 8 E.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The rocks in the area are derived from Devonian felsic to intermediate volcanic rocks, mainly andesite, dacite, and quartz keratophyre flows and tuffs, and from Devonian or older shale, marl, and marble (Nokleberg and others, 1992 [MF]; 2002 [\Open-File]; Bittenbender and others, 2007). The rocks were intensely deformed into chlorite schist, limestone, and greenstone that were first metamorphosed to lower amphibolite facies in the Early Cretaceous and then retrograded to lower greenschist facies in the mid-Cretaceous.

The Roberts #1 occurrence was first identified by Nokleberg and others in the early 1980s (Nokleberg and Lange, 1985; Nokleberg and others, 1991; Lange and others, 1993). It was examined and sampled by the Bureau of Land Management in the early 2000s (Bittenbender and others, 2007). There are no workings on the occurrence and no published record of industry activity.

The Roberts #1 occurrence is one of several volcanogenic massive-sulfide deposits that lay along the north side of the Alaska Range (Lange and others, 1993, Newberry and others, 1997). As described by Bittenbender and others (2007), the mineralization at the prospect consists of semi-massive to massive sulfides that form several layers up to 6 feet thick that are conformable to the foliation of the calcareous quartz-chlorite schist and limestone host rock. The sulfides are mainly pyrrhotite and pyrite with some chalcopyrite, galena, and sphalerite The thickest layer extends for about 60 feet. Mineralization in float to the southeast suggests continuity to the Roberts #2 occurrence (MH010). A sample across 3.2 feet of mineralization in place contained 102 parts per billion (ppb) gold, 1.3 part per million (ppm) silver, 94 ppm lead, and 1.58 percent zinc. Float samples contained up to 97 ppb gold, 30.1 ppm silver, 1.63 percent copper, 2.56 percent lead, and 7.49 percent zinc.

Alteration:

Age of mineralization:

Probably Devonian, the pre-metamorphic age of the host rocks.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

The Roberts #1 occurrence was first identified by the U.S. Geological Survey in the early 1980s (Nokleberg and Lange, 1985; Nokleberg and others, 1991; Lange and others, 1993). It was examined and sampled by the Bureau of Land Management in the early 2000s (Bittenbender and others, 2007). There are no workings on the occurrence and no published record of industry activity.

Site name(s): Roberts No. 2

Site type: Prospect

ARDF no.: MH010

Latitude: 63.5922 **Quadrangle:** M C-5

Longitude: 146.2491

Location description and accuracy:

The Roberts No. 2 prospect is at an elevation of about 6,800 feet about about 3.7 miles north-northeast of McGinnis Peak. It is about 0.7 mile northwest of the center of section 29 T. 15 S., R. 8 E.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, marcasite, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

The rocks in the area are derived from Devonian felsic to intermediate volcanic rocks, mainly andesite, dacite, and quartz keratophyre flows and tuffs, and from Devonian or older shale, marl, and marble (Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The rocks were intensely deformed into chlorite schist, limestone, and greenstone that were first metamorphosed to lower amphibolite facies in the Early Cretaceous and then retrograded to lower greenschist facies in the mid-Cretaceous.

The Roberts #2 prospect is one of several volcanogenic massive-sulfide deposits that lay along the north side of the Alaska Range (Lange and others, 1993, Newberry and others, 1997). The prospect was first identified by Nokleberg and others in the early 1980s (Nokleberg and Lange, 1985; Nokleberg and others, 1991; Lange and others, 1993). It was examined and sampled by the Bureau of Land Management in the early 2000s (Bittenbender and others, 2007). The prospect was examined and sampled by the American Copper and Nickel company in the 1980s but there are no workings on the prospect.

The mineralization at the Robert #2 prospect consists of massive to semi-massive lenses of sulfides in a layer up to 30 feet thick that can be traced for about 200 feet (Nokleberg and others, 1991; Lange and others, 1993; Bittenbender and others, 2007). The sulfides are mainly pyrrhotite, some oxidizing to marcasite, with lesser pyrite, chalcopyrite, sphalerite, and galena. The hanging wall of the layer is graphitic calcite-quartz schist. A 45-foot-thick layer of gray marble lies about 75 feet structurally below the sulfide layer; some metaconglomerate and metagraywacke is also present.

Samples collected by the U.S. Geological Survey contained up to 0.69 percent copper, 0.3 percent lead, 2.3 percent zinc, and 45.4 parts per million (ppm) silver (Nokleberg and others, 1991; Lange and others, 1993). Bittenbender and others (2007) collected 12 samples. The highest grade sample in place was a 18 feet that contained 44 parts per billion gold, 1.0 ppm silver, and 2,470 ppm copper. One float sample contained 1.17 percent zinc.

Alteration:

Not specifically noted.

Age of mineralization:

Probably Devonian, the pre-metamorphic age of the host rocks.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Workings/exploration:

The Roberts #2 occurrence was first identified by Nokleberg and others in the early 1980s (Nokleberg and Lange, 1985; Nokleberg and others, 1991; Lange and others, 1993). It was examined and sampled by the Bureau of Land Management in the early 2000s (Bittenbender and others, 2007). The prospect was examined and sampled by the American Copper and Nickel company in the 1980s but there are no workings on the prospect.

Site name(s): Zackly; Stellar

Site type: Prospect

ARDF no.: MH067

Latitude: 63.2181 **Quadrangle:** M A-6

Longitude: 146.6984

Location description and accuracy:

The Zackly prospect is about one-half mile north-northwest of peak 5375, a northwest-aligned ridge about 1.8 miles east of the West Fork Maclaren River. The deposit is exposed from about 4,000 to 4,650 feet in elevation near the north end of the ridge. The location for this record is at the approximate center of the deposit, about 2,400 feet south of the center of section 36, T. 19 S., R. 5 E., Fairbanks Meridian. The property is accessible by a bulldozer trail from the Kathleen-Margaret mine trail (see MH087), not shown on the A-6 quadrangle. The location corresponds to locality [figure] A26 of Kurtak and others (1992) and locality 26 in table 2 of Nokleberg and others (1991).

Commodities:

Main: Au, Cu

Other: Ag, Mo, W

Ore minerals: Azurite, bornite,chalcopyrite, gold, malachite, molybdenite?, native copper, scheelite?

Gangue minerals: Chalcedony, clay, clinopyroxene, garnet, limonite, pyroxene, wollastonite

Geologic description:

The Zackly skarn prospect is hosted in Triassic tuff and sedimentary rocks (Nokleberg and others, 1991). These rocks have been intruded by quartz monzodiorite and monzonite of Cretaceous age. Numerous east-trending high-angle faults cut out or repeat skarn, limestone, volcanic rocks, and intrusive rocks. In general, the contact between sedimentary and intrusive rocks that host the main ore body strikes nearly east-west and is very steep (Kurtak and others, 1992, figure A26). It can be traced for about a mile. The main so-called skarn ore body consists of pods and irregular stratabound lenses of skarn at the contact of Upper Triassic marble with albitized quartz monzodiorite. The body is crudely zoned; the mineral sequence outward from the quartz monzodiorite consists of: (1) brown garnet with chalcopyrite, (2) green garnet with bornite and chalcopyrite, (3) clinopyroxene and wollastonite, and (4) marble with magnetite and bornite. Fine-grained silica (chalcedony) and clay occur irregularly throughout and appear to be late, retrograde minerals.

Stellar project work in 2016 (Millrock Resources Inc., in a joint venture with Vista Minerals Pty Ltd.) consisted of collecting 7 lines of induced-potential measurements over the Zackly copper-gold skarn. They identified chargeability anomalies within copper-in-soil anomalies, which appear to extend the strike length of the skarn to both the east and west (Athey and Werdon, 2017).

Gold occurs only with skarn; the higher gold values are in a supergene (?) assemblage of malachite, limonite, chalcedony, and native copper. Unoxidized ore contains chalcopyrite and bornite. A high-grade sample collected by the U.S. Geological Survey assayed 6.6 percent copper, 4.4 parts per million (ppm) gold, 35 ppm silver, and 30 ppm molybdenum (Nokleberg and others, 1991). Sample 1681 collected by the Bureau of Mines assayed 0.18 ounce of gold per ton, 2.45 ounce of silver per ton, 7.1 percent copper, and 0.11 percent tungsten (Kurtak and others, 1992); a representative 7-foot sample (1675) cut across the skarn assayed 0.05 ounce of gold per ton, 0.31 ounce of silver per ton, 1.35 percent copper, and 430 ppm tungsten. Tungsten is probably contained in scheelite; molybdenum is either in molybdenite or in solid solution in scheelite. Lead, zinc, and arsenic are generally not strongly enriched in the ore.

A resource exists mainly in a gold-skarn body about 2,600 feet long and about 9 feet thick that has been

followed down-dip about 1,000 feet. The deposit is fairly high grade; it contains about 1.24 million tons averaging 2.69 percent copper, 0.18 ounce of gold per ton, and 0.96 ounce of silver per ton (UNC Teton Exploration and Drilling, Inc., 1982).

Metallurgical testing by the U.S. Bureau of Mines suggests that most of the gold in the ore is particulate but fine grained. Oxidized copper minerals contained in the ore seem to be serious cyanogens. Ordinary leaching with 20 pounds of NaCN per short ton of concentrate recovered only about 45 percent of the gold. Satisfactory recovery of gold was made on a test sample pre-leached with sulfuric acid to dissolve oxidized copper minerals (R.W. MacDonald, written communication, 1989); MacDonald pointed out the potential hazard involved with the acid pre-leach and later production of HCN if acid was not neutralized. An alkaline ammonia pre-leach of oxidized copper minerals apparently was not tried.

Alteration:

Alteration zoning is recognized within the endoskarn and exoskarn (Kurtak and others, 1992). Endoskarn development is related to the degree of original rock calcium metasomatism and spatial distribution of the original limestone and volcanic rocks (UNC Teton Exploration and Drilling, Inc. 1982). Four stages of exoskarn development are recognized: (1) skarnoid, (2) main, (3) hydrosilicate, and (4) late hydrothermal. The skarns consist mainly of garnet and clinopyroxene and have undergone retrograde metamorphism and silica-clay alteration (Kurtak and others, 1992).

Age of mineralization:

Cretaceous.

Generic deposit model:

Deposit model:

Cu-gold skarn, similar to the Cu skarn of Cox and Singer (1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b?

Production Status: None

Site Status: Active

Workings/exploration:

Resource Associates of Alaska discovered the Zackly skarn deposit and staked claims in 1979-1980; they drilled 9,723 feet of core in 1981. A partnership with UNC Teton Exploration and Drilling, Inc. was formed, and 19,210 feet of diamond drilling was conducted in 1982 along with trenching and geophysical surveying. Copper, silver, and mercury soil geochemistry was successfully utilized to locate skarn mineralization in overburden areas (Ford, 1988; Resource Associates of Alaska, 1981). In 1986 the property reverted to Resource Associates of Alaska, which was subsequently bought out by Nerco. In 1987 a joint venture of Nerco and Boulder Gold conducted 12,000 feet of reverse circulation and 3,000 feet of diamond drilling. By 1990, the Zackly property was controlled by Pacific Northwest Resources and was optioned to Phelps Dodge Corporation, which completed a limited drilling program. The property was optioned to Hemlo Gold in 1993-34, which completed rock and soil sampling, IP geophysical surveys, and 1,500 feet of reverse circulation drilling. Since 1994 only limited exploration and assessment work has been done on the property.

The U.S. Bureau of Mines collected a 300-pound bulk sample for beneficiation studies at the U.S. Bureau of Mines Salt Lake Research Center (Kurtak and others, 1992). Only 18 percent of the gold in a sample that assayed 0.072 ounces of gold per ton were recovered in a bulk flotation test. Forty-five percent of the gold was recovered in a cyanide amenability test of a 1,000-gram sample ground to -325 mesh and leached for 72 hours (R.W. McDonald, written communication, 1989). Using a 3,965-gram sample ground to various sizes from +20 to -325 mesh improved recovery only to 48 percent. A factor that inhibits gold recovery is the high content of oxidized copper minerals in the ore, which interferes with the NaCN solution. Gold

recovery increased to 98 percent after a sulfuric acid preleach of oxidized copper minerals (R.W. McDonald, written communication, 1989).

As part of their 2016 Stellar project work, Millrock Resources Inc., in a joint venture with Vista Minerals Pty Ltd., collected 7 lines of induced-potential measurements over the Zackly copper-gold skarn. They identified chargeability anomalies within copper-in-soil anomalies, which appear to extend the strike length of the skarn to both the east and west (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

UNC Teton Exploration and Drilling, Inc. (1982) defined a resource of 1.24 million tons of 2.69 percent copper, 0.176 ounce of gold per ton, and 0.96 ounce of silver per ton. This mineralization occurs in a steeply dipping east-west striking body with 2,600 feet of strike length and an average thickness of 8.5 feet extending 1,000 down-dip. U.S. Bureau of Mines beneficiation studies indicated enhanced gold recovery will be necessary for the deposit to become economic (Balen, 1990 [USBM OF 40-90]).

Ross Glanville and Associates (1996) estimated that the resource defined by exploration through 1989 consisted of 1,407,000 tons that graded 2.19 percent copper, 0.83 ounce of silver per ton, and 0.132 ounce of gold per ton. The reserves in the so-called main ore body are not yet sufficiently delineated to be able to carry out a feasibility study; however, a preliminary evaluation was completed by consultants in 1996. On the basis of the number of limiting input parameters and utilizing a mineable reserve of 1,080,000 tonnes of ore, the net present value of the Zackly project was calculated to be $0.7 million. A 50 percent increase in reserves was considered likely to be achieved by additional exploration, which would increase the net present value to $7.4 million (Ross Glanville and Associates, 1996).

Additional comments:

The copper-rich Nikolai Greenstone assimilated by the quartz monzodiorite is speculated to be the source of the metals in the skarn deposit (UNC Teton Exploration and Drilling, Inc., 1982). Pacific Alaska Resources (PO Box 145, Battleground, WA 98604; ph 360 687-2763) controls the property and has additional information about the Zackly prospect.

Last report date: 2017-08-26

Site name(s): Maclaren Glacier

Site type: Occurrence

ARDF no.: MH089

Latitude: 63.3014 **Quadrangle:** M B-5

Longitude: 146.4932

Location description and accuracy:

This prospect extends for about 0.3 mile along a gully from an elevation of about 4,000 to 5,500 feet. The center of the prospect is about 2.6 mile north-northeast of the mouth of the East Fork Maclaren River. It is about 0.6 mile west-northwest of the center of section 6, T.19 S., R. 7 E.

Commodities:

Main: Cu, Fe

Other: Ag, Au, Cr, Ni, Zn

Ore minerals: Azurite, chalcopyrite, gold, magnetite, malachite, sphalerite

Gangue minerals: Calcite, diopside, garnet

Geologic description:

The Maclaren Glacier deposit is along a steeply dipping, west-northwest-striking fault that separates Triassic limestone and gabbro to the south from Triassic argillite to the north (Rose, 1966; Nokleberg and others, 1991; 1992 [MF]; 1992 [Open-File]. Locally, the argillite is intruded by granodiorite of probable Cretaceous age. For about 0.3 mile, limestone is replaced by garnet, diopside, up to 20 percent magnetite, and locally sphalerite and chalcopyrite which is partly oxidized to azurite and malachite. The skarn zone is up to several hundred feet in width. The source of the mineralization may be the Cretaceous granodiorite (Nokleberg and others, 1991).

The mineralized zones are only a few feet or less in length and width. A sample of magnetite skarn contained 16.9 percent iron, 2.8 percent copper, 0.12 percent chromium, 0.14 percent nickel, 45 parts per billion (ppb) gold, and 1 ppb silver (Kurtak and others, 1992). Locally the skarn contains more zinc and precious metals; one sample contained 5.5 percent zinc, 2.5 percent copper, 30 parts per million (ppm) silver, and 3.7 ppm gold (Nokleberg and others, 1991).

Alteration:

Base and precious metals in skarn zones in limestone.

Age of mineralization:

Possibly Cretaceous based on the nearness of a granitic pluton of that age.

Generic deposit model:

Deposit model:

Cu skarn? (Cox and Singer, 1986; model 18b?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b?

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling by state and federal agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Bird's Foot

Site type: Prospect

ARDF no.: MH093

Latitude: 63.3259 **Quadrangle:** M B-5

Longitude: 146.38

Location description and accuracy:

The Bird's Foot prospect is at an elevation of about 5,300 feet, about a 0.3 mile west of lower Eureka Glacier, and 0.6 mile northeast of elevation 6120. It is near the center of section 27, T. 18 S., R. 7 E.

Commodities:

Main: Cr, Cu, Ni

Other: Pd, Pt

Ore minerals: Chalcopyrite, chromite, magnetite, pentlandite, pyrrhotite

Gangue minerals: Olivine, serpentinite

Geologic description:

The Bird's Foot prospect is in Upper Triassic ultramafic and mafic rocks that are faulted into a Tertiary to Cretaceous composite, granitic to dioritic pluton (Nokleberg and others, 1991). Rose (1966) mapped dunite bodies within diorite, quartz diorite, and gabbro in this area. The Broxson Gulch thrust appears to form the hanging wall of the ultramafic and mafic rocks and it has been inferred that dunite bodies lubricated the bottom of the thrust (Kurtak and others, 1992). The hanging wall of the thrust is schist.

The occurrence was found during geologic reconnaissance by the USGS in the early 1990s (Nokleberg and others, 1991) and examined by industry in about 2001 (W.T. Ellis, unpublished field notes, 2001). In 2001, the prospect was on claims of the MAN project of Pure Nickel Inc. Sampled by the Bureau of Land Management in 2003.

This occurrence consists of chromite and magnetite disseminated in a serpentinized olivine inclusion in metagranodiorite (Nokleberg and others, 1991). A grab sample contained more than 0.5 percent chromium.

As described by W.T. Ellis (unpublished data, 2001) rubble of olivine melagabbro and feldspathic peridotite hosts sulfide mineralization. The rubble appears to be derived from a sill-like body of Upper Triassic gabbro and serpentinized peridotite and dunite in the cliffs on the south side of the cirque to the west. The sulfide mineralization consists of coarsely-crystalline clots and disseminations of pyrrhotite, chalcopyrite, and pentlandite. The sulfides rarely exceed about 5 percent of the float.

Bittenbender and others (2007) collected several samples. Most grab samples from the extensive fresh peridotite at the prospect contained no metals of note. A float sample of iron-stained peridotite with 3 to 5 percent sulfides contained 553 parts per billion (ppb) platinum, 3,821 ppb palladium, 148 ppb gold, 2,190 parts per million (ppm) copper and 2,970 ppm nickel. Bittenbender and others (2007) concluded that the mineralized area is small and unlikely to be economic.

Alteration:

The ultramafic rocks are serpentinized.

Age of mineralization:

Probably Late Triassic; synchronous with emplacement of the mafic-ultramafic rocks.

Generic deposit model:

Deposit model:

Disseminated chromite in layered mafic-ultramafic complex and nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The occurrence was found during geologic reconnaissance by the USGS in the early 1990s and examined by industry in about 2001 (W.T. Ellis, unpublished field notes, 2001). In 2001, the prospect was on claims of the MAN project of Pure Nickel Inc. Sampled by the Bureau of Land Management in 2003.

Production notes:

Last report date: 2012-05-13

Site name(s): Bird's Beak; Bird Beak

Site type: Prospect

ARDF no.: MH094

Latitude: 63.3174 **Quadrangle:** M B-5

Longitude: 146.3966

Location description and accuracy:

The Bird Beak prospect is at an elevation of about 5,900 feet, about 1,600 feet southwest of peak 6120 and about 0.8 mile west of lower Eureka Glacier. It is in about 0.7 mile northwest of the center of section 34, T. 18 S., R. 7 E., of the Fairbanks Meridian. Bittenbender and others (2007, figure 14) show an aerial view of the prospect.

Commodities:

Main: Ni, Pd, Pt

Other: Au, Cr, Cu

Ore minerals: Chalcopyrite, chromite, magnetite, moncheite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Bird Beak prospect is in an Upper Triassic ultramafic and mafic sill-like complex in fault contact with a Tertiary to Cretaceous composite granitic to dioritic pluton (Nokleberg and others, 1991). Rose (1966) mapped dunite bodies associated with diorite, quartz diorite, and gabbro in this area. Mafic and ultramafic rocks in the Broxson Gulch thrust may have lubricated the footwall of the thrust (Kurtak and others, 1992). The hanging wall of the thrust consists of schist. Olivine metagabbro and serpentinized dunite host the ore minerals at the prospect.

The U.S. Bureau of Mines collected samples of dunite and gabbro from the prospect (Kurtak and others, 1992). Sample 3038 of olivine gabbro with disseminated pyrrhotite and chalcopyrite assayed 0.15 percent copper, 0.21 percent chromium, 0.36 percent nickel, 550 parts per billion (ppb) palladium, and 80 ppb platinum. Sample 2644 of limonite-stained serpentine contained 0.13 percent copper, 896 parts per million (ppm) nickel, 280 ppb palladium, and 570 ppb platinum. A pentlandite(?)-bearing pyroxenite sample assayed 0.2 percent nickel and 25 ppb platinum.

Foley (1992) reported similar values in red, iron-oxide-stained, sulfide-rich, olivine gabbro; microprobe examination of the gabbro showed minute particles of moncheite (PtTe) along grain boundaries between chalcopyrite and ferromagnesian silicate minerals.

Bittenbender and others (2007) sampled the prospect. Their best samples were from a gabbro sill that cuts peridotite. Two selected samples contained up to 167 ppm gold, 462 ppb platinum, 385 ppb palladium, 1,820 ppm copper, and 4,450 ppm nickel. A more representative sample of approximately a 10 by 10 foot area of the gabbro contained 34 ppb gold, 105 ppb platinum, 94 ppb palladium, 592 ppm copper, and 1,815 ppm nickel. They indicate that the mineralization is well exposed but is unlikely to be of significant size.

In 2001, the prospect was on claims of the MAN project of Pure Nickel Inc. Pure Nickel sampled the Bird's Beak showing in 2011 and grab samples returned values of 1.39 percent nickel, 0.48 percent copper, and 7.0 grams of platinum group elements + gold + silver per tonne (Pure Nickel Inc., 2011).

Alteration:

All of the ultramafic rock units are moderately to strongly serpentinized (Bittenbender and others, 2007).

Age of mineralization:

Probably Late Triassic; synchronous with emplacement of the mafic-ultramafic complex (Nokleberg and others, 1991).

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was sampled by the U.S. Bureau of Mines (Kurtak and others, 1992) and the Bureau of Land Management (Bittenbender and others, 2007).

In 2001, the prospect was on claims of the MAN project of Pure Nickel Inc. Pure Nickel sampled the Bird's Beak showing in 2011 and grab samples returned values of 1.39 percent nickel, 0.48 percent copper, and 7.0 grams of platinum group elements + gold + silver per tonne (Pure Nickel Inc., 2011).

Last report date: 2014-12-10

Site name(s): BOS

Site type: Prospect

ARDF no.: MH101

Latitude: 63.3345

Quadrangle: M B-5

Longitude: 146.3224

Location description and accuracy:

The BOS prospect as identified by Bittenbender and others (2007) is at the terminus of a hanging glacier about 0.7 mile east-northwest of elevation 6568 and about 6.3 miles northwest of the junction of Eureka Creek and Broxson Gulch. It is about 0.3 mile south of the center of section 24, T. 18 S., R. 7 E. The location is accurate.

Commodities:

Main: Au, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The BOS prospect is in the Late Triassic, Eureka mafic-ultramafic complex. The host for the complex is Pennsylvanian to Permian rocks of the Slana Spur Formation which is intruded by Late Jurassic to Cretaceous granodiorite (Nokleberg and others, 1991). At the prospect, the complex is mainly a sill-like body of serpentinized peridotite, with lesser pyroxenite and gabbro (Bittenbender and others, 2007). The complex crops out along strands of the Broxson Gulch thrust fault (W.T. Ellis, oral communication, 2001).

As described by W.T. Ellis (oral communication, 2001) the mineralization consists of coarsely-crystalline clots and disseminations of pyrrhotite, chalcopyrite, and pentlandite in olivine melagabbro and feldspathic peridotite. Sulfide abundance rarely exceeds about 5 percent. A float sample contained 117 parts per billion (ppb) gold, 393 ppb platinum, 493 ppb palladium, 0.14 percent copper, and 0.4 percent nickel.

Bittenbender and others (2007) could not locate mineralized rock at the Ellis's supposed location and samples they took in that area had insignificant metal values. However, after talking with industry geologists in 2004, they determined that the most likely location for what is commonly known as the BOS prospect is at the coordinates used for this record. (The Ellis location may be about a mile to the northwest but it uncertain whether there are two sites of mineralization or confusion about the location of a single location.) A sample collected by Bittenbender and others (2007) across 1 foot of peridotite with about 1 percent chalcopyrite contained 36 ppb gold, 106 ppb platinum, 86 ppb palladium, 594 parts per million (ppm) copper, and 2,030 ppm nickel. A sample of serpentinite with disseminated sulfides contained 11 ppb gold, 292 ppb platinum, 308 ppb palladium, 1,145 ppm copper, and 3,710 ppm nickel. The prospect is at the toe of a small ice field and may extend under the ice.

Alteration:

Moderate to strong serpentinization of ultramafic rocks.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Examined and sampled by American Copper and Nickel Company in the early 2000s and by Pure Nickel Inc. as part of their MAN project. As of 2001, the prospect was on claims held by Pure Nickel. Sampled by the Bureau of Land Management in 2003.

Production notes:

None.

Reserves:

None.

Site name(s): Boot Flap

Site type: Prospect

ARDF no.: MH102

Latitude: 63.3226 **Quadrangle:** M B-5

Longitude: 146.3174

Location description and accuracy:

The Boot Flap prospect is at an elevation of 5,100 feet about three-quarters of a mile east of the lower Eureka Glacier and 6.8 mile northwest of the junction of Eureka Creek and Broxton Gulch. It is about 5.5 mile south of peak 6563 and about 0.3 mile south of the center of section 25, T. 18 S., R. 7 E.

Commodities:

Main: Cr, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Boot Flap prospect is associated with a east-trending, northward-dipping sill-like body of mafic and ultramafic rocks that are part of a Middle Triassic unit informally called the Eureka complex (Rose, 1966; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The complex is mostly gabbro and serpentinized peridotite that occur along strands of the Broxson Gulch thrust fault (W.T. Ellis, unpublished data, 1996). The complex structurally overlies light-colored fine-grained andesite, dacite, and graywacke that are part of the Pennsylvanian to Permian, Slana Spur Formation.

The prospect was examined and sampled by several companies in the 1990s and 2000s and by the Alaska Division of Mines and Minerals, the U.S. Geological Survey, and the U.S. Bureau of Land Management at various times from the late 1980s to 2007.

The Boot Strap prospect as sampled by Bittenbender and others (2007) is in a sill of ultramafic rocks 50 to 200 feet thick that may extend for at least 5 miles based on aeromagnetic evidence. The sill which is largely gabbro has a base of serpentinized ultramafic rocks. It overlies volcanic rocks and underlies porphyritic granitic rocks.

The mineralization consists of: 1) disseminated sulfides in the serpentine; 2) up to 5 percent, net-textured pyrrhotite, with lesser chalcopyrite, pentlandite, and magnetite in olivine gabbro; and 3) gossan zones leached of sulfides in the gabbro (Bittenbender and others, 2007). Two representative samples of the serpentine contained up to 1,290 parts per million (ppm) chromium, 586 ppm, copper, 2,260 ppm nickel, 52 parts per billion (ppb) platinum, and 56 ppb palladium. Two samples of gossan from the gabbro contained 711 ppm copper, 1,515 ppm nickel, 112 ppb platinum, and 83 ppb palladium. Samples of the gabbro contained up to 17 ppb platinum, 28 ppb palladium, 1,75 ppm nickel, and 430 ppm chromium.

Alteration:

Ultramafic rocks at the bottom of the sill are moderately to strongly serpentinized.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was examined and sampled by several companies in the 1990s and 2000s and by the Alaska Division of Mines and Minerals, the U.S. Geological Survey, and the U.S. Bureau of Land Management at various times from the late 1980s to 2007.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Tres Equis

Site type: Prospect

ARDF no.: MH104

Latitude: 63.2796 **Quadrangle:** M B-5

Longitude: 146.3087

Location description and accuracy:

The Tres Equis prospect is located one-quarter mile northwest of peak 3710, east of the headwaters of Eureka Creek below Eureka Glacier. The prospect is at the center of the SE1/4 section 12, T. 19 S., R.7 E., of the Fairbanks Meridian. The location is accurate to within 1/4 mile.

Commodities:

Main: Cu, Ni, Pd

Other: Co, Pt

Ore minerals: Chalcopyrite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Tres Equis prospect is in the Fish Lake ultramafic-mafic intrusive complex, a layered lopolith of Late Triassic age considered to be a comagmatic with lava flows of the Nikolai Greenstone (Nokleberg and others, 1991). The rocks at the Tres Equis prospect consist of layered wehrlite cut by irregular, mainly gabbroic dikes. A 50- to 100-foot-thick layer of taxitic gabbro overlies the wehrlite and is overlain in turn by a thick, massive peridotite of a later magmatic cycle. The taxitic gabbro contains leucocratic and anothorositic phases and commonly has clinopyroxenitic margins. The dikes range from melagabbro to leucrocratic pegmatite.

Magmatic layering in the lopolith strikes east to southeast and dips 45 to 50 degrees to the south. The dikes also strike east to southeast but cut the layering at high angles. All units are cut by high-angle, north- to northeast- trending faults having offsets of 20 to 50 feet.

The Tres Equis deposit is a magmatic breccia in the lower portion of the gabbroic unit of the second magmatic cycle of the Fish Lake complex. The breccia strikes east to southeast, subparallel to the gabbroic dikes. The breccia is along the margin of an irregular dike and consists of clasts of peridotite and gabbro in an oxidized and leached (post-mineralization) matrix. Some of the clasts, which are as much as 2 feet in diameter, contain disseminated pyrrhotite, chalcopyrite, and pentlandite. The sulfides also form networks and massive clots containing individual crystals more than an inch across. The average grade of six clasts containing massive sulfides was 3.2 percent copper, 5.2 percent nickel, 0.33 percent cobalt, 1,750 parts per billion (ppb) palladium, and 28 ppb platinum. A net-textured clast assayed 0.3 percent copper, 1.0 percent nickel, 0.07 percent cobalt, 712 ppb palladium, and 100 ppb platinum (W.T. Ellis, unpublished data, 1996).

Pure Nickel sampled the Tres Equis showing in 2011 and grab samples returned values of 6.7 percent nickel, 1.0 percent copper, and 1.5 grams of platinum group elements per tonne. Diamond drill holes were drilled to test possible extensions of mineralization (Pure Nickel, 2011).

Alteration:

The host rock is oxidized and leached. The peridotite is moderately serpentinized; hairline joint fractures are filled with fibrous serpentine (chrysotile). The gabbro dikes are amphibolitized along their margins but are essentially fresh for a half-inch into the dikes (W.T. Ellis, Project Geologist, American Copper Nickel Inc., oral communication, 1996).

Age of mineralization:

Late Triassic, the age of the host rock (Nokleberg and others, 1991).

Generic deposit model:

Deposit model:

Nickel-copper-PGE in differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

One hydraulically washed hand trench 20 to 30 feet wide and 100 feet long was completed in 1996. A 627-foot hole was drilled in 1997; two 200-foot holes were drilled in 1998. None of the drill holes penetrated significant mineralization.

Pure Nickel sampled the Tres Equis showing in 2011 and grab samples returned values of 6.7 percent nickel, 1.0 percent copper, and 1.5 grams of platinum group elements per tonne. Diamond drill holes were drilled to test possible extensions of mineralization (Pure Nickel, 2011).

Production notes:

None.

Reserves:

None.

Additional comments:

The Tres Equis breccia prospect is important because it demonstrates that the Fish Lake complex contains high-grade nickeliferous massive sulfide.

Site name(s): Mini Y Landslide

Site type: Prospect

ARDF no.: MH106

Latitude: 63.3221 **Quadrangle:** M B-5

Longitude: 146.2872

Location description and accuracy:

The Mini Y Landslide prospect is at an elevation of about 5,100 feet, about 1.5 miles east of the toe of the Eureka Glacier and about 5.9 miles northwest of the junction of Eureka Creek and Broxton Gulch. The prospect is about 0.2 mile south of the center of section 30, T. 18 S., R. 8 E.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Au, Cr

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals: Diopside, epidote, serpentine

Geologic description:

The rocks in the vicinity of the Mini Y Landslide prospect consists of Upper Triassic serpentinized peridotite and mafic gabbro interlayered with quartz diorite (Rose, 1966). The serpentinized rocks, informally called the Eureka ultramafic complex, occupy strands of the Broxson Gulch thrust fault (Nokleberg and others, 1991).

The prospect was examined and sampled by several companies in the 1990s and the 2000s and at various times from the 1980s to the early 2000s by the Alaska Division and Mines and Minerals, the U.S. Geological Survey, and the U.S. Bureau of Land Management.

Disseminated sulfide minerals are present in several types of ultramafic rocks and in skarn of probable ultramafic parentage in upper Landslide Creek. Plagioclase peridotite with pyrite, pyrrhotite, pentlandite, and chalcopyrite assayed 0.15 percent copper, 0.35 percent nickel, 0.4 percent chromium, 300 parts per billion (ppb) palladium, and 380 ppb platinum. A sample of magnetite-chalcopyrite-epidote-diopside skarn assayed 0.5 percent copper and 130 ppb gold (Foley and others, 1989; Foley and Summer, 1990; Foley, 1992; W.T. Ellis, unpublished data, 1996).

Bittenbender and others (2007) did not find any outcrop at this site; rather they found rubble that may be piled up by recent glaciation. They collected four samples of ultramafic and mafic rocks from the rubble; the best contained 13 ppb gold, 118 parts per million (ppm) cobalt, 806 ppm copper, 2,420 ppm nickel, 45 ppb platinum, and 41 ppb palladium.

Alteration:

All of the ultramafic rock units are moderately to strongly serpentinized; diopside-epidote skarn is locally developed.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:
Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

Last report date: 2012-05-13

Site name(s): UM Landslide; Dunite Diatreme

Site type: Prospect

ARDF no.: MH107

Latitude: 63.3054 **Quadrangle:** M B-5

Longitude: 146.2795

Location description and accuracy:

This mile-long and half-mile-wide prospect is on the west side of an southeast-flowing tributary of Eureka Creek that is informally called Landslide Creek. It is about 5.1 mile northwest of the junction of Eureka Creek and Broxson Gulch, about 0.7 mile southeast of the center of section 31, T. 17 S., R. 8 E, and about 0.3 mile southeast of peak southeast of peak 5460. The site includes not only conglomerate outcrops on the 5460 ridge but also a large landslide that flows down to the east from peak 5460.

Commodities:

Main: Au, Cu, Ni, Pd, Pt

Other: Hg

Ore minerals: Cinnabar, gold, magnetite, pyrite

Gangue minerals:

Geologic description:

The geology of this prospect has been variously interpreted. Most early workers have interpreted it as a sedimentary conglomerate composed mostly of clasts of peridotite and dunite and lesser gabbro in a serpentine matrix with hematite. (Moffit, 1912; Rose, 1966, Stout, 1976; Foley, 1992; Nokleberg and others, 1992 ([MF]; Nokleberg and others, 1992 [Open-File]) . The conglomerate caps the ridge of hill 5460 and is the source of landslide material below it to the east. The landslide covers an area about a mile long and one-half mile wide. Conglomeratic material in the slide consists of angular to subrounded boulders, cobbles, and pebbles of ultramafic rocks, mainly dunite, in a sand-size serpentine matrix rich in magnetite. The magnetite particles are as much as an inch in diameter. However, L.D. Hulbert (oral communication, 2000) interpreted the conglomerate as a diatreme that contains as much as 700 parts per billion (ppb) platinum and palladium.

Grab samples of the conglomerate and heavy-mineral concentrates produced by panning pulverized conglomerate and regolith overlying the conglomerate contained traces of gold and platinum-group minerals (Foley and others, 1989; Foley and Summers, 1990). The panned samples contained up to 102 ppb gold, 150 ppb palladium, and 240 ppb platinum. Panned concentrates from the creek to the east of peak 5640, informally named Landslide Creek, contained abundant pyrite and cinnabar and gold particles as heavy as 4 milligrams.

Bittenbender and others (2007) visited and resampled the prospect and concluded that it is in a conglomerate. Samples contained up to 9 ppb gold, 132 parts per million (ppm) copper, 1,810 ppm nickel, 70 ppb platinum, and 52 ppb palladium.

Alteration:

The ultramafic clasts in the conglomerate are remarkably fresh looking and essentially unaltered (L. Hulbert, oral communication, 2000).

Age of mineralization:

The landslide and associated placer deposits are Holocene. The source of the mafic and ultramafic rocks in

the conglomerate are probably the Late Triassic, Eureka ultramafic-mafic complex that is widely exposed in the vicinity.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au-PGE (Cox and Singer, 1986; model 39a); conglomerate with precious metal values.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Active

Workings/exploration:

Examined and sampled by a succession of companies and government agencies from before 1912 into the 2000s.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Lower Crash

Site type: Prospect

ARDF no.: MH108

Latitude: 63.3146 **Quadrangle:** M B-5

Longitude: 146.2585

Location description and accuracy:

The Lower Crash prospect is at an elevation of about 4,700 feet, about 5.0 miles northwest of the junction of Broxson Gulch and Eureka Creek. It is on the east side of a southeast-flowing tributary of Eureka Creek that is locally called Landslide Creek. It is about 0.5 mile north-northwest of the center of section 32, T. 18 S., R. 8 E.

Commodities:

Main: Au, Cu, Pd, Pt

Other: As, Cr, Hg, Mn

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Lower Crash prospect is in an east-trending, northward-dipping sill of Late Triassic, ultramafic and mafic rocks that is part of Triassic Eureka complex (Rose, 1966; Nokleberg and others, 1992 [MF]; Nokleberg and others, 1992 [Open-File]. The rocks at the prospect consist mainly of peridotite, gabbro and serpentine. The peridotite contains up to 5 percent sulfides, mainly pyrrhotite with sparse chalcopyrite, and pentlandite.

The prospect was found by industry in about 1990 and they may have dug a 50-foot trench on the mineralization (Bittenbender and others, 2007). Bittenbender and others (2007) collected six rock-chip samples; they contained up to 56 parts per billion (ppb) gold, 93 ppb platinum, 91 ppb palladium, 1,385 parts per million (ppm) copper, and 2,590 ppm nickel.

They also collected several samples below the prospect in the complex; one notable float sample contained 2.59 percent copper, 11.6 ppm silver, 282 ppm arsenic, 150 ppb gold, 668 ppm chromium, 0.68 ppm mercury, 2,490 ppm manganese, and 115 ppb palladium.

Alteration:

Moderate to strong serpentinization of the ultramafic rocks.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

Found by industry in the 1990s; they may have dug a 50-foot trench. Examined and sampled by the Bureau of Land Management in the 2000s.

Production notes:

None.

Reserves:

None.

Gangue minerals:

Geologic description:

The West Crash prospect is in an east-trending, northward-dipping sill of Late Triassic, ultramafic and mafic rocks that are part of the Eureka complex (Rose, 1966; Nokleberg and others, 1992 [MF]; Nokleberg and others, 1992 [Open-File]. The sill is about 100 feet thick at this prospect; it dips north about 40 degrees, and consists of differentiated pyroxenite and gabbro. The footwall of the sill is siliceous volcanic rocks; the hanging wall is argillite, slate, and graywacke. The rocks are locally iron-stained and altered with plagioclase going to saussurite and pyroxene going to actinolite. Malachite and garnierite staining is locally prominent.

The West Crash prospect was found by industry in the 1990s. It was examined and sampled by the Bureau of Land Management in about 2003. Bittenbender and others (2007) collected four samples. Two samples of gossanous material contained up to 37 parts per billion (ppb) gold, 399 parts per million (ppm) chromium, 872 ppm copper, 4,020 ppm nickel, 118 ppb platinum, and 168 ppb palladium. The other two did not have any notable metals.

Alteration:

The ultramafic rocks rock units are moderately to strongly serpentinized. The rocks are locally iron-stained and altered with plagioclase going to saussurite and pyroxene going to actinolite. Malachite and garnierite staining is locally prominent.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Found by industry in the 1990s. Examined and sampled by the Bureau of Land Management in about 2003.

Production notes:

None.

Reserves:

None.

Additional comments:

Site name(s): Notar

Site type: Prospect

ARDF no.: MH112

Latitude: 63.3173

Quadrangle: M B-5

Longitude: 146.2028

Location description and accuracy:

The Notar prospect is at an elevation of about 4,900 feet about 3.8 miles north-northwest of the junction of Broxson Gulch and Eureka Creek. It is near the northwest corner of section 34, T. 18 S., R. 8 E. The location is accurate.

Commodities:

Main: Cr, Cu, Ni, Pd, Pt

Other: Au

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Notar prospect is in an east-trending, northward-dipping sill of Late Triassic, ultramafic and mafic rocks that are part of the Eureka complex (Rose, 1966; Nokleberg and others, 1992 [MF]; Nokleberg and others, 1992 [Open-File]; Bittenbender and others, 2007). The rocks in the area are mainly variably serpentinized dunite with some peridotite and gabbro.

The prospect was found by industry in the 1990s (W.T. Ellis, unpublished data, 1996). The mineralization is in olivine melagabbro that contains as much as 7 percent disseminated sulfides, mainly pyrrhotite with small amounts of chalcopyrite and pentlandite, and magnetite. Samples contained up to 0.11 percent copper, 0.17 percent nickel, 42 parts per billion (ppb) palladium, and 40 ppb platinum.

The prospect was examined and sampled by Bittenbender and others (2007). They collected 5 samples that contained up to 17 ppb gold, 88 ppb platinum, 344 parts per million (ppm) copper, 822 ppm chromium, and 2,900 ppm nickel. A sample of peridotite they collected south of the prospect contained 49 ppb gold, 27 ppb platinum, 22 ppb palladium, 653 ppm copper, and 1,540 ppm nickel.

Alteration:

Dunite is variably serpentinized.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

Found and sampled by industry in the 1990s; examined and sampled by the Bureau of Land Management in the early 2000s.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (near Broxson Gulch)

Site type: Occurrence

ARDF no.: MH121

Latitude: 63.3458 **Quadrangle:** M B-5

Longitude: 146.0829

Location description and accuracy:

This occurrence is at an elevation of about 4,900 feet on the easternmost narrow ridge between the two forks of of Broxson Gulch that meet just above its mouth on Eureka Creek. It is about 1.8 mile northeast of elevation 4080 and about 0.6 mile northeast of the center of section 19, T. 18 S., R. 9 E.

Commodities:

Main: Cu

Other: Ag, Au, Co, Ni, Pd, Pt, Zn

Ore minerals: Chalcopyrite, covellite, digenite, pentlandite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

As originally described by Rose (1965), this occurrence is in amphibolitized 'serpentinite' inferred to be in the hanging wall of a major thrust fault. Rose (1966) later described the rock as basalt, part of the Mississippi to Pennsylvanian, Rainy Creek basalt unit which is at least 1,500 feet thick. Boulders containing massive sulfides were found along a 20-foot-wide zone on the north side of the ridge. Rose's samples contained 0.9 percent copper, a trace of zinc, and less than 0.1 percent nickel. Fifty feet south, a layer of pyrrhotite a few inches thick crops out for several feet. Nokleberg and others (1991) collected a sample with pyrite, pyrrhotite, pentlandite, and chalcopyrite that contained 500 parts per million (ppm) cobalt. Samples collected by Foley (1992) of massive-sulfide-bearing boulders in the area contained as much as 2.4 percent copper, 0.66 percent nickel, 0.1 percent cobalt, 13 ppm silver, 416 ppm gold, and 137 parts per billion (ppb) platinum, and 137 ppb palladium.

Bittenbender and others (2007) reexamined and sampled the site. They identified the rocks as strongly altered volcaniclastic rocks made up mainly of fine-grained amphibole and epidote with relict plagioclase clots. They sampled boulders up to 1.5 feet in size which originally identified by Rose. The volcaniclastic rocks contain small pockets of disseminated pyrrhotite and chalcopyrite with minor covellite and digenite and semi-massive sulfides. Samples contained up to 4,800 ppm copper, 633 ppm cobalt and up to 23 parts per billion (ppb) gold and 23 ppb platinum-group elements.

A 1982 unpublished report by the Bureau of Mines (cited in Bittenbender and others, 2007) describe a '...persistently mineralized sulfide zone adjacent to the contact of hornblende gabbro with thermally metamorphosed limestone. The mineralization has a width of 15 to 20 feet and was traced intermittently along strike for approximately 600 feet...'. Samples were said to contain from 0.1 to 1 percent copper and 0.2 to 0.4 percent cobalt. However, the 1982 Bureau of Mines report notes the presence of limestone, a significant difference from the descriptions of Rose (1965, 1966) and Bittenbender and others (2007).

Alteration:

Host rocks are highly altered but may be due to metamorphism.

Age of mineralization:

Ambiguous in view of the different descriptions of the rocks in the area.

Generic deposit model:

Deposit model:

Massive sulfides with chalcopyrite and pyrrhotite but notably different descriptions of the geology.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Sampled by state and federal agencies several times between 1966 and the early 2000s. Claims staked over it in the 2000s.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Green Wonder

Site type: Prospect

ARDF no.: MH126

Latitude: 63.3067 **Quadrangle:** M B-5

Longitude: 146.081

Location description and accuracy:

The Green Wonder prospect is at an elevation of about 4,400 feet about 2.6 miles northeast of the junction of the two forks of Broxson Gulch that diverge just about its mouth. The prospect is about 0.6 mile west-southwest of the center of section 32, T. 18 S., R. 9 E.

Commodities:

Main: Cu, Zn

Other: Ag, Cr, Cu, Ni, V

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals: Diopside, quartz, uvarovite garnet

Geologic description:

Rose (1965) describes the geology of the area as near the contact of volcanic and sedimentary rocks to the north and Rainy Creek basalt to the south. Nokleberg and others (1992 [MF[; 1992 [Open-File]) assigned the rocks in the area to the Lower Permian to Middle Pennsylvania, Slana Spur Formation. The rocks are intensely faulted and deformed.

As described by Rose (1965) and Bittenbender and others (2007), the occurrence is in an outcrop about 2 feet by 6 feet in size of a bright-green stained, almost white marble with quartz, epidote, uvarovite (green garnet), blebs of epidote, chrome diopside, and traces of sphalerite. The green staining may be garnierite, a secondary nickel mineral. Bittenbender and others (2007) tentatively classify the deposit as a skarn, possibly related to nearby ultramafic rocks based on the presence of nickel and chromium in analyzed samples. Rose's samples contained 10 percent or more zinc, 4 percent chromium, and 2 percent nickel. Samples collected by Bittenbender and his colleagues contained up to 9,980 parts per million (ppm) nickel, 2,190 ppm chromium, and 1,195 ppm zinc.

A 60-foot-wide diabase dike with disseminated chalcopyrite cuts meta-andesite near the prospect (Nokleberg and others, 1991). A sample contained 0.72 percent copper, 0.3 percent vanadium, and 7 ppm silver.

The deposit apparently was found by Moneta-Porcupine prior to 1965. They reportedly did some minor hand trenching but there was little sign of it by the early 2000s. Bittenbender and others (2007) suggest that the prospect may be more of interest to rock collectors for its green marble than as a valuable metal deposit.

Alteration:

Development of quartz-uvarovite-diopside skarn(?) in small marble outcrop.

Age of mineralization:

Unclear but younger than the Pennsylvanian or Permian host rocks.

Generic deposit model:

Deposit model:

Zinc-nickel-chromium skarn?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The deposit apparently was found by Moneta-Porcupine prior to 1965. They reportedly did some minor hand trenching but there was little sign of it by the early 2000s. Subsequently examined and sampled by state and federal geologists.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (lower Broxson Gulch)

Site type: Occurrence

ARDF no.: MH127

Latitude: 63.3018 **Quadrangle:** M B-5

Longitude: 146.0826

Location description and accuracy:

This occurrence is at an elevation of about 4,150 feet, about 2.1 mile northeast of the junction of the two forks of Broxton Gulch that diverge just about its mouth. The occurrence is about 0.6 mile northeast of the center of section 6, T. 19 S., R. 9 E.

Commodities:

Main: Au, Cu, Ni

Other:

Ore minerals: Chalcopyrite, gold, malachite, pentlandite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

Rose (1965) first described this occurrences in altered limestone with copper staining and serpentine. Nokleberg and others (1992 [OF]; 1992 {MF]) assigns the ultramafic rocks to the Triassic. Bittenbender and others (2007) describes the deposit as being in bleached white limestone with epidote and garnet. Sporadic small pods and lenses, generally about a foot in size, of semi-massive sulfides occur for about 500 feet along the contact of limestone and oxidized ultramafic rocks. The sulfides are mostly pyrrhotite, chalcopyrite, and pyrite, with some pentlandite. One sample contained 1.97 percent copper but most contained less than 0.5 percent. The highest gold value was 27 parts per billion; the highest nickel value was 2,180 parts per million but most samples contained much less. Bittenbender and others (2007) classify the deposit as a skarn.

Alteration:

Mineralized skarn developed at limestone-serpentine contact.

Age of mineralization:

Triassic or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Copper-nickel skarn.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only brief examination and sampling by state and federal geologists.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): East Broxson Gold

Site type: Prospect

ARDF no.: MH130

Latitude: 63.3471 **Quadrangle:** M B-5

Longitude: 146.0033

Location description and accuracy:

The East Broxton Gold prospect is at an elevation of about 4,400 feet in the headwaters of east fork of Broxson Gulch near the terminus of two unnamed glaciers. It is about 0.8 mile northwest of elevation 6045 and about 0.5 mile north of the center of section 22, T. 18 S., R. 9 E.

Commodities:

Main: Au, Cu, Pd, Pt

Other:

Ore minerals: Chalcopyrite, gold, pyrrhotite

Gangue minerals:

Geologic description:

The East Broxson Gold prospect is in the Late Triassic Rainey ultramafic-mafic complex that intrudes the Slana Spur Formation of Pennsylvanian and Permian age. The Rainy complex is up to 5,000 feet thick, dips shallowly north and is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro (Nokleberg and others, 1992 [Open-File]; Nokleberg and others, 1992 [MF]; Bittenbender and others, 2007). In this area, the base of the complex is a layered gabbro as much as 1,500 feet thick.

From 1995 to 1999, the prospect was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. in their regional search for copper-nickel-PGE mineralization. Their work in the area included rock sampling, and airborne and ground geophysical surveys W.T. Ellis, oral communication, 2001). Claims held by MAN Resources were active through at least 2001 (W.T. Ellis, personal communication, 2001).

The mineralization consists of disseminated pyrrhotite and pentlandite in a peridotite near the northern contact of the Rainy complex (W.T. Ellis, oral communication, 2001). A mineralized sample contained 0.05 percent nickel, 0.58 percent copper, 1,950 parts per billion (ppb) gold, 36 ppb palladium, and 140 ppb platinum. (W.T. Ellis, oral communication, 2001). Bittenbender and others (2007) searched the area but could not find mineralized rock. They collected three samples but none had base or precious metals significantly above background.

Alteration:

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Gold-nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

From 1995 to 1999, the prospect was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. in their regional search for copper-nickel-PGE mineralization. Their work in the area included rock sampling, and airborne and ground geophysical surveys W.T. Ellis, oral communication, 2001). Claims held by MAN Resources were active through at least 2001 (W.T. Ellis, personal communication, 2001). Examined and sampled by the Bureau of Land Management in the early 2000s.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): East Canyon

Site type: Occurrence

ARDF no.: MH131

Latitude: 63.3382 **Quadrangle:** M B-4

Longitude: 145.9984

Location description and accuracy:

The East Canyon prospect is about 0.8 mile north-northwest of peak 6346 at an elevation of about 4,850 feet. It is about 4.6 miles northwest of the junction of the North Fork and West Fork of Rainy Creek, near the center of section 22, T. 18 S., R. 9 E.

Commodities:

Main: Cu, Ni, Pd, Pt

Other:

Ore minerals: Native copper, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The East Canyon prospect is in the Late Triassic Rainy ultramafic-mafic complex that intrudes the Slana Spur Formation of Pennsylvanian and Permian age. The Rainy complex is up to 5,000 feet thick, dips shallowly north and is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro (Nokleberg and others, 1992 [Open-File]; Nokleberg and others, 1992 [MF]; Bittenbender and others, 2007). In this area a basal layered gabbro is as much as 1,500 feet thick.

From 1995 to 1999, the prospect was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. Their work included rock sampling, and airborne and ground geophysical surveys (W.T. Ellis, oral communication, 2001). MAN Resources held active claims through at least 2001 (W.T. Ellis, personal communication, 2001). The mineralization consists of disseminated pyrrhotite and pentlandite in a peridotite near the southern contact of the Rainy complex. A mineralized sample contained 0.187 percent nickel, 282 parts per billion (ppb) palladium, and 108 ppb platinum (W.T. Ellis, oral communication, 2001).

Bittenbender and others ((2007) examined the prospect and found little but native copper and copper-staining associated with discontinuous veinlets of serpentine, magnetite, and chrysotile or antigorite that cut serpentinized peridotite. The only metal of note in the two samples they collected was 1,905 parts per million copper in one sample.

Alteration:

The olivine melagabbro and peridotite are variably serpentinized.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Last report date: 2012-05-13

Site name(s): Unnamed (near head of east fork of Broxson Gulch)

Site type: Occurrence

ARDF no.: MH132

Latitude: 63.3346 **Quadrangle:** M B-5

Longitude: 146.0087

Location description and accuracy:

This occurrence is at an elevation of about 4,900 feet about a mile south of the head of the east fork of Broxson Gulch. It is about 0.7 mile northwest of peak 6346, about 0.4 mile northeast of peak 5995, and about 0.6 mile southwest of the center of section 22, T. 18 S., R. 9 E.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, magnetite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The rocks in the area are limestone and calcareous sedimentary rocks of the Pennsylvanian and Permian, Slana Spur Formation that are intruded by Triassic gabbro dikes (Rose, 1965; Nokleberg and others, 1992 [MF]; 1992 [Open-File]). Bittenbender and others (2007) identified an area about 5 feet by 20 feet in outcrop of iron-stained clinopyroxene-garnet-magnetite skarn with a small amount of chalcopyrite, pyrrhotite, and pyrite. A sample contained more than 15 percent iron, but only 177 parts per million (ppm) copper and no gold. A sample collected by Nokleberg and others (1991) contained 1.2 ppm gold, 300 ppm silver, and 720 ppm zinc. The source of the mineralization at this occurrence may be the gabbro dikes.

Alteration:

Silver-gold-copper mineralization in skarn near gabbro dikes.

Age of mineralization:

Possibly related to nearby Triassic gabbro dikes.

Generic deposit model:

Deposit model:

Skarn related to gabbro dikes.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Examined and sampled only by state and federal agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): West Bowl; Rainy

Site type: Prospect

ARDF no.: MH133

Latitude: 63.3384 **Quadrangle:** M B-4

Longitude: 145.9767

Location description and accuracy:

The West Bowl prospect extends between 5,200 to 5,600 feet in elevation in a cirque basin west of the upper North Fork Rainy Creek. The occurrences are centered about 0.4 mile south-southeast of elevation 6045 and about 0.4 miles west-southwest of the center of section 23, T. 18 S., R. 9 E.

Commodities:

Main: Ag, Au, Cu, Pd

Other:

Ore minerals: Bornite, chalcocite, chalcopyrite, covellite, digenite, pyrite pyrrhotite

Gangue minerals:

Geologic description:

The rocks in the vicinity of the West Bowl prospect are limestone and calcareous sedimentary rocks of the Pennsylvanian and Permian, Slana Spur Formation. It has been intruded by sills or dikes of Triassic mafic and ultramafic rocks, part of the Rainy complex, that varies from gabbro to dunite Rose, 1965; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007).

The prospect was discovered by MAN Resources in 2000 (L.D. Hulbert, oral communication, 2001) but apparently has no workings on it. MAN Resources transferred the property to Nevada Star Resources who held claims on it until at least 2005. Bittenbender and others (2007) of the Bureau of Land Management examined and sampled the prospect in the early 2000s.

The prospect includes two sites of mineralization about a 1,000 feet apart. One is a mineralized skarn inclusion within the mafic-ultramafic complex, and the other is mineralized skarn at the contact of the complex. The skarn has varying proportions of calcite, vesuvianite, garnet, wollastonite, epidote, olivine, and clinopyroxene, and minor plagioclase and actinolite. The ore minerals occur in pods that consist mainly of pyrrhotite, bornite, and chalcopyrite with minor digenite, chalcocite, covellite, and pyrite.

Samples of the skarn collected by MAN Resources within the mafic-ultramafic complex contained up to 4.6 percent copper, 1,040 parts per billion (ppb) gold, 7.7 parts per million (ppm) silver, 52 ppb palladium, and 11 ppb platinum (L.D. Hulbert, oral communication, 2001). Samples of the skarn at the contact of the mafic-ultramafic complex contained up to 2.5 percent copper, 258 ppb gold, 263 ppb palladium, and 55 ppb platinum. Bittenbender and others (2007) collected 6 samples. The highest metal values were 1.21 percent copper, 237 ppb gold, 19.7 ppm silver, and 57 ppb palladium.

Alteration:

Limestone adjacent or in a Triassic mafic-ultramafic complex is altered to a mineralized skarn.

Age of mineralization:

Source of the mineralization is probably the Triassic mafic-ultramafic complex at the prospect.

Generic deposit model:

Deposit model:

Copper skarn adjacent to and within a mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

The prospect was discovered by MAN Resources in 2000 (L.D. Hulbert, oral communication, 2001) but apparently has no workings on it. Last report date: 2012-05-13

Site name(s): Unnamed (east of peak 6346)

Site type: Prospect

ARDF no.: MH134

Latitude: 63.3249 **Quadrangle:** M B-4

Longitude: 145.981

Location description and accuracy:

This prospect is on the southeast side of a ridge about 0.4 mile southeast of the top of peak 6346 at an elevation of about 5,900 feet. It is on the west side of the North Fork Rainy Creek about 0.4 mile west of the center of section 26, T. 18 S., R. 9 E., Fairbanks Meridian.

Commodities:

Main: Au, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals: Serpentine

Geologic description:

This prospect is in the Late Triassic, Rainy complex, a shallowly north-dipping ultramafic-mafic body that varies from less than 100 feet to more than 5,000 feet thick and extends for more than 12 miles (Nokleberg and others, 1992 Open-file]; Nokleberg and others, 1992 [MF]; Bittenbender and others, 2007). It is largely dunite with lesser peridotite and gabbro. A discontinuous marginal gabbro extends along most of the southern (lower) contact and is more discontinuous along the northern (upper) contact (W.T. Ellis, oral communication, 2001). The body intrudes the Pennsylvanian-Permian, Slana Spur Formation of the Wrangellia terrane.

The prospect was found by the American Copper and Nickel Company (ACNC) in 1994. Working in conjunction with Fort Knox Gold Resources Inc. they sampled and mapped it, did airborne and ground geophysical surveys over it, and diamond drilled one hole (W.T. Ellis, oral communication, 2001). Sampled by the Bureau of Land Management in the early 2000s (Bittenbender and others, 2007).

The prospect is in the footwall of the complex in a layered marginal gabbro. The layer, which is up to 1,500 feet thick at the prospect includes gabbronorite, coarsely-crystalline clinopyroxene gabbro, wehrlite, and mineralized mafic gabbro. The mineralized gabbro contains 5 to 15 percent disseminated pyrrhotite with minor chalcopyrite and pentlandite and is iron and copper stained. Two samples contained 0.15 to 0.23 percent copper, 0.12 to 0.21 percent nickel, 153 to 180 parts per billion (ppb) palladium, 58 to 72 ppb platinum, and 18 to 51 ppb gold (W.T. Ellis, oral communication, 2001).

Bittenbender and others (2007 collected two samples from the mineralized gabbro. A sample with about 5 percent pyrrhotite and chalcopyrite contained 29 ppb gold, 75 ppb platinum, 236 ppb palladium, 1,690 parts per million (ppm) copper, and 1,045 ppm nickel. They also sampled a thin dike of leucocratic, pegmatitic gabbro dike that had disseminated chalcopyrite; an analysis showed insignificant precious and base metals.

Alteration:

Mafic and ultramafic rocks are variably serpentinized.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was found by the American Copper and Nickel Company (ACNC) in 1994. Site name(s): Rainy; East Peak

Site type: Prospect

ARDF no.: MH135

Latitude: 63.3281 **Quadrangle:** M B-4

Longitude: 145.9917

Location description and accuracy:

The East Peak prospect is a few hundred feet east of peak 6346 at an elevation of 6,000 feet. It is about 4.0 miles northwest of the mouth of the West Fork of Rainy Creek and about 0.4 mile northeast of the center of section 27, T. 18 S., R. 9 E., of the Fairbanks Meridian. The location is accurate to within 1/4 mile.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Au, Co, Cr

Ore minerals:

Gangue minerals:

Geologic description:

The East Peak prospect is in an Upper Triassic ultramafic-mafic Rainy complex which intrudes the Slana Spur Formation of Pennsylvanian and Permian age (Nokleberg and others, 1992; Nokleberg and others, 1992; Bittenbender and others, 2007). In this area the complex includes a basal layered gabbro sequence as much as 1,500 feet thick; prominent rock types are gabbronorite, coarsely-crystalline clinopyroxene melagabbro, wherlite, and minor serpentinized dunite.

From 1995 to 1999, the prospect was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. Their work included rock sampling, airborne and ground geophysical surveys, and one diamond drill hole (W.T. Ellis, oral communication, 2001). Active claims were held by MAN Resources through at least 2001.

Mineralization consists of 5 to 15 percent disseminated pyrrhotite with minor chalcopyrite and pentlandite in coarse-grained olivine melagabbro with 15 to 25 percent feldspar. Two rock samples collected by American Copper and Nickel Company contained 0.27 and 0.30 percent copper, 0.13 and 0.08 percent nickel, 84 and 510 parts per billion (ppb) palladium, and 110 and 55 ppb platinum. A sample collected by MAN Resources contained 46 ppb gold, 0.03 percent copper, 0.085 percent nickel, 510 ppb palladium, and 55 ppb platinum (W.T. Ellis, oral communication, 2001).

Bittenbender and others (2007) collected two samples at the prospect and 5 more in the general area. The two samples from the prospect contained up to 100 ppb platinum, 65 ppb palladium, 36 ppb gold, 2,010 parts per million (ppm) copper, and 1,175 ppm nickel. The five samples nearby contained lesser precious metals but up to 2,590 ppm nickel, 1,090 ppm chromium and 138 ppm cobalt.

In 2011, Pure Nickel Inc. reported a mapping program on the Rainy complex, identifying several gossanous areas at the complex's contact with the sedimentary host rocks. Grab samples from these gossanous contact rocks returned values up to 130 ppb gold, 150 ppb platinum, and 550 ppb palladium. The gossanous zones are interpreted to reflect deposition of sulfides at the basal contact of the Rainy complex and, thus this stratigraphic interval is thought to offer significant potential for economic mineralization (Pure Nickel Inc., 2011).

Alteration:

The olivine melagabbro and dunite are locally serpentinized (Bittenbender and others, 2007).

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex (Nokleberg and others, 1992).

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

From 1995 to 1999, the prospect was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. Their work included rock sampling, airborne and ground geophysical surveys, and one diamond drill hole (W.T. Ellis, oral communication, 2001). Claims held by MAN Resources were active through at least 2001. Examined and sampled by the Bureau of Land Management in the early 2000s.

In 2011, Pure Nickel Inc. reported a mapping program on the Rainy complex, identifying several gossanous areas at the complex's contact with the sedimentary host rocks. Grab samples from these gossanous contact rocks returned values up to 130 parts per billion (ppb) gold, 150 ppb platinum, and 550 ppb palladium. The gossanous zones are interpreted to reflect deposition of sulphides at the basal contact of the Rainy complex and, thus this stratigraphic interval is thought to offer significant potential for economic mineralization (Pure Nickel Inc., 2011).

Production notes:

None.

Reserves:

None.

Last report date: 2014-12-11

Site name(s): Unnamed (West Fork Rainy Creek)

Site type: Prospect

ARDF no.: MH143

Latitude: 63.2938 **Quadrangle:** M B-4

Longitude: 145.9666

Location description and accuracy:

This prospect is at an elevation of about 4,000 feet, about 2.2 miles west-northwest of the junction of the North and West Forks of Rainy Creek. It is 0.3 mile southeast of the center of section 2, T. 19 S., R. 9 E.

Commodities:

Main: Ag, Cu, Ni

Other: Zn

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The rocks in the area are tuffs and sediments that are interbedded with Triassic mafic and ultramafic rocks (Rose, 1965; Nokleberg and others, 1992 [MF], 992 [Open-File]). Bittenbender and others (2007) found an iron-stained outcrop of gabbro about 10 by 20 feet in size with pyrrhotite, pyrite, and chalcopyrite. Samples contained up to 7,040 parts per million (ppm) copper, 1,720 ppm nickel, 2.9 ppm silver, and 258 ppm zinc; most samples contained about a 10th as much. They identified a 30 by 50 foot xenolith nearby of garnet-epidote skarn in gabbro as well as several smaller such bodies. The skarn has a few percent disseminated chalcopyrite. They ascribe the source of the mineralization and the skarns to Triassic(?) gabbro intrusions nearby.

Alteration:

Mineralized skarn developed near gabbro intrusions.

Age of mineralization:

Mineralization possibly related to Triassic(?) gabbro.

Generic deposit model:

Deposit model:

Copper-nickel mineralization in skarn and gabbro.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Examined and sampled by Bureau of Management in the early 2000s.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (south of West Fork Rainy Creek)

Site type: Occurrence

ARDF no.: MH144

Latitude: 63.3008 **Quadrangle:** M B-4

Longitude: 146.001

Location description and accuracy:

The prospect is at an elevation of about 4,800 feet, about 3.3 miles northeast of the mouth of Specimen Creek on Eureka Creek. It is about 0.3 mile north-northeast of the center of section 3, T. 19 S., R. 9 E.

Commodities:

Main: Ag, Au, Cu, Ni

Other:

Ore minerals: Chalcopyrite, marcasite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

As described by Nokleberg and others (1992 [OF]; 1992 [MF]), the rocks in the area are Triassic gabbro to the south and Triassic greenstone to the north. Rose (1965) described the mineralization as a flat-lying lens about 3 feet thick and 10 feet long that consists of massive pyrrhotite, pyrite, and minor pyrite. The pyrrhotite is partly altered to marcasite. The lens is overlain by white, bleached marble with diopside and brown garnet; gabbro is beneath it (Bittenbender and others, 2007). A sample collected by Rose (1965) contained 0.37 percent copper, 0.5 percent nickel, 0.03 ounce of gold per ton, and 0.33 ounce of silver per ton. A sample collected by Nokleberg and others (1991) contained 0.43 percent copper and 12.5 parts per million silver. Bittenbender and others (2007) collected a sample across 2.5 feet of the lens of mineralization; it contained more than 15 percent iron, 659 ppm copper, 982 ppm nickel, 0.0003 ounce of gold per ton, and 0.009 ounce of silver per ton. As of 2007, the prospect was covered by a large block of claims held by Nevada Star Resource Corp. but there was no indication of any workings on it.

Alteration:

Pyrrhotite oxidized to marcasite. Lens of mineralization associated with a diopside-garnet marble.

Age of mineralization:

Possible Triassic or younger based on the age of some of the host rocks in the area but may be related to nearby Permian intrusive rocks.

Generic deposit model:

Deposit model:

Copper-nickel skarn deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

As of 2007, the prospect was on claims held by Nevada Star Resource Corp. but there was no indication of any substantial workings on it.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (northeast side of West Fork Rainy Creek)

Site type: Prospect

ARDF no.: MH145

Latitude: 63.3036 **Quadrangle:** M B-4

Longitude: 145.984

Location description and accuracy:

This prospect is at an elevation of about 4,200 feet on the north side of West Fork Rainy Creek. It is about 0.7 mile northwest of the center of section 2 T. 19 S., R. 9 E.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, gold, magnetite, malachite, pyrite, pyrrhotite

Gangue minerals: Amphibole, calcite, epidote, garnet, pyroxene, quartz

Geologic description:

Mineralization in Rainy Creek has been known since 1916 (Brooks, 1918; Martin, 1920). There has been some hand trending of unknown age at this prospect and it was covered by regionally extensive claims staked by MAN Resources as of 2007. It was examined and sampled in several episodes by state and federal agencies from 1964 to the 2000s.

The prospect is in Pennsylvanian to Permian limestone to limey sedimentary rocks of the Slana Spur Formation (Rose, 1965; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007).

The mineralization is associated with a band of magnetite-pyroxene-garnet skarn about 200 feet long. The limestone adjacent to the skarn is bleached and silicified. There is a gabbro dike nearby that may be related to the nearby Late Triassic Rainy mafic-ultramafic complex. Chalcopyrite occurs widely in the skarn in small amounts and there are lenses of sulfides made up mainly of pyrrhotite, pyrite, and chalcopyrite. Rose (1965) collected a sample of skarn that contained 0.42 percent copper, 0.01 ounce of gold per ton, and 0.40 ounce of silver per ton. The U.S. Geological Survey collected grab samples that contained up to 5.6 percent copper, 0.07 percent zinc, 0.009 ounce of silver per ton, and 0.035 ounce of gold per ton (Nokleberg and others, 1991). Bittenbender and others (2007) collected a sample from a pile of massive-sulfide rubble that contained 2.49 parts per million (ppm) gold, 4,770 ppm copper, and 3.4 ppm silver.

Alteration:

Mineralization associated with a band of magnetite-pyroxene-garnet skarn.

Age of mineralization:

Perhaps related to a nearby Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Silver-gold-copper skarn near a Triassic mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

The mineralization at this prospect has been known since 1916 (Brooks, 1918; Martin, 1920). There has been some hand trending of unknown age on it and it was covered by regionally extensive claims staked by MAN Resources as of 2007. It was examined and sampled several times by state and federal agencies from 1964 to the the 2000s.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Moneta-Porcupine

Site type: Prospect

ARDF no.: MH149

Latitude: 63.3167 **Quadrangle:** M B-4

Longitude: 145.9924

Location description and accuracy:

The Moneta-Porcupine prospect is along a narrow ridge about 4.3 miles northeast of the mouth of Specimen Creek on Eureka Creek. It is about 0.5 mile north-northeast of the center of section 34, T. 18 S., R. 9 E.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Bornite, chalcopyrite, malachite

Gangue minerals:

Geologic description:

As originally described by Rose (1965), chalcopyrite and bornite occur in tactite or hornfels about 3 feet thick. As described by Bittenbender and others (2007), the mineralization is in a small xenolith or pendant of light-colored skarn developed from Pennsylvanian or Permian marble that is in serpentinized ultramafic rocks. The skarn is copper stained and has small areas of disseminated bornite. Bornite also occurs in a foot-wide zone in a thin, silicified gabbro dike several feet from the marble. A select sample of the skarn contained 1.65 percent copper and a representative sample across the dike contained 0.34 percent copper.

Nokleberg and others (1991; 1992 [MF]; 1992 [Open-File]) have a notably different description of the prospect. They identified chalcopyrite, bornite, and malachite in and next to north-northeast-trending fractures in meta-andesite that is part of the Slana Spur Formation of Pennsylvanian and Permian age. The sulfide-bearing zones are as much as a meter thick and several meters long.

The prospect was staked by Moneta-Porcupine in 1964 but there is no indication that they did any substantial work on it. Claims held by MAN Resources Corp. were active in 2007.

Alteration:

Mineralization associated with skarn xenolith or pendant in serpentinized ultramafic rocks. Silicification of gabbro dike.

Age of mineralization:

Generic deposit model:

Deposit model:

Cu skarn associated with serpentinized ultramafic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was staked by Moneta-Porcupine in 1964 but there is no indication that they did any substantial work on it. Claims held by MAN Resources Corp. were active in 2007.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (west of upper North Fork Rainy Creek)

Site type: Occurrence

ARDF no.: MH150

Latitude: 63.3201 **Quadrangle:** M B-4

Longitude: 145.9692

Location description and accuracy:

This occurrence is at an elevation of about 4,950 feet on the hillside west of the middle section of the North Fork Rainy Creek. It is about 3.1 miles northwest of the junction of the North and West Forks of Rainy Creek and about 0.4 mile south of the center of section 26, T. 18 S., R. 9 E.

Commodities:

Main: Ag, Au, Cu, Ni

Other:

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

This occurrence is in a unit of hornfelsed calcareous sedimentary rocks that are part of the Pennsylvanian and Permian, Slana Spur Formation, which has been intruded by Triassic gabbro dikes and sills (Rose, 1965; Nokleberg and others, 1992 [MF], 1992 [Open-File]). Bittenbender and others (2007) describe discontinuous lenses with sulfides, mainly pyrrhotite, with minor chalcopyrite and pyrite, that they traced for about 700 feet in silicified sedimentary rocks. The source of the metals may be the nearby gabbro dikes. A sample of mineralized hornfels collected by Rose (1965) contained less than 0.1 percent each of copper and nickel, 0.02 ounce of gold per ton, and 0.4 ounce of silver per ton Nokleberg and others (1991) cited a sample that contained 0.6 percent copper, 0.2 percent cobalt, 0.004 ounce of gold per ton, and 0.09 ounce of silver per ton.

Examined and sampled by the Alaskan geological survey before 1965, by the U.S. Geological Survey in before 1991, and by the Bureau of Land Management before 2007. Covered by a regionally extensive block of MAN Resources claims in 2007.

Alteration:

Scattered copper-nickel mineralization is associated with hornfelsed and silicified sedimentary rocks near gabbro dikes.

Age of mineralization:

Source of metals may be nearby Triassic gabbro dikes.

Generic deposit model:

Deposit model:

Weak copper-nickel mineralization in sedimentary rocks cut by gabbro dikes.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Examined and sampled by the Alaskan geological survey before 1965, by the U.S. Geological Survey in before 1991, and by the Bureau of Land Management before 2007. Covered by a regionally extensive block of MAN Resources claims in 2007.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Hail Creek

Site type: Prospect

ARDF no.: MH152

Latitude: 63.3264 **Quadrangle:** M B-4

Longitude: 145.931

Location description and accuracy:

The Hail Creek prospect is at an elevation of about 4,200 feet, about 2.8 miles north-northwest of the junction of the North Fork and West Fork of Rainy Creek. It is about 0.2 mile east of the center of section 25, T. 18 S., R. 9 E.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Co, Cr, Zn

Ore minerals: Chalcopyrite, magnetite, malachite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The North Rainy prospect is in the Late Triassic, Rainy ultramafic-mafic complex that intrudes the Slana Spur Formation of Pennsylvanian and Permian age. The Rainy complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles; it is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro (Nokleberg and others, 1992 [Open-File]; Nokleberg and others, 1992 [MF]; Bittenbender and others, 2007). The base of the complex is a layered gabbro as much as 1,500 feet thick.

The area was staked by American Copper and Nickel Company ACNC in 1995 but the Hail Creek prospect was not discovered until 1998 when their exploration followed up a reconnaissance large-loop geophysical survey and an anomalous float sample found in 1995 (W.T. Ellis, oral communication, 2001). They drilled a 250-foot hole in 1998 but it failed to intersect mineralization.

The Hail Creek prospect is on an elongate east-northeast-trending magnetic high that coincides with nine airborne electromagnetic anomalies (W.T. Ellis, oral communication, 2001). The eastern string of four anomalies marks an iron oxide-stained, serpentinized and silicified zone in a dunite that contains local copper- and iron-stained fractures. (W.T. Ellis, oral communication, 2001). Downhill to the west along this trend, the dunite is intruded by variably serpentinized olivine gabbro. A copper-stained, sulfide-bearing serpentinized zone is present at one location along the poorly exposed gabbro contact. The sulfide minerals range from a trace to 2 percent disseminated chalcopyrite, pentlandite, pyrrhotite, and magnetite. Strong large-loop electromagnetic geophysical conductors were detected on three surveyed lines.

Float sample contained up to 0.39 percent nickel, 0.24 percent copper, 0.09 percent cobalt, 216 parts per billion (ppb) palladium, and 295 ppb platinum. A rock grab sample from the prospect assayed 0.25 percent nickel, 0.48 percent copper, 68 ppb palladium, and 95 ppb platinum. The 250-foot drill hole failed to intersect significant mineralization at one of the stronger geophysical anomalies.

Bittenbender and others (2007) examined and sampled the prospect in 2002. A sample with copper sulfides and copper staining from a contact zone between a gabbro dike and serpentinized dunite contained 2,430 parts per million (ppm) copper, 578 ppm zinc, 31 ppm chromium, 70 ppm nickel, 1.3 ppb platinum, and 2 ppb palladium. A sample of dunite contained 455 ppm chromium, 1,910 ppm nickel, 21 ppb platinum, and 19 ppb palladium.

Alteration:

Local silicification and serpentinization of dunite and gabbro.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The area was staked by American Copper and Nickel Company ACNC in 1995 but the Hail Creek prospect was not discovered until 1998 when their exploration followed up a reconnaissance large-loop geophysical survey and an anomalous float sample (W.T. Ellis, oral communication, 2001). A 250-foot hole was drilled in 1998 but failed to intersect mineralization. Examined and sampled by the Bureau of Land Management in 2002.

Production notes:

None.

Reserves:

None.

Geologic description:

The North Rainy prospect is in the Late Triassic, Rainy ultramafic-mafic complex that intrudes the Slana Spur Formation of Pennsylvanian and Permian age. The Rainy complex is up to 5,000 feet thick, dips shallowly north and is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro (Nokleberg and others, 1992 [Open-File]; Nokleberg and others, 1992 [MF]; Bittenbender and others, 2007). In this area, the base of the complex is a layered gabbro as much as 1,500 feet thick.

The rocks at this prospect are variably serpentinized dunite near fine-grained gabbro. Near the hanging wall contact of the complex, there is a well-developed breccia zone at a dunite-gabbro contact that is locally mineralized. The breccia consists of angular dunite clasts of various sizes and at least one large inclusion of hornfelsed sedimentary rocks in a fine-grained gabbro matrix.

From 1995 to 1999, the area was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. in their regional search for copper-nickel-PGE mineralization. Their work in the area included rock sampling, and airborne and ground geophysical surveys W.T. Ellis, oral communication, 2001). They found the North Rainy prospect in 1998 and carried out a large-loop geophysical survey. over it. There were active claims on the prospect to at least 2002. It was examined and sampled by the Bureau of Land Management in the early 2000s.

The mineralization consists of 2 to 4 percent sulfides, mainly pyrrhotite, with chalcopyrite, and pentlandite (?), disseminated in gabbro, (W.T. Ellis, oral communication, 2001). Float of sulfide-bearing dunite, gossan, and copper-stained serpentinite occur in a few places along the breccia contact. Rock samples contained as much as 0.18 percent nickel, 0.63 percent copper, 0.02 percent cobalt, 76 parts per billion (ppb) palladium, and 80 ppb platinum.

Bittenbender and others (2007) examined and sampled the prospect. Their best sample was dunite that contained 74 ppb platinum, 62 ppb palladium, 29 ppb gold, and 2,590 ppm nickel. They also identified: 1) lenses of massive to semi-massive sulfides, mainly pyrite or pyrrhotite and chalcopyrite, and 2) mineralized silica-flooded fault zones in an area of about 150 square feet in hornfelsed sedimentary rocks at the contact of the complex. Samples of the massive sulfides contained up to 158 ppb gold and 1.04 percent copper. Samples from the mineralized fault zones contained up to 445 ppb gold, 25 parts per million (ppm) silver, 2.08 percent copper, and 4,070 ppm lead.

Alteration:

Irregular serpentinization; oxidization of iron and copper minerals.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex; massive sulfides and mineralized veins near the contact of the complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Last report date: 2012-05-13

Site name(s): Unnamed (north fork of Ann Creek)

Site type: Prospect

ARDF no.: MH155

Latitude: 63.3484 **Quadrangle:** M B-4

Longitude: 145.8777

Location description and accuracy:

This prospect is at the head of the north fork of Ann Creek at an elevation of about 4,300 feet. It is about 0.6 mile south-southwest of peak 5317 and about 0.6 mile south of the center of section 17, T. 18 S., R. 10 E.

Commodities:

Main: Au, Cu

Other:

Ore minerals: Chalcopyrite, malachite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

As described by W.T. Ellis (oral communication, 2001), this prospect consists of copper stained pods of pyrrhotite, chalcopyrite, and pyrite in hornfelsed sedimentary rocks of the Pennsylvanian and Permian, Slana Spur Formation. The sedimentary rocks are below serpentinized peridotite of the Upper Triassic, Rainy mafic-ultramafic complex (Rose, 1965; Nokleberg and others, 1992 [MF; 1992 [Open-File]). Samples contained up to 1.3 percent copper and 629 parts per billion gold.

Bittenbender and others (2007) identified slivers of hornfelsed sedimentary rocks in faulted ultramafic rocks here. They found only sparse disseminated sulfides in both the sedimentary rocks and the ultramafic rocks and none of their samples contained nearly the metal values of the Ellis samples.

Alteration:

Peridotite is serpentinized; the sedimentary rocks are hornfelsed; copper minerals are oxidized.

Age of mineralization:

Probably related to the Late Triassic mafic and ultramafic rocks in the area.

Generic deposit model:

Deposit model:

Cu in hornfels (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Inactive

Workings/exploration:

Limited sampling by government and industry.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Rainy Breccia

Site type: Prospect

ARDF no.: MH156

Latitude: 63.3328 **Quadrangle:** M B-4

Longitude: 145.9002

Location description and accuracy:

The Rainy Breccia prospect is at an elevation of about 5,600 feet, 2.9 miles north of the junction of the North and West Forks of Rainy Creek. It is 0.6 mile south-southwest of the center of section 19, T. 18 S., R. 10 E.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Co

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Rainy Breccia prospect is near the north margin of the Late Triassic, Rainy Creek ultramafic-mafic complex that intrudes volcanic and sedimentary rocks of the Tetelna Volcanics and the Slana Spur Formations, both of Pennsylvanian and Permian age (Stout, 1976, Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles. It is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro. The base of the complex is a layered gabbro as much as 1,500 feet thick.

The prospect was discovered by the American Copper and Nickel Company (ACNC) in 1995 and later examined and sampled by the Bureau of Land Management (Bittenbender and others, 2007). As described by W.T. Ellis (oral communication, 2001), the Rainy Breccia prospect is in breccia that consists of subrounded clasts of dunite in a dark-colored gabbronorite matrix. The unit is several hundred feet long and approximately 50 feet thick. The breccia strikes S65E and dips 75N. The mineralization in the matrix consists of up to 6 percent disseminated pyrrhotite and magnetite, with traces of chalcopyrite and pentlandite as inclusions in the pyrrhotite. A grab sample of the sulfide-bearing breccia contained 0.12 percent nickel, 0.15 percent copper, 0.01 percent cobalt, 26 parts per billion (ppb) palladium, and 25 ppb platinum.

Bittenbender and others (2007) examined the area but were not certain that they located the the prospect described by Ellis. They did locate two breccia zones with disseminated sulfides in the immediate area; one with peridotite clasts in a leucogabbro matrix and the other brecciated peridotite. However, their samples had low base- and precious-metal values. The best contained 135 parts per million (ppm) copper, 1,285 ppm nickel, 13.9 ppb platinum, and 16 ppb palladium.

Alteration:

Irregular serpentinized zones occur along the breccia contact.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The prospect was discovered by the American Copper and Nickel Company (ACNC) in 1995 and was later examined and sampled by the Bureau of Land Management (Bittenbender and others, 2007).

Production notes:

None.

Reserves:

None.

Site name(s): White Band

Site type: Prospect

ARDF no.: MH158

Latitude: 63.3179 **Quadrangle:** M B-4

Longitude: 145.9143

Location description and accuracy:

The White Band prospect is at an elevation of about 4,800 feet on the east valley wall of upper North Fork Rainy Creek. It is about 2.1 miles north-northwest of the junction of the North and West Forks of Rainy Creek and about 0.6 mile south-southwest of the center of section 30, T. 18 S., R. 10 E.

Commodities:

Main: Au, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, malachite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The White Band prospect is in the Late Triassic, Rainy mafic-ultramafic complex which intrudes the Slana Spur Formation of Pennsylvanian and Permian age. The complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles; it is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro (Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The base of the complex is a layered gabbro as much as 1,500 feet thick.

The White Band prospect was found in the 1990s by American Copper and Nickel Company during their regional exploration for nickel and copper (W.T. Ellis, oral communication, 2001). The prospect consists of 2 to 3 percent of disseminated pyrite, pyrrhotite, and chalcopyrite in a prominent band of white, anorthosite gabbro in a peridotite unit near the southern contact of the Rainy complex. Samples of the sulfide-bearing white gabbro contained 3,688 parts per billion (ppb) gold, 210 ppb palladium, 95 ppb platinum, 0.27 percent copper, and 0.11 percent nickel (W.T. Ellis, oral communication, 2001). Samples of apparently the same rock collected by Bittenbender and others (2007) contained lower precious metal values: up to 16 ppb gold, 74 ppb platinum, 2,700 parts per million (ppm) copper, and 2,030 ppm nickel. They also collected a float sample of iron- and copper-stained melagabbro about 300 feet higher in elevation from the white gabbro that contained 1,070 ppb gold, 227 ppb platinum, 348 ppb palladium, 1,570 ppm copper, and 1,270 ppm nickel.

Alteration:

The olivine-bearing ultramafic rocks are variably serpentinized; copper minerals are locally oxidized.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The White Band prospect was found in the 1990s by American Copper and Nickel Company during their regional exploration for nickel and copper (W.T. Ellis, oral communication, 2001). Examined and sampled by the Bureau of Land Management in the early 2000s.

Last report date: 2012-05-13

Site name(s): Ann Fork

Site type: Prospect

ARDF no.: MH163

Latitude: 63.3278 **Quadrangle:** M B-4

Longitude: 145.8641

Location description and accuracy:

The Ann Fork prospect is at an elevation of about 4,280 feet, about 2.8 mile north-northeast of the junction of the North Fork and West Forks of Rainy Creek. It is about 0.5 mile east-northeast of the center of section 29, T. 18 S., R. 10 E.

Commodities:

Main: Au, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, ilmenite, magnetite, pentlandite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The Ann Fork prospect is near the north margin of the Late Triassic, Rainy mafic-ultramafic complex that intrudes volcanic and sedimentary rocks of the Tetelna and Slana Spur Formations of Pennsylvanian and Permian age (Stout, 1976, Nokleberg and others, 1992; Nokleberg and others, 1992; Bittenbender and others, 2007). The complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles; it is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro . The bas of the complex is a layered gabbro as much as 1,500 feet thick.

The prospect was first sampled by Barker (1988); it was examined and sampled by industry in the early 1990s, and it was examined and sampled by the Bureau of Land Management in 2002 (Bittenbender and others, 2007).

The mineralization at the Ann Fork prospect consists of semi-massive, net-textured, and disseminated sulfides, mainly pyrrhotite, with pentlandite, chalcopyrite, magnetite, and ilmenite, in gabbro dikes(?) that cut serpentinized peridotite and pyroxenite (Bittenbender and others, 2007). The mineralization is locally brecciated and oxidized to gossan; the brecciated mineralization is probably remobilized from primary magmatic mineralization in the Rainy complex. Some of the semi-massive mineralization has up to 80 percent sulfides across 1 to 2 feet. Garnet-pyroxene skarn has replaced marble beds near the contact of the Rainy ultramafic-mafic complex. Dunite in the complex is strongly serpentinized near a diorite intrusion at the contact.

Bittenbender and others (2007) collected 4 samples up to 6.5 feet long in the gabbro. The highest grade was a sample of semi-massive sulfides with 39 parts per billion (ppb) gold, 2.15 percent copper, 1,820 parts per million nickel, 72 ppb platinum, and 375 ppb palladium. Barker (1988) had previously analyzed samples that showed similar metal values.

Alteration:

Garnet-pyroxene skarn has replaced marble beds near the contact of the Rainy ultramafic-mafic complex. Dunite in the complex is strongly serpentinized near a diorite intrusion at the contact.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Primary and remobilized nickel-copper-PGE mineralization in and adjacent to a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The prospect was first sampled by Barker (1988); it was examined and sampled by industry in the early 1990s, and it was examined and sampled by the Bureau of Land Management in 2002 (Bittenbender and others, 2007).

Production notes:

None.

Reserves:

None.

Site name(s): East Rainy

Site type: Prospect

ARDF no.: MH164

Latitude: 63.3301 **Quadrangle:** M B-4

Longitude: 145.8792

Location description and accuracy:

The East Rainy prospect is at an elevation of 4,900 feet about 2.8 miles N10E from the junction of the North and West Forks of Rainy Creek. It is about 0.4 mile north of the center of section 29, T. 18 S., R. 10 E., of the Fairbanks Meridian. Figure 18 of Bittenbender and others (2007) is a geologic map of the prospect.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Au, Co, Ir, Os, Rh, Ru

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The East Rainy prospect is near the north margin of the Late Triassic, Rainy Creek ultramafic-mafic complex that intrudes volcanic and sedimentary rocks of the Tetelna Volcanics and the Slana Spur Formations, both of Pennsylvanian and Permian age (Stout, 1976, Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles; it is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro. The base of the complex is a layered gabbro as much as 1,500 feet thick.

The East Rainy prospect was discovered by American Copper and Nickel Company in 1995 or 1996 using data from airborne resistivity and magnetic geophysical surveys (Bittenbender and others, 2007). A joint venture with Fort Knox Gold Resources drilled a 246-foot hole in 1998. The property was acquired by Nevada Star Resources who drilled 7 holes totaling 980 feet in 2003 (Freeman, 2004).

The rocks at the East Rainy prospect are layered and gradually grade upward from porphyritic gabbro, through dunite, peridotite, feldspathic peridotite, and mafic-rich gabbro. There are at least two leucocratic gabbro dikes. (Figure 18 of Bittenbender and others (2007) is a geologic map of the geology). The mineralization is mostly in the feldspathic and mafic gabbro. The mineralization consists mainly of disseminated or net-textured pyrrhotite, pentlandite, and chalcopyrite.

Bittenbender and others (2007) collected 5 samples to characterize the mineralization. They averaged 4,085 parts per million (ppm) copper, 4,516 ppm nickel, 679 parts per billion (ppb) platinum, 774 ppb palladium, and 322 ppb gold. The highest platinum value was 950 ppb; the highest palladium value was 898 ppb.

Freeman (2004) reported that two holes in the 2003 Nevada Star drilling were in bad ground and the others did not intersect mineralization. The only notable mineralization were two, 5-foot intercepts in one hole. One intercept in feldspathic peridotite contained 1,366 ppm nickel, 833 ppm copper, 150 ppb platinum, and 148 ppb palladium. The other in leucogabbro contained 2,488 ppm nickel, 1,443 ppm copper, 205 ppb platinum, and 215 ppb palladium. The drilling indicated that the the mineralization is cut off at shallow depth by a younger intrusive body.

In 2011, Pure Nickel Inc., drilled two drill holes at East Rainy, totaling 488 meters. Platinum Group Element (PGE) values of up to 650 ppb over 2.52 meters of drill core were reported. Pure Nickel also

completed a mapping and sampling program in 2011. Highlights of metal concentrations from grab sampling at East Rainy are 2.0 percent nickel, 1.3 percent copper, and 7.9 grams of PGE + gold + silver per tonne (Pure Nickel, 2011).

Alteration:

The gabbroic rocks are moderately serpentinized (Bittenbender and others, 2007).

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex (Bittenbender and others, 2007).

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): Marsha

Site type: Prospect

ARDF no.: MH165

Latitude: 63.3436 **Quadrangle:** M B-4

Longitude: 145.848

Location description and accuracy:

The Marsha prospect is at an elevation of about 4,300 feet, about 3.3 miles west of the mouth of Ann Creek. It is about 0.4 mile north-northwest of the center of section 21, T. 18 S., R. 10 E.

Commodities:

Main: Cu, Ni, Zn

Other:

Ore minerals: Chalcopyrite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Marsha prospect is associated with the Late Triassic, Rainy Creek ultramafic-mafic complex that intrudes volcanic and sedimentary rocks of the Tetelna Volcanics and the Slana Spur Formations, both of Pennsylvanian and Permian age (Stout, 1976, Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles. It is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro. The prospect is just south of the Broxson Gulch thrust fault and is between splays of imbricated thrust faults that juxtapose slivers of dark ultramafic rocks with volcaniclastic rocks of the Slana Spur Foundation. Both are intruded by gabbro dikes up to 30 feet thick.

From the late 1980s into at least the 1990s, the Marsha prospect was examined and sampled by several companies, including Teck Cominco America, Northeast Mining Company, MAN Resources Inc., and Nevada Star Resource Corp. but there are no workings on it. Examined and sampled by the Bureau of Land Management in the early 2000s (Bittenbender and others, 2007).

At least three discontinuous lenses and nodules of oxidized chalcopyrite, pyrrhotite, and pentlandite are along the contact of a gabbro dike and serpentinized ultramafic rock. The largest sulfide lens is about 6 feet by 5 feet in area. Samples contained up to 6.25 percent copper, 1,540 parts per million (ppm) nickel, and 1,470 ppm zinc. The mineralization is discontinuous and does not extend far along strike.

Alteration:

The ultramafic rocks are extensively serpentinized.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Site name(s): Ann Creek

Site type: Prospect

ARDF no.: MH166

Latitude: 63.3392 **Quadrangle:** M B-4

Longitude: 145.7794

Location description and accuracy:

The Ann Creek prospect trends northwest for about a mile and parallels a short tributary to lower Ann Creek. The center of the prospect is about is 1.2 miles west of the mouth of Ann Creek and near the center of section 23, T. 18 S., R. 10 E. Figure 20 of Bittenbender and others (2007) has an aerial photography of the prospect.

Commodities:

Main: Ag, Au, Cu, Ni

Other: Co, Cr, Pb, Pd, Pt

Ore minerals: Chalcopyrite, galena, pentlandite, pyrite, pyrrhotite, sperrylite

Gangue minerals:

Geologic description:

The Ann Creek prospect is in a tabular ultramafic-mafic sill 80 to 120 feet thick that trends approximately east for about a mile on the north side of a small tributary to lower Ann Creek (Rose, 1965). The rocks north of the sill are dark, siliceous sedimentary rocks and light-colored tuff. The rocks south of the sill are andesite and dacite. The rocks on both sides are part of the Pennsylvanian and Permian, Slana Spur Formation; the different lithologies rocks suggests it was intruded along a fault (Rose, 1965). Airborne magnetic data indicate that this body may connect with the Late Triassic, Rainy ultramafic-mafic complex three miles to the west (W.T. Ellis, oral communication, 2001). The Rainy complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles. It is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro (Stout, 1976; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The base of the sill is a layered gabbro as much as 1,500 feet thick.

The Ann Creek prospect was discovered in the 1950s (Barker and others, 1985) and subsequently examined and sampled by Saunders (1962), Hanson (1963), Rose (1965), and the Bureau of Mines from 1981 to 1984 (Barker and other, 1985; Barker, 1988). Falconbridge Exploration U.S., Inc. examined the property in 1997 and had airborne, total-field-magnetics and resistivity surveys flown over it (Wells, 1998; Pritchard, 1997). The Bureau of Land Management examined and sampled the prospect several times in the early 2000s (Bittenbender and others, 2007).

The rocks in the sill at the Ann Creek prospect vary from fresh dunite, peridotite, and mafic gabbronorite to serpentinite. A dike of serpentinized peridotite extends southeast from the gabbronorite; it appears to be cut off by a fault. Near the east end of the sill, shattered and serpentinized diorite or quartz diorite is in contact with the dunite. Rose (1965) believed that the diorite may be a differentiate of the ultramafic-mafic Rainy complex.

Small lenses of massive sulfide occur in an approximately 50-foot-thick layer of gabbro that also contains disseminated pyrrhotite, pyrite, pentlandite, chalcopyrite, and a trace of galena (Rose, 1965). Serpentinite at this location also carries small amounts of sulfides. Disseminated and massive sulfide samples contained 0.17 to 2.01 percent nickel and 0.1 to 0.61 percent copper (Saunders, 1962). Samples of sulfides from a 1-foot vein assayed 0.20 ounce of gold per ton and 0.32 ounce of silver per ton (Rose, 1965). Foley (1992) collected a sample from a massive-sulfide lens that contained 1.9 percent nickel, 3.5 percent copper, 0.02

percent cobalt, 540 parts per billion (ppb) palladium, and 340 ppb platinum. Sperrylite was identified in a gabbronorite sample that contained 0.44 percent nickel, 0.3 percent copper, 0.02 percent cobalt, and 340 ppb palladium.

The Bureau of Land Management examined the Ann Creek prospect on several occasions in the early 2000s and collected 35 samples (Bittenbender and others, 2007). Their best sample was from a massive sulfide lens about 1 foot thick in serpentinized peridotite. It contained 35 ppb gold, 483 ppb platinum, 825 ppb palladium, 7,890 parts per million (ppm) copper, 6.74 percent nickel, and 1,765 ppm cobalt. Such massive sulfide lens were rare. They also collected several measured samples to determine the average grade of the deposit. A sample 40 feet long averaged 30 ppb gold, 1 ppm silver, 100 ppm cobalt, 1,000 ppm copper, 1,800 ppm nickel, 105 ppb platinum, and 145 ppb palladium.

Alteration:

Local serpentinization.

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site name(s): Foley

Site type: Prospects

ARDF no.: MH167

Latitude: 63.3179 **Quadrangle:** M B-4

Longitude: 145.9238

Location description and accuracy:

The Foley prospect includes several prospects centered at an elevation of about 4,300 feet about 2.1 miles north-northwest of the junction of the North and West Forks of Rainy Creek It is near the northeast corner of section 36, T. 18 S., R. 9 E.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Au, Co, Cr, Ir, Rh, Ru

Ore minerals: Chalcopyrite, chromite, cobaltite, magnetite, malachite, pentlandite, pyrite, pyrrhotite, safflorite

Gangue minerals: Garnet, olivine, pyroxene, serpentine

Geologic description:

These prospect consist of: 1) several sulfide-bearing, garnet-pyroxene skarns in carbonate beds intruded by the Rainy ultramafic-mafic complex, and 2) sulfide-bearing basalt, diorite, gabbro, and serpentinite in the complex (Foley, 1992). The Rainy complex intrudes the Slana Spur Formation of Pennsylvanian and Permian age; the Formation includes some some carbonate layers. The Rainy complex is up to 5,000 feet thick, dips shallowly north, and can be traced for more than 15 miles; it is mainly serpentinized dunite with subordinate peridotite, pyroxenite, and gabbro (Nokleberg and others, 1992; Nokleberg and others, 1992; Bittenbender and others, 2007). The base of the complex is a layered gabbro as much as 1,500 feet thick.

The prospects were found by industry in the 1990s; examined and sampled by the Bureau Mines (Foley, 1992), the U.S. Geological Survey (Nokleberg and others, 1991), and the Bureau of Land Management (Bittenbender and others, 2007).

The mineralization examined by Nokleberg and others (1991) consists of disseminated and nearly massive pods of pyrite, pyrrhotite, magnetite, and chalcopyrite with trace pentlandite, cobaltite, and safflorite, in chromite-bearing olivine cumulates. A sample contained more than 5,000 parts per million (ppm) chromium. A U.S. Bureau of Mines sample of gabbronorite rubble contained 0.9 percent nickel, 0.25 percent copper, 0.02 percent cobalt, 1,070 parts per billion (ppb) palladium, 725 ppb platinum, 300 ppb iridium, 70 ppb rhodium, and 60 ppb ruthenium. Massive sulfide float contains 0.41 percent copper, 0.09 percent cobalt, and 65 ppb palladium (Foley, 1992). Mineralized skarn samples taken near the contact of the Rainy complex contain as much as 6.2 ppm silver, 85 ppb gold, 0.05 percent cobalt, 2.0 percent copper, and 0.09 percent nickel. The area was examined by Bittenbender and others (2007) but they did not locate the prospects.

Alteration:

Age of mineralization:

Genetically related to the emplacement of a Late Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic complex; disseminated chromite in a layered mafic-ultramafic complex; Cu skarn (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Active?

Workings/exploration:

Found by industry in the 1990s. Examined and sampled by the Bureau Mines (Foley, 1992), the U.S. Geological Survey (Nokleberg and others, 1991), and the Bureau of Land Management (Bittenbender and others, 2007).

Production notes:

None.

Reserves:

None.

Site name(s): Emerick; Rainbow; Talnakh

Site type: Prospect

ARDF no.: MH209

Latitude: 63.3564 **Quadrangle:** M B-4

Longitude: 145.701

Location description and accuracy:

The Emerick prospect is at an elevation of about 2,900 feet south of the terminus of the Canwell Glacier and about 1.1 mile southeast of Millers Roadhouse on the Richardson Highway. It is about 0.6 mile east-northeast of the center of section 18, T. 18 S., R. 11 E. Figure 23 in Bittenbender and others (2007) is a geologic map of the prospect.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Au, Co, Ir, Os, Rh

Ore minerals: Bornite, chalcopyrite, garnierite, malachite, pentlandite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The Emerick prospect is in a fault-bounded sliver of Triassic serpentinized dunite, peridotite, and gabbro (Nokleberg and others, 1992 [MF]; 1992 [Open-File]]; Bittenbender and others, 2007). The prospect is in sheared and mineralized body of gabbronorite that was initially thought to be a dike (Barker, 1988; Foley and others, 1989; Foley, 1992), but is more likely a fault block within the ultramafic rocks (Wells, 1998; Bittenbender and others, 2007). The prospect is adjacent to the Broxson Gulch fault near its intersection with the Denali fault.

The prospect was discovered in 1955 by Rollie Emerick (Saunders, 1962; Bittenbender and others, 2007). Through the late 1950s, the property was examined by several individuals, the Alaska Alaska Department of Mines, and the U.S. Bureau of Mines (Saunders, 1961, 1962). Newmont Mining Company optioned the claims and dug a 1,600-foot road cut along the deposit. In 1971, the U.S. Bureau of Mines reexamined the property (Barker and others, 1985). Cominco Alaska re-staked the property in 1980s as the Rainbow claims, dug several long trenches with a dozer in 1988, and mapped and sampled them. Falconbridge Exploration U.S., Inc. staked the Talnakh claims over the property in 1990. They mapped the geology, did ground and aerial geophysical surveys over the claims, and drilled one hole 350 meters deep. Northridge Exploration re-excavated the old trenches and dug more trenches from 2000 to 2002.

The mineralization consists of several massive sulfide lenses in the ultramafic rocks and gabbro 'dike', and disseminated sulfides. (Figure 23 in Bittenbender and others (2007) is a geologic map of the prospect.) The ore minerals are mainly pyrrhotite and pentlandite with minor chalcopyrite and pyrite; bornite and garnierite have been noted and the copper minerals are locally oxidized to malachite. Saunders (1962) described nine mineralized lenses up to 20 feet long and 10 feet wide. They generally parallel the northwest trend of the ultramafic and mafic rocks (Hanson, 1963; Rose, 1965). The rocks adjacent to the lenses are strongly sheared and brecciated.

Samples from the northernmost prospect pit averaged 0.91 percent copper and 3.4 percent nickel; those from the southernmost pit averaged 1.0 percent copper and 2.6 percent nickel (Saunders, 1961). Samples of three other showings between the two pits respectively averaged 1.1, 2.6, 0.6 percent copper and 7.6, 8.1, and 2.6 percent nickel. U.S. Bureau of Mines samples from the Emerick property averaged about 1.0 percent copper and nickel and 0.02 percent cobalt, 193 parts per billion (ppb) gold, 977 ppb palladium, 989

ppb platinum, and minor amounts of osmiridium, osmium, and rhodium (Barker, 1988). Samples collected by the U.S. Bureau of Mines contained merenskyite, palarstanide, and irarsite which were identified with a scanning-electron microprobe. Samples collected by Bittenbender and others (2007) from the peridotite contained up to 6.31 percent nickel, 2.5 percent copper, 1,175 parts per billion (ppb) platinum, and 2.280 ppb palladium. Samples from the gabbro contained up to 8,050 parts per million (ppm) copper, 1.38 percent nickel, 1,175 ppb platinum, and 1,330 ppb palladium. Samples consistently show high chromium values, some more than 2,000 ppm.

Alteration:

The peridotite and gabbronorite are sheared and serpentinized. Copper minerals are oxidized.

Age of mineralization:

Probably genetically related to the emplacement of a Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic dike or fault silver.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Site name(s): Glacier Lake; Forbes

Site type: Prospect

ARDF no.: MH216

Latitude: 63.3515 **Quadrangle:** M B-4

Longitude: 145.662

Location description and accuracy:

The Glacier Lake prospect is at an elevation of about 3,700 feet. It is south of the terminus of the Canwell Glacier, about 2.3 miles east-southeast of Millers Roadhouse and about 0.5 mile west-southwest of the center of section 16, T. 18 S., R. 11 E. Figure 22 of Bittenbender and others (2007) is a geologic map of the prospect.

Commodities:

Main: Cu, Ni, Pd, Pt

Other: Au, Co, Ir, Os, Rh

Ore minerals: Chalcopyrite, pentlandite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The oldest unit in the area is the Pennsylvania to Early Permian, Slana Spur Formation which consists mainly of volcaniclastic sedimentary rocks (Nokleberg and others, 1992 [MF]; 1992 [Open-File]); Bittenbender and others, 2007). It hosts the Canwell mafic-ultramafic complex that varies from dunite to gabbronorite and includes much serpentinized rock. Both of these units are intruded by Cretaceous quartz diorite to granodiorite. The rocks at the Glacier Lake prospect are serpentine intruded by granodiorite and quartz diorite (Bittenbender and others, 2007).

The Glacier Lake prospect was discovered in 1962 by R.B. Forbes of the University of Alaska (Forbes, 1962; Hanson, 1963). Several companies explored the prospect within the next few years, including Newmont Mining Company (Barker and others, 1988). The property was examined and sampled by the Alaska Division of Mines and Minerals in 1963 (Kaufman, 1963) and by the U.S. Bureau of Mines from 1981 to 1984 (Barker, 1988). Claims were held by Northridge Exploration from 1997 to at least 2002. Falconbridge optioned the property in 1997 and the property was examined for Pacific Northwest Capital Corp. in 2002 (Freeman, 2002). The Bureau of Land Management examined and sampled the prospect in 2004 (Bittenbender and others, 2007). The work on the property includes considerable geologic mapping and sampling and several geophysical surveys.

The area of mineralization is about 25 feet long and 3 feet wide (Hanson, 1963; Barker, 1988; Bittenbender and others, 2007). It is at the contact of a nearly circular outcrop about 25 feet in diameter of granodiorite and quartz diorite (perhaps a roof pendant?) that is surrounded by serpentinite, serpentinized gabbro, peridotite and irregular masses of the granitic intrusive rocks. Pyrrhotite, chalcopyrite, and pentlandite occur in a narrow zone at a contact of peridotite and gabbro; chalcopyrite and pyrite are disseminated in the granodiorite and quartz diorite. The gabbro locally contains quartz lenses with 20 to 50 percent pyrrhotite; chalcopyrite and pentlandite. Disseminated sulfides are present in serpentinized peridotite away from the contact. Local hydrothermal alteration is characterized by secondary chlorite, epidote, mica, and anthophyllite veins near the contact of the serpentinite and quartz diorite.

There are two interpretations of the source of the mineralization. Barker (1988) and some industry geologists concluded that the mineralization is a result of the intrusion of Cretaceous quartz diorite into the ultramafic rocks. Rose (1965) and Bittenbender and others (2007) thought that it is a magmatic segregation

in the mafic and ultramafic rocks.

Grab samples of a massive sulfide lens in gabbro and of quartz diorite with disseminated sulfides at the contact of serpentinized peridotite contained as much as 16,000 parts per million (ppm) copper, 7 ppm silver, 700 ppm cobalt, and more than 5,000 ppm nickel (Nokleberg and others, 1991). Samples containing disseminated sulfides assayed from 1.9 to 6.0 percent copper, 1.0 to 1.5 percent nickel, and a trace to 0.4 ounce of gold per ton. A massive sulfide lens assayed 1.1 percent copper, 6.6 percent nickel, and 0.04 ounce of gold per ton (Hanson, 1963). A 3-foot chip sample across the contact of peridotite and diorite assayed 2.1 percent copper, 0.05 percent nickel, a trace of gold, and 0.35 ounce of silver per ton, and a massive sulfide sample contained 8.1 percent nickel (Rose, 1965). The U.S. Bureau of Mines collected nine mineralized samples that averaged 1.46 percent copper, 2.89 percent nickel, 0.07 percent cobalt, 25 parts per billion (ppb) gold, 90 ppb iridium, 495 ppb palladium, 410 ppb platinum, 57 ppb rhodium, and 29 ppb ruthenium (Barker, 1988). Samples collected by Bittenbender and others (2007) along 24.5 feet of the mineralization averaged 122 ppb gold, 450 ppb platinum, 658 ppb palladium, 560 ppm cobalt, 1.97 percent copper, and 2.59 percent nickel.

Alteration:

The peridotite and gabbro are extensively silicified and serpentinized near the quartz diorite-granodiorite contact. Local hydrothermal alteration is characterized by secondary chlorite, epidote, mica, and anthophyllite near the contact of the serpentinite and quartz diorite.

Age of mineralization:

Interpreted as either related to a Cretaceous quartz diorite to granodiorite intrusion or as a magmatic segregation deposit in a Triassic ultramafic-mafic complex.

Generic deposit model:

Deposit model:

Intrusion-related copper-nickel-PGE deposit or a magmatic segregation deposit in a ultramafic-mafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Glacier Lake prospect was discovered in 1962 by R.B. Forbes of the University of Alaska (Forbes, 1962; Hanson, 1963). Site name(s): Upper Glacier

Site type: Prospect

ARDF no.: MH217

Latitude: 63.3386 **Quadrangle:** M B-4

Longitude: 145.6199

Location description and accuracy:

The Upper Glacier prospect is at an elevation of 4,150 feet on the southwest valley wall of lower Canwell Glacier. It is about 2.1 miles east-northeast of VABM 5422 'Canwell' near the center of section 22, T. 18 S., R. 11 E. The location is accurate.

Commodities:

Main: Au, Co, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, magnetite, malachite, pentlandite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The Upper Glacier prospect is in the Triassic, Canwell mafic-ultramafic complex (Nokleberg and others, 1992 [MF]; 1992 [Open-File]]; Bittenbender and others, 2007). The complex is a sill-like body that trends west-northwest for about 3.5 miles, dips to the south at about 40 degrees, and is about 2,000 to 3,000 feet thick. It has a dunite core that grades outward to wehrlite, peridotite, and gabbro. The body was subsequently intruded by a Cretaceous quartz-diorite to granodiorite pluton.

The Upper Glacier prospect was found in 1995 by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources Inc. (Bittenbender and others, 2007). ACNC flew an airborne geophysical survey over the prospect in 1997 (Burns and Clautice, 2003). Nevada Star Resources Corp. did a Max-Min electromagnetic survey in 2004 and drilled 5 holes in 2003(?) and 2004. The Bureau of Land Management examined and sampled the prospect in the early 2000s (Bittenbender and others, 2007).

The mineralization consists of disseminated pyrrhotite, pyrite, and traces of chalcopyrite and pentlandite in feldspathic peridotite near the base of the Canwell complex (W.T. Ellis, oral communication, 1998; Bittenbender and others, 2007). The peridotite is surrounded by dunite and it is cut by high-angle faults; the peridotite is copper-stained and is cut by magnetite seams as much as 1 inch thick. The mineralized rock extends north-northwest for about 200 feet and is about 75 feet thick. Bittenbender and others (2007) collected 5 samples. A chip sample across 21 feet of mineralized peridotite contained 35 parts per billion (ppb) gold, 102 ppb platinum, 132 ppb palladium, 798 parts per million (ppm) copper, and 3,140 ppm nickel. Their highest grade sample was from peridotite with 3-5 percent coarsely-crystalline, disseminated sulfides. It contained 144 ppb gold, 259 ppb platinum, 280 ppb palladium, 2,330 ppm copper, and 3,600 ppm nickel.

Alteration:

Oxidation of copper minerals.

Age of mineralization:

Probably genetically related to the emplacement of a Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Site name(s): Odie

Site type: Prospect

ARDF no.: MH218

Latitude: 63.3322 **Quadrangle:** M B-4

Longitude: 145.6151

Location description and accuracy:

The Odie prospect is at an elevation of about 4,200 feet on the southwest valley wall of lower Canwell Glacier. It is about 2.2 miles east of VABM 5422 'Canwell' at the north end of Rainbow Ridge and 0.6 mile south-southeast of the center of section 22, T. 18 S., R. 11 E.

Commodities:

Main: Au, Co, Cu, Ni, Pd, Pt

Other: Ir, Os, Rh, Ru

Ore minerals:

Gangue minerals:

Geologic description:

The Odie prospect is in the Triassic Canwell mafic-ultramafic complex (Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The complex is a sill-like body that trends west-northwest for about 3.5 miles, dips to the south at about 40 degrees, and is about 2,000 to 3,000 feet thick. It has a dunite core that grades outward to wehrlite, peridotite, and gabbro. The body was subsequently intruded by a Cretaceous quartz-diorite to granodiorite pluton.

The Odie prospect was found in 1995 by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources Inc. (Bittenbender and others, 2007). ACNC flew an airborne geophysical survey over the prospect in 1997 (Burns and Clautice, 2003), and mapped and sampled it. Nevada Star Resources Corp. did a Max-Min electromagnetic survey in 2004 and drilled at least one hole in 2003 or 2004 that was at least 400 feet deep. The Bureau of Land Management examined and sampled the prospect in the early 2000s (Bittenbender and others, 2007). There are some small trenches.

The rocks at the Odie prospect are mostly weakly serpentinized dunite that has been intruded by a gabbronorite dike that is about 15 feet thick and can be traced for about 100 feet. The dike throughout has clots of or disseminated magnetite and pyrrhotite with minor chalcopyrite and pentlandite. It is locally copper stained and gossanous. The Nevada Star drilling cut 12 feet that contained 0.56 percent nickel, 0.15 percent copper, 106 parts per billion (ppb) platinum, and 136 ppb palladium. W.T. Ellis (oral communication, 1998) reported a high-grade sample that contained 0.86 percent copper, 1.2 percent nickel, 137 ppb gold, 12,330 ppb platinum, 1,247 ppb palladium, 537 ppb osmium, 289 ppb iridium, 89 ppb rhodium, and 662 ppb ruthenium. Bittenbender and others (2007) collected five samples. A chip sample across 16 feet of the dike contained 14 ppb gold, 47 ppb platinum, 49 ppb palladium, 124 parts per million (ppm) cobalt, 262 ppm copper, and 1,725 ppm nickel. A select sample of gossanous material near the footwall of the dike contained 2,120 ppb gold, 2,780 ppb platinum, 5,250 ppb palladium, 338 ppm cobalt, 1.70 percent copper, and 1.70 percent nickel.

Alteration:

Oxidation of copper minerals; some gossan.

Age of mineralization:

Probably genetically related to the emplacement of a Triassic mafic-ultramafic complex.

Generic deposit model:

Deposit model:

Nickel-copper-PGE mineralization in a gabbronorite dike that cuts a differentiated mafic-ultramafic sill.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The Odie prospect was found in 1995 by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources Inc. (Bittenbender and others, 2007). ACNC flew an airborne geophysical survey over the prospect in 1997 (Burns and others, 2003), and mapped and sampled it. Nevada Star Resources Corp. did a Max-Min electromagnetic survey in 2004 and drilled it in 2003(?) and 2004. The Bureau of Land Management examined and sampled the prospect in the early 2000s (Bittenbender and others, 2007). There are some small trenches.

Site name(s): Canwell Ridge; Canwell Glacier; Upper Canwell; Lower Canwell

Site type:

Prospect

ARDF no.: MH226

Latitude: 63.3291 **Quadrangle:** M B-4

Longitude: 145.5919

Location description and accuracy:

The Canwell Ridge prospect includes several exploration sites strung out for about 1,100 feet in an ultramafic-mafic complex. The center of the sites is about 2.8 miles east of VABM 5422 'Canwell' at the north end of Rainbow Ridge. It is about 0.3 mile north-northwest of the center of section 26, T. 18 S., R. 11 E., of the Fairbanks Meridian. This location is accurate to within 1/4 mile.

Commodities:

Main: Au, Co, Cu, Ni, Pd, Pt

Other: Ir, Rh, Ru

Ore minerals: Chalcopyrite, garnierite, malachite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Canwell Ridge prospect is in the Triassic, Canwell mafic-ultramafic complex (Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The complex is a sill-like body that trends west-northwest for about 3.5 miles, dips to the south at about 40 degrees, and is about 1,000 feet thick at this prospect. It has a dunite core that grades outward to wherlite, peridotite, and gabbro. The complex is intruded by Cretaceous quartz-diorite to granodiorite.

Although mineralization at the the Canwell Ridge prospect was recognized earlier (Hanson, 1963, Barker, 1988), serious exploration began in 1994 when American Copper and Nickel Co. (ACNC) working with Fort Knox Gold Resources staked claims over the prospect and flew an airborne geophysical survey that collected magnetic and resistivity data.

Nevada Star Resources Corp. optioned the property in 2001. They drilled 5 holes in 2002. In 2003, Nevada Star built a road to the prospect, brought in a backhoe, dug six trenches across the mineralization, did additional ground geophysical surveys and collected geochemical samples to define drill targets. They drilled 6 holes in 2004 that totaled 2,275 feet. The Bureau of Land Management examined the prospect in the early 2000s and collected a few samples (Bittenbender and others, 2007).

The mineralization at the Canwell Ridge prospect consists of disseminated to massive pyrrhotite with chalcopyrite and pentlandite that is mainly in gabbro near the base of the Canwell complex. Additional sulfide mineralization was introduced in gabbro dikes. The 2003 trenching by Nevada Star indicated that the mineralization extends for 1,100 feet and is up to 25 feet wide. The most impressive mineralization is a layer of massive sulfides about a foot thick that parallels the trend of the Canwell complex and can be traced for about 300 feet.

There is abundant assay data from the many episodes of sampling and drilling by several companies and organizations (Ellis, 2002 [Delta River]; Ellis, 2002 [Eureka Creek}; Freeman, 2004; Bittenbender and others, 2007).

Alteration:

The gabbro is moderately silicified and serpentinized (Bittenbender and others, 2007).

Age of mineralization:

Magmatic sulfides are related to the emplacement of a Triassic mafic-ultramafic complex (Bittenbender and others, 2007).

Generic deposit model:

Deposit model:

Synorogenic-synvolcanic Ni-Cu (Cox and Singer, 1986; model 7a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

7a

Production Status: None

Site Status: Active?

Workings/exploration:

Although mineralization at the the Canwell Ridge prospect was recognized earlier (Hanson, 1963, Barker, 1988), serious exploration began in about 1995 when American Copper and Nickel Co. (ACNC) working with Fort Knox Gold Resources staked claims over the prospect and flew an airborne geophysical survey that collected magnetic and resistivity data. In 1997, a UTEM Ground geophysical survey identified several targets and they drilled two holes. They did additional ground geophysical surveys in 1998 and drilled five holes. Nevada Star Resources Corp. optioned the property in 2001 and after Fort Knox abandoned their claims, Nevada Star re-staked the property. They drilled 5 holes in 2002. In 2003, Nevada Star built a road to the prospect, brought in a backhoe, dug six trenches across the mineralization, did additional ground geophysical surveys and collected geochemical samples to define drill targets. They drilled 6 holes in 2004 that totaled 2,275 feet. The Bureau of Land Management examined the prospect in the early 2000s and collected a few samples (Bittenbender and others, 2007).

In 2009, Pure Nickel Inc. reported grab sample assay result highlights of up to 13.7 percent nickel, 2.9 percent copper, 0.2 percent cobalt, 19.9 grams per tonne of platinum, 5.13 grams per tonne of palladium, 0.19 grams per tonne of rhodium, 0.26 grams per tonne of iridium, and 0.36 grams per tonne of ruthenium (Pure Nickel Inc., 2009).

Production notes:

Site name(s): Summit Hill

Site type: Prospect

ARDF no.: MH241

Latitude: 63.1312 **Quadrangle:** M A-3

Longitude: 145.4738

Location description and accuracy:

The Summit Hill prospect is at an elevation of 3,600 feet, 0.75 mile east of mile 195 on the Richardson Highway. It is at the northeast corner of section 5, T. 20 S., R. 12 E.

Commodities:

Main: Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, magnetite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

The Summit Hill prospect was discovered and claimed in about 1998 by American Copper and Nickel Company (ACNC). It was restaked by Nevada Star Resource Corp. in 2003 and claims were active as of 2005.

An airborne geophysical survey over the region area defined a circular core zone mainly of biotite diorite with a low magnetic response and a surrounding magnetic high of pyroxene hornblendite and associated mafic-ultramafic rocks (Burns and Clautice, 2003). Bittenbender and others (2007) dated the diorite as 123.2 +/- 1.1 Ma by 40Ar/39Ar methods and the mafic-ultramafic rocks as 123.4 +/-1.3 Ma. Olivine in the mafic-ultramafic rocks is partly serpentinized, and the pyroxene is mostly altered to amphibole. There is also local iron staining.

An ACNC sample of mineralized, medium grained to pegmatitic olivine gabbro with magnetite, chalcopyrite, pyrrhotite, and pentlandite contained 1.07 percent copper, 1.58 percent nickel, 484 parts per billion (ppb) palladium, 300 ppb platinum, and 110 ppb gold (W.T. Ellis, oral communication, 1998). Bittenbender and others (2007) examined and sampled the prospect. Two samples of pyroxenite with 20-30 percent magnetite and minor chalcopyrite were from near the ACNC discovery. The highest metal values were less than 5 ppb platinum, 29 ppb palladium, 195 parts per million (ppm) copper, and 55 ppm nickel. They collected one sample of gabbro and two samples of diorite at the contact of the diorite and the mafic-ultramafic rocks. The highest metal content in them was 22 ppb gold and 495 ppm copper.

Alteration:

Olivine is partly serpentinized, and the pyroxene is mostly altered to amphibole. There is also local iron staining.

Age of mineralization:

Mid-Early Cretaceous (123 Ma) based on 40Ar/39Ar analyses.

Generic deposit model:

Deposit model:

Copper-nickel-PGE mineralization associated with a diorite surrounded by mafic and ultramafic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The Summit Hill prospect was discovered and claimed in about 1998 by American Copper and Nickel Company (ACNC). It was restaked by Nevada Star Resource Corp. in 2003 and claims were active as of 2005. A 2003 airborne geophysical survey covered the area. Examined and sampled by the Bureau of Land Management in the early 2000s.

Site name(s): Unnamed (east of Gakona Glacier); JS

Site type: Occurrence

ARDF no.: MH267

Latitude: 63.2308 **Quadrangle:** M A-3

Longitude: 145.0992

Location description and accuracy:

This occurrence is at an elevation 6,400 feet on a sharp ridge east of Gakona Glacier. It is about 5.3 miles north-northeast of the center of Devils Lake in the terminus of Gakona Glacier and near the northeast corner of section 32, T. 19 S., R. 14 E.

Commodities:

Main: Ag, Au, Cu, Pd, Pt

Other:

Ore minerals: Bornite, chalcopyrite, covellite, digenite, magnetite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

Rose (1967) identified gabbro, pyroxenite, peridotite, and dunite here. Nokleberg and others (1992 [MF]; 1992 [Open-File]) included them in their 'ultramafic and associated rocks' unit that occur as klippen above thrust faults. The ultramafic rocks are thrust over volcanic and sedimentary rocks of the Pennsylvanian and Permian, Slana Spur Formation. Nokleberg and others suggest that an Early Cretaceous (123-126 Ma) age from the ultramafic unit probably represents regional metamorphism. However, Bittenbender and others (2007) suggest that Early Cretaceous ages on biotite and hornblende in similar rocks indicates primary crystallization.

Bittenbender and others (2007) identified several mineralized occurrences along the ridge in this vicinity. The rocks at the mineralized occurrences are mainly gabbro, pyroxenite and and peridotite that commonly contains patches of fresh biotite with minor tremolite and calcite (Bittenbender and others, 2007). The rocks are cut by thin, locally altered, pegmatitic gabbro dikes. The dikes contain 2-3 percent, chalcopyrite, bornite, and pyrrhotite, with minor digenite, covellite, and pyrite. Magnetite is a common accessory mineral and locally comprises up to 10 percent of the rock. At one location, 5-6 square feet in area, Bittenbender and others (2007) collected 5 iron-stained samples. The best contained 29 parts per billion (ppb) gold, 3.9 parts per million (ppm) silver, 363 ppb platinum, 72 ppb palladium, and 7,570 ppm copper. A 5.3-foot sample contained 17 ppb gold, 1.1 ppm silver, 258 ppb platinum, 68 ppb palladium, and 3.320 ppm copper. Other iron-stained occurrences in the area may be up to 100 feet long and 50 feet wide (Rose, 1967).

Alteration:

Rocks are generally fresh but thin mineralized gabbro dikes are locally altered.

Age of mineralization:

Unclear, possibly Early Cretaceous but may be older.

Generic deposit model:

Deposit model:

Disseminated copper-PGE minerals in thin gabbro dikes that cut mafic and ultramafic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only limited surface sampling by state and federal agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (east of toe of Gakona Glacier)

Site type: Occurrence

ARDF no.: MH269

Latitude: 63.2005 **Quadrangle:** M A-3

Longitude: 145.0938

Location description and accuracy:

This occurrence is at an elevation of about 5,250 feet, about 2 miles east of the terminus of the Gakona Glacier and 1.0 mile north-northeast of VABM 5206 'Ona'. It is about 0.6 mile northeast of the center of section 8, T. 20 S., R. 14 E.

Commodities:

Main: Cu

Other:

Ore minerals: Chalcopyrite, copper, pyrite

Gangue minerals:

Geologic description:

Rose (1965) mapped the rocks in the area as argillite intruded by small diorite plutons. Nokleberg and others (1991; 1992 [MF]; 1992 [Open-File] considered that the argillite is part of the Pennsylvanian and Permian, Slana Spur Formation and that the diorite is Triassic. Bittenbender and others (2007) identified isolated outcrops of bleached white marble and mineralized skarn with chalcopyrite and pyrite here; they consider the diorite to be Cretaceous. The marble and skarn is copper stained near the contact with the diorite and their samples contained up to 2,020 parts per million copper and 18 parts per billion gold. They also identified thin veinlets of native copper in diorite rubble. The mineralization is spotty and discontinuous.

Alteration:

Skarn developed at marble-diorite contact.

Age of mineralization:

Unclear whether the diorite that developed the mineralized skarn is Cretaceous or Triassic.

Generic deposit model:

Deposit model:

Cu skarn deposit (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling by state and federal agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (northwest of the terminus of Chistochina Glacier)

Site type: Occurrence

ARDF no.: MH286

Latitude: 63.1998 **Quadrangle:** M A-2

Longitude: 144.8786

Location description and accuracy:

This occurrence is on a ridge on the northwest side of the terminus of the Chistochina Glacier at an elevation of about 5,700 feet. It is about 0.4 mile northeast of the center of section 9, T. 20 S., R. 15 E.

Commodities:

Main: Au, Cu, Pd, Pt

Other:

Ore minerals: Chalcopyrite, magnetite

Gangue minerals:

Geologic description:

The rocks in the area consist of mafic and ultramafic intrusive rocks associated with volcanic rocks, probably part of the Pennsylvanian to Permian, Slana Spur Formation (Rose, 1967; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). Nokleberg and others (2007 [MF] suggest that Cretaceous K/Ar dates (123-126 Ma) from the mafic and ultramafic rocks reflect regional metamorphism of rocks deposited in the Paleozoic. Bittenbender and others (2007) have also dated the rocks as Early Cretaceous but interpret the dates as the age of primary crystallization. The mafic and ultramafic rocks are cut by discontinues inch-wide veinlets of magnetite.

As described by Rose (1967), the host rock of the mineralization is dunite in a composite ultramafic body that also contains peridotite, pyroxenite, and hornblendite (Rose, 1967). Thin veinlets of cross-fiber chrysotile cut the dunite. Boulders of hornblendite near the site contain as much as 10 percent magnetite. Bittenbender and others (2007) examined the occurrence and collected four samples. The richest sample was from serpentinized pyroxenite with minor chalcopyrite and copper staining. It contained 1.8 percent copper, 125 parts per billion (ppb) palladium, 48 ppb platinum, and 58 ppb gold. A sample from a gabbro dike contained 3,870 parts per million (ppm) copper, 462 ppb palladium, 326 ppb platinum, and 348 ppb gold.

Alteration:

Mafic and ultramafic rocks are locally serpentinized.

Age of mineralization:

Uncertain whether the host rocks are Late Cretaceous or as old as Paleozoic.

Generic deposit model:

Deposit model:

Disseminated chalcopyrite and magnetite in mafic-ultramafic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only limited sampled by state and federal agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): Unnamed (west of Chistochina Glacier)

Site type: Occurrence

ARDF no.: MH287

Latitude: 63.1932 **Quadrangle:** M A-2

Longitude: 144.8808

Location description and accuracy:

This occurrence is west of the terminus of the Chistochina Glacier and about 1.6 mile north of the mouth of Slate Creek on the Chistochina River. It is about 0.2 mile southeast of the center of section 9, T. 20 S., R. 15 E. There is some question about the location of this site in the old literature but this location is accurate as described by Bittenbender and others (2007).

Commodities:

Main: Au, Cu

Other: Ag, Ni

Ore minerals: Chalcopyrite?, magnetite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The rocks in the area consist of mafic and ultramafic intrusive rocks associated with volcanic rocks, probably part of the Pennsylvanian to Permian, Slana Spur Formation (Rose, 1967; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). Nokleberg and others (2007 [MF] suggest that Cretaceous K/Ar dates (123-126 Ma) from the mafic and ultramafic rocks probably reflect regional metamorphism of rocks deposited in the Paleozoic. However, Bittenbender and others (2007) also dated the rocks as Early Cretaceous but interpret the dates as the age of primary crystallization.

As described by Rose (1967), this occurrence is in a mile-long northeast-trending body of gabbro and mafic gabbro south of quartz monzonite of probable Mesozoic age. Rose (1967) identified a 50-foot-wide zone of pyritized rocks at the contact between peridotite and monzonite. A grab sample collected contained 0.02 ounce of gold per ton, 0.18 ounce of silver per ton, 0.2 percent copper, and a trace of nickel.

Probably at or near the Rose location, Bittenbender and others (2007) identified a iron-stained, lens-shaped area about 125 feet long of coarse-grained pyroxenite, gabbro, and some dunite. The pyroxene in the gabbro is altered to amphibole and the plagioclase is saussuritized. The iron-stained area contains up to 10 percent ore minerals, mainly pyrite and magnetite with minor pyrrhotite and chalcopyrite. A composite chip sample across 54 feet contained 2.7 parts per million (ppm) gold and 837 ppm copper. No other of their samples contained more than 0.032 ppm gold and the highest copper value was 1,900 ppm.

Alteration:

The site is notable for its iron staining. The pyroxene in the gabbro host rock is altered to amphibole and the plagioclase is saussuritized.

Age of mineralization:

No definitive information.

Generic deposit model:

Deposit model:
Unclear; gabbro and peridotite with sulfides and anomalous gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:
Only limited sampling by state and federal agencies.

Production notes:
None.

Reserves:
None.

Site name(s): Northland Mines

Site type: Prospect

ARDF no.: MH300

Latitude: 63.1371 **Quadrangle:** M A-2

Longitude: 144.8118

Location description and accuracy:

This prospect is on the north side of Powell Gulch about 0.7 mile northeast of its mouth. It is about 0.3 mile east of the center of section 35, T. 20 S., R. 15 E.

Commodities:

Main: Cu

Other: Ag, Fe, W

Ore minerals: Chalcopyrite, hematite

Gangue minerals: Garnet

Geologic description:

This record specifically describes the mineralization at this site as reported by Nokleberg and others (1991) and Bittenbender and others (2007). However, the work is within several generations of large block of claims and exploration that not only covers this site but several other sites nearby, notably ARDF sites MH380 and MH365. Those records may include data that applies to this site.

C.W. Monroe prospected in the area from 1964 to at least 1973 and staked more than 142 lode claims that covered this site and several square miles south of Chisna Pass (Bittenbender and others, 2007). Paul Glavinovich staked at least 36 claims in the area that may have covered this site and Resource Associates of Alaska (RAA) staked a large block of claims in the late 1970s and early 1980s that probably covered this site. The location of three holes that RAA drilled is uncertain but they were probably about 0.5 mile north at ARDF site MH365. AMAX Exploration was apparently active in the area in about 1990 and Cominco Alaska Exploration explored in the early 90s. In 2010, Corvus Gold Inc. drilled three holes about 0.5 mile to the north at ARDF site MH365 as part of an extensive regional exploration program (Taylor, 2010). Their work included surface sampling and mapping and geochemical and geophysical surveys that undoubtedly covered this prospect.

As described by Bittenbender and others (2007) citing Nokleberg and others (1992 [MF]; 1992 [Open-File]), the rocks in the area consist of hypabyssal Permian andesite to rhyolite, stocks, dikes, and sills that intrude marine volcanic rocks, volcaniclastic sedimentary rocks, and thin limestones of the Pennsylvanian and Permian, Slana Spur Formation. The area is cut by a series of high angle faults.

Rose (1967) did not visit the site but was shown specimens of chalcopyrite replacing silicified limestone. Nokleberg and others (1991) identified a skarn-like deposit about 75 feet wide and 270 feet long that parallels a dip slope. Veins as much as about 3 feet wide of chalcopyrite and massive hematite cut garnet skarn in limestone. A grab sample of chalcopyrite-bearing rock assayed 1.5 percent copper, 100 parts per million (ppm) tungsten, and 7 ppm silver.

Bittenbender and others (2007) described a steep, south-dipping, northwest-trending zone of near-massive specular hematite with disseminated chalcopyrite. The zone can be traced for at least 500 feet along strike and it is it up to 30 feet thick. A 20-foot sample across the hematite band averaged 3,770 ppm copper, 11.7 percent iron, and 428 ppm zinc. The hematite zone is underlain by limestone and overlain by volcaniclastic sedimentary rocks. Small outcrops of epidote-garnet-hematite skarn. are nearby. A 5-foot sample contained up to 2.89 percent copper, 776 ppm zinc, and more than 15 percent iron. The highest gold value was only 22

ppb. Bittenbender and others (2007) suggest that the mineralization is related to a 300.4 +/- Ma quartz monzonite intrusion nearby.

Alteration:

Small outcrops of mineralized skarn.

Age of mineralization:

Early Permian or younger.

Generic deposit model:

Deposit model:

Hematite layer with disseminated chalcopyrite; copper-iron skarn (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Undetermined

Workings/exploration:

C.W. Monroe prospected in the area from 1964 to at least 1973 and staked more than 142 lode claims that covered this site and several square miles south of Chisna Pass (Bittenbender and others, 2007). Paul Glavinovich staked at least 36 claims in the area that may have covered this site and Resource Associates of Alaska (RAA) restaked a large block of claims in the late 1970s and early 1980s that almost certainly covered this site. The location of the three holes RAA drilled is uncertain but they were probably about 0.5 mile north at ARDF site MH365. AMAX Exploration was apparently active in the area in about 1990 and Cominco Alaska Exploration explored in the early 90s. Corvus Gold Inc. drilled three holes about 0.5 mile north ARDF site MH365 as part of an extensive exploration program. The work included surface sampling and mapping and geochemical and geophysical surveys on a large block of claims that undoubtedly covered this prospect. Examined and sampled by several state and federal minerals agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2012-05-13

Site name(s): MID

Site type: Prospect

ARDF no.: MH340

Latitude: 63.2485

Quadrangle: M A-1

Longitude: 144.0965

Location description and accuracy:

The MID prospect is approximately 4 miles south-southeast of the junction of the Robertson River and Rumble Creek. It is at an elevation of about 5,700 feet at the toe of a remnant glacier on the section line between sections 16 and 17, T. 17 N., R. 7 E., Copper River Meridian. The deposit is concealed by glacial material. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, magnetite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Quartz

Geologic description:

The MID massive sulfide deposit is in metarhyolite of the upper Lagoon unit of Devonian age. The deposit is a sheet-like body as much as 47 feet thick in its longest drill intersection. It is the thickest block in what was once a single continuous massive sulfide layer that extends more than 2 miles along strike and is more than 40 feet thick. The layer is now offset by high-angle faults into six segments . The MID deposit is a blind deposit covered by glacial ice and moraine (Dashevsky and others, 2003).

The massive sulfide mineralization was intersected by drilling through the overlying Tiger unit into the metavolcanic rocks of the upper Lagoon unit which hosts the mineralization. The rocks surrounding the MID prospect are part of the Tiger unit; however, the massive sulfide mineralization was intersected by drilling into the underlying metavolcanic rocks of the upper Lagoon unit that host the mineralization. The Lagoon unit is a succession of dark gray, rusty, phyllitic metamorphosed mudstones interbedded with light-gray to white to pale green siliceous quartz-sericite(-chlorite) schist. Locally the rocks contain coarse, blue quartz eyes and rare fragmental volcanic textures preserved as chloritized lithic fragments. The upper part of the unit is dominated by white to pale green, massive to laminated quartz-eye-bearing quartz-sericite(-chlorite-pyrite) schist; finely laminated schist with minor metamorphosed black mudstone; and thin intercalations of quartzite and fine-grained metamorphosed grit. The protoliths of the volcanic rocks of the upper Lagoon unit are mainly rhyodacite and dacite, but they also include rare rhyolite and minor andesite and basalt (Dashevsky and others, 2003).

MID was discovered when massive sulfide float boulders were found during stream-sediment reconnaissance in 1976 (Rodney A. Blakestad and others, unpublished Resource Associates of Alaska Inc. report, 1976). The MID deposit is a blind target beneath glacial ice and moraine. Electromagnetic geophysical surveys were instrumental in recognizing this deposit. Extensive geological, geochemical, geophysical surveys and drilling were conducted by Resource Associates of Alaska from 1976 to 1981, by Phelps Dodge in 1990, and by American Copper and Nickel Company from 1994 to 1997. The alteration associated with the mineralization is characterized by the development of sericite, quartz, pyrite, and carbonate in the hanging wall and extensive chlorite and magnesium enrichment and sodium depletion in the footwall. Fifteen core holes totaling 11,655 feet have been drilled by 2002 (S.S. Dashevsky, unpublished data, 2002). The Drum unit, which is part of the metamorphic sequence that includes the rocks at this

deposit is near the Devonian-Mississippian boundary on the basis of one SHRIMP U-Pb zircon age of 359 +/- 6 Ma at the nearby DD South prospect (MH325).

The MID deposit has an inferred resource of 7.2 million tons averaging 0.4 percent copper, 1.6 percent lead, 4.5 percent zinc, 62 parts per million (ppm) silver, and 1.6 ppm gold. The resource calculation includes only those contiguous bodies with a true thickness greater than 8 feet and a gross metal value of greater than $80.00 per ton at 1998 prices (S.S. Dashevsky and others, 2003).

In 2011, Heatherdale Resources Inc. (2011) drilled 3 holes at the MID prospect; two cut significant mineralization. Six intercepts were especially notable; they varied from 5.0 to 75.7 feet long with metal contents of from 0.12 to 0.56 percent copper, 0.01 to 5.21 percent zinc, 1.07 to 2.36 percent lead, 0.79 to 1.56 grams of gold per tonne, and 44 to 98 grams of silver per tonne. The best was 43.9 meters with 0.56 percent copper, 5.21 percent zinc, 2.36 percent lead, 1.56 grams of gold per tonne, and 85 grams of silver per tonne. Heatherdale also collected massive-sulfide boulders and outcrop samples. Thirty massive-sulfide boulders averaged 0.91 percent copper, 3.11 percent zinc, 3.57 percent lead, 14.86 grams of gold per tonne, and 477 grams of silver per tonne. Six outcrop samples contained 0.09 to 1.34 percent copper, 0.11 to 11.95 percent zinc, 0.59 to 11.54 percent lead, 0.25 to 11.25 grams of gold per tonne, and 28 to 280 grams of silver per tonne.

Alteration:

The alteration associated with the mineralization is characterized by the development of sericite, quartz, pyrite, and carbonate in the hanging wall and extensive chlorite and magnesium enrichment and sodium depletion in the footwall.

Age of mineralization:

The Drum unit, which is part of the metamorphic sequence that includes the rocks at this deposit is near the Devonian-Mississippian boundary on the basis of one SHRIMP U-Pb zircon age of 359 +/- 6 Ma at the nearby DD South prospect (MH325).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active

Workings/exploration:

MID was discovered when massive sulfide float boulders were found during stream-sediment reconnaissance in 1976 (Rodney A. Blakestad and others, unpublished Resource Associates of Alaska Inc. report, 1976). The MID deposit is a blind target beneath glacial ice and moraine. Electromagnetic geophysical surveys were instrumental in recognizing this deposit. Extensive geological, geochemical, geophysical surveys and drilling were conducted by Resource Associates of Alaska from 1976 to 1981, by Phelps Dodge in 1990, and by American Copper and Nickel Company from 1994 to 1997. Fifteen core holes totaling 11,655 feet had been drilled to 2002 (S.S. Dashevsky, unpublished data, 2002). Heatherdale Resources Inc. (2011) drilled 3 holes in 2011, sampled massive-sulfide boulders, and collected outcrop samples.

Production notes:

None.

Reserves:

The MID deposit has an inferred resource of 7.2 million tons averaging 0.4 percent copper, 1.6 percent lead, 4.5 percent zinc, 62 parts per million (ppm) silver, and 1.6 ppm gold. The resource calculation includes only those contiguous bodies with a true thickness greater than 8 feet and a gross metal value of greater than $80.00 per ton at 1998 prices (S.S. Dashevsky and others, 2003).

Site name(s): POW; Chisna Ridge

Site type: Prospect

ARDF no.: MH365

Latitude: 63.1441 **Quadrangle:** M A-2

Longitude: 144.8069

Location description and accuracy:

The POW prospect is one of several in the area that have been repeatedly covered by large blocks of claims south of Chisna Pass and Slate Creek, that have repeatedly been explored by a succession of companies. The coordinates for this record are at the site of the 2010 Corvus Gold drilling. It is about 1.0 mile north of the junction of the Chisna River and Powell Gulch, near the northeast corner of section 35, T. 16 N., R. 14 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other: Pb, Zn

Ore minerals: Bornite, chalcopyrite, galena, gold, magnetite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

This record specifically describes mineralization at this site as reported by Taylor (2010) and Bittenbender and others (2007). However, there has been a succession of large claim groups over this prospect and extensive work in the area that not only covers it but several other nearby ARDF sites, notably MH380 and MH300. Those records may include data that applies to this site.

C.W. Monroe prospected in the area from 1964 to at least 1973 and staked more than 142 lode claims that covered this site and several square miles south of Chisna Pass (Bittenbender and others, 2007). Paul Glavinovich staked at least 36 claims in the area that may have covered this site. Resource Associates of Alaska (RAA) staked a large block of claims in the late 1970s and early 1980s that covered this prospect and drilled three holes in 1980 that cannot now be accurately located. AMAX Exploration was apparently active in the area in about 1990 and Cominco Alaska Exploration explored in the early 90s. From 2006 to 2008, International Tower Hills Inc. (ITH) staked a large block of claims south of Chisna Pass and Slate Creek that covered this prospect and did considerable mapping and sampling, and carried out extensive geochemical and geophysical surveys. Corvus Gold Inc. (who spun off from ITH) drilled 3 holes in 2010 to test a breccia zone and did more geologic mapping, sampling, and geochemical and geophysical surveys. The prospect has also been examined and sampled by several several state and federal agencies.

There have been several descriptions of the mineralization here. As described by Nokleberg and others (1991), the mineralization consists of disseminated sulfides and local massive to semi-massive sulfides in the Permian (?) meta-andesite and meta-dacite. A prominent zone of sulfidized rock that strikes northwest crops out in a gully near the northeast corner of section 35, T. 20 S., R. 15 E. (Randy Moore and C. C. Hawley, written communication, 1996). One sample of semi-massive pyrite, chalcopyrite, and possibly bornite assayed 0.488 ounce of gold per ton and more than 1 percent copper. Other samples from the mineralized area collected by Moore and Hawley contained less than 500 parts per million (ppm) copper.

As described by Taylor (2010), the POW deposit consists of a structurally-controlled chalcopyrite-bearing breccia several meters wide in a 200-foot-wide, silica-pyrite alteration envelope. The host rocks are porphyritic andesite and dacite of the Devonian or Lower Carboniferous Chisna Formation, and flysch, chert, and limestone of the Pennsylvanian to Permian Mankomen Group. These rocks are cut by many

porphyry dikes and by stocks of diorite and monzonite. A large stock of gabbro notable for its magnetic anomaly is about 2 miles to the northwest at peak 5850.

Nokleberg and others (1991) report altered rocks with disseminated galena and sphalerite. Samples contained up to 28.4 parts per million (ppm) silver, 1,235 ppm arsenic, 2,690 ppm lead, and 1,560 ppm zinc. A sample, probably of massive sulfides assayed 2 ppm gold, 70 ppm silver, 2 percent copper, 1,500 ppm arsenic, 30 ppm tin, and 530 ppm zinc. They suggest that the deposit may be a distal porphyry copper deposit, possibly of Permian age.

Bittenbender and others (2007) examined and sampled the prospect. Samples of highly oxidized volcanic rocks from a small trench on what was probably the site of one of the 1980 holes RAA drilled contained up to 23.4 ppm gold, 53.9 ppm silver, and 3.2 percent copper. They also found skarn mineralization here or nearby. They suggest that the mineralization is related to a nearby 300.4 +/- 1.4 Ma (Pennsylvanian) quartz monzonite.

Although the three holes that were drilled by RAA in 1980 cannot be located exactly, it is known that their best intercept was 2 feet with 3.4 percent copper, 0.9 ounce of gold per ton, and 0.25 ounce of silver per ton (Taylor, 2010). An intercept 68 feet long averaged 0.676 percent copper, 0.306 ounce of silver per ton, and 0.0416 ounce of gold per ton. The holes indicated a complicated geologic structure. The best intercepts in the 2010 Corvus drilling was 0.35 meter with 3.69 grams of gold per tonne and 8.71 grams of silver per tonne; 1.98 meters with 0.26 percent copper, 1.58 grams of gold per tonne, and 4.67 grams of silver per tonne; and 23 meters with 0.38 percent copper, 0.43 gram of gold per tonne, and 7.5 grams of silver per tonne.

The preceding information is specific in location and geology to the immediate area around the Corvus 2010 POW drilling. However, their claims and their work covered an area at least 2 kilometers wide and 5,5 kilometers long oriented generally northwest of their POW drill site. Many of their samples in this broad contained 0.1 to 13.7 percent copper. ARDF sites MH380, MH290, MH314, and MH315 are in this area and further work will probably be necessary to fully understand the extent and continuity of the mineralization. Taylor (2010), for instance, notes that magnetite-breccia pipes are associated with porphyry dikes in the western half of the claim block.

In April 2016, Corvus Gold Inc. announced that its wholly owned Alaskan subsidiary, Raven Gold Alaska Inc. signed an agreement with Millrock Resources Inc. on the Chisna project in south-central Alaska (Athey and Werdon, 2017). The purchase included a proprietary exploration database covering the claims and the surrounding district. The data represents an estimated US$11 million worth of exploration work to date in the Chisna project area.

Alteration:

Strong silica-pyrite alteration zones.

Age of mineralization:

Conflicting or uncertain assignments from several companies and agencies; Pennsylvanian and Permian ages have been suggested.

Generic deposit model:

Deposit model:

Variously interpreted as a structurally controlled, copper-gold breccia zone; as disseminated, copper-gold massive and semi-massive sulfides in Paleozoic volcaniclastic rocks; as being a distal porphyry copper deposit, and as having skarn affinities.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

C.W. Monroe prospected in the area from 1964 to at least 1973 and staked more than 142 lode claims that covered this site and several square miles south of Chisna Pass (Bittenbender and others, 2007). Paul Glavinovich staked at least 36 claims in the area that may have covered this site. Resource Associates of Alaska (RAA)staked a large block of claims in the late 1970s and early 1980s that covered this prospect and drilled three holes in 1980 that cannot now be accurately located. AMAX Exploration was apparently active in the area in about 1990 and Cominco Alaska Exploration explored in the early 90s. From 2006 to 2008, International Tower Hills Inc. (ITH) staked a large block of claims south of Chisna Pass and Slate Creek that covered this prospect and did considerable mapping and sampling, and carried out extensive geochemical and geophysical surveys. Corvus Gold Inc. (who spun off from ITH) drilled 3 holes in 2010 to test a breccia zone and did more geologic mapping, sampling, and geochemical and geophysical surveys. The prospect has also been examined and sampled by several several state and federal agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Sneaker; Hadjukovich

Site type: Prospect

ARDF no.: MH366

Latitude: 63.5701 **Quadrangle:** M C-2

Longitude: 144.9801

Location description and accuracy:

The Sneaker prospect is on peak 4937, about 7.5 miles east-northeast of Mount Hajdukovich. It is near the center of section 35, T. 21 N., R 13 E. A detailed map of the Sneaker prospect is figure 7 of Freeman (2009).

Commodities:

Main: As, Au, Bi, Cu, Pb, Sb, Zn

Other: Ag, Mo, Sn, W, Zn

Ore minerals: Arsenopyrite, bismuth, bismuthinite, chalcopyrite, galena, gold, sphalerite, stibnite

Gangue minerals: Quartz, tourmaline

Geologic description:

The numerous prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005 Canaco Resources optioned the property and drilled 3 holes at the Sneaker prospect. They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco prospects. These claims were current as of 2009 and constitute the Hajdukovich project.

The geology of the area is dominated by a Paleocene multiphase, composite intrusive complex about 5 by 15 kilometers in size (Nokleberg and others, 1992; Freeman, 2009). The main rocks in the complex are mafic and ultramafic intrusive rocks, diorite and monzonite, alkali feldspar granite, and megacrystic granite; these are cut by a variety of aplite, rhyodacite, rhyolite, and basalt dikes. The intrusive rocks cut metamorphic rocks of the Jarvis Creek unit, which consists mainly of pelitic schist, gneiss, and quartzite. The Jarvis Creek unit is metamorphosed to greenschist facies north of the complex and to amphibolite(?) facies south of it. The structure of the area is dominated by steep northeast- and northwest-trending faults that range from the regional to the prospect-level scale. Six distinctive but related styles of mineralization have been identified in the Hajdukovich project area: 1) low sulfide, gold-quartz veins; 2) gold-sulfide-carbonate-quartz veins and veinlets; 3) sulfide-quartz veinlets; 4) gold-PGE-bearing chalcopyrite-magnetite pods and veins; 5) gold-bearing sulfide-quartz breccias; and 6) gold-bearing semi-massive sulfides.

Canaco drilled 3 holes at Sneaker in 2005 but they were relatively unsuccessful due to extremely fractured ground and equipment failures; the holes were terminated short of their intended targets (Freeman, 2009). At the Sneaker prospect there are two styles of mineralization: 1) low-sulfide gold-quartz veins, and 2) gold-sulfide-carbonate-quartz veins. There are 5 sets of northeast-trending, steeply dipping low-sulfide gold-quartz veins. They average about 15 centimeters wide, pinch and swell, and form a network of anastomosing veins and veinlets. They typically contain arsenopyrite, chalcopyrite, bismuthinite, native bismuth, and locally visible gold; analyses show anomalous silver, arsenic, bismuth, copper, molybdenum, and tungsten. The average gold values of 21 select samples from the low-sulfide gold-quartz veins was 9,022 parts per billion (ppb). The gold-sulfide-carbonate-quartz veins are along northwest-trending shear

zones and are characterized by pervasive carbonate and sericite alteration. They are generally less than 5 centimeters thick, have abundant black tourmaline and iron carbonate; the sulfides include arsenopyrite, stibnite, galena, and sphalerite. Analyses show anomalous gold, arsenic, lead, antimony, tin, and zinc. The average gold value of of 21 selected samples was 5,843 ppb. The host rock for both sets of veins is megacrystic granite and granodiorite.

Alteration:

Pervasive carbonate and sericite alteration.

Age of mineralization:

Paleocene or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Gold quartz veins; polymetallic gold-quartz veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active?

Site Status: Undetermined

Workings/exploration:

This and the other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005, Canaco Resources optioned the property and drilled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco prospects. There has beenonly limited surface sampling at this prospect.

Production notes:

None.

Reserves:

None.

Site name(s): Diamondback; Hajdukovich

Site type: Prospect

ARDF no.: MH369

Latitude: 63.5723 **Quadrangle:** M C-3

Longitude: 145.0322

Location description and accuracy:

The Diamondback prospect consists of three mineralized occurrences on the north flank of peak 7837. It is about 6.3 miles northeast of Mount Hajdukovich and about 0.6 mile west-northwest of the center of section 34, T. 21 N., R. 13 E. The location is accurate. A map of the Diamondback prospect is figure 9 of Freeman (2009).

Commodities:

Main: As, Au, Cu, Mo, Sb

Other:

Ore minerals: Arsenopyrite, chalcopyrite, pyrite, molybdenite

Gangue minerals: Carbonate, quartz

Geologic description:

The Diamondback and other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005, Canaco Resources optioned the property and drilled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco prospects. These claims were current as of 2009 and constitute the Hajdukovich project.

The geology of the area is dominated by a Paleocene multiphase, composite intrusive complex about 5 by 15 kilometers in size (Nokleberg and others, 1992; Freeman, 2009). The main rocks in the complex are mafic and ultramafic intrusive rocks, diorite and monzonite, alkali feldspar granite, and megacrystic granite; these are cut by a variety of aplite, rhyodacite, rhyolite, and basalt dikes. The intrusive rocks cut metamorphic rocks of the Jarvis Creek unit, which consists mainly of pelitic schist, gneiss, and quartzite. The Jarvis Creek unit is metamorphosed to greenschist facies north of the complex and to amphibolite(?) facies south of it. The structure of the area is dominated by steep northeast- and northwest-trending faults that range from the regional to the prospect-level scale. Six distinctive but related styles of mineralization have been identified in the Hajdukovich project area: 1) low sulfide, gold-quartz veins; 2) gold-sulfide-carbonate-quartz veins and veinlets; 3) sulfide-quartz veinlets; 4) gold-PGE-bearing chalcopyrite-magnetite pods and veins; 5) gold-bearing sulfide-quartz breccias; and 6) gold-bearing semi-massive sulfides.

The Diamondback prospect includes three gold occurrences on the flanks of peak 7837 (Freeman, 2009). At the eastern occurrence, trachytic alkali-feldspar granite is cut by thin, gold-sulfide-quartz veins with arsenopyrite, chalcopyrite, and pyrite; samples contained up to 586 parts per billion gold. A molybdenite-quartz vein contained 2,220 parts per million (ppm) molybdenite. At the western occurrence, broken quartz vein material and carbonate-altered breccia occur in fault gouge; samples contained up to 205 ppb gold and 172 ppm antimony. At the north occurrence, rock samples contained up to 4,220 ppb gold. Only surface sampling has been done at this prospect.

Alteration:

Zones of intense tourmaline-carbonate-sericite alteration.

Age of mineralization:

Paleocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Polymetallic gold-quartz veins (Cox and Singer, 1986, model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Undetermined

Site name(s): UPEG Saddle; Hajdukovich

Site type: Mine?

ARDF no.: MH370

Latitude: 63.5773 **Quadrangle:** M C-3

Longitude: 145.0557

Location description and accuracy:

The UPEG Saddle prospect is about a mile northwest of peak 7837 and about 5.6 miles northeast of Mount Hajdukovich. It is near the northwest corner of section 33, T. 21 N., R. 13 E. The location is accurate. A map of the UPEG Saddle prospect is figure 11 of Freeman (2009).

Commodities:

Main: Ag, As, Au, Bi, Cu, Pb, Sb

Other:

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Quartz

Geologic description:

The Upeg Saddle and other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005, Canaco Resources optioned the property and drilled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco and Canaco prospects. These claims were current as of 2009 and constitute the Hajdukovich project.

The geology of the area is dominated by a Paleocene multiphase, composite intrusive complex about 5 by 15 kilometers in size (Nokleberg and others, 1992; Freeman, 2009). The main rocks in the complex are mafic and ultramafic intrusive rocks, diorite and monzonite, alkali feldspar granite, and megacrystic granite; these are cut by a variety of aplite, rhyodacite, rhyolite, and basalt dikes. The intrusive rocks cut metamorphic rocks of the Jarvis Creek unit, which consists mainly of pelitic schist, gneiss, and quartzite. The Jarvis Creek unit is metamorphosed to greenschist facies north of the complex and to amphibolite(?) facies south of it. The structure of the area is dominated by steep northeast- and northwest-trending faults that range from the regional to the prospect-level scale. Six distinctive but related styles of mineralization have been identified in the Hajdukovich project area: 1) low sulfide, gold-quartz veins; 2) gold-sulfide-carbonate-quartz veins and veinlets; 3) sulfide-quartz veinlets; 4) gold-PGE-bearing chalcopyrite-magnetite pods and veins; 5) gold-bearing sulfide-quartz breccias; and 6) gold-bearing semi-massive sulfides.

Several types of mineralization are at the UPEG Saddle prospect (Freeman, 2009). Pods of massive stibnite are exposed in old prospect pits and trenches along the ridge. Although, there apparently is no previous record of the massive stibnite here, Freeman (2009) suggests that it was mined in the 1940s as part of the war effort. Several samples were analyzed; none contained anomalous gold. South of the stibnite occurrence, east-trending aplite dikes cut porphyritic alkali-feldspar granite. The dikes are cut by arsenopyrite-quartz veins; samples contained up to 5,900 parts per billion (ppb) gold, 2.6 parts per million (ppm) silver, 64 ppm lead, and 327 ppm antimony. Still farther south, disseminated porphyry-style, copper-gold mineralization is in potassic-altered trachytic and porphyritic alkali-feldspar granite. Samples contained up to 6,850 ppb gold, 75.2 ppm silver, 4,230 ppm copper, and have anomalous amounts of bismuth, lead,

and antimony. The mineralized alkali-feldspar granite is cut in several places by quartz veins containing pyrite, arsenopyrite, and stibnite. The numerous samples from the UPEG Saddle prospect contained up to 6,850 ppb gold, more than 1 percent arsenic, 20,500 ppm copper, 2,090 ppm lead, 2,680 ppm antimony, and 584 ppm bismuth. Other than the old pits and trenches, there has been only surface sampling at this prospect.

Alteration:

Potassic alteration of trachytic and porphyritic alkali-feldspar granite associated with porphyry-style mineralization.

Age of mineralization:

Paleocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Polymetallic gold-quartz veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Undetermined

Workings/exploration:

This and the other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005, Canaco Resources optioned the property and drilled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco prospects. Since the late 1990s, there has been only surface sampling at this prospect. However there are old prospect pits and trenches from which stibnite may have been mined during WWII.

Production notes:

Some stibnite may have been mined during the 1940s.

Reserves:

None.

The mineralization at the Gert prospect consists of vuggy quartz and calcite-quartz veins with sparse sulfides, mainly arsenopyrite, in monzodiorite and diorite near the contact with Jarvis Creek metamorphic rocks (Freeman, 2009). Selected samples from the veins contained up to 8,310 parts per billion (ppb) gold, 2.9 parts per million (ppm) silver, 4,110 ppm arsenic, 33 ppm bismuth, 206 ppm lead, and 150 ppm antimony. At the Gert West prospect, vuggy, oxidized quartz veins with pyrite and arsenopyrite are in trachytic and porphyritic alkali-feldspar granite. Samples of the veins contain up to 12,620 ppb gold, 399 ppm silver, more than 1 percent arsenic, 802 ppm copper, 2,200 ppm lead, and 2,500 ppm antimony. Only surface sampling has been done at this prospect.

Alteration:

Not specifically mentioned.

Age of mineralization:

Paleocene or younger based on the age of the host rock.

Several types of mineralization are in porphyritic alkali-feldspar granite and diorite at the Calypso prospect (Freeman, 2009). Vuggy quartz veins with trace to modest arsenopyrite, galena, and stibnite contained up to 4,750 parts per billion (ppb) gold, 98.6 parts per million (ppm) silver, 5,310 ppm arsenic, 3,390 ppm copper, 23,300 ppm lead, and 9,180 ppm antimony. Tech Cominco reported veinlets and pods of 'semi-massive' chalcopyrite and magnetite; samples contained up to 19.41 grams of gold per tonne, 6,120 ppm copper, 6,600 ppm silver, 890 ppb palladium, 73.5 ppb platinum, and 2,670 ppm nickel. A float sample of calc-silicate rock with semi-massive arsenopyrite and pyrite contained 1.16 grams of gold per

tonne. Only surface sampling has been done at this prospect.

Alteration:

Age of mineralization:

Paleocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Polymetallic gold-quartz veins (Cox and Singer, 1986; model 22c); 'semi-massive' chalcopyrite and magnetite; skarn?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Undetermined

Workings/exploration:

The Calypso and other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005, Canaco Resources optioned the property and driled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco prospects. Geologic description:

The Caliente and other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005, Canaco Resources optioned the property and drilled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco and Canaco prospects. These claims were current as of 2009 and comprise the Hajdukovich project. Although discovered during the exploration of the area by Teck Cominco and Canaco, the Caliente prospect is outside the Anglo Alaska block of claims.

The geology of the area is dominated by a Paleocene multiphase, composite intrusive complex about 5 by 15 kilometers in size (Nokleberg and others, 1992; Freeman, 2009). The main rocks in the complex are mafic and ultramafic intrusive rocks, diorite and monzonite, alkali feldspar granite, and megacrystic granite; these are cut by a variety of aplite, rhyodacite, rhyolite, and basalt dikes. The intrusive rocks cut metamorphic rocks of the Jarvis Creek unit, which consists mainly of pelitic schist, gneiss, and quartzite. The Jarvis Creek unit is metamorphosed to greenschist facies north of the complex and to amphibolite(?) facies south of it. The structure of the area is dominated by steep northeast- and northwest-trending faults that range from the regional to the prospect-level scale. Six distinctive but related styles of mineralization have been identified in the Hajdukovich project area: 1) low sulfide, gold-quartz veins; 2) gold-sulfide-carbonate-quartz veins and veinlets; 3) sulfide-quartz veinlets; 4) gold-PGE-bearing chalcopyrite-magnetite pods and veins; 5) gold-bearing sulfide-quartz breccias; and 6) gold-bearing semi-massive sulfides.

The Caliente prospect was not sampled in detail because of the steep and hazardous terrain. Quartz veins cut mineralized aplite dikes in monzonite and diorite (Freeman, 2009). The aplite dikes contain disseminated chalcopyrite; a sample contained 5,940 parts per billion (ppb) gold, 3.9 parts per million (ppm) silver, 8 ppm bismuth, and 3,500 ppm copper. A sample from a 1- to 3-centimeter-thick quartz-calcite vein contained 9,330 ppb gold, 212 ppm arsenic, 28 ppm bismuth, and 705 ppm copper. Only surface sampling has been done at this prospect.

Alteration:

Age of mineralization:

Paleocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Polymetallic gold-quartz veins (Cox and Singer, 1986, model 22c); disseminated chalcopyrite in aplite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Undetermined

Workings/exploration:

The Calinete and other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005. Canaco Resources optioned the property and drilled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco prospects. Only surface sampling has been done at this prospect.

Production notes:

None.

Reserves:

None.

ARDF no.: MH374

Latitude: 63.5431 **Quadrangle:** M C-3

Longitude: 145.0123

Location description and accuracy:

The PW prospect is about 8 miles east of Mount Hajdukovich, near the center of section 10, T. 21 N., R. 14 E. A map of the PW prospect is figure 15 of Freeman (2009).

Commodities:

Main: Ag, As, Au, Bi, Cu, Pb, Sb

Other: Sn, W, Zn

Ore minerals: Arsenopyrite, gold, pyrite

Gangue minerals: Calcite, quartz

Geologic description:

The PW and other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). The area was dormant from 2002 to 2004. In 2005, Canaco Resources optioned the property and drilled 3 holes at the nearby Sneaker prospect (MH366). They terminated their option in 2006 and the property reverted to Teck-Cominco. Teck-Cominco abandoned the property in 2008. A contiguous block of 49 State of Alaska claims was staked by Anglo Alaska Gold Corp. that covered almost all of the original Teck-Cominco and Canaco prospects. These claims were current as of 2009 and constitute the Hajdukovich project.

The geology of the area is dominated by a Paleocene multiphase, composite intrusive complex about 5 by 15 kilometers in size (Nokleberg and others, 1992; Freeman, 2009). The main rocks in the complex are mafic and ultramafic intrusive rocks, diorite and monzonite, alkali feldspar granite, and megacrystic granite; these are cut by a variety of aplite, rhyodacite, rhyolite, and basalt dikes. The intrusive rocks cut metamorphic rocks of the Jarvis Creek unit, which consists mainly of pelitic schist, gneiss, and quartzite. The Jarvis Creek unit is metamorphosed to greenschist facies north of the complex and to amphibolite(?) facies south of it. The structure of the area is dominated by steep northeast- and northwest-trending faults that range from the regional to the prospect-level scale. Six distinctive but related styles of mineralization have been identified in the Hajdukovich project area: 1) low sulfide, gold-quartz veins; 2) gold-sulfide-carbonate-quartz veins and veinlets; 3) sulfide-quartz veinlets; 4) gold-PGE-bearing chalcopyrite-magnetite pods and veins; 5) gold-bearing sulfide-quartz breccias; and 6) gold-bearing semi-massive sulfides.

Several types of mineralization are at the PW prospect (Freeman, 2009). A 3-centimeter-thick quartz vein with arsenopyrite and pyrite cuts gabbro; a sample contained 50,700 parts per billion (ppb) gold, 32.2 parts per million (ppm) silver, 43 ppm lead, and 719 ppm antimony. Several other narrow veins and veinlets are adjacent to rhyodacite and rhyolite dikes; samples of the veins contained up to 94 ppb gold, more than 1 percent arsenic, 172 ppm lead, and 32 ppm antimony. Samples of silicified breccias in the mafic rocks contained from 249 to 2,180 ppb gold, and up to 198 ppm silver, 7,290 ppm arsenic, 166 ppm copper, 1,345 ppm lead, 237 ppm antimony, and sporadic amounts of anomalous tin, tungsten, and zinc. There also is a horizon in the metamorphic that contains semi-massive sulfides up to 2 meters thick, associated with pervasive clay alteration and abundant black tourmaline. A sample contained 2,480 ppb gold, 23.6 ppm silver, more than 1 percent arsenic, 6 ppm bismuth, 583 ppm lead, and 324 ppm antimony. Only surface

sampling has been done at this prospect.

Alteration:

Clay alteration of semi-massive-sulfide horizon; silicified breccia.

Age of mineralization:

Paleocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Polymetallic gold-quartz veins (Cox and Singer, 1986, model 22c); 'semi-massive' sulfides.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Undetermined

Workings/exploration:

The PW and other prospects of the Hajdukovich project were first identified by Teck-Cominco from 1999 to 2001 through regional geochemical sampling followed by mapping and sampling in the steep terrain in the headwaters and east of the Little Gerstle River (Freeman, 2009). Last report date: 2011-02-28

Site name(s): Unnamed (near Cony Mountain)

Site type: Occurrence

ARDF no.: MH375

Latitude: 63.29 **Quadrangle:** M B-4

Longitude: 145.4257

Location description and accuracy:

This occurrence is on a nunatak about 0.6 mile east-southeast of Cony Mountain. It is about 0.4 mile south of the center of section 3, T. 19 S., R. 12 E.

Commodities:

Main: Au, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, pentlandite, pyrrhotite, violarite

Gangue minerals:

Geologic description:

Nokleberg and others (1992 [MF]; 1992 [Open-File]) map the rocks in the area as undivided gabbro, diabase, and metagabbro on their regional 1:250,000-scale geologic map. Ragan and Hawkins (1966) and Bittenbender and others (2007), who examined the geology in more detail, identified a nearly horizontal thrust fault under the occurrence. The upper plate rocks consist of highly deformed, quartz-biotite schist cut by dikes and plugs of Triassic(?) gabbro, pyroxenite, and peridotite. About 300 feet away, the schist has been intruded by Cretaceous(?) granodiorite. The mafic and ultramafic rocks are strongly altered. Peridotite is serpentinized; clinopyroxene is replaced by hornblende, biotite, and chlorite; and plagioclase is sericitized. The rocks in the lower plate are relatively undeformed basalt and fine-grained gabbro. Attempts to date the rocks were unsuccessful.

This occurrence was first identified by Bittenbender and others (2007). Most of the gabbro and peridotite samples that they collected contained at least some chalcopyrite, pyrrhotite, and pentlandite altered to violarite. They collected 6 samples; all contained at least some nickel, copper, and precious metals. The best was a 7-foot sample that contained 3,710 parts per million (ppm) nickel, 4,740 ppm copper, 385 parts per billion (ppb) platinum, 827 ppm palladium, and 340 ppb gold.

Alteration:

The mafic and ultramafic rocks are strongly altered. The peridotite is serpentinized; clinopyroxene is replaced by hornblende, biotite, and chlorite; and plagioclase is sericitized.

Age of mineralization:

Unclear but may be related to Triassic(?) dikes and plugs of mafic and ultramafic rocks.

Generic deposit model:

Deposit model:

Nickel-copper-PGE-gold mineralization possibly related to Triassic? dikes and plugs of mafic and ultramafic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only surface sampling by the Bureau of Land Management from 2001 to 2003.

Production notes:

None.

Reserves:

None.

Latitude: 63.2966 **Quadrangle:** M B-4

Longitude: 145.4128

Location description and accuracy:

This occurrence is at an elevation of about 6,400 feet, about 1.0 mile east-northeast of Cony Mountain on a ridge at the head of the Gulkana Glacier. It is about 0.5 mile south of the center of section 3, T. 19 S., R. 12 E.

Commodities:

Main: Au, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

Nokleberg and others (1992 [MF]; 1992 [Open-File]) map the rocks in the area as undivided gabbro, diabase, and metagabbro on their regional 1:250,000-scale geologic map. Ragan and Hawkins (1966) and Bittenbender and others (2007), who examined the geology in more detail, identified a nearly horizontal thrust fault under the occurrence. The upper plate rocks consist of highly deformed, quartz-biotite schist cut by dikes and plugs of Triassic(?) gabbro, pyroxenite, and peridotite. About 300 feet away, the schist has been intruded by Cretaceous(?) granodiorite. The mafic and ultramafic rocks are strongly altered. Peridotite is serpentinized; clinopyroxene is replaced by hornblende, biotite, and chlorite; and plagioclase is sericitized. The rocks in the lower plate are relatively undeformed basalt and fine-grained gabbro.

Bittenbender and others (2007) collected several samples of copper stained peridotite from a small plug in the metamorphic rocks of the upper plate. They did not note any specific ore minerals but this occurrence is similar to ARDF site MH375 about a mile to the southwest, where chalcopyrite, pyrrhotite, and pentlandite are present in similar mafic and ultramafic rocks. A representative sample of peridotite from the southern portion of the occurrence contained 50 parts per billion (ppb) platinum, 56 ppb palladium, 12 ppb gold, 330 parts per million (ppm) copper, and 1,500 ppm nickel. A select sample of iron-stained rubble in the middle of the occurrence contained 409 ppb platinum, 414 ppb palladium, 17 ppb gold, 1,500 ppm copper and 1,880 ppm nickel.

Alteration:

Mineralized mafic and ultramafic rocks in a small plug are variably serpentinized.

Age of mineralization:

Probably related to Triassic(?) dikes and plugs of mafic and ultramafic rocks.

Generic deposit model:

Deposit model:

Disseminated copper-nickel-PGE mineralization in a plug of mafic and ultramafic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only surface sampling by the Bureau of Land Management in the early 2000s.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (east of Gakona Glacier)

Site type: Occurrence

ARDF no.: MH377

Latitude: 63.213 **Quadrangle:** M A-3

Longitude: 145.072

Location description and accuracy:

This site includes several outcrops of mineralized rock in the cirque of an unnamed glacier east of the Gakona Glacier. They are centered about 2.1 miles north-northeast of VABM 5206 'Ona' and about 0.2 mile north of the center of section 4, T. 20 S., R. 14 E.

Commodities:

Main: Au, Cu, Pd, Pt

Other: Co

Ore minerals: Chalcopyrite, magnetite, pyrrhotite

Gangue minerals:

Geologic description:

The rocks in the area consist of mafic and ultramafic intrusive rocks associated with volcanic rocks that are probably part of the Pennsylvanian to Permian, Slana Spur Formation (Rose, 1967; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; 1992 [Open-File]; Bittenbender and others, 2007). The volcanic rocks are hornfelsed near the intrusive rocks. Cretaceous K/Ar dates from the mafic and ultramafic rocks probably reflect regional metamorphism and their protoliths may be Paleozoic.

Numerous stream-sediment samples collected by the U.S. Geological Survey and Bureau of Land Management that contained anomalous platinum-group elements led to the search for their source (O'Leary and others, 1982; Bittenbender and others, 2003). Bittenbender and others (2007) identified several outcrops, one up to 160 feet long, of pyroxenite and peridotite with persistent but minor chalcopyrite, pyrrhotite, and pyrite. Two, 20-foot samples contained 127 and 65 parts per billion (ppb) palladium, 52 and 36 ppb platinum, 18 and 15 ppb gold, and 824 and 1,005 parts per million (ppm) copper. A sample selected for its high sulfide content contained 144 ppb palladium, 104 ppb platinum, 34 ppb gold, 1,055 ppm copper, and 34 ppm nickel. They considered the mineralization to be too low grade to account for the anomalous PGE in the geochemical samples.

Alteration:

Hornfelsing of volcanic rocks adjacent to mafic and ultramafic intrusive rocks.

Age of mineralization:

Unclear whether the host rocks are Cretaceous or Paleozoic.

Generic deposit model:

Deposit model:

Disseminated chalcopyrite, pyrrhotite, and pyrite in mafic and ultramafic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only limited sampling by state and federal agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (in upper Miller Gulch)

Site type: Occurrences

ARDF no.: MH378

Latitude: 63.1765 **Quadrangle:** M A-2

Longitude: 144.8226

Location description and accuracy:

The dikes, sills, and plugs that are described in this record are scattered widely at the head of Miller Gulch. Their center is at an elevation of about 4,800 feet in Miller Gulch and about 0.5 mile south-southwest of the center of section 14, T. 20 S., R. 15 E.

Commodities:

Main: Au, Ir, Os, Pt

Other:

Ore minerals: Gold, osmiridium, tetraferroplatinum

Gangue minerals:

Geologic description:

Bittenbender and others (2007) summarized the occurrences of lode platinum group elements (PGE) and gold in the so-called 'dikes' in upper Miller Gulch. They are in Upper Jurassic to Cretaceous, black slatey argillite (Matteson, 1973; Summers, 1990; Nokleberg and others, 1992 [MF]; 1992 [Open-File]). The 'dikes' include dikes, sills, and plugs of gabbro, dunite, peridotite, hornblendite, and diorite that were intruded in several episodes. Matteson (1973) dated a mafic-ultramafic body nearby at the head of Quartz Creek (MH379) by K/Ar methods at a minimum age of 120-123 Ma.

Foley and Summers (1990) identified tetraferroplatinum, osmiridium, and native gold in the mafic and ultramafic rocks and in the argillite nearby. They believe that the platinum and at least part of the gold in the Miller Creek placer (MH296) that drains drains this area came from the mafic and ultramafic rocks. However, analyses of a considerable number of samples collected both by Foley and Summers (1990) and by Bittenbender and others (2007) failed to show significant amounts of the PGE or gold in these rocks in spite of the physical identification of PGE minerals and native gold in them. One reason may be their erratic distribution, i.e., the 'nugget' effect. In the samples collected by Bittenbender and others (1970), the maximum values in any of them was 7 parts per billion (ppb) gold, 0.2 part per million (ppm) silver, 479 ppm copper, 0.685 ppm mercury, 24 ppb palladium, and 19 ppb platinum.

Alteration:

Not noted.

Age of mineralization:

Associated with dikes, sills, and plugs that may be older than 120-123 Ma mafic-ultramafic rocks nearby but younger than the Upper Jurassic to Cretaceous argillite host rock.

Generic deposit model:

Deposit model:

PGE and gold mineralization in mafic to ultramafic dikes, sills, and plugs.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only sampling by state and federal agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Picric Hill

Site type: Occurrence

ARDF no.: MH379

Latitude: 63.3179 **Quadrangle:** M B-4

Longitude: 145.8634

Location description and accuracy:

The Picric Hill occurrence is at an elevation of about 5,250 feet on a ridge between headwater tributaries of Ann Creek. It is about 2.1 miles north-northeast of the junction of the North and West Forks of Rainy Creek and about 0.6 mile north-northeast of the center of section 32, T. 18 S., R. 10 E.

Commodities:

Main: Au, Cu

Other:

Ore minerals: Chalcopyrite, magnetite, pyrite

Gangue minerals:

Geologic description:

This occurrence was first identified and sampled by Bittenbender and others (2007) in 2002. As of 2007 there is no indication of industry work on it.

The rocks in the area are mainly olivine-rich basalt (picrite) of probable Triassic age (Rose, 1965; Nokleberg and others, 1992 [MF]; 1992 [Open-File]; Bittenbender and others, 2007). The occurrence is in a band of interfingering skarn and sulfides that is exposed for 44 feet along strike and is 5-11 feet thick. The wall rock of the band is altered felsic intrusive rock. The band is highly fractured and locally brecciated. The skarn consists mainly of fine- to medium-grained massive garnet with minor epidote and actinolite. The sulfides are mainly pyrite with about a third chalcopyrite and some magnetite. The sulfides generally occur in the interstices of euhedral garnet . Bittenbender and Gensler (2003) collected three, 5 to 6 foot samples across the skarn. The highest gold value was only 37 parts per billion and the highest copper value was 1,205 parts per million (ppm). A select sample of float contained 2,750 ppm copper.

Alteration:

Mineralization in an altered band of felsic intrusive rocks.

Age of mineralization:

Source of skarn mineralization is probably the Triassic basalt (picrite) in the area.

Generic deposit model:

Deposit model:

Band of copper skarn associated with a basalt.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

This occurrence was first identified and sampled by Bittenbender and others (2007) in 2002. As of then, there was no indication of industry work on it.

Production notes:

None.

Reserves:

None.

Other:

Ore minerals: Chalcopyrite

Gangue minerals:

Geologic description:

This record refers specifically to mineralization at this site as described by Bittenbender and others (2007). However, their description also covers several large claim groups and extensive work in the area that not only covers this site but several other nearby ARDF sites, MH300 and MH365. Those records may include data that applies to this site before it was separately recognized.

C.W. Monroe (as Northland Mines) prospected in the area from 1964 to at least 1973 and staked more than 142 lode claims that covered this site and several square miles south of Chisna Pass (Bittenbender and others, 2007). Paul Glavinovich staked at least 36 claims that probably covered this site and Resource Associates of Alaska (RAA) staked a large block of claims in the late 1970s and early 1980s. Their claims probably covered this site but the three holes they drilled were probably about 0.4 miles to the southeast at ARDF site MH365 . AMAX Exploration apparently was active in the area in about 1990 and Cominco Alaska Exploration explored in the early 90s. In 2010, Corvus Gold Inc. drilled three holes to the southeast in 2010 as described in ARDF record MH365 as part of an extensive exploration program. The work included surface sampling and mapping and geochemical and geophysical surveys on a large block of claims that undoubtedly covered this prospect.

As described by Bittenbender and others (2007) citing Nokleberg and others (1991; 1992 [MF]; 1992 [Open-File]), the rocks in the area are hypabyssal stocks, dikes, and sills of Permian andesite to rhyolite that intrude marine volcanic rocks, volcaniclastic sedimentary rocks, and thin limestones of the Pennsylvanian and Permian, Slana Spur Formation. The area is cut by a series of high angle faults. The mineralization is in a thin limestone that crops out over an area about 50 feet wide and 200 feet long; It has been replaced by a chalcopyrite-calcite-jasper-epidote-garnet skarn Select samples contained up to 50.5 parts per million silver and 6.43 percent copper. Bittenbender and others (2007) suggest that the mineralization is related to a 300.4 +/- Ma quartz monzonite intrusion to the northwest.

Alteration:

Mineralized skarn developed in limestone.

Age of mineralization:

Skarn thought to be related to a nearby 330.4 Ma, quartz-monzonite intrusion.

Generic deposit model:

Deposit model:

Silver-copper skarn.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): Mars

Site type: Prospect

ARDF no.: MH381

Latitude: 63.2371 **Quadrangle:** M A-6

Longitude: 146.8297

Location description and accuracy:

The Mars Prospect is located within the Stellar Project in the northeastern portion of the Clearwater Mountains; 0.15 mile from the center of section 29, T. 19 S., R. 5 E., of the Fairbanks Meridian. This location is accurate to within about 100 feet.

Commodities:

Main: Au, Mo, Cu

Other: Ag, W

Ore minerals: Azurite, chalcopyrite, galena, gold, malachite, molybdenum, pyrite, sphalerite

Gangue minerals: Albite, carbonate, chlorite, epidote, garnet, quartz, sericite

Geologic description:

The Mars Prospect is located in the northeastern portion of the Clearwater Mountains, west of the Zackly deposit and on the west side of the West Fork of the Maclaren River. The deposit geology is described as skarn hosted in andesite, basalt, gabbro, and limestone (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014). The geology of the area is dominated by a major, terrain-bounding, low angle thrust fault where Cretaceous argillite from the Maclaren metamorphic belt is thrust over Late Triassic greenstone, limestone and argillite of the Clearwater Terrane. In the southeastern portion of the prospect area, another thrust fault juxtaposes the Clearwater Terrane atop basalt and andesites with interlayered limestones from the Amphitheater Group (Eden, 2013).

The Mars Prospect contains several mineral occurrences including the historical Copper Knob and Joy Creek occurrences. In the northern portion of the Mars Prospect, two occurrences record porphyry-type mineralization with disseminated pyrite and chalcopyrite in argillite and felsic intrusive rocks and mineralized quartz veins. The 'Mex' scheelite skarn occurrence, previously explored by Cominco, is also located in the Mars Prospect area (Eden, 2013).

In the center of the Mars Prospect are several poly-metallic occurrences in Late Triassic andesite-basalt in footwall of the major low-angle thrust fault. These occurrences include gold-bearing quartz-carbonate veins, galena and sphalerite in brecciated greenstone and abundant pyrite in greenstone with locally abundant chalcopyrite, azurite and malachite (Eden, 2013).

Other major occurrences include the historical Joy Creek and Copper Knob occurrences of the Clearwater Mountains claim group. The Joy Creek occurrence occurs in the complexly faulted rocks of the thrust footwall that include a Late Triassic greenstone, Triassic limestone and argillite and andesite of uncertain age. Mineralization is diverse and includes disseminated pyrite and chalcopyrite in an epidote-silica altered rock with local malachite staining, a gold-bearing copper skarn that occurs parallel to a quartz porphyry dike and gold-bearing altered sedimentary rocks (Eden, 2013).

The Copper Knob occurrence also occurs in conjunction with a thrust fault that juxtaposes metabasalt of the Nikolai greenstone against argillite slate and limestone of uncertain age intruded by Cretaceous or early Tertiary dikes. The area is complex with gold, silver, copper, molybdenum and tungsten anomalies in diverse mineralization types including copper-gold skarn, mineralized dikes and shear zones and quartz veins. One significant occurrence in the area is a strongly pyritized fault zone as much as 15 feet wide that

strikes west-northwest in Copper Creek and can be traced from 4700 feet to 5000 feet in elevation and for 500 feet on strike. Samples collected from this zone average 2.7 parts per million (ppm) gold (Eden, 2013).

The Mars Prospect was first visited by Millrock in 2010 following up on the large, orange color anomaly. The color anomaly is attributed to gossanous rocks, weathered carbonate rocks, and hornfelsed sediments. Copper, gold or both copper and gold were anomalous in many of the surface samples collected. The main Copper-gold geochemical anomaly is coincident with a strong circular magnetic anomaly, the center of which is composed of diorite with chalcopyrite veins. Significant geochemical results include a 1.2-kilometer soil traverse averaging 462 ppm in copper, a 950-meter soil traverse averaging 763 ppm copper and a 900-meter soil traverse averaging 891 ppm copper. In addition, a sample of altered diorite collected from the center of the magnetic anomaly returned 0.51 percent copper, 0.21 ppm gold and high grade rock samples of 7.4 percent copper and 1.79 ppm gold were collected from float and a gossanous gully, respectively (Eden, 2013).

This prospect consists of altered gabbro/diorite intruding Triassic volcanic and lesser sedimentary rocks, locally containing extensive gossan exposures. The altered zones commonly contain variable copper mineralization. Soil sampling across the prospect has defined a 420 ppm copper anomalous zone measuring approximately 950 meters by 1.7 kilometers. Rock samples of altered volcanic rock have returned assays as high as 7.4 percent copper. Anomalous gold-in-soil values are common within the area of 420 ppm copper anomaly including multiple samples assaying 0.100 ppm gold. Assays as high as 1.78 ppm gold have been returned from rock samples. The Mars prospect is bounded on the northwest by a post-mineral (?) thrust fault. Potential exists for the discovery of additional mineralization to the northwest below the fault contact (Eden, 2013).

The Mars Prospect is located in the northeastern portion of the Clearwater Mountains, west of the Zackley Prospect and on the west side of the West Fork of the Maclaren River. Mention of high grade copper lodes in the Clearwater Mountains dates back to 1918.

Kurtak et al. (1992) state that claims in the Mars area (formerly known as MEX) were first staked in 1974. In 1980, Mankomen Exploration Inc. staked several claims in the Mars area, which was followed by claim staking by Cominco American in 1981. The same year, Cominco and Mankomen formed a joint venture, which lasted until 1982. During the JV period, geochemical sampling and geological mapping conducted on the MEX claims, as well as, a ground magnetic survey, an electromagnetic (EM) survey, a very low frequency (VLF) electromagnetic survey (Kurtak et al., 1992) and limited hand trenching.

In 1983 the only work that was performed on the Mars Property was performed by Mankomen. Their work consisted of limited hand trenching, rock and stream sediment sampling, as well as, minor geologic mapping. Later in 1983, the MEX claims were leased to Anschutz Mining Corp. (Kurtak et al., 1992). Work performed by Anschutz in 1984 on the MEX claims consisted of trenching, although it is not known how much trenching was conducted. Anschutz Mining probably dropped the lease in 1985 as no Affidavit of Labor certificates could be found mentioning Anschutz Mining.

In 1988, Amax Exploration leased the MEX claims from Mankomen, but later turned them back to the owner (Kurtak et al., 1992).

In 1992, Noranda flew an aeromagnetic survey over the MEX claims and produced an interpretive total field magnetics map. The total area covered by the magnetics survey was approximately 6,000 acres. The survey revealed several large magnetic anomalies that were not followed-up on until 2012.

In 2010, Millrock staked claims covering the MEX area and gave the prospect area the name Mars. Millrock collected 27 soil and 5 rock samples within the Mars area. The results indicated a zone anomalous in copper, gold and molybdenum. In 2012, 26 rock and 54 soil samples were taken over a portion of the magnetic anomalies identified by Noranda (Hemlo Gold). The results showed a 2 mile long zone of anomalous copper-gold with an isolated zone of anomalous molybdenum. Some of the strongest geochemical anomalies are coincident with the stronger magnetic anomalies (Eden, 2013).

In 2012 and 2013, Millrock performed soil, stream sediments, and rock sampling, in addition to airborne electromagnetic geophysical survey and spectroscopy (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

Alteration:

Disseminated pyrite and chalcopyrite in an epidote-silica altered rock with local malachite staining, a gold-bearing copper skarn that occurs parallel to a quartz porphyry dike and gold-bearing altered sedimentary rocks (Eden, 2013). Generally potassic, sericite, albite, chlorite, epidote, and garnet.

Age of mineralization:

Probably Late Cretaceous or early Tertiary, nearly synchronous with thrust faulting (Eden, 2013).

Generic deposit model:

Deposit model:

Porphyry Cu-Au? (Cox and Singer, 1986, model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c?

Production Status: None

Site Status: Active

Site name(s): Moonwalk; North Moonwalk; South Moonwalk

Site type: Prospect

ARDF no.: MH382

Latitude: 63.3205 **Quadrangle:** M B-6

Longitude: 146.6592

Location description and accuracy:

The Moonwalk Prospect area is located between Cathedral Creek and the West Fork Maclaren River in the northern part of the Stellar Property; 0.5 mile south-southeast of the center of section 30, T. 18 S., R. 6 E., of the Fairbanks Meridian. This location is accurate to within about 100 feet.

Commodities:

Main: Au, Mo, Zn

Other: Bi, Sb

Ore minerals: Arsenopyrite, chalcopyrite, gold, molybdenum, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

The Moonwalk Prospect, also referred to as North Moonwalk and South Moonwalk, is a mesothermal gold prospect consisting of altered granodiorite intruding mainly black shale. The intrusive rock and surrounding sediments are commonly altered with local zones of stockwork quartz-sulfide veining. The Moonwalk ridge consists of a broad, granodiorite altered zone locally containing anomalous to ore grade gold values in rock and soil (Eden, 2013).

The Moonwalk Prospect area is in the northern part of the Stellar Property, situated on the southern flank of the Central Alaska Range south of the Denali fault. The rocks south of the Denali fault are part of two major terranes. The Maclaren terrane is bounded by the Denali fault on the north and the Broxsen Gulch thrust fault on the south, and consists of metamorphosed granodioritic plutons and batholiths that were emplaced in Jurassic-Cretaceous metasediments. South of the Broxson Gulch thrust fault the Wrangellia terrane contains Upper Paleozoic island arc volcanics and sediments overlain by Triassic rift related volcanics and sediments that are locally overlain by Jurassic and Tertiary sediments (Eden, 2013).

Millrock Resources Inc. conducted exploration work at the Moonwalk Prospect in 2010 and 2012 consisting of geochemical sampling and geological mapping. Nineteen soil samples within the granitic intrusion average 1.15 grams per tonne of gold with a high of 3.54 grams per tonne of gold. The granodiorite covers an exposed area of around 700 meters by 500 meters. Talus and outcrop rock chip samples were collected over the western and eastern portion of the granodiorite. Samples from the western area averaged 1.10 grams per tonne of gold over 140 meters, while the eastern area samples averaged 0.55 grams per tonne of gold over 85 meters. A grab sample in a quartz-sulfide vein within the granodiorite assayed 30.45 grams per tonne of gold. The Moonwalk Prospect is also highly anomalous in arsenic, bismuth, antimony and zinc. The mineralization at Moonwalk is indicative of an intrusion-related gold system. Mineralized samples at North Moonwalk also tend to be anomalous in bismuth, arsenic and antimony, common trace elements associated with 'Tombstone-style' gold deposits and prospects found within the Tintina gold belt of Alaska and the Yukon (Eden, 2013).

Millrock conducted an electromagnetic airborne survey during 2013 summer field season (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

Alteration:

Stockwork gold quartz-vein mineralization with some sericite(Eden, 2013; P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

Age of mineralization:

Cretaceous? (Millrock Resources Inc., 2014).

Generic deposit model:

Deposit model:

Intrusion-related gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

A grab sample in a quartz-sulfide vein within the granodiorite assayed 30.45 grams per tonne of gold. The Moonwalk Prospect is also highly anomalous in arsenic, bismuth, antimony and zinc. The mineralization at Moonwalk is indicative of an intrusion-related gold system. Mineralized samples at North Moonwalk also tend to be anomalous in bismuth, arsenic and antimony, common trace elements associated with 'Tombstone-style' gold deposits and prospects found within the Tintina gold belt of Alaska and the Yukon (Eden, 2013).

Millrock conducted an electromagnetic airborne survey during 2013 summer field season (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

Production notes:

None.

Reserves:

None.

Site name(s): Gemini

Site type: Prospect

ARDF no.: MH383

Latitude: 63.2631 **Quadrangle:** M B-6

Longitude: 146.7012

Location description and accuracy:

The Gemini prospect is located on a northwest-aligned ridge about 2.0 miles east of the West Fork Maclaren River within the Stellar Project; 0.5 mile south-southeast of the center of section 13, T. 19 S., R. 5 E., of the Fairbanks Meridian. This location is accurate to within about 100 feet.

Commodities:

Main: Au, Cu

Other:

Ore minerals: Chalcopyrite, gold, pyrite, pyrrhotite

Gangue minerals: Albite, chlorite, epidote, garnet

Geologic description:

The Gemini prospect, part of the Stellar Project area, appears to be hosted primarily within Triassic volcanic rocks, specifically andesites and basalts. The mineralization is characterized by disseminated chalcopyrite and gold (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

This newly discovered prospect was defined in August of 2013, the result of a wide-spaced, property-wide soil sampling program. The Gemini 420 parts per million (ppm) copper-in-soil anomaly, while variable in outline, averages approximately 1.0 kilometer by 1.6 kilometers. Anomalous gold-in-soil results tend to occur coincident with elevated copper values with gold assays typically ranging from 0.150 – 0.250 ppm gold (Millrock Resources Inc., 2014).

Between 2011 and 2013 field seasons, Millrock conducted rock, soil, stream sediments sampling, and an airborne geophysical and spectrometry survey (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

Alteration:

Disseminated chalcopyrite and gold with albite, chlorite, epidote, and garnet alteration minerals (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

Age of mineralization:

Triassic or younger based on age of host rock.

Generic deposit model:

Deposit model:

Porphyry Cu-Au? (Cox and Singer, 1986, model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c?

Production Status: None

Site Status: Active

Longitude: 146.6921

Location description and accuracy:

The Jupiter prospect is located on a northwest-aligned ridge about 2.0 miles east of the West Fork Maclaren River within the Stellar Project; 0.5 mile southeast of the center of section 25, T. 19 S., R. 5 E., of the Fairbanks Meridian. This location is accurate to within about 100 feet.

Commodities:

Main: Au, Cu

Other:

Ore minerals:

Gangue minerals: Albite, chlorite, epidote, garnet

Geologic description:

The Jupiter prospect is hosted in altered Triassic volcanic rocks near a contact with dioritic intrusive rocks. The prospect, located approximately 1.8 kilometers (1.1 miles) north of the main Zackly skarn, is characterized by east- and northerly-trending,altered,copper/gold-bearing fracture/vein zones and disseminated chalcopyrite and gold hosted in andesites and basalts (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014; Millrock Resources Inc., 2014). Soil sampling has defined a 420 parts per million (ppm) copper anomaly measuring approximately 800 meters by 1.9 kilometers. Anomalous gold-in-soil values are commonly associated with elevated copper values with assays up to 0.330 ppm gold returned (Millrock Resources Inc., 2014).

Between 2011 and 2013 field seasons, Millrock conducted rock, soil, stream sediments sampling, and an airborne geophysical and spectrometry survey (P. St. George, Chief Exploration Officer, Millrock Resources Inc., oral communication, 2014).

Site name(s): Eureka Zone; Alpha Complex

Site type: Prospect

ARDF no.: MH388

Latitude: 63.2481 **Quadrangle:** M A-5

Longitude: 146.1786

Location description and accuracy:

The Eureka Zone is a prospect within the Alpha Complex, an ultramafic-mafic complex composed of a sill-dike body 18 kilometers long and up to 600 meters wide, elongated northwest-southeast (Stone, 2005). The coordinates in this record are located approximately at the center of the prospect, about 2.5 miles from where Eureka Creek meets Broxson Gulch. It is located about 0.7 mile northeast of the center of section 27, T. 19 S., R. 8 E., of the Fairbanks Meridian. The accuracy is unknown; the location was estimated using a map of Eureka Zone on Pure Nickel Inc.'s website (Pure Nickel, 2014). The location is accurate to within 1/4 mile.

Commodities:

Main: Ag, Au, Co, Cu, Ni, Pd, Pt

Other:

Ore minerals: Ni-Cu-PGE sulfides

Gangue minerals: Olivine, serpentine

Geologic description:

The Alpha complex lies within an area called the Eureka Zone (Findlay, 2013) or Eureka Complex (Stone, 2005). The Alpha Complex and Eureka Zone are part of Pure Nickel's MAN Project, designed for exploration of Nickel (Ni), Copper (Cu), and Platinum Group Element (PGE) mineralization in a series of mafic-ultramafic intrusive complexes that are part of the Wrangellia Terrane (Pure Nickel, 2011; Findlay, 2013).

The region is known for the Nikolai Greenstone, a Late Triassic meta-basalt; associated are cogenetic ultramafic-mafic intrusions. These ultramafic-mafic intrusions characteristically weather to an orange-brown color, are generally serpentinized in tectonized zones, and may contain chromiferous magnetite, chromite, and/or disseminated sulfides (Ellis, 2002).

The intrusion complex is a very elongate sill-dike body composed dominantly of massive dunite with thin, marginal gabbro-norite layers. The complex dips moderately to the north, is slightly oblique to the stratigraphy, intruding sedimentary rocks of the Slana River Formation. A discordant magnetic high joins the Eureka Zone with the Fish Lake Complex to the south, interpreted as a potential feeder dike at depth (Ellis, 2002).

The Eureka Complex is truncated by faults related to the Broxson Gulch Thrust and felsic intrusions. Wall rock contacts are generally strongly serpentinized. Copper-magnetite skarns formed in calcareous rocks in contact with the Eureka Complex (Ellis, 2002).

Ni-Cu-PGE mineralization in this prospect is characterized by disseminated sulfides in ultramafic rock at contact with gabbro-norite layers (Stone, 2005). Electron microprobe results indicated most of the nickel is in sulfides with only 0.14 percent contained in olivine and 0.04 percent contained in serpentine, indicating that most of the nickel is recoverable (Findlay, 2013).

Alteration:

Serpentinization (Stone, 2005).

Age of mineralization:

Triassic, about 230 Ma (Findlay, 2013).

Generic deposit model:

Deposit model:

Disseminated Ni-Cu-PGE in gabbro (Cox and Singer, 1986; model 5b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

5b

Production Status: None

Site Status: Active

Workings/exploration:

From 1991 to 1997, this area was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. Their work included drilling, surface UTEM, and borehole and EM on three holes. From 1997 to 2003, the area was explored by Nevada Star Resource Corp (US), whose work included a geological mapping program in addition to an AEM survey over the northern and southern portion of the MAN Project area. From 2004 to 2005, the area was briefly explored by Anglo American Exploration (USA). Their work included geological mapping, prospecting, and a soil geochemical sampling survey (Pure Nickel Inc., 2014).

In 2005, Nevada Star Resources Corp., resumed work and completed a 35-kilometer TEM survey over four loop areas, 177-kilometer ground magnetometry, and 1057 soil samples over the general MAN Project area, including eight diamond drill holes in Alpha, which is in the central part of the property. Alpha is a prospect area within the MAN Project area (Pure Nickel Inc., 2014).

In 2007, Pure Nickel gained control of the leases, and it is now 100 percent owned by them, after a joint venture partnership with ITOCHU Corporation of Japan from 2008 to 2013. During this partnership, approximately 23.5 million US dollars were spent on exploration at the general MAN Project area (Pure Nickel Inc., 2014).

In 2011, Pure Nickel completed exploration work focused on the Alpha complex. One of the key objectives of the 2011 program was to evaluate the potential for 'reef' style Platinum Group Elements (PGE) mineralization in the Alpha complex. The possible presence of this type of mineralization was inferred from the occurrence of highly anomalous PGE values associated with a distinctive gabbro/pyroxenite sequence interpreted as discrete layers in the complex. Three holes targeting the potential 'reef' successfully intersected the correct lithological sequence, but assay results did not confirm the presence of economic concentrations of PGE (Findlay, 2013).

In 2012, Pure Nickel completed detailed mapping, and soil and IP surveys at the Alpha complex. Follow-up drilling tested the soil and IP anomalies (Findlay, 2013).

In 2013, Pure Nickel completed an exploration program that included an eight hole, 2,991-meter drill program primarily targeting the Eureka Zone in the central part of the Alpha mafic-ultramafic complex. The drill program successfully intersected the Eureka Zone, first recognized in 2012, in six of the seven holes that were targeted (Pure Nickel Inc., 2014).

The drill results confirm the presence of what is now interpreted as a continuous zone of magmatic sulfide mineralization containing elevated concentrations of nickel, copper, cobalt, gold, silver, platinum and palladium. Estimated true widths of intersection for 2013 drill holes cutting the Eureka Zone in the central Alpha segment range from 120 meters to 250 meters. Composite intersection grades across the mineralized zone in the drill holes range from 123 parts per billion (ppb) to 212 ppb gold + platinum + palladium, 0.05 to 0.16 percent copper, and 0.17 to 0.24 percent nickel. The mineralization also includes minor silver and cobalt. Higher grade mineralization over narrower widths is present in most of the holes (Pure Nickel Inc., 2014).

Production notes:

None.

Reserves:

None.

Additional comments:

In 2007, Pure Nickel gained control of the leases, and it is now 100 percent owned by them, after a joint venture partnership with ITOCHU Corporation of Japan from 2008 to 2013. During this partnership, approximately US$23.5 million was spent on exploration at the general MAN Project area (Pure Nickel Inc., 2014).

Workings/exploration:

From 1991 to 1997, this area was explored by American Copper and Nickel Company (ACNC) working with Fort Knox Gold Resources, Inc. Their work included drilling, surface UTEM, and borehole and EM on three holes. From 1997 to 2003, the area was explored by Nevada Star Resource Corp (US), whose work included a geological mapping program in addition to an AEM survey over the northern and southern portion of the project area. From 2004 to 2005 the area was briefly explored by Anglo American Exploration (USA). Their work included geological mapping, prospecting, and a soil geochemical sampling survey (Pure Nickel Inc., 2014).

In 2005, Nevada Star Resources Corp., resumed work and completed a 35-kilometer TEM survey over a four loop area, 177-kilometer ground magnetometry, and 1057 soil samples over general MAN Project area (Pure Nickel Inc., 2014).

In 2007, Pure Nickel gained control of the leases, and it is now 100 percent owned by them, after a joint venture partnership with ITOCHU Corporation of Japan from 2008 to 2013. During this partnership, approximately 23.5 million US dollars were spent on exploration at the general MAN Project area (Pure Nickel Inc., 2014).

In 2008, the field program by Pure Nickel focused on diamond drilling, which targeted geophysical anomalies, including VTEM conductors, in the Beta Complex. The drilling intercepted wide zones of disseminated sulfides, including 0.50 meter grading 1.39 percent nickel and 1.27 percent copper (Pure Nickel Inc., 2008).

Pure Nickel's 2009 field program included four drill holes in the southern Beta Complex. Interpretation of 2D modeling of 2009 ZTEM data and previous 3D inversions of aeromagnetic data, as well as several widely spaced deep drill holes indicate thick ultramafic bodies with localized deep feeders (Pure Nickel Inc., 2009).

The 2010 exploration program executed by Pure Nickel on the Beta Complex included three drill holes in the southern Beta complex. Drill results highlights include 1.1 meters of 1.76 percent copper; 8 meters of 202.7 parts per billion (ppb) platinum + palladium; 11 meters of 150.6 ppb platinum + palladium; and 1.14 meters of 835.5 ppb platinum + palladium (Findlay, 2013).

Additional comments:

In 2007, Pure Nickel gained control of the leases, and it is now 100 percent owned by them, after a joint venture partnership with ITOCHU Corporation of Japan from 2008 to 2013. During this partnership, approximately US$23.5 million was spent on exploration at the general MAN Project area (Pure Nickel Inc., 2014).

Reporter(s): V.C. Zinno (Alaska Earth Sciences, Inc.)

Last report date: 2016-03-15

Site name(s): Unnamed (Hulahula River)

Site type: Occurrence

ARDF no.: ML018

Latitude: 69.0657 **Quadrangle:** ML A-2

Longitude: 144.6652

Location description and accuracy:

The location is the ridge two miles northwest of the confluence of Itkillik Creek with the Hulahula River, and about three miles south of the airstrip. This location is part of a group of copper occurrences that occur within an area that extends five miles north and south and four miles east to west. The area is in the Mount Michelson A-2 Quadrangle. The site is referred to as USGS Location 41 reported in Brosgé and Reiser, 1976, and is in the NW¼ sec. 34, T. 4 S., R. 31 E., of the Umiat Meridian. Accuracy of the location is about 0.75 mile.

Commodities:

Main: Cu

Other: Ag, Co, Pb, Zn

Ore minerals: Chalcopyrite, malachite

Gangue minerals: Clay, hematite, sericite

Geologic description:

Regional potential for copper mineralization had been advanced by Brosgé and Reiser (1976), who suggested that the vicinity of the upper Hulahula River is favorable for copper mineralization due to widespread mafic volcanic rocks (Reiser and others, 1971) with a high intrinsic copper content, and multiple copper showings in the area. They reported a group of stream sediment samples were consistently anomalous along the upper 10 miles of the west-to-southwest flowing upper segment of the Hulahula River (Brosgé and Reiser, 1976). They believed this regional copper anomaly reflects widespread copper enrichment in mafic rock including sills.

At the USGS Location 41site, chalcopyrite was reported by Brosgé and Reiser (1976), to occur in sheared mafic volcanic rocks with individual minor malachite occurrences up to 40 feet across (Barker, 1983, and Brosgé, written commun., 1982). Samples indicate copper values are generally elevated in samples of sills. Several sites of minor malachite staining also occur in the area to the west and are associated with pyritic zones and limonite in fractured, bleached mafic volcanic rocks, and is locally associated with disseminated sulfide grains. (Note a copy of Brosgé's written communication is available upon request from Alaska Division of Geological and Geophysical Surveys Geologic Materials Center, Anchorage, Alaska, in the archive for project files of J.C. Barker, U.S. Bureau of Mines.)

Alteration:

Bleaching, sericite, pyrite, and limonite staining are common features, locally with hematite staining, silicification, quartz stockwork, and minor veining (Brosgé and Reiser, 1976, and Brosgé written commun., 1982).

Age of mineralization:

Mineral occurrences are hosted in lower Paleozoic mafic rocks and clastic rocks of the pre-Mississippian Neruokpuk basement (Reiser, and others, 1971).

Generic deposit model:

Deposit model:

The copper occurrences in mafic rocks here are similar to Besshi-type copper deposit model (Cox and Singer, 1986, model 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b

Production Status: None

Site Status: Inactive

Workings/exploration:

The prospect area was selected for field examination and sampling by the U.S. Bureau of Mines in 1982 as part of Alaska-wide critical and strategic mineral investigations as reported in Barker, 1983. On the basis of the previous work by Reiser and other. 1971, the contact relationships were examined for evidence of alteration and mineralization. Copper mineralization was found restricted to a zone up to 15 ft wide within the mafic rocks; minor silicification, bleaching due to argillic alteration, and traces of copper minerals were present. Although summer at the time of the examination the area was partly snow-covered.

Production notes:

None.

Reserves:

None.

Additional comments:

The area was selected for study by the U.S. Bureau of Mines in 1982 as part of Alaska-wide critical and strategic mineral investigations. The region is closed to mineral development; site is located in the Arctic National Wildlife Range and presently classified as ‘Wilderness’.

Site name(s): Unnamed (Hulahula River) USBM Location A

Site type: Occurrence

ARDF no.: ML019

Latitude: 69.0967 **Quadrangle:** ML A-2

Longitude: 144.6228

Location description and accuracy:

Location A in an unpublished report (Barker, 1983) is on the east cut-bank of the Hulahula River and east of the airstrip. This location is part of a group of copper occurrences found over an area that extends five miles north to south and four miles east to west.

The Hulahula River flows north to the Arctic Ocean and its headwaters drain the north flank of the Continental Divide. The occurrence site is referred to as Location A in Barker, 1983, is in the W½ sec. 15, T. 4 S., R. 31 E, of the Umiat Meridian. Accuracy of the location is about 0.75 mile.

Commodities:

Main: Cu

Other: Ag, Co, Pb, Zn

Ore minerals: Chalcopyrite, galena, malachite, sphalerite

Gangue minerals: Chlorite, clays, hematite, sericite

Geologic description:

Malachite and occasionally chalcopyrite blebs can be found in quartz-carbonate veins and as stratiform replacement in clastic sedimentary rocks of the pre-Mississippian Neruokpuk shale and phyllite that are interbedded with chert and mafic volcanic rocks. Location A is an area less than 1,000 feet across including bedrock exposures in the river bank. Clastic sedimentary rocks include sandstone, calcareous sandstone, dolostone, and argillite-phyllite rocks. Stratiform mineralization is concentrated in areas of rapid facies change over short distances. Two chip samples collected across outcropping, southwest-dipping black phyllite and shale at Location A in a river cut bank outcrop assayed 255 and 510 parts per million (ppm) copper. A small shale boulder on the river bar nearby was assayed and reported 2.6 percent copper with .07 percent cobalt, 0.17 percent nickel and 52 ppm silver. A narrow veinlet with trace galena and sphalerite in another nearby outcrop at Location A assayed 0.79 percent lead and 5.25 percent zinc. Another nearby cut bank site exhibits disseminated chalcopyrite occurring along thin southwest-dipping strata of calcareous shale up to 1.5 inches thick; a sample assayed 590 ppm copper with elevated cobalt (Barker, 1983).

Alteration:

Bleaching and iron staining are common features, locally with hematite staining and silicification, quartz stockwork, and minor veining (Barker, 1983).

Age of mineralization:

Mineral occurrences are hosted in pre-Mississippian clastic rocks of the Neruokpuk formation (Brosgé and Reiser, 1976).

Generic deposit model:

Deposit model:

Besshi-type copper (Cox and Singer, 1986, model 24b); sedimentary-hosted copper in shale and phyllite (Cox and Singer, 1986, model 30b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b, 30b

Production Status: None

Site Status: Inactive

Workings/exploration:

Two chip samples collected across outcropping, southwest-dipping black phyllite and shale near Location A in a river cut bank assayed 255 and 510 parts per million (ppm) copper. A small shale boulder on the river bar nearby was assayed and reported 2.6 percent copper with 0.07 percent cobalt, 0.17 percent nickel and 52 ppm silver. A narrow veinlet with trace galena and sphalerite in another nearby outcrop at Location A assayed 0.79 percent lead and 5.25 percent zinc. Another nearby cut bank site exhibits disseminated chalcopyrite occurring along thin southwest-dipping strata of calcareous shale up to 1.5 inches thick; a sample assayed 590 ppm copper with elevated cobalt (Barker, 1983).

Site name(s): Unnamed (Hulahula River) USBM Location B

Site type: Occurrence

ARDF no.: ML020

Latitude: 69.0822 **Quadrangle:** ML A-2

Longitude: 144.5457

Location description and accuracy:

Location B is in rugged mountainous terrain about two miles east-southeast of the airstrip on the Hulahula River and Location A of Barker (1983). Hulahula River flows north to the Arctic Ocean and is headwaters drain the north flank of the Continental Divide. The occurrence site is referred to as Location B (Barker, 1983) situated above the 5000 foot contour level. The site is in the SW1/4, sec. 24, T. 4 S., R. 31 E., of the Umiat Meridian. Accuracy of the location is about 0.75 mile.

Commodities:

Main: Cu

Other: Ag, Co, Ni, Pb, Zn

Ore minerals: Chalcopyrite, malachite

Gangue minerals: Clays, limonite, hematite

Geologic description:

Location B is hosted in pre-Mississippian clastic rocks and mafic sills cutting a sequence of green and brown argillite (Reiser and others, 1971).

U.S. Bureau of Mines samples 19059-60 at Location B occur near the ridgetop and exhibit minor copper mineralization at the contact of green and brown argillite (Barker, 1983). Intermittent snow cover at the time of the examination precluded definitive contact relationships. It was uncertain if the green argillite(?) may have actually been a highly altered mafic rock. Samples 19059 and 19060 from a shear zone with spotty malachite assayed 405 and 1700 parts per million (ppm) copper, respectively. Elevated silver, cobalt, and nickel were also present. Thinly bedded, foliate dolostone that outcrops at sample 19104 near this location also contained finely disseminated sulfide grains that included trace to minor chalcopyrite; a sample assayed 334 ppm copper.

Favorability for regional copper potential has been advanced by Brosgé and Reiser (1976) who suggested that the vicinity of the upper Hulahula River is favorable for copper mineralization due to widespread mafic volcanic rocks with high intrinsic copper content; several copper showings were reported in the region. A group of stream sediment samples were also consistently anomalous along the upper 10 miles of the Hulahula River (Brosgé and Reiser, 1976).

Alteration:

Bleaching and iron staining are common features in the area, limonite in shear zone locally with hematite staining and silicification, minor quartz stockwork and veining. Pyritic quartz carbonate mineralized zone cuts the host rock (J.C. Barker, unpublished data).

Age of mineralization:

Mineral occurrences appear to be hosted in rocks of the pre-Mississippian clastic rocks and mafic sills of the Neruokpuk Formation (Brosgé and Reiser, 1976).

Generic deposit model:

Deposit model:

Besshi-type copper (Cox and Singer, 1986, model 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b

Production Status: None

Site name(s): Utopia Creek

Site type: Mine

ARDF no.: MZ006

Latitude: 65.9822 **Quadrangle:** MZ D-2

Longitude: 153.7379

Location description and accuracy:

The Utopia Creek placer mine follows the channel of Utopia Creek for about 3 miles upstream from its junction with the Indian River. The coordinates are at about the midpoint of the mined portion of the creek, which is shown on the 1:63,360-scale topographic map. The mined area is centered about 0.6 mile northeast of the center of section 26, T. 7 N., R. 24 E. and R. 25 E. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Galena, gold, sphalerite, tetrahedrite

Gangue minerals:

Geologic description:

The rocks in the Utopia Creek area consist of Cretaceous andesite and basalt interlayered with chert, cherty tuff, conglomerate, and coquinoidal limestone (Patton and others, 1977). The Indian Mountain granodiorite pluton crops out approximately 2 miles northwest of the placer workings, and podlike intrusions of fine-grained, pyritiferous, silicified, felsic rock occur along an east-northeast-trending fault about 1.5 miles south of the workings. The gradient of upper Utopia Creek is about 200 feet per mile; the gradient at the mouth is about 75 feet per mile. Unlike other gold-bearing streams in the area, Utopia Creek does not drain the Indian Mountain granodiorite intrusion (Miller and Ferrians, 1968).

Bedrock in Utopia Creek is slightly metamorphosed andesite cut by fine-grained felsic rock (Miller and Ferrians, 1968). Boulders of massive barite are in the tailings of an abandoned placer mine near the head of Utopia Creek, and some of those boulders contain tetrahedrite, sphalerite, and galena (Miller and Ferrians, 1968). That mineralization is described in record ARDF MZ005.

Gold was discovered in Utopia Creek in about 1906 (Cobb, 1975) and mining was reported as early as 1915. J.Q. Hackett, R.B. Norris, and C.B. Frank prospected and did a little mining on Utopia Creek in 1929 (Wimmler, 1929). L. McGee and a crew of 12 men began prospecting on Utopia Creek in 1936 (Smith, 1938). Overburden was stripped and a bedrock drain dug in 1937 by about a 20-man crew employed by McGee (Smith, 1939 [B 910A]). Large-scale mining was started in 1938 (Smith, 1939 [B 917-A]). McGee ran the operation and for several years employed approximately 30 men. At the time, Utopia Creek was the largest placer operation in the district (Smith, 1941). In 1939, McGee divided the property into two segments. The upstream section was mined by hydraulic methods when water was available. The pay streak in that portion of the creek was on the south side of the drainage. Heavy machinery and draglines were used on the downstream portion, where gravels were as much as 25 feet thick (Smith, 1941). Large-scale mining continued until 1952 (Cobb, 1973). U.S. Geological Survey topographic maps of the Melozitna quadrangle show workings along approximately 3.5 miles of Utopia Creek; the upper tailings continuing along a draw on the south side of the creek. The remains of a 40-foot long washing plant lie in a heavily vegetated area along the lower creek (Kurtak and others, 2002). The configuration of the tailings piles indicates that mining concentrated on deposits in the modern stream channel. The average grade of the placer, which started at 0.032 ounce of gold per cubic yard, was down to 0.003 ounce per cubic yard by the last year of production

(Kurtak and others, 2002). The fineness of a placer gold sample from Utopia Creek was 849 (Metz and Hawkins, 1981).
At least 8,850 ounces of gold were mined on Utopia Creek (Cobb and Miller, 1981).

Alteration:

Age of mineralization:
Quaternary.

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; medium

Site Status: Probably inactive

Workings/exploration:
Gold was discovered in Utopia Creek around 1906 (Cobb, 1975; Eberlein and others, 1977) and mining was reported as early as 1915. J.Q. Hackett, R.B. Norris, and C.B. Frank prospected and did a little mining on Utopia Creek in 1929 (Wimmler, 1929). L. McGee and a crew of 12 men began prospecting on Utopia Creek in 1936 (Smith, 1938). Overburden was stripped and a bedrock drain dug in 1937 by about a 20-man crew employed by McGee (Smith, 1939 [B 910A]). Large-scale mining was started in 1938 (Smith, 1939 [B 917-A]). McGee ran the operation and for several years employed approximately 30 men. At the time, Utopia Creek was the largest placer operation in the district (Smith, 1941). In 1939, McGee divided the property into two segments. The upstream section was mined by hydraulic methods when water was available. The paystreak in that portion of the creek was on the south side of the drainage. Heavy machinery and draglines were used on the downstream portion, where gravels were as much as 25 feet thick (Smith, 1941). Large-scale mining continued until 1952, when interest apparently waned (Cobb, 1973). U.S. Geological Survey topographic maps of the Melozitna quadrangle show workings along approximately 3.5 miles of Utopia Creek, with the upper tailings continuing along a draw on the south side of the creek. The remains of a 40-foot long placer wash plant lie in a heavily vegetated area along the lower creek (Kurtak and others, 2002). The configuration of the tailings piles indicates that mining concentrated on deposits in the modern stream channel.

Production notes:
Utopia Creek was probably the largest gold producer in the Koyukuk district (Smith, 1941) but there is no detailed record of production. Cobb and Miller (1981) estimate that about 8,850 ounces of gold were mined on Utopia Creek but it may have been more than 10,000 ounces. Kurtak and others (2002) reported that 8,854 ounces of gold were recovered from 1939 to 1950, but the records are incomplete and there was substantial production before 1939.

Reserves:
None.

Last report date: 2011-02-01

Site name(s): City; Golden Range

Site type: Prospect

ARDF no.: NB110

Latitude: 62.866

Quadrangle: NB D-6

Longitude: 143.9511

Location description and accuracy:

The City prospect is about 10.8 miles north of Slana. It is about 1.3 mile west-northwest of VABM 6677 'Ahtell' and about 0.5 mile west-northwest of the center of section 32, T. 3 S., R. 8 E., Copper River Meridian. The location is accurate to within 30 feet of the center of the prospect (C. Brown, Alaska Exploration Manager, Corvus Gold, written commun., 2014).

Commodities:

Main: Ag, Au

Other: As

Ore minerals: Arsenopyrite, gold, pyrite

Gangue minerals: Carbonate minerals, quartz, sericite

Geologic description:

The rocks in the area of the City prospect are diorite and quartz diorite of the Permian to Pennsylvania Ahtell pluton (Richter, 1966; Richter and others, 1975; Wilson and others, 1998; Corvus Gold Inc., 2012). The rocks are cut by extensive dike swarms and faults. The mineralization is on the northeast side of a regional-scale northwest-striking fault.

The City prospect may have been sampled in 1980 when WGM Inc. on behalf of the Ahtna Native Corporation searched for the source of geochemical anomalies in gold that outlined a northwest-trending area several miles long that WGM had identified in 1979 (WGM Inc., 1979, 1980). In 1980, they collected several rock samples at scattered locations along the trend that contained up to 3,260 parts per billion (ppb) gold.

In 2010, Corvus Gold Inc. revisited the area, outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range target. They collected more than 300 rock and soil samples in the area. The 151 rock samples averaged 0.6 gram of gold per tonne; 29 of the 151 had more than 0.10 gram of gold per tonne, and the best had 50.4 grams of gold per tonne.

By 2011, Corvus had identified at least 5 prospects in the Golden Range target area that they had sampled and drilled (Corvus Gold, Inc., 2012). One is the City prospect where they drilled 3 holes. Notable intercepts were 0.7 metes that averaged 6.21 grams of gold per tonne and 6.68 grams of silver per tonne, and 2.8 meters that averaged 1.57 grams of gold per tonne and 0.38 gram of silver per tonne. Details of the mineralization are unavailable but it is probably similar to that at the nearby Notch prospect (GU045) where arsenopyrite-quartz veins are in a thick mineralized zone marked by sericitic and quartz-carbonate alteration (Meyers and others, 2011).

Alteration:

Extensive silica-carbonate alteration of diorite and quartz diorite? In addition, quartz, sericite, and pyrite (W.T. Ellis, Vice President, Alaska Earth Sciences, Inc., written communication, 2014).

Age of mineralization:

Younger than the Permian to Pennsylvanian host rocks.

Generic deposit model:

Deposit model:
Polymetallic vein? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
22c?

Production Status: None

Site Status: Active

Site name(s): Round Top; Roundtop

Site type: Prospect

ARDF no.: NL011

Latitude: 64.1703 **Quadrangle:** NL A-4

Longitude: 157.5334

Location description and accuracy:

The Round Top prospect is about 1.4 miles southwest of VABM 1954 'Round Top' in the Kaiyuh Mountains. It is on an east-west trending ridge at the headwaters of Minnesota Creek near the center of section 20, T. 15 S., R. 7 E., of the Kateel River Meridian. The location is between the drill collars RT-3 and RT-7 drilled by Anaconda Minerals Company in 1981. The location is accurate to 100 meters.

Commodities:

Main: Ag, Cu, Mo

Other: Pb, W, Zn

Ore minerals: Argentojarosite, beudantite, chalcocite, chalcopyrite, covellite, galena, jarosite, molybdenite, native Cu, pyrite, pyrrhotite, scheelite, sphalerite

Gangue minerals: Quartz

Geologic description:

Outcrop in the prospect area is scarce and the geology is largely defined by rubble. The country rocks in the area of the Round Top prospect are Paleozoic to Proterozoic(?) pelitic schist and quartzite of greenschist- and amphibolite-grade, locally accompanied by blueschist-grade (Patton and others, 2009). Lesser amounts of carbonate rocks and metavolcanic rocks are also present (Gemuts and others, 1983). All rocks have undergone multiple periods of deformation and generally trend northeast. The country rocks are intruded by a large intrusive complex that trends northwest, parallel to a major regional fault about 0.6 mile southwest of the prospect. The intrusive complex can be divided into a western lode and an eastern lobe that together cover an area of about 0.8 square mile.

Harris (1985) identified six types of porphyritic intrusive rocks and an intrusive microbreccia in the complex. The two oldest porphyries, which are quartz monzonite, appear to be the parent lithology for the microbreccia and are associated with the mineralization. They are crosscut by later porphyritic intrusive rocks. A K/Ar date on a potassium-feldspar phenocryst from the oldest intrusive gave an age of 74 +/- 2.8 Ma. The microbreccia is composed of lithic fragments that are cemented and replaced by biotite, potassium feldspar, and quartz, or by chlorite and quartz, with lesser amounts of chalcedonic quartz and montmorillonite, calcite and actinolite. The biotite-potassium feldspar-quartz replacement indicates potassic alteration and suggests that the microbreccia formed during copper mineralization. Gradational contacts between the microbreccia and the older quartz monzonite porphyry indicate that the microbreccia formed from it. The second-oldest porphyry, which is also quartz monzonite, is in sharp contact with the microbreccia; textural evidence suggests that the microbreccia was emplaced in pulses along shear zones, possibly coincident with explosive degassing during cooling of the intrusive rocks.

The wall rocks of the intrusive complex are mainly fine- to medium-grained pelitic schist. Near the intrusive, the calcareous rocks have locally been altered to calc-silicate hornfels. Two small outcrops of light-green metavolcanic rocks (possibly meta-andesite) are known (Harris, 1985).

The early potassic and propylitic alteration encloses an approximately 330-foot-diameter zone of stockwork quartz veins. Potassic alteration extends west for about 3,600 feet, and gradually grades into propylitic alteration. The propylitic alteration consists of chlorite, epidote, calcite, actinolite,

montmorillonite, and chalcedonic quartz. The later sericite-quartz-pyrite alteration is fracture controlled and pervasive throughout the intrusive complex (Harris, 1985).

Mineralization at Round Top occurs as: 1) veins containing molybdenite, chalcopyrite, pyrite, and pyrrhotite; 2) gossan containing argentojarosite, jarosite, and beudantite; 3) a supergene zone beneath the gossan containing chalcocite, covellite, native copper, and chalcopyrite; and 4) calc-silicate wall rocks near the intrusive that contain pyrite, chalcopyrite, and sphalerite (Harris, 1985).

Quartz veins in the stockwork zone make up to 90 percent of the rock. Older, smaller 'A'- type veins with potassium-feldspar margins locally contain molybdenite, pyrite, and chalcopyrite. Younger, larger, 'B'- type veins usually contain molybdenite in their cores or along selvages. Sericite, anhydrite, and andalusite occur along some vein margins (Harris, 1985).

Molybdenite occurs primarily in an elliptical area of quartz veins that encloses an intensely veined stockwork zone at the eastern lobe of the intrusive. Chalcopyrite mineralization also occurs in this zone, and in potassically-altered microbreccia. The dominant sulfide in this zone is pyrite with traces of pyrrhotite. Chalcopyrite content decreases outward from the zone of intense stockwork veins and there is a concentric zone of tungsten mineralization as scheelite in quartz veins (Ellis and Roberts, 2014); lead, zinc, and silver increase at the western boundary of the intrusive complex. Within the schist, iron enrichment is marked by iron sulfides in calc-silicate hornfels.

A zone of supergene enrichment underlies the oxide (gossan) zone, which typically extends to a depth of 300 to 400 feet. The supergene zone contains chalcocite, sparse covellite and native copper, as well as pyrite and chalcopyrite. Within the oxide zone, goethite, hematite, jarosite, and limonite are common in a kaolinite-sericite-quartz assemblage that is leached of all sulfides (Harris, 1985).

Alteration:

Alteration consists of early potassic and propylitic alteration in the microbreccia and earlier porphyritic intrusions, and later sericite-quartz-pyrite alteration throughout the intrusive complex. The deposit also has undergone supergene enrichment, and calcareous schist near the intrusive complex have undergone calc-silicate hornfelsing and iron metasomatism (Harris, 1985).

Age of mineralization:

A K/Ar date on potassium feldspar from the oldest porphyry at Round Top is 74 +/- 2.8 Ma. Mineralization is likely younger than this (Harris, 1985).

Generic deposit model:

Deposit model:

Porphyry Cu-Mo (Cox and Singer, 1986; model 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

21a

Production Status: None

Site Status: Active

Workings/exploration:

The Round Top porphyry prospect was discovered in 1980 during a reconnaissance exploration program by Anaconda Minerals Company (Anaconda) (Harris, 1985). Between 1980 to 1983 Anaconda completed geologic mapping, geochemical sampling, drilling, and geophysical surveys including MaxMin (small loop frequencey domain electromagnetics) survey, ground magnetics, electromagnetics (EM), gravity, and induced polarization surveys, and airborne magnetic regional survey (Ellis and Roberts, 2014).

The geochemical sampling in 1981 resulted in 874 soil samples and 730 rock samples being collected over the Round Top prospect. Results showed concentric zoning with molybdenum in the center grading outward through tungsten, to copper-lead and finally lead-silver-tin-copper. The molybdenum center anomaly coincides with the occurrence of quartz vein stockwork within quartz monzonite porphyry. The outer lead-

silver halo is associated with a contact between the intrusive quartz monzonite porphyry and the schist (Ellis and Roberts, 2014).

Anaconda drilled at the Round Top prospect in 1981. They drilled 1,668.4 meters in seven drill holes. Highlights from the drilling include: hole RT-7 with 0.48 percent copper over 18.6 meters in a zone of supergene chalcocite enrichment, and 5 other mineralized zones that contained 0.36 to 1.10 percent copper; hole RT-3 had 5 intercepts with thicknesses between 26.3 to 62.7 meters that contained from 0.22 to 0.72 percent copper and up to 0.07 percent molybdenum; hole RT-2 intersected three zones of copper-silver mineralization that contained 0.98 to 1.8 percent copper and 4.5 to 23.0 grams per tonne silver (Ellis and Roberts, 2014; Western Alaska Copper and Gold, 2015).

Western Alaska Copper and Gold completed a complex resistivity induced polarization (CR-IP) survey on the Round Top prospect in 2010. Data was collected from 29 stations along two survey lines for a total of 5.4 line kilometers (Ellis and Roberts, 2014).

In 2012 Western Alaska Copper and Gold completed a soil geochemistry program collecting samples on a 500 by 100 meter grid covering the Round Top prospect, TG (NL028), and TG North (NL027) in order to determine the extent of the Round Top geochemical signature. They collected over 1,050 soil samples. The molybdenum results confirmed the concentric anomaly discovered by Anaconda in 1981. The copper soil anomaly is slightly west of the molybdenum anomaly and covers a 2.5 by 2.5 kilometer area. Western Alaska Copper and Gold also completed an airborne magnetic and radiometric survey in 2012 (Ellis and Roberts, 2014).

In 2016, Western Alaska Copper & Gold conducted exploration drilling at their Roundtop property in western Alaska, a combined porphyry copper-molybdenum, skarn, and lead-zinc-silver carbonate-replacement deposit. The 6-hole, 1,461-meter-total-length drill program tested historical drilling by Anaconda, as well as soil-geochemical anomalies and geophysical targets. Western Alaska discovered secondary chalcocite beneath the East Lobe Porphyry, including 39 meters of 0.50 percent copper within a 75-m interval of 0.31 percent copper. Chalcocite was found at depths of greater than 330 meters (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Additional comments:

In the 2015 record update, Tim's Gossan or TG was separated into a separate record (ARDF number NL028).

Site name(s): Honker

Site type: Prospect

ARDF no.: NL018

Latitude: 64.1272 **Quadrangle:** NL A-4

Longitude: 157.9818

Location description and accuracy:

The Honker prospect is about 4.2 miles southwest of the summit of Khotol Mountain (VABM 2844) in the Kaiyuh Mountains. It is in the southwest quarter of section 1, T. 16 S., R. 4 E., of the Kateel River Meridian. The prospect location is at the top of hill 1810 and centered on the Main Vein which trends north-northeast for approximately 600 meters.

Commodities:

Main: Ag, Au

Other: As, Bi, Cu, Pb, Sb, W

Ore minerals: Arsenopyrite, bismuth, bismuthinite, chalcocite, chalcopyrite, electrum, galena, gold, malachite, marcasite, pyrite, pyrrhotite, scheelite, scorodite, selenides, stibnite, sulfosalts, tellurides

Gangue minerals: Quartz

Geologic description:

The country rocks at the Honker prospect consist of Paleozoic to Proterozoic (?) schists of mostly greenschist facies and include chlorite schist, quartz-chlorite-muscovite schist, variably hornfelsed, banded, light and dark gray metasedimentary rocks, and minor graphitic schist rubble (Flanigan, 1998; Patton and others, 2009). Medium-grained granodiorite float also occurs at the prospect. The metamorphic rocks generally strike east-west and dip 20 to 40 degrees south. High-temperature contact metamorphism is indicated by the presence of andalusite crystals and garnet porphyroblasts. The metasedimentary rocks are very resistant and cap the top of hill 1810. Hornfelsing and silicification of these rocks are probably due to the intrusion of the nearby Early Cretaceous Khotol Mountain pluton (Patton and others, 2009). A schistose quartzite unit overlies the metasedimentary rocks (Flanigan, 1998).

The Honker prospect consists mainly of two subparallel, gold- and silver-bearing quartz-arsenopyrite veins that trend N 20 E to N 25 E. It also includes gossan; banded and massive sulfides in calcareous chlorite schist; and disseminations, blebs, and clots of sulfides in hornfelsed sedimentary rocks (Flanigan, 1998). These principal veins are brecciated and oxidized. The larger vein (Main Vein or Honker East) may be as long as 950 meters, has a true thickness (identified by drilling) of 1-5 meters, and a vertical extent of 150 meters. The smaller vein (West Vein or Honker West) is up to 3 meters thick and is traceable at the surface intermittently along strike for up to 300 meters (Flanigan, 1998).

Large, resistant, boulders up to 0.5 meters in diameter of dark reddish-brown, massive, ropy and siliceous, vuggy gossan are more prominent than boxwork gossan and fracture-veined limonitic material. Gossan at the Honker prospect is not as abundant as at Waterpump Creek (NL020) or Illinois Creek (NL023), but is also due to the oxidation of sulfides (Flanigan, 1998). The most abundant vein material at Honker is milky-white or pale green quartz and scorodite, and siliceous breccia that locally contains limonite. Disseminated arsenopyrite and traces of malachite are present locally. The arsenopyrite is generally euhedral and coated with chalcocite (Flanigan, 1998). Brecciated material is matrix supported and composed of rounded and angular fragments of schist, quartz, arsenopyrite, and minor gossan, cemented by quartz, scorodite, iron oxide, and small amounts of arsenopyrite. Additional sulfides occur as disseminated grains, blebs, and pods in the metasedimentary rocks, generally without gold (Flanigan, 1998). Electron microprobe analysis and

polished section petrography also identified gold and silver tellurides, selenides, and sulfosalt minerals, chalcopyrite, marcasite, bismuth-bismuthinite solid solution, stibnite, galena, electrum, and native gold (Flanigan, 1998).

Drill holes intersected three narrow zones of banded and massive pyrrhotite and pyrite, with traces of chalcopyrite, arsenopyrite, and scheelite. These zones appear to be conformable with the quartz-chlorite-muscovite schist. Sparse, disseminated, very-fine-grained arsenopyrite and pyrite occur between the intercepts (Flanigan, 1998).

Mineralized rock samples from the Honker prospect average 0.13 ounce per ton (oz/t) gold and 0.17 oz/t silver. Copper ranges up to 5400 parts per million (ppm), lead up to 935 ppm, and several samples contained anomalous tungsten (25-270 ppm). The mineralization includes little or no zinc, manganese, antimony, or mercury, but arsenic values range higher than 5 percent in the richest drill hole intercepts. Samples of drill core assay up to 1.12 oz/t gold and 2.33 oz/t silver, and average 0.13 oz/t gold and 0.27 oz/t silver. The banded and massive sulfide intercepts assay up to 0.078 oz/t gold and 0.08 oz/t silver (Flanigan, 1998).

Arsenopyrite thermometry indicates that ore mineralization temperatures at the Honker prospect were between 300 and 350 degrees Celsius (Flanigan, 1998). These temperatures and the fact that the veins cut the schistosity of the host rocks make it unlikely that metamorphism is responsible for mineralization (Ellis, 2013; Flanigan, 1998).

K-Ar and Ar/Ar dating of sericite near the ore and white mica from the Khotol pluton demonstrate that mineralization and Khotol plutonism were coeval at about 113 Ma (Flanigan, 1998). The presence of anomalous Sb, Sn, and native Bi suggests that mineralization at Honker was related to magmatic fluids derived from the pluton, and the distribution of Au, Ag, As, and Bi among the Honker, Waterpump Creek (NL020), and the Illinois Creek (NL023) deposits indicates zoning peripheral to it (Flanigan, 1998).

Alteration:

Metasedimentary rocks are hornfelsed and silicified. Locally, the schist is altered to clay and iron-stained. Oxidation of sulfides has produced gossan (Flanigan, 1998).

Age of mineralization:

K-Ar and Ar/Ar dating of sericite near the ore and white mica from the Khotol pluton demonstrate that mineralization and Khotol plutonism were coeval at about 113 Ma (Flanigan, 1998).

Generic deposit model:

Deposit model:

Plutonic-related, epigenetic lode Au-Ag; Polymetallic veins? (Cox and Singer, 1986, model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

The Honker vein system was discovered in 1981 by Anaconda Mining Company (Anaconda) during a regional exploration program. In 1982, Anaconda conducted follow-up geological mapping, ground magnetometer, induced polarization (IP), and electromagnetic (EM) surveys, geochemical sampling, and tested the Main Vein with 10 diamond drill holes totaling 1001.2 meters (Ellis, 2013). Anaconda collected 103 rock chip samples and 31 soil samples. Rock samples containing vein material averaged 8.58 grams per tonne (g/t) silver and wall rock samples averaged 0.97 g/t silver. Gold values were as high as 39 g/t. Both the Main Vein and the West Vein did not yield a geophysical response where the veins and associated gossans are exposed at the surface. However, the geophysical surveys produced magnetic and EM anomalies to the south of the outcrop area on hill 1810, and along strike of both veins. Anaconda interpreted the anomalies to the south of the outcrop areas to result from an increase in pyrrhotite and clay gouge along

the veins (Ellis, 2013). Drilling highlights from the 10 drill holes include 4.8 meters at 0.211 ounce/ton (oz/t) gold and 0.42 oz/t silver, 4.9 meters at 0.11 oz/t gold and 0.21 oz/t silver, and 2.0 meters at 0.11 oz/t gold and 0.9 oz/ silver. Also in 1982, Anaconda collected two bulk samples from float material (160 and 72.7 pounds) along the Main Vein for metallurgical testing. The two bulk samples averaged 29.14 g/t gold (0.85 oz/t) and 29.48 g/t silver (0.86 oz/t) (Ellis, 2013).

Exploration on Honker ceased until 2009 when Western Alaska Copper and Gold retraced the veins, located the Anaconda drill collars and took 25 samples of vein material. In 2010 J & G Gold LLC did geologic mapping and sampling under an option with Western Alaska Copper and Gold. Channel samples were taken at 8 to 10 meter intervals along the veins. The highest gold value from the samples was 86.9 parts per million (ppm) (Ellis, 2013). In 2012 Western Alaska Copper and Gold completed an airborne magnetic and radiometric survey.

In 2014 Western Alaska Copper and Gold completed a trenching program at the Main Vein and West Vein to collect multiple samples of mineralization. These metallurgical samples were evaluated for gravity and leaching extraction methods for gold (Western Alaska Copper and Gold, 2015).

Production notes:

None.

Reserves:

Inferred resources for the Honker prospect are estimated to be greater than 250,000 ounces of gold in ore averaging 1.0 ounce of gold per ton (Flanigan, 1998).

Site name(s): Silver Chalice; Kaiyah

Site type: Prospect

ARDF no.: NL024

Latitude: 64.0829 **Quadrangle:** NL A-6

Longitude: 158.771

Location description and accuracy:

The Silver Chalice prospect is about 1 mile west of the Yukon River, and 3 miles east of Poison Creek. The coordinates are for the approximate center of the prospect near VABM Kaiyah in section 24, T. 16 S., R. 1 W. The location is accurate.

Commodities:

Main: Ag, Au

Other: As, Bi, Hg

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The rocks in the area of the Kaiyah prospect consist of Cretaceous deltaic sandstone, shale, and conglomerate adjacent to the Poison Creek caldera. The caldera is expressed topographically as a curvilinear fault contact between the volcanic rocks inside the caldera and Koyukuk sedimentary rocks around it. Landsat and magnetic data suggest that the caldera system may be over 20 kilometers in diameter. The Tertiary volcanic rocks include intermediate to felsic ash flow tuff, massive basaltic andesite, and a small area of siliceous sinter (North Star Exploration, Inc., 2001; Patton and others, 2009).

Gold and silver are anomalous in surface samples of silicified sedimentary rocks east of the caldera rim in an area of radial faulting. The silicified rocks are cut by chalcedonic quartz veinlets, vuggy drusy coatings, and blue-gray quartz veinlets. In addition to the silicification, the host rocks locally are argillized (clay altered). Core holes drilled in 2000 intersected extensive zones of polyphase quartz veining, advanced argillic alteration, polymetallic sulfides, and mineralized dikes. The drill holes were targeted at two east-west-trending vein systems, the Main and South veins, which are approximately 250 feet apart (Avalon Development newsletter, Jan., 2001).

Bundtzen and Miller (1997) first reported gold in epithermal quartz veins at the prospect in 1997. Subsequent fieldwork by North Star Exploration Inc. in 1999 resulted in the definition of more widespread mineralization. In 250 rock samples, gold averages 110 parts per billion (ppb) and silver averages 20 parts per million (ppm). Samples contain up to 0.4 ppm gold and up to 13.6 ounces of silver. Samples also contain anomalous values of arsenic, bismuth, and mercury (North Star Exploration, Inc., 2001).

Next Gen Metals Inc. (2009) acquired the property in late 2009. As described by them, the quartz veins are associated with northeast structures that radiate from the margin of the caldera. The veins are in an outer zone of propylitic alteration and an inner zone of weak to moderate argillic alteration; there also is weak silicification adjacent to the veins. Rock samples from surface rubble contain up to 10 grams of gold per tonne and 462 grams of silver per tonne; the gold:silver ratio is about 40:1. The main Silver Chalice vein is up to 25 feet thick as cut in two drill holes; the South vein is 27 feet thick as cut in one hole. Fluid inclusion work suggests an epithermal origin.

Alteration:

Silicification, propylitic and argillic alteration.

Age of mineralization:
The veins cut Tertiary volcanic rocks.

Generic deposit model:

Deposit model:
Epithermal Au-Ag (Cox and Singer, 1986; model 25c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
25c

Production Status: None

Site Status: Active

Workings/exploration:
During 1999 and 2000, North Star Exploration Ltd. explored the Kaiyah prospect with geologic mapping, geophysics, and Landsat image analysis. In 2000, 2,776 feet of core drilling were completed. Next Gen Metals Inc. acquired the property in late 2009 and plans extensive work in 2010.

Production notes:
None.

Reserves:
None.

Additional comments:
This prospect is on Doyon, Ltd. selected land.

Site name(s): TG North

Site type: Prospect

ARDF no.: NL027

Latitude: 64.1933 **Quadrangle:** NL A-4

Longitude: 157.5927

Location description and accuracy:

The TG North prospect is about 3.1 miles west-northwest of VABM 1954 'Round Top', and about 0.3 mile north of the center of section 13, T. 15 S., R. 7 E. The location is accurate.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The TG North prospect was discovered in 1980 by Anaconda Minerals as part of a regional exploration program that also found the nearby and better defined Round Top and Tim's Greisen prospects (NL011). They drilled four shallow 'Winkie' holes in late 1984, and covered it with geophysical and geochemical surveys. The prospect was being explored by the Western Alaska Copper and Gold Company in 2012 in conjunction with their work at the Round Top prospect.

As described by Western Alaska Copper and Gold (2012), the mineralization consists of gossan and vuggy, quartzite breccia along a north-trending linear. The host rock is brittle quartzite. Samples of from a prospect pit contained up to 5.7 percent lead and 1,203 grams of silver per tonne. Drill core shows evidence of many crosscutting fractures, replacement textures, and silicification. Western Alaska Copper and Gold suggests that the deposit may be Bonanza-style epigenetic silver-gold-lead-zinc mineralization in structurally controlled veins, breccia and replacement deposits.

Alteration:

Silicification; abundant gossan.

Age of mineralization:

Possibly related to the nearby Round Top prospect (NL011) which is probably Late Cretaceous or Early Tertiary based on a 74 Ma K/Ar date.

Generic deposit model:

Deposit model:

Bonanza-style epigenetic silver-gold-lead-zinc mineralization in structurally controlled veins, breccia and replacement deposits.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): Tim's Gossan; TG

Site type: Prospect

ARDF no.: NL028

Latitude: 64.1724 **Quadrangle:** NL A-4

Longitude: 157.5841

Location description and accuracy:

Tim's Gossan prospect is 2.8 miles west of VABM 1954 'Round Top' in a saddle between hill 1730 and 1560 on an east-west trending ridge in the Kaiyuh Mountains. The prospect drains into the headwaters of California Creek and Minnesota Creek in the southeast corner of section 24, T. 15 S., R. 6 E., of the Kateel River Meridian. The location of the site is where the rubble crop of mineralized gossan is found.

Commodities:

Main: Ag, Pb, Zn

Other: As, Au, Cu, Sn

Ore minerals:

Gangue minerals: Quartz

Geologic description:

Outcrop in the prospect area is scarce and the geology is largely defined by rubble. The country rocks in the area of Tim's Gossan prospect are Paleozoic to Proterozoic(?) pelitic schist and quartzite of greenschist- and amphibolite-grade, locally accompanied by blueschist-grade (Patton and others, 2009). Lesser amounts of carbonate rocks and metavolcanic rocks are also present (Gemuts and others, 1983). All rocks have undergone multiple periods of deformation and generally trend northeast. The country rocks are intruded by a large intrusive complex that trends northwest, parallel to a major regional fault about 0.6 mile east of the prospect (Harris, 1985).

Tim's Gossan is interpreted by Harris (1985) to be part of the Round Top system (Flanigan, 1998). The gossan is hosted in locally brecciated quartz-chlorite-muscovite schist. The brecciated schist is mildly bleached, iron-stained, and altered to clay. The gossan is black or gray, massive, and extends over an approximately 250 by 820 foot area. Sooty, amorphous, yellow, black or gray, and red-orange supergene oxides fill 0.6- to 1.2-cubic-inch voids in the gossan. The gossan is composed of a thick, dark, iron and manganese coating on small, foliated siliceous structures (Flanigan, 1998). Work carried out between 1980 and 1983 defined silver-lead-zinc replacement style mineralization in chloritic limestone and dolomite dipping 40 to 50 degrees northeast into a northwest trending fault zone (Ellis and Roberts, 2014).

Tim's Gossan prospect contains high levels of lead, zinc, silver, and manganese and anomalous values of tin and arsenic. Drilling at Tim's Gossan in 1983 intersected graphite-siderite gouge zones containing high levels of zinc, lead, and silver (Ellis and Roberts, 2014).

Alteration:

The brecciated schist is mildly bleached, iron-stained, and altered to clay (Flanigan, 1998). Mineralization in chloritic limestone and dolomite is also observed (Ellis and Roberts, 2014).

Age of mineralization:

A K/Ar date on potassium feldspar from the oldest porphyry at the nearby Round Top prospect (NL011) is 74 +/- 2.8 Ma. Mineralization is likely younger than this (Harris, 1985).

Generic deposit model:

Deposit model:
Zn-Pb Skarn? or Polymetallic veins? (Cox and Singer, 1986; model 18c or 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
18c? or 22c?

Production Status: None

Site Status: Active

Workings/exploration:

Tim's Gossan was first discovered in 1980 during a regional reconnaissance program completed by Anaconda Minerals Company (Anaconda). In 1982 and 1983 Anaconda completed soil sampling at Tim's Gossan and nearby Round Top (NL011), a MaxMin (small loop frequency domain electromagnetics) survey, and a few shallow drill holes (Ellis and Roberts, 2014). The surface gossan and corresponding geochemical anomaly is 30 to 110 meters wide by 800 meters long. Surface gossan samples contain values up to 4.52 percent lead, 0.84 percent zinc, 211 grams per tonne (g/t) silver, 1700 parts per million (ppm) tin, 415 parts per billion (ppb) gold, 1255 ppm copper, and more than 1000 ppm arsenic (Flanigan, 1998; Western Alaska Copper and Gold, 2015). Anaconda drilled 7 shallow holes at Tim's Greisen in 1982 that totaled 400 meters. Four of the shallow drill holes explored the surface anomaly and intercepted gossan zones of 5.9 meters, 7.8 meters and 3.75 meters in width (Western Alaska Copper and Gold, 2015).

In 2012 Western Alaska Copper and Gold completed a soil geochemistry program collecting samples on a 500 by 100 meter grid covering Tim's Gossan, Round Top (NL011), and TG North (NL027) in order to determine the extent of the Round Top geochemical signature. They collected over 1,050 soil samples. Silver and lead were the most anomalous metals in soil samples over Tim's Gossan. Western Alaska Copper and Gold also completed an airborne magnetic and radiometric survey in 2012 over Tim's Gossan (Ellis and Roberts, 2014).

Production notes:
None.

Reserves:
None.

Site name(s): Divide

Site type: Prospect

ARDF no.: NM058

Latitude: 64.8451 **Quadrangle:** N D-1

Longitude: 165.2954

Location description and accuracy:

The Divide prospect is northwest of the junction of the Nome River and Divide Creek (NM049). It is bounded on the west by Quartz Creek (NM111) and Boer Creek; on the south by Divide Creek (NM057), and on the west by the Campion Ditch. The prospect area extends north for nearly 1 mile and is more than one-half mile wide. The coordinates are approximately at the center of this large mineralized area that extends north across a low hill (locally called Boer Mountain). The prospect is in the upper part of section 35 and in the center of section 26, T. 7 S., R. 33 W. The location is accurate. Stevens (2010) provides numerous detailed maps of the prospect.

Commodities:

Main: Au

Other: As, Fe, Pb, Sb, Zn

Ore minerals: Arsenopyrite, galena, gold, jamesonite, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Albite, ankerite, quartz

Geologic description:

Work on the Divide prospect began in the 1990s (Chris Gierymski, Cominco American, written communication, December 1995; Stevens, 2010). In 1994, David and Daniel Lajack sampled the southeast flank of Boer Mountain (the hill between Boer Creek and the Nome River) on a 2,000- by 2,500 foot grid Seventeen of 57 soil samples contained 100 parts per billion (ppb) or more of gold; the highest was 370 ppb gold. In 1995, Cominco expanded the grid to a 1 mile by 1.5 mile area elongated to the north; they collected almost 700 soil samples, and ran VLF and ground magnetics. A series of 21 trenches with a total length of 5,822 feet. was also dug at that time. About 1,000 samples were collected from the trenches.

At least two major northeast-trending vein zones were found as a result of Cominco's exploration. Trench 1 trends east; it starts about 1,300 feet east of Quartz Creek approximately on the section line between sections 26 and 35 on the southeast flank of Boer Mountain. Several 1- to 3-foot-wide gold-bearing quartz veins that strike northeast and dip nearly vertically were mapped and sampled near trench 1. The channel samples along a 50-foot interval in trench 1 assayed 0.663 ounce of gold per ton. The trench was partly frozen; strong 'muck' anomalies were found along the trench in three sections that aggregated 250 feet in length. Trench D-12 cut approximately the same zone as trench 1, and it was also well mineralized. Trenches D-10 and D-11 were cut nearly on the divide between Quartz Creek and Boer Creek; these trenches also exposed quartz veins that strike northeast and dip steeply to gently. Trench 10 exposed a section 8-feet long that contained 0.047 ounce of gold per ton; trench D-11 exposed 55 feet with 0.437 ounce of gold per ton; 40 feet contained 0.044 ounce of gold per ton; it included an interval of 20 feet long hat contained 0.080 ounce of gold per ton. Trench D-9, north of trenches 10 and 11 and on trend with upper Boer Creek, had a 70-foot interval with 0.024 ounce of gold per ton; it included a section 20 feet long with 0.067 ounce of gold per ton.

The prospect was drilled by Cominco American in 1996 (written communication, August 22, 1996; Stevens, 2010). In general, the drill results were not as good as the trench results. Five holes were drilled at the head of the divide between Quartz Creek and Boer Creek. The best drill hole, D-6, intersected 28 feet

with 0.011 ounce of gold per ton. Three holes were drilled southeast of Boer Mountain; hole Div-9 intersected 10 feet with 0.235 ounce of gold per ton. About 2,000 feet east of Boer Mountain, hole Div-3 had 37 feet with 0.055 ounce of gold per ton,; it included 24.7 feet with 0.091 ounce of gold per ton.

In 2002, Rio Fortuna Exploration Corp. drilled 18 holes that totaled 1,357 meters (Stevens, 2010). Lajack Minerals explored the property from 2003 to 2006 and drilled 9 holes that totaled 273 meters.

In 2007, Millrock Resources Inc. and their partner Alix Resources Corp. (2008) drilled 5 holes and cut intervals with significant gold values in each (Stevens,2010). The intervals vary from 0.30 to 8.99 meters thick and contain 1.0 to 10.0 grams of gold per ton.

In 2008, Millrock drilled 22 holes that totaled 2,656 meters and dug 1244 meters of trenches (Stevens, 2010). Some notable intercepts in the drilling were 15.24 meters with 0.09 ounce of gold per ton, 1.52 meters with 0.29 ounces of gold per ton, 10.67 meters with 0.035 ounce of gold per ton, and 6.10 meters with 0.04 ounce of gold per ton. On Dec. 2, 2009, Millrock terminated their agreement with Alix.

In summary, a total of 68 holes totaling 5,848 meters have been drilled on the Divide prospect to 2010 and 45 trenches have been dug that total 3,018 meters (Stevens, 2010).

The gold-bearing quartz veins occur along joints and fractures (Stevens, 2010). The veins have albite and local silicified selvages; larger veins have several feet of selvage with iron-bearing carbonate (ankerite). In general, pyritization appears to be a favorable indication of nearby gold mineralization. In decreasing order of abundance, the ore minerals in the veins are pyrite, arsenopyrite, pyrrhotite, galena, stibnite, sphalerite, and jamesonite.

The host rocks at the Divide prospect are metasedimentary rocks of retrograde greenschist or lower amphibolite facies; these include graphitic and calcareous schist; blue-gray, gray, and black marble; and black quartz schist and quartzite (Hummel, 1962). Strata west and northwest of Quartz Gulch, including most of the canyon of Boer Creek, are less graphitic. Projection of bedrock geology from the west suggests that some of these metamorphic rocks could be biotite-bearing (Sainsbury, Hummel, and Hudson, 1972; Bundzten and others, 1994). The schistose rocks are mostly phyllonite with slip schistosity approximately parallel to lithologic contacts and original bedding. The schistosity strikes northeast to east-northeast and dips about 30 degrees southeast.

The metamorphic rocks are probably part of the Nome Group, derived from Proterozoic to early Paleozoic protoliths (Till and Dumoulin, 1994). The Nome Group underwent regional blueschist facies metamorphism in the Late Jurassic or Early Cretaceous (Sainsbury, Coleman and Kachadoorian, 1970; Forbes and others, 1984; Thurston, 1985; Armstrong and others, 1986; Hannula and McWilliams, 1995). The blueschist facies rocks were recrystallized to greenschist facies or higher metamorphic grades in conjunction with regional extension, crustal melting, and magmatism in the mid-Cretaceous (Hudson and Arth, 1983; Miller and Hudson, 1991; Miller and others, 1992; Dumitru and others, 1995; Hannula and others, 1995; Hudson, 1994; Amato and others, 1994; Amato and Wright, 1997, 1998). Lode gold mineralization on Seward Peninsula is mostly related to the higher temperature metamorphism in the mid-Cretaceous (Apodoca, 1994; Ford, 1993, Ford and Snee, 1996; Goldfarb and others, 1997).

Alteration:

Local silicification and pervasive introduction of pyrite and ankerite near vein systems.

Age of mineralization:

Mid-Cretaceous; the veins postdate regional metamorphism and are probably similar in age to other lode gold deposits of Seward Peninsula.

Generic deposit model:

Deposit model:

Low sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Work on the Divide prospect began in the 1990s after its discovery by David and Daniel Lajack (Stevens, 2010). Cominco American dug 21 trenches that totaled 1,775 meters and drilled 14 holes that totaled 1,000 meters in 1996. In 2002, Rio Fortuna Exploration Corp. drilled 18 holes that totaled 1,357 meters (Stevens, 2010). Lajack Minerals explored the property from 2003 to 2006 and drilled 9 holes that totaled 273 meters. In 2007, Millrock Resources Inc. and their partner Alix Resources Corp. (2008) drilled 5 holes. In 2008, Millrock drilled 22 holes that totaled 2,656 meters and dug 1,744 meters of trenches (Stevens, 2010). On Dec. 2, 2009, Millrock terminated their agreement with Alix. In summary, a total of 68 holes totaling 5,848 meters have been drilled on the Divide prospect to 2010 and 45 trenches have been dug that total 3,018 meters (Stevens, 2010).

Last report date: 2011-02-28

Site name(s): Bulk Gold

Site type: Prospect

ARDF no.: NM071

Latitude: 64.7912 **Quadrangle:** N D-1

Longitude: 165.2874

Location description and accuracy:

The Bulk Gold prospect of Altar Resources consists of a large block of State claims in the upper valley of Dorothy Creek. The coordinates are near the center of the block of claims; the widespread mineralization include much of sections 13 and 14, parts of section 15, and much of sections 23 and 24, T. 8 S., R. 33 W., Kateel River Meridian. The claims include the old Hed and Strand mine (NM070). The location is accurate.

Commodities:

Main: Au, Sb

Other: As, Bi

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Calcite, quartz

Geologic description:

The Bulk Gold prospect was first identified in 1992 by Altar Resources by following up stream sediment samples anomalous in gold, arsenic, and antimony (Andover Ventures, 2006, Nome Drill Program; 2007, Gold Results; 2008, Bulk Gold). Between 1993 and 2003, Altar, variously with Teck Exploration and Consolidated Aston collected over 400 soil samples over the deposit and about 50 rock-chip samples. They drilled 8 shallow holes in the deposit. The most encouraging intercepts were 0.78 gram of gold per ton over 45 feet and 25 feet that averaged 0.9 gram of gold per ton. A sample in the saddle at the head of Dahl Creek contained 1.65 grams of gold per tonne, and 9,510 parts per million (ppm) arsenic. This saddle area was trenched and drilled in 1998. Four pits were dug at 300-foot intervals across the saddle. Bedrock samples from these pits contained 575 to 1,210 parts per billion (ppb) gold and 3,960 to 10,000 ppm arsenic. Andover Ventures is now (2008) the 100% owner.

In late 2006, Andover (2006, Nome Drill Program; 2007, Gold Results; 2008, Bulk Gold) drilled 8 shallow holes that totaled 285.7 meters. The most significant intercepts were 6.2 meters that that averaged 0.20 gram of gold per ton, 5.7 meters that averages 1.20 gram of gold per ton, and 6.7 meters that averaged 0.51 gram of gold per ton.

The property now being explored by Andover Resources (2008) has 4 types of mineralization on the property: 1) discordant, high-angle, high-grade stibnite-arsenopyrite-gold quartz veins (such as at the Hed and Strand mine (NM070)); 2) stratiform, possibly strata-bound disseminated gold mineralization at marble-schist contacts, 3) disseminated gold and arsenopyrite in metamorphosed felsic intrusive rocks, and 4) low-angle, high-grade gold-quartz veins. In 2001, Altar identified a 1400-foot-long geochemical anomaly, the 'Dripping Gold Zone', associated with marble and mineralized schist; soil samples contained as high as 5.1 grams of gold per ton and more than 10,000 ppm arsenic. One float sample of altered arsenopyrite-bearing intrusive rock contained 4.5 grams of gold per ton; another contained 1.5 gram of gold per ton, more than 200 ppm silver, and 338 ppm bismuth. There are also several other notable geochemical anomalies; the Dorothy Creek gold-arsenic anomaly which is about 3,000 feet long and the Discovery Hole gold-arsenic-antimony anomaly which is 1,600 feet long and 200 to 400 feet wide.

The Bulk Gold prospect is underlain mainly by massive marble and feldspathic epidote-bearing schist.

The epidote-bearing schist may be part of a regional mafic metavolcanic assemblage that has an Ordovician protolith (Till and Dumoulin, 1994). Hummel (1962 [MF 248]) mapped an approximately east-west, high-angle fault in Dahl Creek; the fault is upthrown on the south side. Earlier authors, including Mertie (1918 [B 662-I, p. 425-449]) and Cathcart (1922) noted a nearby metamorphosed granite body as possibly related to the mineralization at the Hed & [and] Strand mine, and Hummel (1962 [MF 248]) and Bundtzen and others (1994) mapped granitic orthogneisses in the area.

The metamorphic rocks in this area are part of the Nome Group derived from Proterozoic to early Paleozoic protoliths (Till and Dumoulin, 1994). The Nome Group rocks underwent regional blueschist facies metamorphism in the Late Jurassic or Early Cretaceous (Sainsbury, Coleman, and Kachadoorian, 1970; Forbes and others, 1984; Thurston, 1985; Armstrong and others, 1986; Hannula and McWilliams, 1995). The blueschist facies rocks were recrystallized to greenschist facies or higher metamorphic grades in conjunction with regional extension, crustal melting, and magmatism in the mid-Cretaceous (Hudson and Arth, 1983; Miller and Hudson, 1991; Miller and others, 1992; Dumitru and others, 1995; Hannula and others, 1995; Hudson, 1994; Amato and others, 1994; Amato and Wright, 1997, 1998). Lode gold mineralization on Seward Peninsula is mostly related to the higher temperature metamorphism in the mid-Cretaceous (Apodoca, 1994; Ford, 1993 [thesis]; Ford and Snee, 1996; Goldfarb and others, 1997).

Alteration:

Quartz veining and apparently some disseminated pyrite and arsenopyrite in nearby schist.

Age of mineralization:

Lode gold mineralization on Seward Peninsula is mostly related to higher temperature metamorphism in the mid-Cretaceous.

Generic deposit model:

Deposit model:

Disseminated gold and stratabound gold in metamorphic rocks, and in gold-arsenopyrite-stibnite quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Bulk Gold prospect was first identified in 1992 by Altar Resources by following up stream-sediment anomalies in gold, arsenic, and antimony (Andover Ventures, 2006, Nome Drill Program; 2007, Gold Results; 2008, Bulk Gold) . Between 1993 and 2003, Altar variously with Teck Exploration and Consolidated Aston collected over 400 soil samples over the deposit and about 50 rock-chip samples. They drilled 8 shallow holes and dug 4 pits across a prominent area of mineralization. In late 2006, Andover Ventures (2006, Nome Drill Program; 2007, Gold Results) drilled 8 shallow holes that totaled 285.7 meters. In 2001, Altar identified a 1400-foot geochemical anomaly, the 'Dripping Gold Zone'. There are several other strong geochemically anomalous zones the Dorothy Creek gold-arsenic anomaly which is about 3,000 feet long, and the Discovery Hole gold-arsenic-antimony anomaly, which is 1,600 feet long and 200 to 400 feet wide.

Production notes:

None.

Reserves:

None.

Location description and accuracy:

As originally described in ARDF, the Bulk Gold deposit was artificially separated into east and west portions with separate ARDF records. As drilling and exploration continued, it became apparent that there is single Bulk Gold deposit that is now in ARDF as Site NM071 The information that was originally in this record has been integrated into NM071. The number for this record is preserved only for accounting purposes.

Last report date: 2011-03-05

Site name(s): Nelson

Site type: Prospect

ARDF no.: NM090

Latitude: 64.7622 **Quadrangle:** N D-1

Longitude: 165.3888

Location description and accuracy:

The Nelson prospect is in Steep Creek, a tributary of Gold Bottom Creek, at an elevation of about 800 feet. It is about 0.5 mile southeast of the center of section 29, T. 8 S., R. 33 W. The location is accurate.

Commodities:

Main: Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Calcite

Geologic description:

The Nelson prospect contains sphalerite, galena, and pyrite in veinlets subparallel to layering in marble and in stockwork-like fracture zones; it includes a galena vein 2 inches thick (Mertie, 1918; Cathcart, 1922). When the prospect was visited by Cathcart in 1920, mineralization was exposed along 6 feet of an open cut near a contact of marble and mica schist; the schist had a strike of N15W and a dip of 18 degrees west. The marble was bleached in the mineralized zone. An adit, reportedly 55-feet long (Mertie, 1918), was caved and inaccessible to Cathcart (1922). The prospect was visited in 1995 by C.C. Hawley (personal communication) but the exposures were badly sloughed and the nature of the mineralization could not be observed. The Nelson prospect is in the main marble mass of Mount Distin and includes thin, mica schist layers (Hummel, 1962 [MF 248]; Bundtzen and others, 1994). Layering in the marble and the schist generally dips north and the prospect is about one-half mile south of the east-trending axis of the Mount Distin syncline of Hummel (1962).

Till and others (2011) map the host rocks as part of the Devonian-Ordovician Nome Group that consists of mixed marble, graphitic metasiliceous rock, and schist. The rocks were subject to blueschist facies metamorphism, then retrograded to greenschist-facies in the Jurassic and early Cretaceous.

Although earlier workers have classified this deposit as a lead-zinc replacement in marble, Slack and others (2011) classify this and several other prospect in the Nome Group (Aurora, NM140; Wheeler North, SO142, and Christophosen, NM141) as a sedimentary exhalative (Sedex) deposit. Whole-rock analyses of the schist interbedded with the marble indicates that they were originally clastic sedimentary rocks and they see no sign of volcanic protolithic rocks. Sulfur-isotope analysis of the sulfides also indicate a marine origin for the sulfur, as does isotopic analysis of barite in certain of these deposits.

Alteration:

Marble is bleached at the prospect.

Age of mineralization:

Deposited syngenetically in a marine environment during the Devonian; metamorphosed in the Jurassic or early Cretaceous.

Generic deposit model:

Deposit model:

Sedimentary exhalative (SEDEX) lead-zinc-silver-fluorite deposit (Cox and Singer, 1986, model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31a

Production Status: Undetermined

Site Status: Undetermined

Workings/exploration:

Developments included a 55-foot adit, an open cut, and several pits; all are badly sloughed. There apparently has been little work on the prospect since before 1920. Covered by at least one geochemical survey by the USGS and examined by several companies over the years.

Production notes:

None.

Reserves:

None.

Additional comments:

The Nelson prospect is on Bering Straits Native Corporation selected lands.

Site name(s): Aurora

Site type: Prospect

ARDF no.: NM140

Latitude: 64.7158 **Quadrangle:** N C-2

Longitude: 165.5909

Location description and accuracy:

The Aurora prospect is at the head of Aurora Creek, an eastern tributary to the Cripple River, at an elevation of about 1,060 feet. The mineralization trends south-southeast in a zone that extends for about a mile to a similar prospect, the Christophosen (NM141). The Aurora prospect is about 0.6 mile north-northwest of the center of section 13, T. 9 S., R. 34 W. The location is accurate.

Commodities:

Main: Au, Ba, F, Zn

Other: Ag, Cu, Pb, Sb

Ore minerals: Arsenopyrite, barite, chalcopyrite, fluorite, galena, gold?, pyrite, sphalerite, stibnite?, tennantite?

Gangue minerals: Ankerite, dolomite, quartz

Geologic description:

The Aurora zinc-lead prospect was discovered in 1966 by a geochemical survey (Herreid, 1968). Resource Associates of Alaska then found a train of boulders trending north-northwest of disseminated to semi-massive sulfides, mainly sphalerite. Herreid (1970) defined a soil anomaly at least 7,000 feet long that extends to a similar prospect, the Christophosen (NM141). In 1976 and 1977, Cominco explored the deposit and drilled 22 holes. The drilling cut an interval more than 100 feet thick that contained 5 percent zinc but they considered the mineralization to be too thin and low grade to be of further interest. From 1990 to 1993, Kennecott Exploration Company explored the deposit with new soil surveys; they also dug a series of trenches and did some drilling. They proposed that the early mineralization was syngenetic and related to rhyolitic volcanism; the deposit was then remobilized during Cretaceous regional metamorphism when gold was introduced along northeast-striking faults.

The massive sulfides are mainly light orange to brown sphalerite; local barite zones contain disseminated pyrite. There is some arsenopyrite and chalcopyrite. Antimony and arsenic are persistent trace elements in drill samples and the higher-grade samples contain about 0.1 ounce of gold per ton.

Bundtzen and others (1984) identified three rock units that host the mineralization: 1) white, zircon-rich muscovite-quartz schist, 2) feldspar-rich porphyroblastic schist, and 3) tourmaline-bearing muscovite-quartz-feldspar schist. Ankerite and dolomite are common and locally abundant; purple fluorite occurs in knots in the schist. Locally barite is prominent in layers and lenses. Based on whole-rock analyses, they proposed that the white muscovite-quartz schist is a metarhyolite and that the deposit is a volcanogenic massive-sulfide deposit.

Slack and others (2011) reject a volcanogenic massive sulfide origin for the deposit and Till and others (2011) map the host rocks as part of the Devonian Nome Complex that consists of pelitic, calcareous, and graphitic schist. Their work suggests that the protolith of the metamorphic rocks are sedimentary and they see no evidence of volcanic rocks in the area. They base their conclusion on: 1) sulfur isotope analyses of the sulfides that indicate a marine origin for the sulfur, 2) isotopic analysis of the barite that indicate that the probable source of the sulfur is Devonian and Mississippi sea water, and 3) their whole-rock analyses of the host rocks of the mineralization that they interpret as originally being clastic sedimentary rocks. They propose a sedimentary-exhalative (SEDEX) origin for the deposit during rifting of the continental margin in

Devonian-Missisippian(?) time. The rocks subsequently were subject to blueschist-grade metamorphism, then retrograded to greenschist-grade metamorphic rocks in the Jurassic and early Cretaceous.

Alteration:

Remobilization of metallic minerals and carbonates during Cretaceous metamorphism.

Age of mineralization:

Massive sulfides were syngenetic in early Paleozoic (Devonian?) sedimentary and/or marine volcanic rocks with remobilization during mid-Cretaceous deformation and metamorphism. Mineralization along crosscutting structures is probably mid-Cretaceous or younger.

Generic deposit model:

Deposit model:

Metamorphosed Kuroko-type volcanogenic massive sulfide (Cox and Singer, 1986; model 28a) or sedimentary exhalative (SEDEX) deposit (Cox and Singer, 1986, model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 31a

Production Status: None

Site Status: Undetermined

Workings/exploration:

Soil surveys were done by the Alaska Division of Geological and Geophysical Surveys in the late 1960s. Some work by Resource Associates of Alaska in the early 1970s. Cominco explored the deposit in 1976 and 1977 and drilled 22 holes. Kennecott Exploration explored the deposit with soil surveys and trenching from 1990 to 1993 and drilled some holes.

Site name(s): Christophosen

Site type: Prospect

ARDF no.: NM141

Latitude: 64.6988 **Quadrangle:** N C-2

Longitude: 165.5815

Location description and accuracy:
The Christophosen prospect is on the ridge between the headwaters of Oregon Creek and Penny River, just downslope and east of elevation 1620. It is about 0.4 mile north of the center of section 24, T. 9 S., R. 34 W. The location is accurate.

Commodities:

Main: Zn

Other: Ag, Au, Pb, Sb

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite, stibnite

Gangue minerals: Ankerite, dolomite, quartz

Geologic description:
The Christophosen prospect was discovered before 1916. When Mertie (1918) visited the prospect in 1916, he found one caved shaft and reported sphalerite and pyrite with quartz. The locality was visited by Herreid (1968), who reported dolomite with sparsely disseminated galena, chalcopyrite, and sphalerite in an old prospect area. Approximately 500 feet south-southeast of the Christophosen pits, a rubble crop of sphalerite-bearing schist is present that is similar to mineralization found about a mile to the north at the Aurora Creek prospect (NM140). The Christophosen prospect apparently lies stratigraphically above a graphitic quartz schist, as does the Aurora deposit. The zinc content of soils near the rubble crop exceeds 2,000 ppm; the soil also is strongly anomalous in lead and silver. The rubble crop is contained within a broader, north-northwest trending soil anomaly about 1,200 feet long and 400 feet wide notable for samples samples that contain 1,000 ppm or more zinc. A lens of fine-grained cherty rock, possibly an exhalite layer, with disseminated galena, sphalerite, and stibnite appears to be stratigraphically above the sphalerite-bearing schist (Cindy Buxton and C.C. Hawley, written communication 1992). Bundtzen and others (1994) interpret the rocks in the area as a tightly folded complex of felsic metavolcanic schist and mixed chloritic, calcareous, and felsic schist . Till and others (2011) map the host rocks as part of the Devonian Nome Complex that consists of pelitic, calcareous, and graphitic schist and see no evidence of volcanic rocks in the area (Slack and others, 2011).
More detailed work at the Aurora prospect (NM140) about 1.2 miles to the north-northwest indicates that this prospect is part of a north-northwest trending belt of zinc-barite mineralization that has been variously interpreted as a metamorphosed, volcanogenic massive sulfide deposit (Bundtzen and others, 1994) or a Devonian sedimentary exhalative (SEDEX) deposit, metamorphosed in the Cretaceous (Slack and others, 2011). Subsequently, the rocks in the area were subject to blueschist facies metamorphism, then retrograded to greenschist-facies metamorphic rocks in the Jurassic and early Cretaceous.

Alteration:
Not noted.

Age of mineralization:
Either a syngenetic deposit or a volcanogenic massive-sulfide deposit in early Paleozoic (Devonian?)

sedimentary and marine volcanic rocks.

Generic deposit model:

Deposit model:

Metamorphosed Kuroko-type volcanogenic massive sulfide (Cox and Singer, 1986; model 28a) or sedimentary exhalative (SEDEX) deposit. (Cox and Singer, 1986, model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 31a

Production Status: None

Site Status: Undetermined

Workings/exploration:

Several prospect pits are present; a shallow shaft was caved by 1916. Surface examination and sampling by Kennecott Exploration Company in 1991 and 1992.

Production notes:

None.

Reserves:

None.

Site name(s): Arctic Creek (lower)

Site type: Mine

ARDF no.: NM155

Latitude: 64.6095 **Quadrangle:** N C-2

Longitude: 165.7957

Location description and accuracy:

Arctic Creek is an east tributary of lower Cripple River. The mouth of Arctic Creek is about 5 miles upstream from the mouth of Cripple River on Norton Sound. Two segments of the creek have been mined, probably producing gold derived in part from two different sources. Lower Arctic Creek is defined as the part of Arctic Creek below the mouth of Bluff Creek (NM154), an east tributary. This lower part of Arctic Creek was mined by a floating bucket line dredge. The location is the approximate midpoint of the dredge tailings. Information for this mine was summarized by Cobb (1978) but his map location (Cobb, 1972) is on upper Arctic Creek (NM153).

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

From 1914 to at least 1922, an alluvial placer gold deposit was mined for at least a half mile along lower Arctic Creek by a floating bucket line dredge, starting about a mile above its mouth. The placer in lower Arctic Creek appears to have gold sources other than those that supplied gold to the upper part of Arctic Creek (NM153). These sources include Bluff Creek (NM154) and the wall rocks of a discordant quartz-ankerite vein exposed in the bluffs opposite the mouth of Bluff Creek (NM157). The lower part of a south-flowing tributary to Arctic Creek about a half mile below Bluff Creek has also been placer mined and is included here.

Arctic Creek is subparallel to the projection of a strong north-northeast fault mapped by Bundtzen and others (1994) as the Aurora fault. This fault is the control of the nearby vein mineralization (NM157). The rocks along Arctic Creek near Bluff Creek are in part pyritic, graphitic, quartz schist, but most of the country rock is calcareous mica schist.

Also see the record for 'Second Beach' near the mouth of the Cripple River (NM178) for recent prospecting and mining activities in the area that is based from a camp maintained by the Gold Prospectors of America (Gold Prospectors Association of America, 2010). At least some of their activities was on Arctic Creek.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Alluvial placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

A bucket line dredge operated on the lower part of Arctic Creek from 1914 until at least 1922 (Eakin, 1915; Harrington, 1921; Brooks, 1922; Brooks and Capps, 1924) There was probably some hand and small-scale mining along the creek during this period or later. Also see the record for 'Second Beach' (NM178) for recent prospecting and mining activities in the area that is based on a camp maintained by the Gold Prospectors of America (Gold Prospectors Association of America, 2010). At least some of their activities was on Arctic Creek.

Production notes:

There are no systematic records of early mining on Arctic Creek. However, since 1986, The Gold Prospectors Association of America has run a camp each summer near the mouth of the Cripple River; some of their prospecting and mining activity has been on Arctic Creek and at least some gold has been produced each year.

Reserves:

None.

Site name(s): Cripple River

Site type: Mine

ARDF no.: NM156

Latitude: 64.6136 **Quadrangle:** N C-2

Longitude: 165.8536

Location description and accuracy:

Cripple River was reported to be auriferous from its headwaters to its mouth on Norton Sound by Collier and others (1908, plate X). The location given is the approximate midpoint of patented claims along a section of the river that extends from above Stella Creek (NM151) to its mouth on Norton Sound.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Collier and others (1908) reported that Cripple River was auriferous from its head to its mouth on Norton Sound. This was partly confirmed in the upper part of Cripple River during 1989-1990 reconnaissance exploration by Kennecott Exploration Company (written communication, 1992). Panned concentrates containing greater than 10,000 parts per billion (ppb) gold were found in gravels of Cripple River above Aurora Creek. Gold was also panned both above and below Gold Run, a north headwater tributary. A panned concentrate at the mouth of Oregon Creek contained greater than 10,000 ppb gold. Both Cleveland Creek (NM150) and Stella Creek (NM151) were mined just above their confluence with Cripple River. A large right-limit (north side) bench of Cripple River was reported to be rich enough to hydraulic mine (NM152), but water losses in two ditches apparently precluded the mining of the bench deposit. Cripple River is almost continuously covered by patented mining claims from a point about 1 mile above Stella Creek (NM151) downstream to its mouth. There is little information on the distribution of gold along Cripple River itself.

Also see the record for 'Second Beach' (NM178) for recent prospecting and mining activities in the area that is based from a camp maintained by the Gold Prospectors of America (Gold Prospectors Association of America, 2010). At least some of their activity was on lower Cripple River.

Site name(s): Second Beach (near the mouth of Cripple River)

Site type: Mine

ARDF no.: NM178

Latitude: 64.5431 **Quadrangle:** N C-2

Longitude: 165.785

Location description and accuracy:

Somewhat arbitrarily, this site is located about 1,500 feet upstream from the mouth of the Cripple River where Sainsbury and others (1972) reported a placer mine on the so-called Second Beach. However, see the Geologic Description below for more recent and widespread placer mining along the lower Cripple River. The Sainsbury location is about 0.5 mile south of the center of section 12, T. 11 S., R. 36 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

A placer mine near the mouth of Cripple River was reported by Sainsbury and others (1972). The location is on the west side of Cripple River, about 1,500 feet upstream from the mouth. It is inferred to be on a westward extension of the so-called Second Beach that was mined at many places on the coastal plain to the east. Second Beach deposits were originally marked by a moss-covered gravel escarpment about 35 feet above modern sea level. The beach contains quartz sand deposits that contain driftwood, fragments of walrus tusks, and marine shells (Collier and others, 1908; Moffitt, 1906, 1907). There was more garnet in Second Beach deposits than in those of Third Beach. Second Beach commonly is buried by a few feet of material that is usually frozen. The raised beach deposit is essentially at the landward limit of the Pelukian marine transgression mapped by Bundtzen and others (1994).

In 1985, Global Outdoors, Inc. purchased 2,300 acres near the mouth of the Cripple River and in 1986 began building a large camp just east of the mouth of the river. Since then, the Gold Prospectors Association of America has brought large parties to the camp each summer to prospect, mine, and fish in the area (Gold Prospectors Association of America, 2009, is the home page for considerably more information on their camp and a chronology of their activities over the years). The activities includes placer mining along the beach at the mouth of the Cripple River and prospecting and mining at several other sites in the area, for instance on lower Arctic Creek (NM155) and probably elsewhere up the Cripple River (NM156). Some uncertain amount of gold has undoubtedly been produced each summer since the mid-1980s. during their activities.

Alteration:

Age of mineralization:

Late Pleistocene.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Beach and stream, gold placers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Old surface workings and dumps from drift mining prior to 1985 are widespread in the general area. Since 1986, there has been considerable mining and prospecting in the area from a camp run by the Gold Prospectors Association of America at the mouth of the Cripple River.

Production notes:

There was probably some gold production from the lower Cripple River prior to 1986 but the amount and the production history is uncertain. Since 1986, the Gold Prospectors Association of America has brought parties to their camp at the mouth of the Cripple River and some gold has undoubtedly been produced each year from beach and stream placers in the area.

Reserves:

There are probably no defined reserves but at least small amounts of gold can be panned along the beach and in streams in the area.

Site name(s): Rock Creek (lode); Nugent

Site type: Prospect

ARDF no.: NM207

Latitude: 64.6148 **Quadrangle:** N C-1

Longitude: 165.4181

Location description and accuracy:

The Rock Creek lode prospect extends for a strike distance of at least 1,000 feet in the Rock Creek valley above the confluence of Rock Creek and Sophie Gulch (NM208). The coordinates are at about the midpoint of the deposit, about 1.4 miles southwest of Mount Brynetson. The location is just inside the south-central border of section 14, T. 10 S., R. 34 W., of the Kateel River Meridian, and it is accurate to within 500 feet. It is included in locality 43 of Cobb (1972 [MF 463], 1978 [OFR 78-93]).

Commodities:

Main: Au

Other: Ag, Pb, Sb, W, Zn

Ore minerals: Arsenopyrite, boulangerite, galena, gold, hematite, limonite, pyrite, scheelite, stibnite, sphalerite

Gangue minerals: Albite, ankerite, calcite, quartz

Geologic description:

Gold-bearing, northeast-striking quartz veins in schist were known on Rock Creek by 1903 (Collier and others, 1908). Sheeted veins were later described, massive veins were locally worked, and some residual placer gold and scheelite were produced from weathered sheeted vein complexes (Moffit, 1913, p. 75-76; Mertie, 1918 [B 662-I, p. 436]; Cathcart, 1922). Lodes in the Rock Creek area were principal examples of disseminated lode gold deposits identified in a regional mineral assessment during the 1970s (Hudson and others, 1977; Hudson and DeYoung, 1978). This deposit is the most extensively explored gold lode in the Nome mining district. Significant exploration to better define the gold grades, including extensive trenching and drilling, has taken place episodically through from the 1980s to the present (2007) since its relocation by geologist R. V. Bailey of Denver in the early 1980s.

As of early 2006, NovaGold Resources Inc. (2006, Projects) is developing the property and carrying out an aggressive infill drilling program which began in 2003. The 2003 drilling totaled 8,000 m and increased total drilling on the project to 18,960 meters in 217 drill holes. Intensive infill drilling continued in 2004 when 82 core and rotary drill holes totaling 20,000 feet (5,900 meters) were completed. The infill drilling results are incorporated in a feasibility study that was started in late 2003. A positive feasibility study could lead to production from a 500 meter by 1,500 meter by 100 meter open pit by 2007. The proposed mine which would produce 5,000 to 7,000 tons per day is expected to produce about 100,000 ounces of gold per year. NovaGold is also evaluating the feasibility of processing ore from the nearby Saddle deposit (NM223) and the more distant Big Hurrah deposit (SO023) if a mill is built at Rock Creek. As of March 28, 2007, NovaGold Resources Inc. (2007, Reserve) reported the resources at Rock Creek as 9.6 million tonnes of measured and indicated reserves with an average grade of 1.31 grams of gold per ton.

The most typical and highest grade part of the Rock Creek lode consists of a sheeted vein complex. The veins strike northeast and generally dip at a high angle to the northwest. They generally range from 1 inch to 6 inches thick, although some veins are more than 1 foot thick. Vein spacing is locally about one per foot. Cathcart (1922, p. 246) described a sheeted zone near the mouth of Sophie Gulch (NM208), where 23 quartz veins from 1 inch to 8 inches thick are in a zone 28 feet wide. In general, sheeted veins are well exposed in mechanical and hydraulic cuts in a 1,000-foot-long interval north of Sophie Gulch (NM208). Although good

mineralization was found in some drill holes south of the Sophie Gulch fault, such as in Placer Dome RR-8-088, this fault appears to cut off or displace the best mineralization. The quartz and quartz-calcite veins of the sheeted set are composed mainly of white quartz with some internal crustification, but they are not banded. Albite tends to occur on the selvages and in adjacent wall rocks. Cathcart (1922) and others have reported muscovite in the veins. Sulfides tend to be relatively abundant close to the selvage, but are disseminated throughout the quartz. They consist mainly of pyrite, galena, stibnite, and sphalerite. Arsenopyrite is present but is more abundant in schist than in the veins. Lead sulfosalts such as boulangerite occur locally. Limonite tends to form on weathered veins, hematite on weathered arsenopyrite zones. The deposit is relatively long compared to its apparent thickness. Sheeted veins and most of the gold appear to lie above a marble-rich stratum which is at a depth of about 250 to 300 feet. Individual quartz stringers pinch and swell and may end abruptly at a slip plane parallel to schistosity.

The main Rock Creek deposit grades into several other deposits. Opposite the mouth of Sophie Gulch, sheeted veins 2 to 3 feet apart are in quartz-mica schist, but there are extensive arsenic- and albite-rich zones in the schist. Well-developed, fold-controlled quartz-albite zones were exposed in Kennecott trench RCT-94-8. The trench and adjacent hill slopes display arsenic-rich lodes of northwest strike. This area has locally been called Arsenic Hill. The Reinisch hydraulic pit (NM213) is in this area. A distinct vein called the Albion (NM211) was exposed by mine workings in upper Rock Creek; it probably is partly coincident with sheeted veins typical of the main Rock Creek deposit. The deposit at the Walsh Cut (NM214) resembles that at the Reinisch.

Most of the country rocks exposed at the prospect belong to the chlorite-rich metaturbidite schist and marble unit of Bundtzen and others (1994) or to the lower part of the 'mixed unit' of Till and others (1986). Graphitic mica schist and graphitic quartz schist are common; the graphitic quartz schist is locally a good marker unit. Schistosity generally strikes northeast and dips are low to moderate southeast. Quartz veins of the sheeted set are close to orthogonal to the schistosity. The schist appears to be a phyllonite. Although schistosity appears to be close to concordant with lithology, it is penetrative. Some coarse-grained units have incipient augen structure and are believed to have been sheared during a period of metamorphism that could be contemporaneous with early mineralization. Locally, schist is strongly mineralized with arsenopyrite and albite concordant to schistosity. Bedrock in the area probably is of early Paleozoic protolith age (Hummel, 1962 [MF 247]; Sainsbury, Hummel, and Hudson, 1972 [OFR 72-326]; Till and Dumoulin, 1994; Bundtzen and others, 1994).

Detailed mapping for Kennecott Exploration Company identified a strong northeast-striking fault that appears to cut off the Sophie Gulch fault. The fault, called the Arsenic Hill fault, is exposed in Placer Dome trench RRT-87-1 and in Kennecott Exploration Company trench RCT-94-8. The fault appears to localize complexly sheared graphitic quartz veins and may have both pre- and post-mineral history. It is subparallel and en echelon to the Albion (NM211) and proposed Calle (NM212) vein-fault structures.

Apodaca (1994) studied fluid inclusions and other detailed aspects of the vein geology at Rock Creek. Her work indicates that Rock Creek formed from low-salinity fluids relatively rich in carbon dioxide, methane, and nitrogen, with some hydrogen sulfide. Fluid inclusions indicate an estimated temperature of formation in the range of 225 to 275 degrees Centigrade. The Rock Creek deposit is probably similar in age (109 Ma) to the gold-quartz deposits at Bluff (Ford and Snee, 1996).

Alteration:

Early alteration consists of locally extensive albitization and sulfidization (introduction of arsenopyrite; late alteration consists of minor sericitization and albitization along with introduction of sheeted veins; and local development of ankerite.

Age of mineralization:

Mid-Cretaceous. The country rocks are part of the Nome Group derived from Proterozoic to lower Paleozoic protoliths (Till and Dumoulin, 1994). The Nome Group underwent regional blueschist facies metamorphism in the Late Jurassic or Early Cretaceous (Sainsbury and others, 1970 [P 750-C]; Forbes and others, 1984; Thurston, 1985; Armstrong and others, 1986; Hannula and McWilliams, 1995). The blueschist facies rocks were recrystallized to greenschist or higher metamorphic grades in conjunction with regional extension, crustal melting, and magmatism in the mid-Cretaceous (Hudson and Arth, 1983; Miller and Hudson, 1991; Miller and others, 1992; Dumitru and others, 1995; Hannula and others, 1995; Hudson, 1994; Amato and others, 1994; Amato and Wright, 1997, 1998). Lode gold mineralization on Seward

Peninsula is mostly related to the higher temperature metamorphism in the mid-Cretaceous (Apodoca, 1994; Ford, 1993 [thesis]; Ford and Snee, 1996; Goldfarb and others, 1997).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Undetermined

Site Status: Active

Workings/exploration:

Gold-bearing, northeast-striking quartz veins in schist were known on Rock Creek by 1903 (Collier and others, 1908). Sheeted veins were later described, massive veins were locally worked, and some residual placer gold and scheelite were produced from weathered sheeted vein complexes (Moffit, 1913, p. 75-76; Mertie, 1918 [B 662-I, p. 436]; Cathcart, 1922). Lode prospects in the Rock Creek area were principal examples of disseminated lode gold deposits identified in a regional mineral assessment during the 1970s (Hudson and others, 1977; Hudson and DeYoung, 1978). This deposit is the most extensively explored gold lode in the Nome mining district. Significant exploration has taken place episodically from the early 1980s to the present (2007) including extensive trenching and drilling has taken place episodically since the 1980s when the property was relocated by R.V. Bailey to the present (2007).

Bailey reopened trenches in the hydraulic cuts north of Sophie Gulch and exposed and sampled the sheeted veins. His work brought Placer Dome into the project in 1987 to 1989. Placer Dome drilled dozens of holes on regular, northwest-aligned fences approximately 200 feet apart for nearly 2,000 feet northeast from the mouth of Sophie Gulch. Both core and RC holes were drilled, and essentially all were steeply inclined to the southwest, perpendicular to the strike of the sheeted veins.

Some of this drilling was difficult. The water table is close to the surface and some holes had artesian flow. The program was sufficient to outline a geologic resource, but it was considered subeconomic by Placer Dome. An extensive soil geochemical survey was completed in the area by BHP in 1989, and the property was optioned by Newmont Mining Company in 1992. Some new drill holes, including holes to confirm Placer Dome tests, were drilled by Newmont. The property was further explored in 1994 and 1995 by Kennecott Exploration Company, who drilled a few holes along the northwest fences. The holes were inclined to the northwest so that they would be nearly at right angles to bedrock schistosity in lower Rock Creek. Both Placer Dome and Newmont carried out preliminary metallurgical work; it appears that about 70 percent of the gold is present as free gold; the balance is in auriferous sulfides, principally pyrite and arsenopyrite. Exploration continued in 2000 by NovaGold Resources. In 1999, they announced that better recovery and analytic techniques suggested higher average grades for the deposit, perhaps about 3 grams of gold per metric tonne.

As of early 2006, NovaGold Resources, Inc. (2006, Projects) is developing the property and is carrying out an aggressive infill drilling program which began in 2003. The 2003 drilling totaled 8,000 m and increased total drilling on the project to 18,960 meters in 217 drill holes. Intensive infill drilling continued in 2004 when 82 core and rotary drill holes totaling 20,000 feet (5,900 meters) were completed. The infill drilling results are incorporated in a feasibility study that was started in late 2003. A positive feasibility study could lead to production from a 500 meter by 1,500 meter by 100 meter open pit by 2007. Processing of 5,000 to 7,000 tons per day is expected to produce about 100,000 ounces of gold per year. NovaGold is also evaluating the feasibility of processing ore from the nearby Saddle deposit (NM223) and the more distant Big Hurrah deposit (SO023) if a mill is built at Rock Creek.

Production notes:

None.

Reserves:

As of March 28, 2007, NovaGold Resources Inc. (2007, Reserve) reported the resources at Rock Creek as 9.6 million tonnes of measured and indicated reserves with an average grade of 1.31 grams of gold per ton.

Last report date: 2005-10-10

Site name(s): Saddle; New Era; Big Four

Site type: Prospects

ARDF no.: NM223

Latitude: 64.5905 **Quadrangle:** N C-1

Longitude: 165.3897

Location description and accuracy:

This site represents several closely related lode deposits in the headwaters of Snow Gulch, especially above the split of the gulch into two headward forks. The map location is on the Saddle deposit developed above the north fork of Snow Gulch, at an elevation of 450 feet in the SW1/4 section 25, T. 10 S., R. 10 W., Kateel River Meridian. These deposits are included in locality 46 of Cobb (1972 and 1978), and locality 1 of Hummel (1962).

Commodities:

Main: Au

Other: Ag, Sb, W

Ore minerals: Arsenopyrite, galena, gold, pyrite, scheelite, stibnite

Gangue minerals: Albite, calcite, quartz

Geologic description:

The Saddle deposit is of sheeted vein type; it trends northeasterly from near the west portal of the Miocene Ditch tunnel nearly to the top of hill 691. Other gold-bearing veins were developed in the south fork of upper Snow Gulch. One prospect in this group appears to lie on the Bernice No. 1 lode of John Leedy (U.S. Mineral Survey No. 775); the New Era tunnel is also in this vicinity. Another related vein zone possibly exists on the divide between Snow Gulch and Anvil Creek, nearly in line with the trend of Snow Gulch.

Prospecting dating back to at least 1899 has identified several gold lodes near the head of Snow Gulch. The older prospects, such as New Era and Big Four, are difficult to identify, but they can be approximately located. These vein and stratabound mineral occurrences are abundant in upper Snow Gulch and appear to be the main source of placer gold in Snow Gulch.

A prospector named John Leedy located claims on the east side of Snow Gulch and on Bonanza Hill from July 1899 until 1908; his claims were patented in 1908 (U.S. Mineral Survey No. 775). A stamp mill was moved into this area and various tunnels and workings were driven, including the New Era tunnel, reported to be more than 300 feet long. The tunnel was driven on a lode that strikes northeast and dips 40 northwest (Chapin, 1914, p. 400-401). The gold is in pyrite and arsenopyrite. The sulfides are disseminated in schist that is cut by quartz, minor albite, and locally calcite veinlets.

The New Era tunnel which was caved when visited by Chapin, appears to be near Placer Dome trenches ST-88-06, -08 and -010. These trenches expose zones containing more than 0.1 ounce of gold per ton. Mertie (1918, p. 433-434) examined this area in 1916. He repeated Chapin's description of the New Era tunnel, but was able to examine the Big Four shaft. He reported that this shaft was on the east side of Snow Gulch at an elevation of about 500 feet. Quartz stringers in a 60-foot-wide zone in marble strike about N 65 E and contain crystalline gold in vugs in quartz. This area was also described by Cathcart (1922, p. 243-244).

The Saddle deposit, mainly explored between 1986 and 1995, appears to start west of the portal of the Miocene Ditch tunnel and to continue northeasterly for about 1,300 feet. This deposit has been explored by shallow trenches and drill holes. It is irregular but is as much as 200 feet wide. The Saddle deposit is less consistently mineralized than the Rock Creek sheeted zone (NM207), but a small body of material

averaging about 0.05 ounce of gold per ton has been identified, and probably more could be developed. Other trenching and shallow drilling suggest that gold-bearing veins are also present in a west-southwest-trending zone west of the portal of Miocene tunnel. The apparent strike length of the zone is about 1,200 feet. This zone probably includes the New Era deposit.

An isolated deposit, about 1,200 feet northeast of Saddle, was found by Newmont in 1992, and a deposit at the ridge between Snow Gulch and Anvil Creek was intersected in three Placer Dome trenches (ST-88-3, -4, and -5). The deposit in these trenches can be projected about 300 feet on strike.

Bedrock in the area is schist and some marble, probably of early Paleozoic protolith age (Hummel, 1962; Sainsbury, Hummel, and Hudson, 1972; Till and Dumoulin, 1994; Bundtzen and others, 1994). Strata exposed in upper Snow Gulch and continuing southward on Bonanza Hill are chloritic mica schist, marble and occasional graphitic units. In general they belong to the chlorite-rich metaturbidite schist and marble unit of Bundtzen and others (1994).

As of 2007, NovaGold Resources, Inc. (2007, Nome) is exploring the Saddle deposit and they initiated new infill drilling in 2005. The new drilling is being done to define a resource that could be mined and trucked to the proposed Rock Creek (NM207) mill. As of March 28, 2007 NovaGold Resources Inc. (2007, Reserve) lists the the reserves at the Saddle prospect as 3.6 million tonnes of material with a grade of 2.3 ounces of gold per ton.

Alteration:

Albitization, silicification, and sulfidization of schist.

Age of mineralization:

Mid-Cretaceous; veins cross cut regionally metamorphosed schist; see NM207.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Undetermined

Site Status: Active?

Workings/exploration:

Lode prospects were located in this area as early as 1899; there was considerable lode prospecting activity until World War I. n the mid-1980', R.V. Bailey discovered the Saddle deposit and began a trenching program that identified a sheeted vein complex. This exploration was followed by an extensive trenching program and some drilling by Placer Dome in 1987 and 1988, by soil geochemistry and some drilling by BHP in 1990, by detailed mapping and some drilling by Newmont Mining Company in 1992, and by additional drilling by Kennecott Exploration Company in 1994-5.

As of 2006, NovaGold Resources, Inc. (2007, Nome) is exploring the Saddle deposit and they initiated new infill drilling in 2005. The new drilling is to define a resource that could be mined and trucked to the proposed Rock Creek (NM207) mill.

Production notes:

None.

Reserves:

As of March 28, 2007 NovaGold Resources Inc. (2007, Reserve) lists the the reserves at the Saddle prospect as 3.6 million tonnes of material with a grade of 2.3 ounces of gold per ton.

Last report date: 2005-10-12

Site name(s): Nome placer field

Site type: Mines

ARDF no.: NM251

Latitude: 64.5439 **Quadrangle:** N C-1

Longitude: 165.4026

Location description and accuracy:

This extensive placer gold deposit that has been mined intensively since before WWI occupies large parts of sections 11, 12, 13, and 14, T. 11 S., R. 34 W., of the Kateel River Meridian. The coordinates are immediately north of the Nome-Teller road in the SE1/4SE1/4 section 11. The site is accurately located (Bundtzen and others, 1994, sheet 1). It is approximately the same as locality 138 of Cobb (1972 [MF 463]). In his description of location 138, Cobb lists Center, Flat, Holyoke, Lake, Saturday, Wonder, and Little Creek claims and two operating companies: Hammon Consolidated Gold Fields and U.S. Smelting and Refining Company. The field was also extensively mined by the Pioneer Mining Company in the early days of the district. For convenience in this record, this composite placer deposit is hereafter referred to as the Nome placer field.

Commodities:

Main: Au

Other: Ag, W

Ore minerals: Arsenopyrite, gold, hematite, ilmenite, magnetite, pyrite, scheelite

Gangue minerals: Garnet

Geologic description:

The Nome placer field formed where the rich Anvil Creek alluvial placer (NM236) was reworked by marine processes where it flowed out onto a coastal plain. An ancestral Anvil Creek channel flowed southeasterly, turned south near modern Center Creek (not named on the 1970 revision of the topographic map but probably is the drainage near the northeast runway of the Nome airport), and eventually merged with Submarine Beach (NM285 and NM286). The field spreads out along the Third Beach (NM258). It is very wide southwest of Third Beach through the area of buried auriferous abrasion platforms seaward of Third Beach. The deposit includes a large part of the richest portion of Third Beach between Little Creek to the west and Dry Creek to the east (Moffit, 1906, p. 134; Moffit, 1907, p. 134-144; Collier and others, 1908, p. 34, 162-163). The general location of the deposit as it was recognized in 1906 can be inferred from patterns of gold distribution shown by Collier and others (1908, plate X).

The deposit is mainly developed on schist bedrock, but higher level gold concentrations occur in fan and delta-like deposits formed at times when an ancient Anvil drainage flowed into the ocean. The rather complex relations were summarized by Metcalfe and Tuck, 1942, p. 37): 'At the foothill edge of the coastal plain is an indistinguishable zone of intermixed stream and marine deposits... In this area, gold is found throughout the overburden, in horizons, in small stream channels, and as disseminations. Marine and stream gravel is often intermixed. When the shoreline was close to the hills, Anvil, Cooper, and Dry Creeks emptied gold-bearing detritus directly into the sea. In part this material formed an alluvial fan deposit and, when deposited directly into the sea, a delta... Under such conditions, gold distribution is very erratic. Further from the foothills the gold occurs in more regular horizons.'

Placer gold at Nome is very close to 900 fine; Anvil Creek averages 897 and varies from 894 to 905 (Metcalfe and Tuck, 1942, p. 41). Garnet was relatively abundant near Third Beach; sulfides, principally pyrite and arsenopyrite, locally occurred in concentrates seaward of Third Beach. In general, minerals in the

concentrates are magnetite, ilmenite, scheelite, garnet, pyrite, and arsenopyrite. Based on testing done by Fairbanks Exploration Company in 1939, after stripping all available free gold with mercury, the sulfides appear to contain about 0.25 to 0.75 ounce of gold per ton. Metcalfe and Tuck (1942) strongly suggest that some of the gold, and therefore sulfides, could have come from marine erosion of the bedrock surface itself.

The field was first worked by drifting by the Pioneer Mining Company, especially between 1904 and 1910. The average value of an almost continuous drift mine 3,000 feet in length was $4.51 or 0.22 ounce of gold per bedrock foot. Some of the ground contained an ounce of gold to the bedrock foot (Metcalfe and Tuck, 1942, figure 1). The area was mined hydraulically by the Pioneer Company from 1910 to 1922 and then by Hammon and Fairbanks Exploration companies from 1923 until 1934. During the period from 1904 until 1934, about $8,000,000 in gold (about 387,000 ounces of gold) was recovered from the area. The field furnished a significant amount of production of the Nome district (Bundtzen and others, 1994). The deposit was subsequently dredged until 1965. It was last mined as an open pit in 1994.

NovaGold Resources, Inc. (2007, Nome) has owned most of the ground that comprises this site since 1999 and is evaluating the placer gold potential of the Nome coastal plain. They developed a computer database of the approximately 8,000 holes drilled by the the Alaska Gold Company and its corporate predecessors over the long life of this major placer district. In addition, NovaGold and Kennecott Exploration have drilled new holes. The objective is to define mineable reserves that could be produced either by open pit methods or perhaps by rehabilitated dredges that were once operated by Alaska Gold in the area. As of March 28, 2007, an updated resource estimate was produced for NovaGold (2007, Reserve) by the Norwest Corporation. The property contains a measured and indicated resource of 1.6 million ounces of gold and an inferred resource of 300,000 ounces of gold. The gold is in a 194-million-tonne resource of sand and gravel which is valuable in its own right.

Alteration:

Age of mineralization:

Pliocene (?) and Quaternary; sea-level fluctuations are very important in the history of this deposit.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Alluvial placer Au (Cox and Singer, 1986, model 39a); deltaic deposits, buried strand line beach deposits, and offshore abrasion placers seaward from ancient beaches.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; large

Site Status: Active

Workings/exploration:

A buried alluvial gold deposit was discovered in the canyon of Anvil Creek in 1898 by Lindblom, Brynteson, and Lindeberg, who later formed Pioneer Mining Company. The men also located placer claims on the coastal plain along an ancient buried channel of Anvil Creek that lies between Little and Dry Creeks. These claims covered important parts of the Nome placer field deposit. Extensive underground mining of this deposit occurred between 1904 and 1910. In late 1904, the Third Beach deposit (NM258) was discovered. In the Nome placer field area, the upland limit of the Third Beach deposit was sharp and against a bedrock escarpment. The beach deposits contributed to the richness of the ancient Anvil Creek channel, and related abrasion deposits were mined seaward from Third Beach. The deposit as finally mined includes the ancestral Anvil Creek channel, Third Beach, and abrasion and transient or remnant beaches on the abrasion platform offshore from Third Beach. After drifting, the deposit was mined by surface hydraulic methods, generally with hydraulic elevators, from 1910 to 1934; it was then dredged until 1965. Final

production from the area, in the 1980s until 1994, was by open-pit operations that trucked ore to central washing plants. This gold field which was mined nearly continuously for nearly a century was the most important, spatially continuous placer operation in the Nome mining district.

NovaGold Resources, Inc. has owned most of the ground that comprises this site since 1999 and is evaluating the the placer gold potential of the Nome coastal plain (NovaGold Resources Inc., 2007, Nome). They developed a computer database of the some 8,000 holes drilled by the the Alaska Gold Company and its corporate predecessors over the long life of this major placer district. In addition, NovaGold and Kennecott Exploration have drilled new holes. The objective is to define mineable reserves that could be produced either by open pit methods or perhaps by rehabilitated dredges that were once operated by Alaska Gold in the area.

Production notes:

Production by dredges and surface workings of about $8,000,000 in gold (about 387,000 ounces) from 1904 to 1934 and extensive production after WW II.

Reserves:

The property contains a measured and indicated resource of 1.6 million ounces of gold and an inferred resource of 300,000 ounces of gold (NovaGold Resources, Inc., 2007, Reserve). The gold is in a 194 million tonne resource of sand and gravel which is valuable in its own right.

Site name(s): Ganes Creek

Site type:

ARDF no.: OP018

Latitude: **Quadrangle:**

Longitude:

Location description and accuracy:

The mouth of Ganes Creek is about 5 miles southeast of the town of Ophir. Most of Ganes Creek has been mined to the mouth of Spalding Creek, about 13 miles upstream. About half of the creek is in the Ophir quadrangle and half in the Iditarod quadrangle. Much of the information that is available on the placers on Ganes Creek cannot be assigned to a quadrangle and most of the mining took place in the Iditarod quadrangle. The information that was previously in this record has been integrated into a single record (ID022) sited on Ganes Creek in the Iditarod quadrangle near the mouth of Six Gulch where the Discovery claim was located.

Last report date: 2012-04-01

Site name(s): Porphyry Knob

Site type: Prospect

ARDF no.: OP031

Latitude: 63.5394 **Quadrangle:** OP C-1

Longitude: 156.0254

Location description and accuracy:

The Porphyry Knob prospect is on a prominent 1,800-foot hill, informally called Porphyry Knob, near the divide between Cripple Creek and Colorado Creek. It is about 0.4 mile west of the center of section 32, T. 22 S., R. 15 E., Kateel River Meridian. The location is accurate.

Commodities:

Main: Ag, Au

Other:

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

The rocks in the vicinity of the Porphyry Knob prospect consist of highly altered, intermediate to mafic, volcanic, volcaniclastic, and flow-layered rocks interbedded with black shale, graywacke, and minor conglomerate of the Cretaceous Kuskokwim Group (McGinnis and others, 1997). In the Colorado Creek area, high-angle, northeast-trending faults are cut by later, northwest-trending faults.

The rocks at the Porphyry Knob prospect consist of a gently-dipping sequence of intermediate to mafic volcanic, volcaniclastic, and marine sedimentary rocks. What is usually called dacite porphyry is an important hostrock, but petrographic work by Placer Dome Exploration demonstrates that the light-colored, porphyritic rocks characteristic of this prospect are in fact mostly altered andesite and basalt despite their leucocratic appearance in hand specimen (McGinnis and others, 1997). The altered volcanic rocks contain abundant disseminated pyrite and arsenopyrite and are cut by quartz and limonite veins up to 2 centimeters thick. The dacite porphyry contains veins and veinlets of quartz + adularia + pyrite +/- apatite +/- ankerite +/- calcite. The andesite contains veins and veinlets of quartz +/- albite + ankerite +/- calcite + pyrite + arsenopyrite (McGinnis and others, 1997). Fine native gold can be panned from soil on the southeast margin of the prospect area (Avalon Development, 1998).

Placer Dome Exploration drilled ten core holes in 1997. The most significant intercept averaged 1.9 grams of gold per ton over 19.2 meters; this included an intercept 2 meters long with 7.5 grams of gold per tonne (McGinnis and others, 1997). The most abundant sulfides in the core are arsenopyrite, chalcopyrite, pyrite, and stibnite (Duncan, 1999). The gold:silver ratio at Porphyry Knob is generally low and ranges from 1:1 to 1:10 (Duncan, 1999). The prospect is marked by soil samples that contained up to 3,610 parts per billion gold, anomalous amounts of arsenic, antimony, and mercury, and minor bismuth (Avalon Development, 1998).

The igneous rocks display intense levels of phyllic, silicic, and carbonate alteration. The sedimentary rocks exhibit local sericitic, silicic, carbonate, hornfels, and skarn alteration (Avalon Development, 1998; Duncan, 1999).

The Porphyry Knob prospect may be part of a gold-bearing, quartz-adularia- type epithermal system (Avalon Development, 1998; Duncan, 1999; Dashevsky, 2000). Also see the Moose Jaw (OP032), and Eldorado Creek (OP033) prospects.

In 2009, TintinaGold Resources Inc. drilled 4 holes on Porphyry Knob (TintinaGold, 2010; Chutas and

others, 2009). At the surface, the rocks on the knob are mainly rhyodacite quartz porphyry surrounded by siltstone and andesite. The sedimentary and volcanic rocks were also intersected at depth in the drill holes and gold veins were intersected in both the porphyry and its host rock. A 111-meter interval in one hole contained 0.64 gram of gold per tonne; this included a 2.3-meter interval that contained 8.28 grams of gold per tonne and a 2-meter interval that contained 6.38 grams of gold per tonne. Another hole nearby intersected 98.4 meters that contained 0.54 grams of gold per tonne; this included 22 meters with 1.01 grams of gold per tonne.

There are six types of veins, at least two of which are gold bearing. The gold-quartz veins are associated with various suites of arsenic, antimony, and mercury minerals. In addition to the veins, the drilling cut significant intercepts of disseminated sulfide mineralization with bulk-tonnage potential. Several styles of alteration were noted in the porphyry, including pervasive sericitization, clay alteration, carbonate alteration, and a later clay-oxide alteration. Pervasive oxidation persists to at least 225 feet below the surface.

Alteration:

The igneous rocks display intense levels of phyllic, silicic, and carbonate alteration. The sedimentary rocks exhibit local sericitic, silicic, carbonate, hornfels, and skarn alteration (Avalon Development, 1998; Duncan, 1999).

Age of mineralization:

Cretaceous or younger. Mineralized sills intrude Cretaceous sedimentary rocks of the Kuskokwim Group.

Generic deposit model:

Deposit model:

Epithermal gold (quartz-adularia) (Cox and Singer, 1986; model 25b, 25c?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25b, 25c?

Production Status: None

Site Status: Active

Workings/exploration:

Gold mineralization was identified on Porphyry Knob by S. Nerod during the 1970s at the Nerod trench in the southern part of the prospect area. In 1994, 1995, and 1996, Ron Rosander, the claim owner, contracted James Barker to evaluate lode sources of placer gold in the Colorado Creek area. Barker collected 254 soil samples, 93 rock samples, and 12 samples of placer gold for scanning-electron microscope and trace element analysis. Barker also conducted geologic mapping and a ground-based magnetometer survey. In 1996, the Alaska Division of Geological and Geophysical Surveys conducted geologic mapping in the Cripple Creek Mountains, and Placer Dome Exploration flew an east-west-oriented aeromagnetic survey over the Cripple Creek Mountains (Avalon Development, 1998).

Placer Dome Exploration drilled 10 core holes totaling 1,372 meters in the Porphyry Knob prospect during 1997, soil sampled over a large grid, and conducted geologic mapping, trenching, and road construction (McGinnis, 1997). Nova Gold explored the Porphyry Knob prospect in 1998 and conducted further geologic mapping, rock sampling, and soil sampling (Avalon Development, 1998). During 1999, Northern Associates, Inc., was contracted by Poisedon Minerals, Ltd. to conduct further soil sampling in the Colorado Creek area, including Porphyry Knob. In 2009, TintinaGold drilled 4 holes on Porphyry Knob and another 8 nearby in the upper basin of Colorado Creek.

Production notes:

None.

Reserves:

None.

Site name(s): Eldorado Basin; Moose Jaw Mountain

Site type: Prospect

ARDF no.: OP034

Latitude: 63.5366 **Quadrangle:** OP C-1

Longitude: 156.006

Location description and accuracy:

The Eldorado Basin prospect is in the headwaters of Eldorado Creek, which flows into Colorado Creek. The center of the activity is at an elevation of about 1,800 feet along the creek but the several exploration efforts cover an area of about a half square mile in the central part of section 32, T. 22 S., R. 15 E. The location is accurate.

Commodities:

Main: Au

Other: As, Cu, Sb

Ore minerals: Arsenopyrite, chalcopyrite, pyrite, pyrrhotite, scorodite, stibnite

Gangue minerals: Actinolite, epidote, quartz

Geologic description:

The rocks in the vicinity of Eldorado Creek consist of intermediate to mafic volcanic and volcaniclastic rocks, and Cretaceous, Kuskokwim Group black shale, limestone, graywacke, and conglomerate; the strata are intruded by Cripple Mountain monzonite (McGinnis and others, 1997; Avalon Development Corp., 1998; Duncan, 1999). The headwaters of Eldorado Creek contain limonite-stained, gossanous breccia (Avalon Development Corp., 1998).

The Eldorado Basin prospect is on a mineralized zone that trends northeast across the headwaters of Eldorado Creek for about 2,200 meters. This zone extends northeast into the Medfra quadrangle and end at Colorado Creek, northeast of the summit of Moose Jaw Mountain. At the Eldorado Basin prospect, the mineralized zone contains scattered, thin veins of quartz and stibnite, arsenopyrite, and quartz, and locally of actinolite, chalcopyrite, or epidote. Soil samples collected in the vicinity contain up to 674 parts per million (ppm) copper, 2,250 parts per billion (ppb) gold, 2,818 ppm arsenic, 945 ppm antimony, and 12 ppm bismuth (Avalon Development Corp., 1998).

The northeast extension of this zone is defined by soil samples on Moose Jaw Mountain. Two mineralized areas have been identified: a NW-SE-trending, 400-meter by 50-meter area; and an adjacent area 1400 meters long by 200 to 400 meters wide. The 1400-meter-long area is open to the south (Duncan, 1999). Soil samples from these areas contained up to 515 ppb gold, 2,770 ppm arsenic, 2,942 ppm antimony, and 9 ppm bismuth (Avalon Development, 1998). Hypabyssal, porphyritic rocks at the top of Moose Jaw Mountain are cut by veins less than 5 centimeters thick of crystalline quartz, stibnite, arsenopyrite, and scorodite (Avalon Development, 1998).

Exploration in the Eldorado Basin includes geologic mapping and sampling by Barker during 1994, 1995, and 1996; soil sampling, rock sampling, and geologic mapping by NovaGold during 1998; and mobile-metallic-ion (MMI) sampling by Poseidon Minerals Ltd. in 1999 (Barker, 1996; Avalon Development Corp., 1998; Duncan, 1999). Also see OP002 and OP031-033 for similar mineralization nearby.

In 2009, TintinaGold Resources Inc. (TintinaGold, 2009; Chutas and others, 2009) drilled 9 holes in the upper basin of Colorado Creek in the general vicinity of the zones of mineralization and anomalies that had previously been identified. The holes were mostly drilled through colluvium along the creek but some were in quartz monzonite, hornfels, rhyodacite quartz porphyry, andesite, and siltstone. Significant pyrrhotite-

rich replacement mineralization was cut in the hornfels as were quartz-carbonate veins in the hornfels, diorite, and andesite dikes. The quartz-carbonate veins included pyrrhotite, chalcopyrite, pyrite, and arsenopyrite. Broad propylitic alteration as well as chlorite, sericite, and carbonate alteration were noted.

Alteration:

Broad propylitic alteration as well as chlorite, sericite, and carbonate alteration.

Age of mineralization:

Cretaceous or younger based on the age of the Kuskokwim Group rocks in which much of the mineralization occurs.

Generic deposit model:

Deposit model:

Epithermal Au? (Cox and Singer, 1986; model 25b, 25c?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25b, 25c?

Production Status: None

Site Status: Active

Site name(s): Unnamed (near mouth of Port Camden)

Site type: Prospect

ARDF no.: PE001

Latitude: 56.80657 **Quadrangle:** PE D-6

Longitude: 133.9509

Location description and accuracy:

This prospect consists of a number of radioactiive occurrences on northeastern Kuiu Island that consist of outcrops of Tertiary sandstone along the shoreline at the end of the peninsula that juts out between the mouth of Kadake Bay and the north end of Port Camden. These are commonly referred to as the Port Camden prospect. The coordinates are approximately at the center of the radioactive occurrences which are localities 7 and 8 of Grybeck, Berg, and Karl (1984). Called the the 'Kadake Bay' occurrence by Still and others (2002).

Commodities:

Main: Th, U

Other: Ce, La

Ore minerals: Pyrite, unidentified radioactive minerals

Gangue minerals: Apatite, magnetite, siderite

Geologic description:

The Tertiary Kootznahoo Formation consists of light brown, poorly sorted, non-marine, dolomitic sandstone that contains clay clasts, carbonized wood fragments, and dolomitic concretions; thin shale layers are in the sandstone (Muffler, 1967). The sandstone ranges from silty, fine-grained and thin-bedded to medium- and coarse-grained; it is partly conglomeratic, and medium- to thick-bedded. Siderite, magnetite, pyrite, and apatite are present in some lithologies. All carbonized wood fragments show radioactivity when tested in place. Instrument readings varied from 2 to 50 times background. One sample gave readings in eU of 1300, plus-or-minus 400 parts per million (ppm) uranium, and gamma eU of 2300, plus-or-minus 700 ppm uranium. Samples from a four-inch-thick bed of fine-grained Tertiary sandstone contained 11 and 12 ppm uranium and up to 30 percent magnetite. (The description is summarized from Eakins, 1975; Dickinson, 1979; Dickinson and Campbell, 1982; Dickinson and Pierson, 1988; and Still and others, 2002).

Still and others (2002) collected several samples of thin, black carbonaceous shale interbeds in the sandstone that gave slightly elevated readings on a Scintillometer; they contained up to 46 ppm uranium, 23 ppm lanthanum, and 41 ppm cerium.

Alteration:

Age of mineralization:

Tertiary or younger based on age of the host rock, the Tertiary Kootznahoo Formation.

Generic deposit model:

Deposit model:

Sandstone uranium (Cox and Singer, 1986; model 30c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

30c

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Block of 30 claims staked in 1976 and active until at least 1981 (U.S. Bureau of Mines, 1980). A few samples were collected and analyzed by the Bureau of Land Management (Still and others, 2002) but there has apparently been little private work done in recent years.

Production notes:

None.

Reserves:

None.

Additional comments:

This area has been selected for transfer to Sealaska and the Kake Tribal Corporations and in 2002 was classified as 'interim conveyed, pending patent'.

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Unnamed (near Gunnuk Creek)

Site type: Prospect

ARDF no.: PE002

Latitude: 56.9886 **Quadrangle:** PE D-6

Longitude: 133.8809

Location description and accuracy:

These claims are on upper Gunnuk Creek on northwestern Kupreanof Island, about three miles northeast of the town of Kake. The site is locality 9 of Grybeck, Berg, and Karl (1984). The location is known only generally and the coordinates are approximately at the center of the claims.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The only information on this prospect is that four lode claims were staked for gold in 1968; apparently they have not been active since (U. S. Bureau of Mines, 1980; Still and others, 2002). Still and others (2002) searched for some sign of these claims and collected 5 stream sediment samples. They found no sign of the claims and the samples were not anomalous.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Only known to be claims for lode gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

The only information on this prospect is that four lode claims were staked for gold in 1968; apparently they have not been active since (U.S. Bureau of Mines, 1980; Still and others, 2002).

Production notes:

No record of production and highly unlikely that there was any.

Reserves:

None.

Site type:

Prospect

ARDF no.: PE005

Latitude: 56.8877 **Quadrangle:** PE D-5

Longitude: 133.3743

Location description and accuracy:

The Northern Copper prospect is at an elevation of about 1300 feet on the southern spur of Kupreanof Island. It is near the the center of the northern half of section 36, T. 57 S., R. 76 E. The area is heavily wooded and the prospect is is not easy to locate on the ground. Still and others (2002) have published detailed maps of the surface and underground workings.

Commodities:

Main: Cu, Zn

Other:

Ore minerals: Chalcopyrite, magnetite, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

The Northern Copper prospect was first staked in 1900 and had several periods of activity, notably in 1900 and 1901 and between 1918 and 1921. Numerous workings were driven from 1900 to 1921 including a shaft, numerous trenches and open cuts, and three adits that are about 360 feet, 30 feet, and 285 feet long. A road was built part way to the prospect from the head of Duncan Canal and a tram was planned but not built from tidewater to the prospect. It has been active for short periods several times since, notably in 1978 and 1979 when Amoco Minerals Co. staked a large block of claims that covered the area around the Northern Copper prospect, and carried out extensive airborne and ground geophysics, geologic mapping, and soil and stream sediment geochemistry in the area. They also core drilled six holes to test geophysical anomalies near the Northern Copper prospect. There apparently has been no production. The prospect was covered by 4 claims patented in 1907 that were deeded to the Forest Service in 1995 and are now part of the Petersburg Creek-Duncan Salt Chuck Wilderness area. (More detailed information can be found in Wright and Wright (1908), Buddington, (1923); Roehm, 1945 [DGGS IR 195-37]; Twenhofel and others, 1949; Still and others (2002).

The rocks in the older upper workings workings consist of a thick layer of massive greenstone and chlorite schist, locally with garnet and pyroxene (Wright and Wright, 1908; Buddington, 1923; Roehm, 1945 [DGGS IR 195-37]; Twenhofel and others, 1949; Still and others, 2002). Karl and others (1999) consider the rocks to be Devonian in age. The greenstone also has layers or lenses of white crystalline marble. The mineralization consists of massive layers up to several feet thick, patches, and disseminations of sulfides, mainly pyrrhotite, pyrite, chalcopyrite, and minor sphalerite. The sulfide layers are generally oriented parallel to the layering in the greenstone. Still and others (2002) collected 36 samples in the massive greenstone. The highest copper values were 1.7 percent across 1.5 feet, 1.4 percent across 1.8 feet, and 3.5 percent in an outcrop sample. The highest zinc values were 1.2 percent across 3 feet and 2.4 percent across 1.5 feet. The highest silver value was 32.6 parts per million; the highest gold value was 165 parts per billion (ppb). A band of massive sulfides, mainly pyrrhotite, pyrite, and chalcopyrite, 0.2 to 2 feet thick is exposed in the 30-foot adit for about 20 feet. Samples contained up to 12.4 percent copper across 2 feet; the highest gold value was 440 ppb and the highest silver value was 37.7 ppm.

The work in the late 1970s by Amoco Minerals Co. identified a unit of gray argillite under the greenstone. The argillite contains layers 0.2 to 1.7 feet thick of massive pyrrhotite with chalcopyrite and minor sphalerite. Samples contained up to 2.5 percent copper across 1.4 feet; the maximum gold value was 29 ppb, the maximum silver value was 11.5 ppm.

The origin of the deposit is enigmatic. Most likely it is a metamorphosed volcanogenic massive sulfide deposit. But it may be a replacement deposit, or possibly a skarn-type deposit.

Alteration:

Age of mineralization:

Devonian or later based on the age of the host rocks.

Generic deposit model:

Deposit model:

Probably a metamorphosed volcanogenic massive sulfide deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The Northern Copper prospect was first staked in 1900 and had several period of activity, notably in 1900 and 1901 and between 1918 and 1921. Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Taylor Creek

Site type: Prospect

ARDF no.: PE006

Latitude: 56.7937 **Quadrangle:** PE D-5

Longitude: 133.3638

Location description and accuracy:

This is a well known location that is about 1.5 miles upstream from the mouth of Taylor Creek in upper Duncan Canal. It is about 0.4 mile southeast of the center of section 36, T. 59 S., R. 76 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Calcite, dolomite

Geologic description:

The Taylor Creek deposit has been known since 1903 or 1904 (Wright and Wright, 1908; Kerns, 1950) and has been examined numerous times by government and industry. There was considerable activity during the 1940s, mainly restricted to surface sampling and some trenching and pitting (Fowler, 1948 [DGGS IR 195-2]; Fowler, 1948 [DGGS IR 117-5]; Roehm, 1946 [DGGS IR 195-41]; and Roehm, 1946 [DGGS IR 117-4]). The property has been been intermittently active since. Kerns (1950) reported on extensive diamond drilling carried out by the U. S. Bureau of Mines in 1948 and the 14 trenches they dug on several areas of mineralization. In 1997, Kennecott Exploration Company staked a large block of claims that included the deposit.

The deposit consists of Irregular masses and disseminated grains of galena, sphalerite, pyrite, and chalcopyrite in dolomitic limestone (Kerns, 1950). In the best exposures along Taylor Creek, pervasively disseminated pyrite, galena, and sphalerite occur over an area about 3 meters wide by 7 meters long in a brecciated zone. This zone occurs in a thinly laminated to phyllitic, light-gray and white, fine-grained dolomitic marble which overlies green crenulated muscovite-chlorite-calcite schist. The mineralization persists for approximately 100 m along the southwest bank of Taylor Creek. Maximum assay values in drill cores and outcrop samples collected by Kerns (1950) were 4.3 percent zinc, 0.95 percent lead, and 1.2 ounces of silver per ton. Several origins for the deposit has been suggested. Newer work suggests that the deposit is certainly spatially and possibly genetically associated with the Duncan Canal-Zarembo belt of Triassic massive sulfide mineralization defined by Berg and Grybeck (1980), and Berg (1981). Recent geologic mapping by Karl and others (1999) indicate that the rocks at Taylor Creek are part of the Triassic Hyd Group.

Still and others (2002) briefly examined the deposit and collected several samples. The best were: 1) a sample across 0.7 feet that contained 25.9 parts per million (ppm) silver, 7.72 percent lead, and 6.9 percent zinc; 2) a select sample that contained more than 500 ppm silver, 7,217 ppm lead, and 2.1 percent zinc, and 3) a grab sample of gossan that contained 903 parts per billion (ppb) gold, 160 ppm silver, 9.69 percent lead, and 3.0 percent zinc.

Alteration:

Age of mineralization:

Triassic of younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Probably a (remobilized?) volcanogenic massive sulfide deposit based on a spatial relationship to other massive sulfide deposits in the Duncan-Zarembo belt of mineralization defined by Berg and Grybeck, 1980.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The Taylor Creek deposit has been known since 1903 or 1904 (Wright and Wright, 1908; Kerns, 1950) and has been examined numerous times by government and industry. Considerable activity during the 1940s, mainly restricted to surface sampling and some trenching and pitting (Fowler, 1948 [DGGS IR 195-2]; Fowler, 1948 [DGGS IR 117-5]; Roehm, 1946 [DGGS IR 195-41]; and Roehm, 1946 [DGGS IR 117-4]). The property has been been intermittently active since. Kerns (1950) reported on extensive diamond drilling carried out by the U.S. Bureau of Mines in 1948 and the 14 trenches they dug on several areas of mineralization. In 1997, Kennecott Exploration Co. staked a large block of claims that included the deposit.

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Unnamed (near Towers Arm)

Site type: Prospects

ARDF no.: PE007

Latitude: 56.8397 **Quadrangle:** PE D-5

Longitude: 133.3717

Location description and accuracy:

This site is approximately at the center of a large block of at least 492 claims that cover more than 30 square miles around upper Towers Arm and North Arm of Duncan Canal. It is locality 14 of Grybeck, Berg, and Karl (1984). This early ARDF record covers an area where more detailed information has subsequently become available on several sites drilled by the company who staked the block of claims. This information can be found in records PE005, PE082, PE087.

Commodities:

Main: Cu

Other:

Ore minerals: Chalcopyrite

Gangue minerals:

Geologic description:

Numerous diamond drill holes were scattered widely on the claim block (which includes the Northern Copper prospect, PE005) in 1978 and 1979 by AMOCO Minerals from a camp located on the southern end of the peninsula between Towers Arm and the North Arm of Duncan Canal. The target of the exploration was massive-sulfide, base-metal deposits and the drilling was specifically directed to test airborne geophysical anomalies. Most if not nearly all of the holes did not intercept significant metal values and only chalcopyrite in minor amounts was found. The geophysical anomalies largely proved to be associated with graphitic layers (AMOCO Minerals staff, oral communication, 1979).

This early ARDF record covers an area where more detailed information has become available on several sites drilled by the company who staked the block of claims. This information can be found in records PE005, PE091, and PE095. Recent mapping by Karl and others (1999) indicates that some of the area probably includes Triassic Hyd Group rocks, a unit that is commonly associated with volcanogenic massive sulfide deposits in the Duncan Canal area.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Unclear if significant mineralization was ever found.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Numerous diamond drill holes were drilled widely on this claim block in 1978 and 1979 by AMOCO Minerals from a camp located on the southern end of the peninsula between Towers Arm and the North Arm of Duncan Canal. The target of the exploration was massive-sulfide, base-metal deposits and the drilling was specifically directed to test airborne geophysical anomalies. Most if not all of the holes were devoid of significant metal values and the geophysical anomalies largely proved to be associated with graphitic layers (AMOCO Minerals staff, oral communication, 1979).

Production notes:

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Ironton Group

Site type: Prospect

ARDF no.: PE008

Latitude: 56.8261 **Quadrangle:** PE D-5

Longitude: 133.3563

Location description and accuracy:

Roehm's (1946) original description was not entirely clear but his description indicates that the Ironton Group consisted of five claims that were staked along the shoreline of upper half of Tower Arm, probably on the west shore and likely in section 19 or 30, T. 58 S., R. 76 E. Still and others (2002) found workings that are probably this prospect on the west shore about 1 to 1.5 miles from the end of Tower Arm; this would place it in section 19. The coordinate reflect their location.

Commodities:

Main: Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

Roehm (1945 [IR 195-41]) describes the prospects as a zone of mineralized schist that outcrops at high tide. Pyrite is disseminated and in thin seams in the schist. Small specks of sphalerite and galena occur in some of the thicker seams.

Recent geologic mapping by Karl and others (1999) indicates that the rocks on the west side of Tower Arm are mainly part of the Triassic Hyd Group that hosts volcanogenic massive-sulfide deposits in the region. Still and others (2002) located a few cuts, a short adit, and a trench about 1 to 1.5 miles from the head of Towers Arm that are probably at the Ironton Group. The rocks in the vicinity are interbedded greenstone, greenstone schist, quartz-calcite-chlorite schist, sericite schist, and black slate. The rocks commonly contain 3 to 15 percent pyrite but Still and others (2002) did not mention any other sulfides. They collected 10 samples whose metal content was barely above background or background.

Alteration:

Age of mineralization:

Triassic?

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

A few cuts, a short adit, and a trench that probably date to before 1945.

Production notes:

None.

Reserves:

None.

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Silver Star; Silver King

Site type: Prospect

ARDF no.: PE009

Latitude: 56.8485 **Quadrangle:** PE D-4

Longitude: 133.2638

Location description and accuracy:

This prospect is about 1.6 miles west-southwest of Duncan Peak at an elevation of about 400 feet. It is about 0.5 south-southeast of the center of section 10, T. 58 S., R. 77 E.

There is some confusion in the old literature about the location and geology of two prospects in the area. For example, Cobb (1972 and 1978) or Berg and Cobb (1967), and an earlier generation of ARDF almost certainly combine two different prospects on the west side of Portage Mountain. Still and others (2002) spent considerable time in the field and library trying to decipher their locations and descriptions; this record is based on their location for the Silver Star prospect. The other prospect--XXX PE New A1028--which is about 2 miles to the north-northeast is a different type of deposit.

Commodities:

Main: Cu

Other: Pd, Pt

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The rocks in the vicinity of this prospect are mafic intrusions of late Cretaceous age (Brew and others, 1984). Between an elevation of 360 and 480 feet along a creek, there are outcrops of hornblendite and hornblende diorite that were examined by Still and others (2002). Disseminated pyrrhotite, pyrite, and chalcopyrite are common and there are veinlets up to 1 inch thick in the hornblendite with pyrite and pyrrhotite. Copper staining is locally prominent. Still and others (2002) took 17 samples. The maximum copper content was 4,666 parts per million but most samples contained much less. The highest platinum value was 39 parts per billion (ppb) and the highest palladium value was was 59 ppb; all other metals were in the background range. Buddington (1923) reports that the only workings were several cuts. Still and others (2002) suggest that the prospect is a magmatic segregation deposit.

Alteration:

Age of mineralization:

Late Cretaceous or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Magmatic segregation with copper?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The only workings were several open cuts.

Production notes:

None.

Reserves:

None.

Additional comments:

This prospect is now in the Petersburg Creek-Duncan Salt Chuck Wilderness, which is closed to mineral exploration and mining.

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Unnamed (near Kane Peak)

Site type: Occurrences

ARDF no.: PE010

Latitude: 56.9838 **Quadrangle:** PE D-4

Longitude: 133.0989

Location description and accuracy:

This well known mafic-ultramafic body is about 13 miles north-northwest of Petersburg. The body is a slightly elongate pluton about two and a half square miles in area that extends from just east of Kane Peak northeast to exposures for about a mile along the shoreline southeast of Cape Strait. The coordinates are approximately at the center of the body. This site is locality 16 and 17 of Grybeck, Berg, and Karl (1984). It is commonly informally referred to as the Kane Peak deposit or the Kane Peak ultramafic complex.

Commodities:

Main: Cr, Cu, Fe, Pt-group

Other:

Ore minerals: Chalcopyrite, chromite, magnetite, pentlandite, pyrrhotite

Gangue minerals:

Geologic description:

Kane Peak is a classic 'zoned' or Alaska-type mafic-ultramafic complex with a dunite-wehrlite (olivine-clinopyroxenite peridotite) core bordered by a hornblendite shell about 300 feet thick. (The foregoing description is based mainly on Himmelberg and Loney, 1995; but also see Walton, 1951; Taylor, 1967; and Taylor and Noble, 1969, for earlier interpretations of this and other Alaska-type bodies in southeastern Alaska.) About 80% of the body is dunite and wehrlite that grade into each other. Small-scale cumulus layering is present but the body is poorly exposed and its overall structure is uncertain. The body probably has steeply dipping contacts and extends under Frederick Sound to the northeast for a half mile or more (Brew, 1997). The mafic-ultramafic complex intrudes metamorphosed pelite of the Jurassic or Cretaceous Semour Canal Formation and is bordered to the northwest and and south by Cretaceous migmatite. The Kane Peak complex has been dated at 93.4 to 102.0 Ma by K-Ar methods.

Pyrrhotite, pentlandite, and chalcopyrite are sporadically disseminated through the peridotite; sparse disseminated chromite occurs widely in the dunite; and the hornblendite locally contains titaniferous magnetite. Himmelberg and Loney (1995) provide trace metal content of several metals including Co, Ni, and Cr.

Still and others (2002) collected samples at several localities. Analyses of samples collected along the shoreline showed nothing of interest. A stream-sediment sample from a stream on the northeast side of Kane Peak contained 124 parts per billion (ppb) platinum, and two samples from a malachite-stained outcrop on the south-facing slope of the east ridge contained 1,954 and 2,2078 parts per million copper, 113 and 78 ppb platinum, and 180 and 83 ppb palladium.

Alteration:

Age of mineralization:

Late to Early Cretaceous based on 93.4 to 102.0 Ma, K-Ar age dates (Himmelberg and Loney, 1995).

Generic deposit model:

Deposit model:

Zoned or Alaska-type ultramafic complex with disseminated, magmatic sulfides and oxides.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

In 1960, two claims were staked for iron on the body along the coast near Cape Strait, probably on magnetite-bearing hornblendite that crops out there (U.S. Bureau of Mines, 1980). In addition, the Kane Peak body has repeatedly been visited by geologists over the years as a potential site for Fe, Cu, and Pt-group deposits and for its scientific value. With the possible exception of the claims staked for Fe along Frederick Sound, there is little evidence at present (2007) of anything close to an economic deposit in the complex.

Production notes:

None.

Reserves:

None.

Last report date: 2007-04-08

Site name(s): Unnamed (on Wrangell Narrows)

Site type: Prospect

ARDF no.: PE013

Latitude: 56.5485 **Quadrangle:** PE C-3

Longitude: 132.9598

Location description and accuracy:

The only description of this prospect (Roehm, 1945) places it on the east side of Wrangell Narrows near December Point, about 2.8 miles north of Point Alexander and 1.2 mile north of Midway Rock. The coordinates reflect that position which is along the south edge of section 29, T. 61 S, R. 80 E., near the shoreline. The prospect was said to extend up from the shoreline into the forest. However, it could not be found in a recent search (Still and others, 2002).

Commodities:

Main: Ag, Au, Sb

Other: As, Hg

Ore minerals: Pyrite, stibnite

Gangue minerals:

Geologic description:

The only description of this prospect is by Roehm (1945 [IR 195-37]). Needle-like crystals of stibnite and pyrite occur along fractures in reddish-colored granite. One sample assayed 13.9 percent antimony and traces of gold and silver . The only working was a 25-foot trench. Karl and others (1999) map the rocks in the area as Cretaceous porphyritic tonalite with biotite, hornblende, epidote, and garnet.

Still and others (2002 could not locate this prospect but they did sample fractured reddish intrusive rock near December Point . Their samples contained up to 141 parts per million (ppm) antimony, 1,420 ppm arsenic, and 18.68 ppm mercury.

Alteration:

Age of mineralization:

Cretaceous or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Stibnite along fractures.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

This small prospect with a 25-foot trench was described in 1945 but could be found in the late 1990s.

Production notes:

None.

Reserves:

None.

Site name(s): Cascade

Site type: Mine

ARDF no.: PE014

Latitude: 56.9897 **Quadrangle:** PE D-3

Longitude: 132.7938

Location description and accuracy:

This small mine can be been in outcrop just above the high-tide level on the eastern shoreline of Thomas Bay. It is near an unnamed point about 0.6 mile south of Spray Island in the NW1/4, section 25, T. 56 S., R. 79 E. The location is accurate.

Commodities:

Main: Ag, Au

Other: As, Cu, Pb

Ore minerals: Arsenopyrite, chalcopyrite, galena, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

Buddington (1923) described this deposit as a quartz vein that can be traced for about 250 feet. It consists of a sheeted zone at least 12 feet thick; about half of the sheeted zone is milky-white quartz and half schist. The property was active intermittently until at least into the 1940s. In 1949, 6 tons of ore was mined that produced 6 ounces of gold and 1 ounce of silver. The quartz veins contain sparse, disseminated pyrite, arsenopyrite, chalcopyrite, pyrrhotite, and galena; specimens of arsenopyrite several inches across are common on the dump. The workings are less than 200 feet from the shore line and include two short adits, one 21 feet long and the other 71 feet long, and a trench. The rocks in the area consist of biotite schist and gneiss, gneissic granodiorite, and quartz monzodiorite (Brew and others, 1984).

Maas and Redman (1989) mapped and sampled the workings. One of their samples of a 4-inch-wide quartz vein contained 6,975 parts per billion (ppb) gold; their other 7 samples averaged 371 ppb gold. Still and others (2002) examined the property in 1998. They sampled the mineralized zones which are 3.5 to 6 feet thick. Their highest grade sample across 3.5 feet of vein contained 589 ppb gold but the average of their 8 samples was 137 ppb gold.

Alteration:

Unknown or minor.

Age of mineralization:

Cretaceous or younger based on the age of the metamorphic host rock.

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz vein (Cox and Singer, 1986; model 36a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

There was some minor development on the prospect prior to 1921. The property was active intermittently until at least into the 1940s. A claim was active as recently as 1979.

Production notes:

In 1949, 6 tons of ore was mined that produced 6 ounces of gold and 1 ounce of silver.

Reserves:

None.

Site name(s): Buck Bar

Site type: Mines(?)

ARDF no.: PE017

Latitude: 56.7134 **Quadrangle:** PE C-1

Longitude: 132.0848

Location description and accuracy:

Fine placer gold was found on bars of the Stikine River at Buck Bar in the 1860's when Russia still owned Alaska and the Hudson Bay Company maintained a trading post at Wrangell near the mouth of the Stikine River (Blake, 1868; Spurr, 1898). However, there is no record of placer claims on the Stikine, no record of placer mining on the Stikine since at least 1900, and the location of Buck Bar is uncertain. This location follows Still and others (2002) who place Buck Bar between Shakes Slough and the mouth of the Ketili River in about the middle of section 31, T. 59 S., R.85 E.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Fine placer gold was mined at Buck Bar on the Stikine River in the 1860s when Russia still owned Alaska and the Hudson Bay Company maintained a trading post at Wrangell near the mouth of the Stikine River (Blake, 1860, Spurr, 1898). The location of Buck Bar is now uncertain but Still and others (2002) think it most likely that it is between the mouth of Shakes Slough and the mouth of the Ketili River. There is no record of more recent mining and the amount of gold that was mined in the 1860s was probably small. However, Brooks (1923) noted that this must have been the first gold mined in Alaska.

Alteration:

Age of mineralization:

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer gold (Cox and Singer, 1986; model 39a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Fine placer gold was found on bars of the Stikine River in the 1860s during early exploration for gold in Alaska. There is no record of claims of significant gold placers in the Stikine or its tributaries since before the turn of the century. The diggings are probably best thought of as prospects rather than mines even if small amounts of gold were produced.

Production notes:

Probably trivial.

Reserves:

None.

Additional comments:

In view of the many generations of prospectors and others who for more than 100 years have passed along the natural corridor of the Stikine River into the interior of Canada without any further mention of placer gold on the Stikine River, this site should now be considered as little more than a historic artifact.

Site type: Occurrence

ARDF no.: PE019

Latitude: 56.5301 **Quadrangle:** PE C-5

Longitude: 133.5211

Location description and accuracy:

This occurrence is near the center of a large, vivid yellow-orange altered zone on southern Kupreanof Island that extends for up to a mile or more in all directions from the coordinates given above and can be seen for miles from the air. The site is plotted about 2 miles north of the center of Kushneahin Lake at the southeast corner of section 34, T. 61 S., R. 76 E.

Commodities:

Main: Cu?, Mo?, Zn

Other:

Ore minerals: Pyrite

Gangue minerals:

Geologic description:

Extensive vivid exposures of yellow-orange altered rhyolite, rhyolite tuff, and rhyolitic glass of Quaternary or Tertiary age crop out in many of the creeks and cut banks in the vicinity (Brew and others, 1984; Brew, 1997). Several exposures were briefly examined by the USGS in 1982 and 1996. Disseminated pyrite is present locally but there are no obvious signs of copper, molybdenum, or other ore minerals. The rocks are pervasively altered and locally brecciated. Several grab samples of the more-altered rhyolite and associated rocks show 5 parts per million (ppm) or less copper and molybdenum. The pyrite and host rocks are part of a large felsic igneous system; possibly a rhyolite dome. The surrounding area is heavily wooded but aerial reconnaissance shows widespread exposures of similar orange and yellow, iron-stained rocks over an area at least several miles in diameter. Although no obvious mineralization has been found, the site is included because this altered zone is so large, so prominent, and it indicates the presence of a very large felsic hydrothermal system. Resource Associates of Alaska (RAA) staked a hundred claims here in 1973, referring to it as the TB block. Several exposures were briefly examined by Still and others (2002) in the late 1990s. A grab sample contained only 425 ppm zinc.

Alteration:

Pyritization, silicification, and kaolinization(?).

Age of mineralization:

Quaternary or Tertiary.

Generic deposit model:

Deposit model:

Highly altered felsic igneous system.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

None other than probable examination by various industry and government geologists who have worked in the area.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (near Totem Bay)

Site type: Occurrences

ARDF no.: PE021

Latitude: 56.4797 **Quadrangle:** PE B-5

Longitude: 133.4419

Location description and accuracy:

The coordinates are at the approximate center of a block of nine lode claims staked on southern Kupreanof Island in 1955. The center of the claims is in about the middle of the east side of section 19, T. 62 S., R. 77 E.

Commodities:

Main: Th, U

Other: Ce, La, Nd

Ore minerals:

Gangue minerals:

Geologic description:

In 1952, Houston and others (1958) searched the Totem Bay area for radioactive veins similar to those found to the south across Sumner Strait on southern Prince of Wales Island. He found no indications of them. However claims were staked here for radioactives in 1955 under the name Monongehela. Rocks in the vicinity consist of a thick sequence of Quaternary or Tertiary rhyolite (Brew, 1997 [OF 97-156-G]). Still and others (2002) briefly examined the area with a scintillometer and found a 3-foot-by-3-foot zone that was approximately 60 percent above background. A sample contained 7 parts per million (ppm) uranium, 17 ppm thorium, 43 ppm neodymium, 38 ppm lanthanum, and 110 ppm cerium.

Alteration:

Age of mineralization:

Tertiary or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Nine lode claims staked for radioactive minerals in 1955; apparently there has been no work since on these claims other than a brief examination by government geologists in the late 1990s.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (north of mouth of Castle River)

Site type: Occurrence

ARDF no.: PE024

Latitude: 56.6664 **Quadrangle:** PE C-4

Longitude: 133.2596

Location description and accuracy:

The coordinates are at the center of an area of mineralized outcrops that occur discontinuously just above the high tide line for about a half mile along the west shore of the large shallow bay at the mouth of the Castle River. The site is locality 29 of Grybeck, Berg, and Karl (1984) and this may be a continuation of the mineral occurrence at PE025 just to the northeast.

Commodities:

Main: Ag, Ba, Cu, Pb, Zn

Other:

Ore minerals: Pyrite, sphalerite

Gangue minerals:

Geologic description:

Outcrops of phyllitic, light greenish gray to cream, felsic metatuff intercalated with muscovite-rich siliceous phyllite occur discontinuously just above the high tide line for about a half mile along the edge of a large shallow bay. The metatuff locally contains massive-sulfide layers up to 6 feet thick with abundant pyrite and sparse sphalerite(?) (Grybeck, Karl, and Berg, 1984). Grab samples of the massive sulfide layers and felsic metatuff show up to 700 parts per million (ppm) lead, 350 ppm zinc, 10 ppm silver, and 2,000 ppm barium. These outcrops may be a continuation of the mineralized occurrence at PE025 just to the northeast. This is probably the locality noted by Buddington (1923) that he described as a pyrite layer about 4 feet wide exposed for 50 feet. Recent mapping by Karl and others (1999) indicates that these outcrops are part of the Hyd Group of Triassic age.

This occurrence was covered by a large block of claims staked by Pacific Alaska Resources Co in the late 1980s and early 1990s; the company planned to drill to test several geochemical anomalies in copper, zinc, and silver but apparently did not follow through. Still and others (2002) sampled several of these lenses; their samples contained up to 31.8 ppm silver, 1,304 ppm lead, 1.7 percent zinc, and 1,268 ppm arsenic.

Alteration:

Age of mineralization:

Late Triassic based on the age of the host rock.

Generic deposit model:

Deposit model:

Kuroko massive-sulfide deposit model (Cox and Singer, 1986, model 28a); alternately a Sierran Kuroko deposit (Bliss, 1992; 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
28a or 28a.1

Production Status: None

Site Status: Active

Workings/exploration:
In 1979, nine lode claims were staked in the area that probably covered this deposit. By 1995, a considerable block of ground several square miles in area was staked on and northwest of this site and PE025. Informal discussions with industry geologists who worked in the area indicate that they found several to numerous additional occurrences of similar deposits on these claims (D.J. Grybeck, oral communication, 1996). An aerial examination of the area in 1996 indicated no obvious signs of surface exploration. In 1998, there was renewed interest in the area encouraged by the geophysical surveys the State of Alaska had flown over the area.

Production notes:
None.

Reserves:
None.

Last report date: 2007-04-08

Site name(s): Halobia

Site type: Prospect

ARDF no.: PE025

Latitude: 56.672 **Quadrangle:** PE C-4

Longitude: 133.2608

Location description and accuracy:

The prospect is in the intertidal zone at the mouth of a small creek that enters the northern side of the large shallow bay at the mouth of the Castle River; the site is in the NE1/4 section 15, T. 60 S., R. 77E. The locality as seen in 1996 was about 250 feet downstream from a log jam at the high tide mark on the creek. Massive sulfide lenses occur in the center of the creek bed but they are not conspicuous. The location is accurate.

Commodities:

Main: Ag, Pb, Zn

Other: As, barite, Cu

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

Thin lenses of massive sulfides occur in siliceous phyllite that is intercalated with fossiliferous, Upper Triassic black carbonaceous phyllite; garnet-bearing limestone; siltstone; and silvery dark gray muscovite- and quartz-rich phyllite (Berg and Grybeck, 1980; Berg, 1981). The carbonaceous phyllite contains abundant pyrite. The massive sulfide lenses are in several zones 10-12 feet wide and 80-100 feet long in the creek bed in the intertidal zone. Individual lenses within these zones are up to 1 foot wide and 3 feet long; they contain abundant pyrite and up to 5 percent galena and sphalerite. Analyses of grab samples show up to 100 parts per million (ppm) copper, 100 ppm silver, and 1000 ppm arsenic. Several examples of the fossil Halobia collected in rocks interbedded with the sulfide lenses at the deposit unambiguously date the deposit as Late Triassic. Recent mapping by Karl and others (1999) include the rocks at this prospect in the Triassic Hyd Group, which is extensive in the area and hosts several volcanogenic massive sulfide deposits. The deposit is part of the Triassic Duncan Canal-Zarembo Island belt of dismembered, volcanogenic massive-sulfide deposits described by Berg and Grybeck (1980) and Berg (1981). Also see PE024 which is similar in origin and probably a continuation of this deposit.

Pacific Alaska Resources explored in the area in the 1980s and 1990s. They planned to drill several geochemical anomalies in copper, lead, and zinc, about one to one and one-half miles to the west of this occurrence at an elevation of 300 to 700 feet. They apparently did not follow through. Still and others (2002) who mention this work, say that the area to be drilled was east of the Halobia occurrence but that is unlikely as it would be near the shoreline or under Duncan Canal. Bittenbender and others (2000) describe several geochemical anomalies in this area. Still and others (2002) sampled the Halobia occurrence; their samples contained up to 30.8 ppm silver, 5,400 ppm lead, and 5.4 percent zinc.

Alteration:

Age of mineralization:

Unambiguously Late Triassic based on the age of fossils at the site.

Generic deposit model:

Deposit model:

Kuroko massive-sulfide deposit model (Cox and Singer, 1986, model 28a); alternately a Sierran Kuroko deposit (Bliss, 1992; 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Active

Workings/exploration:

Discovered by the U.S. Geological Survey in 1979 (Berg and Grybeck, 1980). Nine lode claims were staked on the deposit in 1979; by 1995, a considerable block of ground several square miles in area was staked on and northwest of the original discovery (Department of Natural Resources unpublished Kardex mining claim information system). Informal discussions with industry geologists who worked in the area indicate that they have identified several to numerous additional occurrences of similar deposits on these claims (D.J. Grybeck, oral communications, 1996). Sampled by Still and others (2002).

Production notes:

None.

Reserves:

None.

Site name(s): Castle Island

Site type: Mine

ARDF no.: PE026

Latitude: 56.6521 **Quadrangle:** PE C-4

Longitude: 133.1667

Location description and accuracy:

The location of the Castle Island mine is well known. However, the original outcrop of the deposit was little more than a large rock at the northeast end of 'Castle Island'; that original outcrop has now been completely mined out to below sea level. Note the mine which is almost universally called 'Castle Island' is not identified as such on the USGS 1:63,360-scale topographic map and none of the Castle Islands is specifically labeled as Castle Island on the current (2007) maps. The island that is the site of the mine and is described here is an islet about about 650 yards long, located about 1,500 feet south of Big Castle Island, which is shown on current topographic maps.

Commodities:

Main: Barite

Other: Ag, Cu, Pb, Sn

Ore minerals: Barite, bornite, chalcopyrite, galena, pyrite, pyrrhotite, sphalerite, tetrahedrite

Gangue minerals:

Geologic description:

The Castle Island barite deposit was known before World War I (Burchard, 1914; Buddington, 1923; Buddington, 1925; Buddington and Chapin, 1929) and was studied several times subsequently (Williams and Decker, 1932 (DGGS IR 117-1); Race, 1963 (DGGS PE 117-9). It was mined nearly continuously from 1966 to 1980 by a succession of companies: Alaska Barite Co from 1966 to 1969; Inlet Oil from from to 1975; and Chromalloy America from 1975 to 1980. The mine closed in 1980 and all the mining equipment and buildings were removed from the island. The original deposit was a small outcrop at the northeast end of the island that was entirely removed by mining. Much of the mining was done underwater from an offshore barge that used a dragline to recover ore fragmented by submarine blasting. The total production was about three-quarters of a million tons of barite, almost all of which was mined from 1968 to 1980 as direct shipping ore.

The ore body consisted of a lenticular, massive barite lens about 300 feet long and up to 200 feet thick that was mined to a depth of about 130 feet below sea level. [This description of the mineralization is synthesized from Burchard (1914); Buddington (1923); Buddington (1925); unpublished written and oral data from David Carnes, U. S. Bureau of Mines; unpublished field notes, analyses, and laboratory studies by the D.J. Grybeck; analyses summarized in Grybeck, Berg, and Karl (1984); and Still and others (2002).] The exact stratigraphic relations are unclear because most of the deposit was under salt water. However, examination of unpublished drilling data and cross sections maintained by the mine indicates that the barite lens probably occurred along the trough of a symmetrical syncline that trends about N30W with limbs that dip about 60NE. The hanging wall was limestone and gray schist; the footwall was graphitic calcareous schist. The drilling also indicated a considerable tonnage of lower grade barite interbedded with 'gray schist,' 'chert,' and 'graphitic schists,' and the possibility of at least one more high-grade barite lens offshore. Mine-run material was massive, white to light gray, almost pure barite that almost invariably contained a percent or so of sulfides as tiny disseminated grains. Assays of the massive barite indicate that it typically contained about 0.5 to 2 percent zinc, about 0.5 percent lead, a small amount of copper, and about 1 ounce of silver per

ton. Under the reflecting microscope, the sulfides are sphalerite, galena, pyrite, pyrrhotite, bornite, tetrahedrite-tennantite, and chalcopyrite, together with minor amounts of other unidentified ore minerals, all as tiny, generally equant grains (D.J. Grybeck, personal observation, 1996). Examination of waste dumps provide many samples that show all transitions from massive barite to layered pyrite(-sphalerite-quartz)-barite rock with the other sulfides noted previously that are disseminated though the rock in minor amount. The association of barite, layered sulfide-barite rocks, schistose metafelsite(?), and black carbonaceous, calcareous phyllite at the mine indicate that it is part of the Triassic Duncan Canal-Zarembo Canal belt of dismembered, volcanogenic massive-sulfide deposits described by Berg and Grybeck (1980) and Berg (1981).

The Castle Islands largely, and the island on which the barite mine occurs specifically, consist largely of Upper Triassic Hyd Group rocks which are dominantly felsic and intermediate volcanic flows and breccia, limestone and argillite. However, some of the islands of the Castle Islands also consist of Devonian limestone and Quaternary basalt whose relationship to the Hyd Group rocks is probably structurally complicated and largely hidden under water (Brew, 1997; Karl and others, 1999).

Alteration:

Age of mineralization:

Late Triassic based on the age of the host rock.

Generic deposit model:

Deposit model:

Barite facies of a Kuroko massive-sulfide model (Cox and Singer, 1986; model 28a); alternatively a barite facies of a Sierran Kuroko model (Bliss, 1992; model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: Yes; medium

Site Status: Inactive

Workings/exploration:

The Castle Island deposit was known before World War I. It was mined nearly continuously from 1966 to 1980 by a succession of companies: Alaska Barite Co from 1966 to 1969; Inlet Oil from from to 1975; and by Chromalloy America from 1975 to 1980. The mine closed in 1980 and all the mining equipment and buildings were removed from the island. The original deposit was a small outcrop at the northeast end of the island that was entirely removed by mining. Much of the mining was then done underwater from an offshore barge that used a dragline to recover ore that was fragmented by submarine blasting. Essentially, the mine was operated as a submarine open pit from a camp on the island. An earlier phase of drilling and sampling on the original barite outcrop that ultimately resulted in mining the deposit was documented by Race (1963 [PE 117-9]) and Williams and Decker (1932 [IR 117-1]).

Production notes:

The exact production was not systematically reported but total production was about three-quarters of a million tons of barite, most of which was mined from 1968 to 1980 as direct shipping ore. Swainbank and others (1995) indicate that the total production was 776,390 tonnes (865,000 tons) of raw and refined barite produced from 1963 to 1980. Still and others (2002) say that Alaska Barite Company produced 234,000 tons of barite by surface mining from 1966 to 1969 and that Inlet Oil and Chromalloy America produced another 552,888 tons of barite from 1970 to 1980 from the submarine portion of the barite lens.

Reserves:

In 1977, Carnes (1980) inferred that the deposit contained 390,000 tons of low-grade barite resources with a grade of 83 percent BaSO4 and 315,000 tons of higher grade barite resources. In 1980, Holdsworth (1980) estimated that the deposit contained 69,600 tons of ore-grade material. (From 1977 to 1980, the mine produced about 35,000 tons of barite.) When it closed, the mine had little if any reserves that could be economically mined with then-current technology (oral and written communication, 1996, from David Carnes, U. S. Bureau of Mines, who was the mining engineer in charge of the mine over most of its life).

Reporter(s): H.C. Berg (Fullerton, California) and D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Helen S

Site type: Mine

ARDF no.: PE028

Latitude: 56.5687 **Quadrangle:** PE C-4

Longitude: 133.0676

Location description and accuracy:

The Helen S Mine is near the northwest corner of Woewodski Island, just inland from the shore and about 100 yards north of the mouth of the creek that drains Harvey Lake. It is in the southwest corner of section 22, T. 61 S., R. R 79 E. The mine is well known and easily accessible. Figure 15 of Still and others is a detailed map of the mine.

Note that there is a massive-sulfide deposit (PE093) that adjoins and/or overlaps the Helen S Mine; it is an entirely entirely different type of deposit and is described separately.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Arsenopyrite, galena, gold, sphalerite

Gangue minerals: Quartz

Geologic description:

The gold-quartz veins of the Helen S mine were discovered in 1902 by a prospector (Wright and Wright, 1908; Buddington, 1923; Still and others, 2002, Roppel, 2005). Later that year, E.N. Harvey, who had taken over the management of the Hattie property (PE032) of the Olympic Mining Company about 2 miles south, largely moved the equipment of the Hattie to the Helen S. There was considerable activity on the Helen S in 1903 and 1904, including the construction of several buildings, setting up a boiler and hoist, sinking two shafts and driving 650 feet of drift out from them. The crew that averaged 31 people. In addition, the 20-stamp mill that was originally meant for the Hattie but had never been set up there was moved to the Helen S. In 1903 and/or 1904, the mill processed an unknown amount of ore that produced about $35,000 (probably mainly if not entirely in gold at $20.67 per ounce). By the end of 1904, however, the mine was in financial difficulties and mining ceased . The Helen S claim was patented in 1910 and Harvey continued to maintain the property as he tried to obtain funds for further work. However, there was little actual mining activity on the property and in 1915, the mine was assigned to a Petersburg bank as a result of a legal judgment against the Olympic Mining Company. The bank soon sold the property and the patented claims have been held since by a succession of private individuals; in 1978 it was sold to a group of residents of Petersburg. More recently, it was examined and sampled by Still and others (2002) as part of a regional mineral assessment by the Bureau of Land Management.

All the early production was from quartz veins of unknown orientation that contained sparse arsenopyrite, pyrite, galena, and sphalerite. There is little outcrop in the immediate vicinity of the workings. Those few and the material on the dumps is black, slate, greenstone, and felsic and intermediate metavolcanic rocks of the Triassic Hyd Group (Brew, 1997; Karl and others, 1999.) Still and others (2002) collected several samples from a 1.5-foot-thick quartz vein that is exposed just below the surface in the shaft about 400 feet north of the old mill site. A grab sample contained 0.328 ounce of gold per ton. Several quartz veins up to 2.3 feet thick are exposed in a small pit behind the cabin near the mouth of the small creek that runs along the west side of the mine. Still and others (2002) collected 6 samples there that contained up to 58 parts per billion gold, 573 parts per million (ppm) copper, and 2,870 ppm zinc.

Note that there is a distinctly different type of deposit, volcanogenic massive sulfides, adjacent to or overlapping the Helen S mine; that deposit is described separately (PE New B1035).

Alteration:

None specifically noted.

Age of mineralization:

The gold-quartz veins are Triassic or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Gold quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The gold-quartz veins of the Helen S mine were discovered in 1902 by a prospector (Wright and Wright, 1908; Buddington, 1923; Still and others, 2002, Roppel, 2005). Later that year, E.N. Harvey, who had taken over the management of the Hattie property (PE032) of the Olympic Mining Company about 2 miles south, largely moved the equipment of the Hattie to the Helen S. There was considerable activity on the Helen S in 1903 and 1904, including the construction of several buildings, setting up a boiler and hoist, sinking two shafts and driving 650 feet of drift out from them. The crew that averaged 31 people. In addition, the 20-stamp mill that was originally meant for the Hattie but had never been set up there was moved to the Helen S. In 1903 and/or 1904, the mill processed an unknown amount of ore that produced about $35,000 (probably mainly if not entirely in gold at $20.67 per ounce). By the end of 1904, however, the mine was in financial difficulties and mining ceased. The Helen S claim was patented in 1910 and Harvey continued to maintain the property as he tried to obtain funds for further work. However, there was little actual mining activity on the property and in 1915, the mine was assigned to a Petersburg bank as a result of a legal judgment against the Olympic Mining Company. The bank soon sold the property and the patented claims have been held since by a succession of private individuals; in 1978 it was sold to a group of residents of Petersburg. More recently, it was examined and sampled by Still and others (2002) as part of a regional mineral assessment by the Bureau of Land Management.

Production notes:

A small amount of ore with a grade of about 0.177 ounce of gold per ton was milled sometime between 1902 and 1915 but total production is uncertain and was probably small (Roehm, 1945). Roehm noted that the ore averaged $3.66 per ton (without specifying the price of gold). Roppel (2005) indicated that the mill processed an unknown amount of ore in 1903 and/or 1904 that produced $35,000 (probably mainly or nearly all in gold at $20.67 per ounce.)

Reserves:

None.

Additional comments:

All the workings are on a patented claim.

Site name(s): Lost Lake

Site type: Prospect

ARDF no.: PE029

Latitude: 56.5734 **Quadrangle:** PE C-4

Longitude: 133.059

Location description and accuracy:

The Lost Lake prospect is on the north bank of the small lake, locally named 'Lost Lake' on northwestern Woewodski Island (lake '175' on the USGS 1:63,360-scale topographic map). The deposit is about 25 feet north of the lake; it extends extends east and west of a small creek that flows to the north from about the center of north shore of the the lake. Drilling pads and landing sites were visible in 1996 at the prospect and there was additional drilling in 2004. The prospect is near the center of section 22, T. 61 S., R. 79 E. The location is known to within 100 yards and easily located.

Commodities:

Main: Ag, Ba, Pb, Zn

Other: Au?

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

This prospect was found in the late 1970s and has been explored or examined by a number of companies since, including Cominco Exploration, Colony Pacific, Amselco, and Kennecott Exploration. In 1996, it was held by Westmin Resources Limited, who had other properties on Woewodski Island. In 2008, the prospect is held by Bravo Ventures Group. The deposit consists of massive sulfide layers that are covered by only a thin layer of vegetation at several outcrops beside the lake. They have been sampled several times in shallow pits but most of the area is covered by muskeg and vegetation. Several drilling sites were obvious at the prospect in 1996 (D. Grybeck, personal observation) and at least 16 holes are said to have been drilled by then. Four more holes were drilled in 2004.

A resistant layer of cream- to light-gray colored schist about 10 feet thick dams in the north side of Lost Lake. The foliation strikes about N 80 E to S 75 E, i.e., roughly parallel to the north side of the lake, and dips about 70-85 S. The schist contains at least two layers of massive sulfides 8 inches to 16 inches thick that consist mainly of sphalerite with moderate amounts of pyrite and sparse galena (D.J. Grybeck, unpublished field notes, 1996). Analyses of a number of samples of similar(?) schist sampled nearly by Newberry and Brew (1989) indicate that: 1) the schist is probably hydrothermally altered basalt, 2) the schist is geochemically analogous to schist at the Greens Creek mine on Admiralty Island, and 3) the deposit is probably Triassic in age.

Still and others (2002) sampled surface exposures of the bands of massive sulfides exposed at the surface. A 4.4-foot chip sample at one outcrop contained 153.8 parts per million (ppm) silver, 5,519 ppm lead, and 11.5 percent zinc. A 7.5-foot sample across another outcrop with two narrow bands of mineralization contained 83.9 ppm silver, 5,180 ppm led, and 4.5 percent zinc. A third outcrop that exposes a 1.1-foot-thick band of pyrite, sphalerite, and galena in schist contained 282 ppm silver, 2.79 percent lead, and 24.15 percent zinc.

Bravo Ventures Group (2008) reported that high grade zinc mineralization was intersected in two of the three holes drilled in 2004. Samples contained up to 70 grams of silver per ton and 13.6 percent zinc across 1.3 meters and 21 grams of silver per ton and 4.5 percent zinc across 5.9 meters.

Westmin Resources (1997) cited a 'geologic reserve' for the Lost Lake deposit as approximately 500,000 tonnes grading 8.1 percent zinc, 0.6 percent lead, and 77.76 grams of silver per ton.

Alteration:

The schist that host the massive sulfide layers is probably hydrothermally altered basalt.

Age of mineralization:

Probably Triassic based on geochemistry of the host rocks (Newberry and Brew, 1989), and the deposit's similarity to other deposits in the Triassic, Duncan Canal-Zarembo belt of massive sulfide deposits defined by Berg and Grybeck (1980) and Berg (1981).

Generic deposit model:

Deposit model:

Barite facies of a Kuroko volcanogenic massive-sulfide model (Cox and Singer, 1986; model 28a). Alternatively a barite facies of a volcanogenic Sierran Kuroko model (Bliss, 1992; model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Active

Workings/exploration:

This prospect was found in the late 1970s and has been explored or examined by a number of companies since, including Cominco Exploration, Colony Pacific, Amselco, and Kennecott Exploration. In 1996, it was held by Westmin Resources Limited, who had other properties on Woewodski Island. In 2008, the prospect is held by Bravo Ventures Group Several drilling sites were obvious at the prospect in 1996 (D. Grybeck, personal observation,) and at least 16 holes are said to have been drilled by then. Four more holes were drilled in 2004. Still and others (2002) sampled surface exposures which expose bands of massive sulfides.

Production notes:

None.

Reserves:

Westmin Resources (1997) cited a 'geologic reserve' for the Lost Lake deposit as approximately 500,000 tonnes grading 8.1 percent zinc, 0.6 percent lead, and 77.76 grams of silver per ton.

Last report date: 2008-03-04

Site name(s): Unnamed (along Harvey Creek)

Site type: Mine

ARDF no.: PE030

Latitude: 56.5664 **Quadrangle:** PE C-4

Longitude: 133.0655

Location description and accuracy:

This small mine on northwestern Woewodski Island is about 900 feet east-southeast of the mouth of the creek that drains Harvey Lake; it is along a trail from saltwater to the Harvey Lake Forest Service cabin. There are several occurrences of mineralization along the creek from about 800 to 2,000 feet above its mouth. The coordinates are at the location of a small mine dump and mill that was active in the 1930s.

Commodities:

Main: Au

Other:

Ore minerals: Arsenopyrite, gold, pyrite

Gangue minerals: Quartz

Geologic description:

The rocks in the area consist of silicified and pyritized phyllite and light greenish gray metatuff (?) that is part of the Triassic Hyd Group (Karl and others, 1999). Still and others (2002), guided by an unpublished 1930s-vintage report found several auriferous quartz stringers along about 800 feet of the creek banks and in nearby outcrops; their samples contained up to 1.89 ounce of gold per ton. There is also a small mill and dump and a small pelton wheel along the creek that probably date to the 1930s. Grab samples of the dump that they thought probably represented the mill feed, contained 5,482 to 7,944 parts per billion. Two shallow holes that were drilled near the dump in 1977 to test the mine did not reveal significant mineralization.

Alteration:

The Triassic phyllite and metatuff that host the deposit are silicified and pyritized in the area.

Age of mineralization:

Triassic or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Low-sulfide gold quartz vein (Cox and Singer, 1986; model 36a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

This mine was active in a small way in the 1930s; a small Pelton wheel and hammer mill remain by a small dump.

Production notes:

Production uncertain but a small amount of gold was probably recovered during the 1930s.

Reserves:

None.

Last report date: 2007-04-08

Site name(s): Maid of Mexico

Site type: Mine

ARDF no.: PE031

Latitude: 56.5652 **Quadrangle:** PE C-4

Longitude: 133.029

Location description and accuracy:

This is a well known mine on central Woewodski Island. It is about 0.5 mile north-northeast of the center of the east end of Harvey Lake and about 0.4 mile south-southeast of the center of section 23, T 61 S, R. 79E. In 1996, a trail was still passable from the center of the north shore of Harvey Lake, north to the mine, but in later years it was difficult to follow in the heavy timber and vegetation. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cu, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Maid of Mexico vein was discovered about 1902 and explored by more than 1000 feet of underground workings from several adits prior to World War II (Still and others, 2002). A small mill was built on the property about 1920 and some production resulted, probably about 1,200 ounces from 1915 to 1938. Roppel (2005) recounts much historical detail about the early history of the Maid of Mexico, the personalities involved in it, and its changes in ownership until World War II. The property was active in 1979 and the owners had cleaned out the drifts in anticipation of production; apparently little has been done done. However, it was still held privately in 2002 according to Still and others. Williams (1953) noted that the Alaska Department of Mines had seven confidential maps dating from 1933 to 1935 of the underground workings in their files. He noted 130 feet of crosscut from 3 adits, 260 feet of drifting on the vein, and several raises and winzes.

The Maid of Mexico vein is about 2-6 feet thick, averaging about 4 feet. It can be traced for at least 1,000 feet on the surface but the underground working expose only a small portion of it (Still and others, 2002). The vein consists mainly of white quartz with sparse sphalerite, pyrite, galena, chalcopyrite, and free gold. It is mostly in black carbonaceous argillite associated with pyrite-bearing, calcareous felsic metatuff, felsic dikes, and minor limestone and mudstone. The black carbonaceous unit is overlain (?) by greenstone, greenschist, and marble. Several faults are known in the underground workings. Brew (1997) correlates the country rock with the Triassic Hyd Group, which in the Duncan Canal area typically consists of felsic and intermediate flows and breccia, argillite, and minor limestone.

Nine samples of the vein collected by Williams (1953) assayed trace to 0.64 ounces of gold per ton, a trace of silver, 0.20-0.68 percent lead, and 0.30 to 0.77 percent Zn. Using several old unpublished maps that date to the 1930s when the property was active, Still and others (2002) compiled a map of the surface workings, the three adits, and at least some of the underground workings. They also sampled a cut at the surface that exposes a quartz vein up to 1.8 feet thick. It contained from 5 to 1,351 parts per billion (ppb) gold. As reconstructed from the old maps, 69 samples taken underground along a 250-foot drift averaged 0.2 ounce of gold per ton across a widths of 1 to 4 feet; two of the raises averaged 0.3 ounce of gold per ton across a width of 1 to 4 feet. Another raise 80 feet long averaged 0.16 ounce of gold per ton, and a sample

from raise another contained 2.80 ounce of gold per ton. Still and other also noted that the samples collected by Williams were considerably less rich than those cited on the old maps and the average grade of the ore that was being mined as noted by Buddington (1923 was about 1 ounce of gold per ton.

Alteration:

None specifically noted.

Age of mineralization:

Triassic or younger based on age of the host rock.

Generic deposit model:

Deposit model:

Gold quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes

Site Status: Active

Workings/exploration:

The deposit was explored by more than 1000 feet of underground workings from three adits prior to World War II. The property was active in 1979 and the owners had cleaned out the drifts in anticipation of production but apparently little has been done since (D.J. Grybeck, unpublished field notes). The mine was still held privately in 2002 according to Still and others. Williams (1953) noted that the Alaska Department of Mines had seven confidential maps dating from 1933 to 1935 of the underground workings in their files. He cited 130 feet of crosscut from the portal of the mine and 260 feet of drifting on the vein; also several raises and winzes. Using several old unpublished maps that date to the 1930s when the property was active, Still and others (2002) compiled a map of the surface workings, the three adits on the property, and at least some of the nearly thousand feet of underground workings.

Production notes:

Small test shipments were made as early as 1917 and the property produced ore during the 1930s. The remains of a small mill are still present on the property. Detailed production records are not available but Still and others (2002) indicate that about 1,200 ounces of gold was produced from 1915 to 1936.

Reserves:

None.

Last report date: 2008-03-04

Site name(s): Hattie

Site type: Mine

ARDF no.: PE032

Latitude: 56.532

Quadrangle: PE C-4

Longitude: 133.0477

Location description and accuracy:

The adit of the Hattie Mine is about 0.1 mile east of the shoreline near the southwest end of Woewodski Island. It it about 0.3 mile east-southeast of the southeast tip of Butterworth Island, near the northwest corner of section 2, T. 61 S., R. 79 E. The location is accurate. Figure 22 of Still and others is a map of the underground workings of the Hattie Mine.

Commodities:

Main: Au

Other: Cu, Pb, Zn

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Hattie Mine dates to at least 1899 and by 1902, the Olympic Mining Company had driven several hundred feet of underground workings and had built a substantial camp and a mill building on the shore below the adit of the mine. Roppel (2005) documents much of the early history and personalities of the property and shows an early picture of the camp. Mill machinery was ordered and shipped to the property but never assembled at the Hattie. Shortly thereafter the underground work proved disappointing and the operations of the company and the new mill equipment moved north on Woewodski Island to the Helen S Mine (PE028). The Hattie camp burned in 1911 and there does not seem to have been any underground work on the property since. There is no documented production. However, there have been persistent rumors of at least a small test ore shipment in the early part of the century that was processed at the nearby Helen S mill with mixed results (Roehm, 1945). Since the 1970s, much of Woewodski Island has been covered by claims by a succession of companies: Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, Westmin Resources, and currently (Feb 2008) the Bravo Venture Group. Many of the claims covered the Hattie property but other than geochemical sampling and routine sampling of the Hattie dump and underground workings for background, there has been no recent work on the Hattie itself. The underground workings were still accessible in the late 1990s when Still and others (2002) sampled them as part of a regional mineral assessment by the Bureau of Land Management. The workings consist of about 325 feet of drifts, a 65-foot raise, and a winze.

The rocks in the vicinity are mainly rusty-weathering, light-greenish gray calcareous metarhyolite that is part of the Triassic Hyd Group (Brew, 1997, Karl and others, 1999). The metarhyolite is intruded by Mesozoic epidote-hornblende gabbro and by fresh, medium-grained Cretaceous diorite.

Four brecciated quartz veins up to 10 feet thick cut sheared diorite in the mine workings (Still and others, 2002); they contain sparse to rare disseminated pyrite, and rare grains of chalcopyrite, galena, and sphalerite. Gold values are uncertain but probably low; the best assay from several samples collected by the USGS on the dump in the early 1980s was 0.05 ounce of gold per ton (Grybeck, Berg, and Karl, 1984). Roehm (1945) noted that the deposit had low silver and gold values. Of the 27 samples collected underground and from the dumps at the Hattie by Still and others (2002), the highest gold value was 134 parts per billion (ppb) gold and all the rest contained less than 37 ppb.

Alteration:

Age of mineralization:

Cretaceous or younger based on the age of the diorite host rock.

Generic deposit model:

Deposit model:

Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

The Hattie Mine dates to at least 1899 and by 1902, the Olympic Mining Company had driven several hundred feet of underground workings and had built a substantial camp and a mill building on the shore below the adit of the mine. Roppel (2005) documents much of the early history and personalities of the property and shows an early picture of the camp. Mill machinery was ordered and shipped to the property but never assembled at the Hattie. Shortly thereafter the underground work proved disappointing and the operations of the company and the new mill equipment moved north on Woewodski Island to the Helen S Mine (PE028). The Hattie camp burned in 1911 and there does not seem to have been any underground work on the property since. Since the 1970s, much of Woewodski Island has been covered by claims by a succession of companies: Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, Westmin Resources, and currently (Feb 2008) the Bravo Venture Group. Many of the claims covered the Hattie property but other than geochemical sampling and routine sampling of the Hattie dump and underground workings for background, there has been no recent work on the Hattie itself. The underground workings were still accessible in the late 1990s when Still and others (2002) sampled them as part of a regional mineral assessment by the Bureau of Land Management. The workings consist of about 325 feet of drifts, a 65-foot raise, and a winze.

Production notes:

There is no documented production. However, there have been persistent rumors of at least a small test ore shipment in the early part of the century that was processed at the nearby Helen S mill with mixed results (Roehm, 1945).

Reserves:

None.

Site name(s): Unnamed (in vicinity 'Brushy Creek')

Site type: Prospect

ARDF no.: PE033

Latitude: 56.5204 **Quadrangle:** PE C-4

Longitude: 133.0188

Location description and accuracy:

This prospect consists of several cuts in the banks of 'Brushy Creek' between elevations of 90 to 170 feet. Brushy Creek is the informal name given to the creek that flows southwest, about 1.3 miles northwest of the southern tip of Woewodski Island. The coordinates are at about the center of the workings which trend southwest through the southwest quarter of section 1, T. 61 S., R. 79 E. The location is accurate.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

During the middle 1990s, Westmin Resources was active on Brushy Creek near the southern tip of Woewodski Island.). They excavated a series of cuts along the creek bank for about 3,000 feet between elevations of 90 to 170 feet and collected gridded soil samples over the area.

The rocks in the area are greenstone and greenschist of the Triassic Hyd Formation (Brew, 1997; Karl and others, 1999). Still and others (2002) collected samples in the cuts of iron-stained silicified volcanic rocks with thin bands of and disseminated pyrite, sphalerite, and galena. The best, a 2-foot chip sample, contained 423 parts per billion gold, 27.9 parts per million (ppm) silver, 7,380 ppm lead, and 2.6 percent zinc. Six others contained 1,731 ppm to 2.2 percent zinc.

Alteration:

Volcanic rocks near the mineralization are silicified.

Age of mineralization:

Late Triassic based on the age of the host rock and similarities to massive sulfide deposits in the Duncan-Zarembo belt of mineralization.

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Last report date: 2008-03-04

Site name(s): East Lake

Site type: Prospects

ARDF no.: PE034

Latitude: 56.5587

Quadrangle: PE C-4

Longitude: 133.0245

Location description and accuracy:

This record includes several prospects scattered in a heavily forested area somewhat larger than 1,000 feet in diameter, centered about 0.5 mile east of the east end of Harvey Lake. The center of the area is about 0.5 miles west-northwest of the center of section 25, T 61 S, R. 79 E. Still and others (2002, figure 18) show the location of 9 holes drilled in 1999 and the location of the several samples they collected.

Commodities:

Main: Ag, Au, Zn

Other:

Ore minerals: Sphalerite

Gangue minerals: Barite

Geologic description:

At various times from the 1970s to the present, much of central Woewodski Island was staked by a succession of companies; these include Resource Associates of Alaska, Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, Houston Oil and Minerals, Westmin Resources, and the Olympic Resources Group. During the late 1980s and early 1990, there was considerable geochemical sampling in this area and a hole was drilled sometime before 1998 that was reported to intersect notable zinc values. (Still and others, 2002). In 1999, P. Beardslee of Petersburg drilled 9 shallow holes in the area that intersected thin bands of massive pyrite. Still and others (2002) found several outcrops in the thick forest that covers the area. One outcrop of iron-stained schist with 10 percent disseminated and banded pyrite did not contain significant metal values. However a sample nearby with 0.4 feet of massive pyrite exposed in a small landslide contained 1,023 parts per million zinc. Brew (1997) correlates the country rock in this area with the Triassic Hyd Group which typically consists of felsic and intermediate flows and breccia, argillite, and minor limestone in the Duncan Canal area.

In 2007, Bravo Ventures Group (2008) drilled two holes that totaled 432.6 meters; the holes were sited on anomalies that were defined with detailed gravity and 3D IP, ground geophysical surveys. The holes intersected several intervals of semi-massive pyrite and fine grained black to gray argillite. Both holes intersected intervals at least 16 meters thick with more than 1 parts per million silver, more than 0.1 percent zinc, and notable but discontinuous gold and barium values.

Alteration:

None noted specifically.

Age of mineralization:

Triassic or younger based on age of the host rock.

Generic deposit model:

Deposit model:

Kuroko massive sulfides.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): Mad Dog; Fortune

Site type: Prospect

ARDF no.: PE035

Latitude: 56.5321 **Quadrangle:** PE C-4

Longitude: 133.0555

Location description and accuracy:

This prospect is at the southeastern tip of Butterworth Island next to the south end of Whiskey Pass, which is the channel between Woewodski Island and Butterworth Island. The deposit extends out into the flat that uncovers at low tide between Butterworth Island and the small unnamed island off its south tip. It is near the northeast corner of section 3, T. 62 S, R. 79 E. The location is accurate.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Barite?

Geologic description:

The Mad Dog prospect has been known since at least 1978 and has been examined and sampled by a succession of companies: Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, and Westmin Resources. It currently (2008) is held by the Bravo Venture Group. Several holes have been drilled over the years; most recently Bravo drilled 4 holes in 2004. Some of the better mineralization is in the intertidal zone and only uncovers at low tide. The mineralization does not appear to extend onto Woewodski Island.

The host rocks on the southern tip of Butterworth Island are greenschist and greenstone of the Triassic Hyd Group (Brew, 1997; Karl and others, 1999). However, most of the island is Upper Cretaceous hornblende diorite.

The deposit consists of volcanogenic massive sulfide layers and lenses in Triassic Hyd Group rocks analogous to other similar deposits in the Duncan-Zarembo mineral belt (Berg and Grybeck, 1980; Berg, 1981). The massive sulfide layers and lenses are from about 0.1 to 1 foot thick , follow the layering in greenschist and phyllite, and consist mainly of pyrite, black sphalerite, and galena. The bands have an unusually high silver content relative to other massive sulfide deposits in the area. One of the better exposed zones of mineralization at the tip of Butterworth Island shows sulfide bands and lenses across 15 feet that extend for about 160 feet along strike. More mineralization was found near the tip of the small unnamed island south of Butterworth Island but it is exposed only at low tide. Still and others (2002) collected 15 samples of the richer portions of the mineralization. They contained from 58 to 3,927 parts per billion gold, 43 to 630.4 parts per million (ppm) silver, 341 to 9.76 percent lead, and 3,951 ppm to 20.1 percent zinc.

In their 2004 drilling, Bravo Venture Group (2008) cut a 20-meter-thick mineralized zone. One intercept 3.8 meters long contained 16.4 ounces of silver per ton, 2.8 percent lead, and 22.4 percent zinc, and several other intercepts contained 131 to 437 grams of silver per ton, 0.59 to 5.03 percent lead, and 10.95 to 20.2 percent zinc.

Alteration:

Age of mineralization:

Upper Triassic based on similarity to other volcanogenic massive sulfide deposits in the area.

Generic deposit model:

Deposit model:

Barite facies of a Kuroko volcanogenic massive-sulfide model (Cox and Singer, 1986, model 28a). Alternatively a barite facies of a volcanogenic Sierran Kuroko model (Bliss, 1992, model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Active

Workings/exploration:

The Mad Dog prospect has been known since at least 1978 and has been examined and sampled by a succession of companies: Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, and Westmin Resources. It currently (2008) is held by the Bravo Venture Group. Several holes have been drilled over the years; most recently Bravo drilled 4 holes in 2004.

Last report date: 2008-03-04

Site name(s): Lake; Margery Group

Site type: Mine

ARDF no.: PE038

Latitude: 56.4737 **Quadrangle:** PE B-1

Longitude: 132.0958

Location description and accuracy:

The location of this mine as shown in Gault and others (1953). It is about two miles east of the east end of Virginia Lake at an elevation of about 1,450 feet and about 0.5 mile southeast of the center of section 23, T. 62 S., R. 86 E. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The Lake mine was first staked in 1905 as the Margery claims and by 1908 was exposed in several open cuts and short tunnels (Wright and Wright, 1905, 1908). One ton of ore was shipped in 1920 (Gault and others, 1953). It was still active in 1925 when it was restaked as the Lake claims and was active until at least 1927 (Buddington, 1926, Smith 1930a, Smith 1930b). It was restaked in 1965 and then again in 1978 by the Pacific Coast Molybdenum Co. who held the claims until 1986 (Still and others, 2002). The workings consist of three adits, numerous trenches, and surface stripping; most probably date to before 1927.

The mineralization occurs along a major fault zone that strikes N25 to 35 E and dips 70 to 90 degrees to the southeast (Gault and others, 1953; Still and others, 2002) The rocks in the vicinity are dark-colored phyllite and slate, quartzite, chlorite schist, and biotite schist that are about 2000 feet west of large Cretaceous biotite tonalite to granodiorite pluton (Gault and others, 1953; Brew, 1997). The fault zone is 5 to 12 feet wide and has been exposed in the adits and numerous trenches and pits for about 1,450 feet. The mineralization is all within the fault zone and consists of quartz breccia with major galena and lesser sphalerite, pyrite, and chalcopyrite, as well as as massive sulfide bands up to 0.5 feet thick, and sulfide-bearing quartz veinlets and pods.

Still and others (2002) collected several samples. A sample in a narrow vein of galena and sphalerite in Adit 1 (of Gault and others, 1953) contained 161 parts per million (ppm) silver, 8.54 percent lead, and 2.10 percent zinc. A 4.6-foot sample across the face of Adit 2 contained 10.3 ppm silver, 1.058 percent lead, and 1.3 percent zinc; a select dump sample from this adit contained 4.73 ounces of silver per ton, 10.5 percent lead, and 6.60 percent zinc. Still and others also sampled several trenches and pits; the samples contained 178 to 411 ppm silver, 2,049 to 3,266 ppm copper, 7.89 to 25.1 percent lead, and 3.60 to 16.4 percent zinc.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Sulfide-bearing quartz breccia along a regional fault.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Probably inactive

Workings/exploration:

The Lake mine was first staked in 1905 as the Margery claims and by 1908 was exposed in several open cuts and short tunnels (Wright and Wright, 1905, 1908). One ton of ore was shipped in 1921 (Gault and others, 1953); It was still active in 1925 when it was restaked as the Lake claims and was active until at least 1927 (Buddington, 1926, Smith 1930a, Smith 1930b). It was restaked in 1965 and again in 1978 by the Pacific Coast Molybdenum Co. who held the claims until 1986 (Still and others, 2002). The workings consist of three adits, numerous trenches, and surface stripping; most probably date to before 1927.

Production notes:

One ton of ore shipped to smelter in 1920 (Gault and others, 1953).

Reserves:

None.

Reporter(s): H. C. Berg (Fullerton, California); D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-03-04

Site name(s): Groundhog Basin

Site type: Prospects

ARDF no.: PE040

Latitude: 56.514 **Quadrangle:** PE C-1

Longitude: 132.0632

Location description and accuracy:

The coordinates are near the center of a group of adits and other workings that extend for nearly a mile on the east side of upper Groundhog Basin The prospect is is in the NW1/4, section 7, T. 62 S., R. 86 E. between elevations of 2,000 and 2,500 feet. Gault and others (1953) includes an excellent detailed geologic map of the prospects, as do Still and others (2002).

Commodities:

Main: Ag, Pb, Sn, Zn

Other: Au, Cu, Mo, Sn

Ore minerals: Arsenopyrite, cassiterite, chalcopyrite, cubanite?, fluorite, galena, magnetite, pyrite, pyrrhotite, sphalerite, tennantite-tetrahedrite

Gangue minerals: Quartz, pyroxene, various calc-silicate skarn minerals

Geologic description:

The country rocks in the area of the Groundhog Basin base-metal deposits are Tertiary to Cretaceous biotite schist, biotite-garnet-quartz schist, quartzofeldspathic gneiss, and minor marble and calc-silicate gneiss, all metamorphosed from Mesozoic or Paleozoic protoliths (Gault and others, 1953; Brew, 1997; Still and others, 2002). The metamorphic rocks near the prospects are cut by several large Tertiary felsic dikes and sills that are related to a biotite granite stock that is well exposed about a mile northeast of the belt of mineralization that contains this deposit. The granite has been dated at 16.3 Ma. Newberry and Brew (1989) classify this stock as a 'zinnwaldite' or 'tin' granite and they genetically relate this granite to the base metal prospects in Groundhog Basin and also the nearby porphyry molybdenum deposit (PE102). A large Cretaceous tonalite pluton intrudes the metamorphic rocks less than 3,000 feet west of the Groundhog Basin deposits.

The Groundhog Basin deposits were discovered in 1904 and were extensively explored in 1916-1917. Four claims were patented over the mineralization in 1930. In the early 40s, Ventures Ltd. did considerable surface trenching, drove about 450 feet of underground workings from four adits, and drilled three holes, 107 to 335 feet deep. Gault and others (1953) described much of this early work and did considerable geologic mapping in the area. In 1976, Bunker Hill Mining Company optioned this property and a large block of claims around it (Still and others, 2002). They collected surface samples and drilled 24 holes, 25 to 350 feet deep, but dropped the property at the end of the field season. From 1968 through 1981, Groundhog Basin and the surrounding area was optioned by a succession of companies: Humble Oil and Refining Co., El Paso Natural Gas Co. and AMAX Exploration Inc.; but they did little work specifically on the Groundhog Basin deposits. In 1983, Houston Oil and Minerals Exploration Company sampled the deposits. In 1988, Newberry and Brew (1989) studied the core from previous drilling and the company reports on the Groundhog Basin prospects; they were the first to publicly report on the tin content of the mineralization. The deposit has undoubtedly been examined by numerous companies since but there has been no extensive work since about 1990.

Four distinct steeply-dipping 'ore beds' have been defined, which collectively extend for nearly a mile and parallel the strike of the metamorphic host rocks. The most extensive and thickest, beds 3 and 4, extend

horizontally for about 3,700 feet through a vertical distance of about 1,500 feet (Gault and others, 1953; Still and others, 2002). The ore beds consist of a) masses of ore minerals up to several feet thick, mainly of sphalerite, pyrite, pyrrhotite, galena, chalcopyrite, magnetite, and cubanite(?); and b) layers containing the same assemblage of ore minerals disseminated through the metamorphic host rock. The ore beds are interlayered with steeply-dipping, medium- to high-grade pelitic and quartzofeldspathic schist and gneiss, and locally with banded calc-silicate gneiss. Garnet, pyroxene, and epidote are common near the ore beds in the calcareous rocks and locally form massive skarns. There is considerable detail available that can be found in Gault and others (1953) and Still and others (2002) on the geometry and sampling of the ore beds that is only summarized here.

Newberry and Brew (1989) identified tin in cassiterite as a major constituent of the ore beds and has classified the deposits as Ag-Sn-Pb-Zn skarns that replace calcareous beds in the schist and gneiss. They genetically tie the skarns to a 16.3 Ma zinnwaldite 'tin' granite that crops out north of the deposits. Near this zinnwaldite granite, massive sulfide samples commonly contain several percent tin and selected samples contain up to 18%. They interpreted the mineral paragenesis as: 1) formation of pervasive albite-zinnwaldite gneiss in the cupola of an evolving granite with formation of pyroxene-garnet in adjacent biotite schist and mafic dikes; 2) deposition of lower temperature zinnwaldite-sphalerite-cassiterite veins in the granite and formation of the Ag-Sn-Pb-Zn ore bodies in Groundhog Basin by replacement of calcareous layers in the schist and gneiss; and 3) peripheral sphalerite-galena-fluorite veins as distal, lower temperature manifestation of the granite-related hydrothermal system.

Gault and others (1953), document various attempts to define the ore reserves and resources of the deposit and to quantify the size and grade of certain portions of the 'ore beds.' They conclude, however, that there is insufficient information to justify making detailed estimates of the ore reserves in Groundhog Basin. However, in summary, they state, '...it appears reasonably certain that several hundred thousand tons each of solid and disseminated ore are present.' There solid ore contains about 8 percent zinc, 1.5 percent lead, and 1.5 ounces of silver per ton. The disseminated ore contains about 2.5 percent zinc and 1 percent lead.

Newberry and Brew (1989) estimated that the deposit contains about 1 million tonnes of ore containing 0.8 percent tin but emphasize the great uncertainty of their estimate. Still and others (2002) note several other estimates of the reserves or resources of the Groundhog Basin deposit. They conclude that the best mineralization is the 'solid ore' in beds 3 and 4 as exposed on the surface, in underground workings, and in drill holes. They estimate that those beds contain about 466,000 tons of 'indicated and inferred resources' with an average grade of 8 percent zinc, 3.5 percent lead, 1 ounce of silver per ton, and 0.39 percent copper.

The molybdenite-fluorite deposits that overlap this site are described separately (PE102).

Alteration:

Deposit associated with formation of pyroxene-epidote-garnet skarn in the host rocks.

Age of mineralization:

16.3 Ma based on a genetic tie to a nearby, zinnwaldite 'tin' granite (Newberry and Brew, 1989).

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The Groundhog Basin deposits were discovered in 1904 and were extensively explored in 1916-1917. Four claims were patented over the mineralization in 1930. In the early 40s, Ventures Ltd. did considerable

surface trenching, drove about 450 feet of underground workings from four adits, and drilled three holes, 107 to 335 feet deep. Gault and others (1953) described much of this early work and did considerable geologic mapping in the area. In 1976, Bunker Hill Mining Company optioned this property and a large block of claims around it (Still and others, 2002). They collected surface samples and drilled 24 holes, 25 to 350 feet deep, but dropped the property at the end of the field season. From 1968 through 1981, Groundhog Basin and the surrounding area was optioned by a succession of companies: Humble Oil and Refining Co., El Paso Natural Gas Co. and AMAX Exploration Inc.; but they did little work specifically on the Groundhog Basin deposits. In 1983, Houston Oil and Minerals Exploration Company sampled the deposits. In 1988, Newberry and Brew (1989) studied the core from previous drilling and the company reports on the Groundhog Basin prospects; they were the first to publicly report on the tin content of the mineralization. The deposit has undoubtedly been examined by numerous companies since but there has been no extensive work since about 1990.

Production notes:

None.

Reserves:

Gault and others (1953), document various attempts to define the ore reserves and resources of the deposit and to quantify the size and grade of certain portions of the 'ore beds.' They conclude, however, that there is insufficient information to justify making detailed estimates of the ore reserves in Groundhog Basin. However, in summary, they state, '...it appears reasonably certain that several hundred thousand tons each of solid and disseminated ore are present.' There solid ore contains about 8 percent zinc, 1.5 percent lead, and 1.5 ounces of silver per ton. The disseminated ore contains about 2.5 percent zinc and 1 percent lead.

Newberry and Brew (1989) estimated that the deposit contains about 1 million tonnes of ore containing 0.8 percent tin but emphasize the great uncertainty of their estimate. Still and others (2002) note several other estimates of the reserves or resources of the Groundhog Basin deposit. They conclude that the best mineralization is the 'solid ore' in beds 3 and 4 as exposed on the surface, in underground workings, and in drill holes. They estimate that those beds contain about 466,000 tons of 'indicated and inferred resources' with an average grade of 8 percent zinc, 3.5 percent lead, 1 ounce of silver per ton, and 0.39 percent copper.

Additional comments:

The Groundhog Basin prospect is covered by 4 patented claims.

Last report date: 2008-03-04

Site name(s): Unnamed (in Glacier Basin)

Site type: Prospects

ARDF no.: PE041

Latitude: 56.4779 **Quadrangle:** PE B-1

Longitude: 132.0264

Location description and accuracy:

The coordinates are at the lower of two adits in an elongate mineralized area that extends southeast from Marsha Peak to Glacier Basin. The adit is near the center of section 20, T. 62 S., R. 86 E.; it includes several small mineral occurrences and two prospects that are mapped in detail on Plate 9 of Gault and others (1953).

Commodities:

Main: Ag, Au, Be, Pb, Zn

Other: Mo?

Ore minerals: Beryl, galena, magnetite, sphalerite

Gangue minerals: Calc-silicate minerals, fluorite, quartz

Geologic description:

The mineralization on the north side of Glacier Basin was first discovered in 1898 and by 1943 was prospected by three short adits and numerous cuts and pits (Gault and others, 1953; Still and others, 2002). Several companies were active in the area from 1964 to the early 1980s but most of their work was to the north and they probably did little on this prospect beyond general reconnaissance.

The Glacier Basin prospects contain two distinct types of deposits that may be genetically related (Gault and others, 1953; Newberry and Brew, 1989; Still and others, 2002). The first consists of small, discontinuous, banded galena-sphalerite-magnetite lenses and layers that are probably continuous with those in Groundhog Basin (PE040). These deposits are relatively small and more scattered as compared to those in Groundhog Basin, but are essentially the same in mineralogy and origin. The host rocks are gneiss and schist that consists mainly of interlayered amphibolite, marble, and calc-silicate units. Four of these layers have been identified north of Glacier Basin below 3,000 feet in elevation. At the surface, they extend for up to 2,000 feet; they strike north-northwest and dip 50 to 60 degrees southwest. They are interpreted as replacement deposits with skarn affinities. The second type of deposit consists of quartz-fluorite veins and breccia with galena; they are exposed in two small adits where they cut a Tertiary rhyolite sill. Berryhill (1964) sampled these occurrences; he found and found found 5 widely spaced fluorite breccias north of Glacier Basin that contain beryllium which occurs as amorphous blebs of pale blue or creamy white beryl The veins average about 0.1 percent beryllium. Several other rhyolite bodies are nearby; most are conformable with the foliation of the metamorphic rocks. The rhyolite sills and dikes are probably cogenetic with the 20 Ma or younger bodies associated with the molybdenite deposits in the area (see PE043) and/or with the 15-17 Ma zinnwaldite 'tin' granite associated with the Groundhog Basin lead-zinc-silver deposits.

Newberry and Brew (1989) provide analytical data for the tin content of several sulfide-rich occurrences at this site. The tin content is distinctly lower than ore samples from Groundhog Basin and their conclusion is that the Glacier Basin deposits are farther from the source of the hydrothermal fluids that formed them, i.e. from the zinnwaldite 'tin' granite at the north end of Groundhog Basin. Still and others (2002) collected several samples at the lower adit of disseminated and massive sulfides at the contact of a quartz rhyolite sill and gneiss; the best contained 3.97 to 7.98 ounces of silver per ton, 4.64 to 33.4 percent lead, and 4.32 to 7.9

percent zinc. Several samples farther north of the quartz-fluorite veins contained up to 611 parts per billion gold, 1,378 parts per million (ppm) lead, and 2,061 ppm zinc.

Alteration:

Deposits locally associated with development of pyroxene-epidote-garnet skarn.

Age of mineralization:

Probably related to nearby 15-20 Ma rhyolite sills and dikes.

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers; (Be)-fluorite-galena veins and breccia.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

The mineralization on the north side of Glacier Basin was first discovered in 1898 and was prospected by three short adits and numerous cuts and pits by 1943 (Still and others, 2002). Several companies were active in the area from 1964 to the early 1980s but most of their work was to the north and they apparently did little on this prospect beyond general reconnaissance.

Production notes:

None.

Reserves:

None.

Additional comments:

Gault and others, (1953) provide detailed maps of the underground workings as well as a detailed surface geologic map that covers Groundhog Basin and extends southward to Glacier Basin to include this this site.

Last report date: 2008-03-04

Site name(s): Berg Basin

Site type: Prospect

ARDF no.: PE042

Latitude: 56.4468 **Quadrangle:** PE B-1

Longitude: 132.0108

Location description and accuracy:

This is a well documented prospect on a unnamed south-flowing tributary to the north end of Berg Creek. However, an extended ground and air search for the prospect by Jan Still of BLM and D. J. Grybeck of the USGS in 1996 showed that the area was covered with thick vegetation and talus; the adit was only seen from the air and difficult of access. The prospect is at an elevation of about 1,780 feet at the top of a steep talus slope about 0.5 mile southwest of the center of section 32, T. 63 S., R. 86 E.

Commodities:

Main: Ag, Au, Pb, Zn

Other: Cu

Ore minerals: Chalcopyrite, galena, native gold, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

This prospect was discovered in 1907. It was explored by several surface pits, a tunnel about 800 feet long, and several hundred feet of diamond drilling in 1947 and 1948 (Fowler, 1950) Seven men were working at the property then but apparently there has been no work since.

The country rocks in the area are biotite schist and subordinate marble and calc-silicate rocks that are intruded by Eocene tonalite and granodiorite and by younger dikes and sills of rhyolite, basalt, and pegmatite (Brew and others, 1984).

The deposit consists of a stockwork of quartz veinlets carrying pyrite, galena, and sphalerite, and of sporadic small masses of sphalerite and galena (Gault and others, 1953; Still and others, 2002). Some of the veins contain moderate values of gold and silver. The small sulfide masses occur in a composite basaltic dike, in thin breccia zones along the contacts of basalt and rhyolite dikes and sills, along contacts of basalt dikes with schist near rhyolite, and disseminated in the rhyolite. One diamond drill hole intersected 5 feet of solid and disseminated galena. No galena or sphalerite have been found except where basaltic dikes are associated with rhyolite sills and dikes. The galena contains up to 28 ounces of silver per ton. A quartz vein reported to carry about 0.68 ounce of gold per ton crops out at the surface but could not be found in the underground workings.

Alteration:

Age of mineralization:

The age of the deposit is inferred to be mid-Cenozoic, based on its spatial and apparently genetic association with dikes and sills that cut the Eocene tonalite.

Generic deposit model:

Deposit model:

Polymetallic veins? (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: Undetermined

Site Status: Undetermined

Workings/exploration:

Site name(s): Unnamed (near Point St. Albans)

Site type: Occurrence

ARDF no.: PE045

Latitude: 56.1097 **Quadrangle:** PE A-6

Longitude: 133.9587

Location description and accuracy:

The veins at this occurrence are exposed on a bedrock bench on the intertidal zone about 2.0 mile north of Point St. Albans. The deposit is about 350 yards southwest of triangulation station 'June' shown on the current (1968) 1:63,360 topographic map, near the northeast corner of section 33, T. 66 S., R. 74 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: As, Sb

Ore minerals: Arsenopyrite, berthierite (FeSb2S4), chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The veins here were first noted by Houston and others (1958) in their work on the uranium resources of Alaska; they provide little information other than they contain less than 0.0001 equivalent uranium and sphalerite. A claim was staked on the deposits in 1954 but Still and others note that as of 2002, there are no claims on the deposit. This description of the occurrence is largely based on field work in the early 1980s during a mineral resource assessment of the Petersburg quadrangle (Grybeck and others, 1984) and later work by Still and others (2002), all of whom examined the deposit as part of government programs.

Several quartz-calcite veins and lenses up to 6 feet thick and up to a hundred feet long are exposed in rocks exposed in the intertidal zone; they contain abundant sphalerite, galena, pyrite, arsenopyrite, and berthierite (FeSb2S4) (Grybeck, Berg, and Karl, 1984). The veins cut the periphery of a Cretaceous hornblende diorite pluton, which intrudes turbidites of the Silurian Bay of Pillars Formation (Brew, and others, 1984). Selected samples of the veins contain up to 0.5 parts per million (ppm) gold, 300 ppm silver, 360 ppm copper, about 2 percent lead, and 14 percent zinc. As described by Still and others (2002), the quartz-calcite veins are widely spaced and contain spotty, high-grade mineralization across narrow widths. The highest gold values were 8,767 and 5,839 parts per billion; four of the samples contained high silver values of from 126 to 342 ppm. Their samples also contained up to 9.9 percent, zinc, up to 8.15 percent lead, and high contents of mercury, arsenic, and antimony. A sample of massive pyrrhotite and pyrite with interstitial quartz contained 3,094 ppm copper.

Alteration:

None or minor.

Age of mineralization:

Veins cut Cretaceous hornblende diorite.

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Undetermined

Workings/exploration:

First noted by Houston and others (1958, p. 24) in their work on the uranium resources of Alaska; they provide little information about the veins other than they contain less than 0.0001 equivalent uranium and sphalerite. A claim had been staked on the deposits in 1954 but Still and others note that as of 2002, there are no claims on the deposit. The description of this site is largely based on field work in the early 1980s during a mineral resource assessment of the Petersburg quadrangle (Grybeck, Karl, and Berg, 1984) and later work by Still and others (2002), all of whom examined the deposit as part of government programs.

Production notes:

None.

Reserves:

None.

Site name(s): Frenchie; BP Adit

Site type: Prospect

ARDF no.: PE058

Latitude: 56.4187 **Quadrangle:** PE B-3

Longitude: 132.9548

Location description and accuracy:

The Frenchie prospect is at an elevation of less than 100 feet on the south bank of an unnamed creek about one-half mile south of the head of St. John Harbor. It is near the center of the SE1/4, section 8, T. 63 S., R. 80 E. The location is accurate.

Commodities:

Main: Au, Cu, Pb, Zn

Other: Ba

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

The Frenchie deposit was first described as a gold prospect by Buddington in 1923. In 1978, BP Alaska Exploration staked 34 claims on the prospect, mapped and sampled it, conducted airborne and ground geophysical surveys, did stream sediment and soil geochemistry in the area, and recognized it as a volcanogenic massive sulfide deposit (Brewer, 1979). In 1979, geologists from the U.S. Geological Survey examined the thick layer of pyrite that is the most prominent outcrop of the prospect (Berg and Grybeck, 1980) and recognized as one of the deposits along the Duncan Canal-Zarembo belt of Upper Triassic volcanogenic, massive sulfide deposits. Three holes were drilled in 1984 and five more were drilled in 1966 by Westmin Resources (Rockingham, 1996). As of 2007, the property is again active (Mark Robinson, oral communication, 2007). Buddington (1923) describes a 100-foot adit in the pyrite bed and a shaft that was sunk about 100 feet north of the adit. (The shaft could not be located by Still and others, 2002).

The main massive sulfide layer is up to 6 feet thick and and crops out for at least 600 feet along the creek bank (Brewer, 1979; Berg and Grybeck, 1980; Still and others, 2002). This layer consists of 50-75 percent massive sulfides in a siliceous matrix. The sulfides are chiefly pyrite, accompanied by minor sphalerite, chalcopyrite, and galena that form lenses, bands, and knots in the massive pyrite. The hanging wall of the deposit consists of a thin layer of black phyllite above the massive sulfide layer, about 18 inches of siliceous argillite and chert with up to 10 percent pyrite and sphalerite above that, and then about 13 feet of pyritized argillite and schist to the top of the outcrop in the cliff beside the creek. The footwall consist of siliceous, quartz-muscovite phyllite. All are intruded by Tertiary(?) andesite dikes. The massive sulfide layer is cut by several faults but none dislocates the layer significantly. The deposit disappears under surficial material to the west and it truncated by a fault to the east. Karl and others (1999) map the rocks in the area as part of the Upper Triassic Hyd Group that is the host of many of the massive sulfide deposits to the north along the Duncan Canal-Zarembo mineral belt.

Thirteen samples were collected by Brewer (1979) across the main massive sulfide layer; they averaged 0.047 ounce of gold per ton, 0.42 ounce of silver per ton, 0.55 percent copper, 0.08 percent lead, and 1.48 percent zinc, and 5 to 20 percent barite. Still and others (2002) also sampled the deposit. Eight chip samples across the main layer of massive sulfides contained 0.019 ounce of gold per ton, 0.32 ounce of silver per ton, 0.25 percent copper, 0.16 percent lead, 2.4 percent zinc, and 0.08 percent arsenic.

In 2016, Zarembo Minerals Co. LLC focused on better defining the grade and distribution of gold at the

Frenchie deposit by conducting metallic-sieve analyses; results indicate 92 percent of the gold in re-analyzed samples is in the coarser, plus-80-mesh size fraction, which is normally discarded in a standard gold fire assay. A previously sampled, 16-foot-thick section of outcrop now has revised grades of 4.4 grams of gold per tonne, up to 4 percent zinc, and minor lead and silver (Freeman, 2016). In 2017, Zarembo Minerals reprocessed public-domain helicopter electromagnetic and magnetic surveys for the area (Burns and others, 1996), contracted for 3D inversions, and field checked inversion interpretations (Mark Robinson, written communication, 2017).

Alteration:

Age of mineralization:

Late Triassic as part of the Duncan-Zarembo Island mineral belt defined by Berg and Grybeck (1980) and Berg (1981).

Generic deposit model:

Deposit model:

Kuroko volcanogenic massive sulfide deposit (Singer and Cox, 1986; model 28a), or Sierran Kuroko volcanogenic massive sulfide deposit (Bliss, 1992; model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Active

Workings/exploration:

The Frenchie prospect was first described as a gold prospect by Buddington in 1923. In 1978, BP Alaska Exploration staked 34 claims on the prospect, mapped and sampled it, conducted airborne and ground geophysical surveys, carried out stream sediment and soil geochemistry surveys in the area, and recognized it as a volcanogenic massive sulfide deposit (Brewer, 1979). Examined by the U.S. Geological Survey in 1979 (Berg and Grybeck, 1980). Three holes were drilled in 1984 and five more were drilled by Westmin Resources in 1996 (Rockingham, 1996). In 2007, the property is again active (Mark Robinson, oral communication, 2007). Buddington (1923) describes a 100-foot adit into the main massive sulfide layer and a shaft that was sunk about 100 feet north of the adit. (The shaft could not be located by Still and others, 2002).

In 2016, Zarembo Minerals Co. LLC focused on better defining the grade and distribution of gold at the Frenchie deposit by conducting metallic-sieve analyses; results indicate 92 percent of the gold in re-analyzed samples is in the coarser, plus-80-mesh size fraction, which is normally discarded in a standard gold fire assay. A previously sampled, 16-foot-thick section of outcrop now has revised grades of 4.4 grams of gold per tonne, up to 4 percent zinc, and minor lead and silver (Freeman, 2016). In 2017, Zarembo Minerals reprocessed public-domain helicopter electromagnetic and magnetic surveys for the area (Burns and others, 1996), contracted for 3D inversions, and field checked inversion interpretations (Mark Robinson, written communication, 2017).

Last report date: 2017-08-26

Site name(s): Unnamed (along Snow Passage)

Site type: Occurrences

ARDF no.: PE060

Latitude: 56.2729 **Quadrangle:** PE B-3

Longitude: 132.936

Location description and accuracy:

There are several occurrences of fluorite for about 1,200 feet of the shoreline of Zarembo Island opposite the east side of Bushy Island. The occurrences are mostly in section 33, T. 64 S., R. 80 E.

Commodities:

Main: F

Other: Au, Ba, Ce, La

Ore minerals: Fluorite

Gangue minerals: Chalcedony, quartz

Geologic description:

Sparse fluorite occurs in Tertiary or Quaternary rhyolite for along 1,200 feet of the shoreline of Zarembo Island opposite Bushy Island (Karl and others, 1999; Still and others, 2002). The fluorite occurs as fillings in narrow, vuggy fracture zones, as a coating on chalcedony- or quartz-encrusted fragments in breccia zones, and as geode-like bodies commonly called 'thunder eggs' (Buddington, 1923). Philpotts and Evans (1992) illustrate the geodes and provide a detailed study of their REE content and mineralogy. Although mineralogically interesting, the site as now known is little more than a mineral occurrence. Now and then, specimens of Zarembo fluorite are offered to mineral collectors by dealers. A few brecciated fracture zones up to 3 feet thick and 100 feet long are filled with cream-colored chalcedony. Still and others (2002) sampled the geodes, silicified zones, and fluorite; their samples contained up to 291 parts per billion (ppb) gold, 1,768 parts per million (ppm) barium, 65 ppm cerium, and 38 ppm lanthanum. The fluorite is probably formed by degassing during cooling of the rhyolite in which it occurs.

Alteration:

Fluorite formed during degassing of the Tertiary or Quaternary host rock.

Age of mineralization:

Tertiary or Quaternary based on the age of the host rock.

Generic deposit model:

Deposit model:

Fluorite in rhyolite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Long known in good exposures along the coast; to date of more interest to mineral collectors than as a viable prospect to the mining industry.

Production notes:

As now known, appears to be no more than an interesting mineralogical occurrence. Some specimens of this fluorite have been sold to mineral collectors.

Reserves:

None.

Site name(s): Lost Zarembo

Site type: Occurrence

ARDF no.: PE062

Latitude: 56.3807 **Quadrangle:** PE B-3

Longitude: 132.9007

Location description and accuracy:

This occurrence is well exposed on the north wall of a rock quarry adjacent to a logging road; the quarry is shown by symbol of the 1:63,360-scale topographic map in the NE1/4, section 27, T. 63 S., R. 80 E. It is at an elevation of about 600 feet about 4.0 mile southeast of the Zarembo Spring at the head of St. Johns Harbor.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

Grybeck, Berg, and Karl (1984) describe this deposit as three, massive sulfide layers in orange-weathering, greenish-gray metarhyolite along the west wall of a quarry. The most prominent exposure of the sulfides is a 4-foot-thick layer that crops out for about 50 feet and is truncated at both ends by faults. Selected portions of the massive sulfide layers contain up to 30 percent sulfides, mainly sphalerite, accompanied by minor pyrite, chalcopyrite, and galena; the matrix is fine-grained silica and barite. Analyses of selected grab samples show up to 0.55 parts per million (ppm) gold, about 8 percent zinc, 0.25 percent lead, 0.39 percent copper, 30 ppm or less silver, and up to 5,000 ppm barium. The occurrence forms a wedge-shaped, fault-bounded outcrop about 30 by 100 feet in size that abuts steeply-dipping Tertiary basalt, diabase, and rhyolite dikes. The outcrop of the massive sulfide deposit is small and the quarry walls are dominated by the steeply dipping Tertiary dikes. The association of massive sulfides interbedded with metarhyolite indicates that this occurrence is part of the Duncan Canal-Zarembo belt of dismembered, Upper Triassic volcanogenic massive sulfide deposits described by Berg and Grybeck (1980) and Berg (1981). Karl and others (1999) map the rocks in this area as part of the Triassic Hyd Group which is the host for most of the other massive sulfide deposit along this mineralized belt.

The occurrence was examined and sampled by Still and others (2002). Their samples across the sulfide layers contained 8.3 to 27.6 parts per million (ppm) silver, 966 to 3,781 ppm copper, 818 to 3,567 ppm lead, 1.9 to 4.6 percent zinc, and 1.53 to 10.10 percent barium.

Alteration:

Outcrop is iron-stained, probably from weathering of sulfides.

Age of mineralization:

As now known, this deposit marks the southern end of the Upper Triassic Duncan-Zarembo volcanogenic mineral belt defined by Berg and Grybeck (1980) and Berg (1981).

Generic deposit model:

Deposit model:

Kuroko volcanogenic massive-sulfide deposit (Cox and Singer, 1986; model 28a); alternatively a Sierran Kuroko volcanogenic massive sulfide deposit (Bliss, 1992; model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Inactive

Workings/exploration:

Originally found by the USGS in the late 70s. Examined and sampled by Still and others (2002).

Location description and accuracy:

The coordinates for this prospect are at the site of the best known mineralization in three claim blocks that total 386 claims. The site is about 1.8 miles west-northwest of Round Point on Zarembo Island at an elevation of about 1500 feet. It is about 0.2 mile northwest of the center of section 36, T. 64 S., R. 82 E. The claim blocks extend over much of the ridge northwest of Round Point, i.e. much of the southeastern third of T. 64 S., R. 82 E.; see Grybeck, Berg, and Karl (1984) for the outline of these claim blocks as of 1980.

Commodities:

Main: Ag, Ba, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals:

Geologic description:

In 1978, Mapco Inc. staked three claim blocks totaling 386 claims on Zarembo Island that covered much of section 36, T. 64 S., R. 82 E., and the area to the southeast of the creek that flows into the south end of Meter Bight. The claims were staked for molybdenum, fluorine, and uranium (although there is no evidence that any of these particular commodities were found in the succeeding exploration or in the samples that have been analyzed). As briefly examined in 1979 with company geologists, the mineralization then being explored was at an elevation of about 1000 feet near the creek that flows southeast across section 36 (Donald Grybeck, unpublished field observations, 1979). The mineralized exposure consisted of rusty-weathering, light green-gray felsic metavolcanic rocks with small lenses, pods, and layers up to a foot thick that contain disseminated sulfides, mainly pyrite and possibly sphalerite and chalcopyrite. The felsic metavolcanic rocks are interbedded with light gray, silicified limestone and dark gray argillite. Mapping by Karl and others (1999) indicates that much of the area of section 36 consists of the Triassic Hyd Group which hosts most of the volcanogenic massive sulfide deposits in the Duncan-Zarembo belt (Berg and Grybeck, 1980). Grab samples contained less than 5 parts per million (ppm) copper, 50 to 150 ppm lead, 200 to 11,000 ppm zinc, and 150 to 5,000 ppm barium.

ATNA Resources Inc. did considerable work in the late 1980s on this prospect which that they called the 'Wally Gator' (DeLancey, 1990). They apparently concentrated their work along the creek that flows through the middle of section 36. They located three massive sulfide showings over a distance of about 800 feet. Samples from a 5-foot-thick layer in quartz-sericite schist, their most impressive mineralization, contained up to 5.5 percent zinc, 1.3 percent lead, 0.3 ounce of silver per ton, and 5.9 percent barium. Samples from a 3-foot-thick section of siliceous quartz-sericite schist contained up to 3.4 percent copper, 1.6 percent zinc, 2.0 ounces of silver per ton, and 2.1 percent barium. ATNA put down two 'Winkie'-drill holes here. The lowest mineralization was in chlorite schist that had chalcopyrite and pyrite in bands in the schist and along fractures. Samples contained up to 3.2 percent copper, and 2.4 percent zinc. They also did a geochemical soil survey in the area that identified soils with up to 1,396 parts per million (ppm) zinc and 16,960 ppm barium. Still and others (2002) also visited this location; their samples generally reflect about the same metal values as the ATNA work.

Alteration:

Age of mineralization:

Upper Triassic based on the age of the host rocks.

Generic deposit model:

Deposit model:

Kuroko volcanogenic massive-sulfide deposit (Cox and Singer, 1986; model 28a); alternatively a Sierran Kuroko volcanogenic massive sulfide deposit (Bliss, 1992; model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Undetermined

Main: Cu, Fe

Other:

Ore minerals: Chalcopyrite, magnetite, pyrite

Gangue minerals:

Geologic description:

Three claims were staked at this site for iron and copper in 1974. Karl and others (1999) map a small Cretaceous gabbro pluton here that is probably the bedrock under all of the claims. Still and others (2002) classified much of the pluton as hornblendite in which they discovered disseminated chalcopyrite, pyrite, and magnetite at several localities along the shoreline and on a logging road which crosses the area. A sample of the best mineralization contained 2,760 parts per million (ppm) copper, 10 parts per billion (ppb) platinum, and 28 ppb palladium. The best sample collected along the road contained 1,172 ppm copper, 10 ppb platinum and 7 ppb palladium.

Alteration:

Age of mineralization:

Cretaceous or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Disseminated chalcopyrite, magnetite, and pyrite in hornblendite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

A block of three claims was staked at this site in 1974. Examined and sampled by government geologists in the late 1990s.

Production notes:

None.

Reserves:

None.

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Exchange

Site type: Prospect

ARDF no.: PE067

Latitude: 56.4219 **Quadrangle:** PE B-2

Longitude: 132.5338

Location description and accuracy:

This long-known prospect is in and just above the intertidal zone near Wedge Point on Woronkofski Island. It is about 0.6 mile west of the center of section 7, T. 63 S., R. 84 E. The location is accurate.

Commodities:

Main: Ag, Au, Pb

Other:

Ore minerals: Galena, gold, pyrite

Gangue minerals: Quartz

Geologic description:

The Exchange prospect was first staked in 1900 and has been described several times in similar terms (Wright and Wright, 1908; Roehm, 1945; Still and others, 2002). The workings include open cuts and two short adits. Two of the claims were restaked in 1974, were active through at least 1982, and were probably still active in 1996. Karl and others (1999) map the rocks in the area as part of the Jurassic or Cretaceous Seymour Canal Formation which is mainly graywacke. However, the prospect is in intrusive rocks that are probably similar to the Cretaceous tonalite that makes up much of Woronkofski Island (Still and others, 2002). The deposit consists of an irregular quartz vein that strikes north and dips 30W; it is up to 16 feet thick and can be traced for 250 feet. The vein contains small amounts of galena and pyrite. Still and others (2002) collected nine samples. The highest grade was a 5-foot sample across the vein; it contained 923 parts per billion gold, 26.6 parts per million (ppm) silver, and 944 ppm lead.

Alteration:

Age of mineralization:

Probably Cretaceous or younger based on the probably age of the intrusive host rocks.

Generic deposit model:

Deposit model:

Gold-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

The property was first staked in 1900 and developed by surface trenches and two short adits. Two of the claims were restaked in 1974, were active through at least 1982, and were probably still active in 1996.

Production notes:

No record of production.

Reserves:

None.

Ore minerals:

Gangue minerals:

Geologic description:

Ten claims at five locations were staked for copper in 1956 on the Niblack Islands in Ernest Sound; apparently they have not been active since (U.S. Bureau of Mines, 1980). A brief examination by the USGS in 1979 did not reveal any signs of mineral deposits (Grybeck, Berg, and Karl, 1984, locality 79). Rocks in the vicinity consist largely of migmatite and granite (Brew and others, 1984). The islands were also searched for indications of mineralization by Still and others, 2002; they found nothing other than a sample of granite that may have had a copper content a bit above background.

Alteration:

Site type: Occurrence

ARDF no.: PE078

Latitude: 56.9889 **Quadrangle:** PE D-6

Longitude: 133.9636

Location description and accuracy:

This occurrence is in a rock pit about a mile northwest of the town of Kake. It is about 0.5 mile, west-northwest of the center of section 27, T. 56 S., T. 72 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals: Calcite

Geologic description:

This occurrence was found in a reconnaissance of logging roads on northwest Kupreanof Island by Still and others (2002) during a Bureau of Land Management mineral assessment. The occurrence consists of two or three calcite veins with pyrite, sphalerite, and chalcopyrite in siliceous argillite. The veins are about 1 inch thick and extend for about 20 feet where they are cut off by a fault. The rocks in the area consist of argillite and graywacke of the Mississippian and Devonian Cannery Formation and Mesozoic phyllite and slate (Brew and other, 1984). A representative sample of the veins contained 1,135 parts per billion gold, 30.5 parts per million (ppm) silver, 7,327 ppm copper, and 5.4 percent zinc.

Alteration:

Age of mineralization:

Mississippian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Thin calcite veins with pyrite, sphalerite, and chalcopyrite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only limited sampling by government geologists.

Production notes:

None.

Reserves:

None.

Additional comments:

This occurrence is on lands that belong to the Kake Village Corporation.
