2008

U.S. DEPARTMENT OF THE INTERIOR
U.S. GEOLOGICAL SURVEY

Site name(s): Lucky Shot; Willow Creek Mines Inc.

Site type: Mine

ARDF no.: AN002

Latitude: 61.779 **Quadrangle:** AN D-7

Longitude: 149.4078

Location description and accuracy:

The portal of the Lucky Shot Mine is on the northwest valley wall of Craigie Creek, 1.8 miles northeast of the junction of Craigie Creek and Willow Creek. The mine is marked by a symbol labeled 'Lucky Shot Mine' on the Anchorage D-7 1:63,360-scale topographic map. It is near the center of section 35, T. 20 N., R. 1 W. of the Seward Meridian. The underground workings and exploration activities extend far beyond the the portal. The adjacent War Baby Mine (AN003) and the Lucky Shot Mine were long ago consolidated into a single property which now is commonly referred to as the Lucky Shot.

Commodities:

Main: Au

Other: As, Cu, Pb, Sb, Te, Zn

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, pyrite, sphalerite, stibnite, tellurides, tetrahedrite

Gangue minerals: Quartz

Geologic description:

The Lucky Shot Mine consists of 4 blocks - the Coleman, Lucky Shot, War Baby, and Murphy blocks. In the early days of the district, these were more or less contiguous if somewhat separate properties at least in name but they are being explored and developed as a single property (Full Metal Minerals, 2010a; Stevens, 2010). The deposit consists of quartz veins along shear zones that cut the Late Cretaceous Willow Creek Pluton, which is jointed and sheeted near the surface but less so underground. The pluton is zoned; the outer part consists of hornblende quartz diorite and lesser hornblende tonalite; the core consists of hornblende-biotite granodiorite and lesser hornblende-biotite quartz monzodiorite and biotite quartz monzonite.

The classic mesothermal quartz veins at the Lucky Shot occur along shear zones that exhibit both ductile and brittle properties; the shear zones are up to 100 feet wide. The veins are between two major northeastward-dipping transverse faults. The quartz veins that were mined prior to WWII were generally 2 to 4 feet wide; they strike about N 80 E, and dip about 40 N. Post mineral faults offset the veins up to 800 feet and the quartz in the veins often is fractured. There are two generations of quartz veins. An older group is generally parallel to southwest-dipping joints in the pluton. These veins contain three different suites of ore minerals: 1) chalcopyrite, pyrite, and arsenopyrite; 2) pyrite and stibnite; and 3) sparse pyrite, sphalerite, and minor gold. The younger and economically important veins occur along the major shear zones. Pyrite is the most common ore mineral in them; arsenopyrite and galena are often present; scheelite is locally present; and there are trace tellurides including nagyagite, altaite, and possibly coloradoite. The wall rocks are intensely altered near the veins. Adjacent to the veins, the wall rock is bleached white or gray-green with much sericite, clay, and carbonates. There is an outer zone of propylitic alteration. There are two periods of mineralization, 66 Ma and 55 to 57 Ma (Madden-McGuire and others, 1988; Harlan, 2003). Fluid inclusion studies and isotope geochemistry indicate that the temperature of the ore forming fluids was 300 to 325 degrees (Burleigh, 1987, Silberman and others, 1978).

During the mining before WWII, the stopes along the vein averaged about 5 feet thick, the grade of the ore was typically a half ounce to two ounces per ton and the workings only went down to 500 feet or less below the surface (Stevens, 2010). The work since 2005 has revealed that there are much wider mineralization,

even if at lower grade, and that the mineralization extends well below and beyond the old workings. The mineralization at the Lucky Shot has been traced for more than 4,000 meters horizontally, has a vertical extent of at least a thousand meters and has an average width of about 400 meters (Stevens, 2010). Over the last half century or more there have been several estimates of the gold resources of the Lucky Shot Mine. Most are now of little more than historic interest in view of the recent exploration. A resource estimate on the Coleman Zone was completed by Miranda Gold Corp. in September 2014 (Linebarger, 2014).

In March 2016, Miranda and Gold Torrent announced an updated resource estimate for the Willow Creek project, including measured and indicated resources of 121,500 ounces of gold averaging 18.3 grams of gold per tonne and 12,100 ounces of silver averaging 1.8 grams of silver per tonne contained in 206,600 tonnes of material. Inferred mineral resources include 59,000 tonnes of material that contain 35,150 ounces of gold averaging18.5 grams of gold per tonne and 2,900 ounces of silver averaging 1.5 grams of silver per tonne (Black and others, 2016a).

Alteration:

The wall rocks are intensely altered near the veins. Adjacent to the veins, the wall rock is bleached white or gray-green, with much sericite, clay, and carbonates. There is an outer zone of propylitic alteration (Madden-McGuire and others, 1988; Harlan, 2003).

Age of mineralization:

Late Cretaceous or younger (66 Ma and 55 to 57 Ma); veins cut the Late Cretaceous Willow Creek Pluton (Madden-McGuire and others, 1988; Harlan, 2003).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

Gold was discovered in the Lucky Shot area in 1918 and mining began in 1922 (Stoll, 1997, is a detailed history of the mining at the Lucky Shot and other mines in the Willow Creek district.). Mining continued fairly regularly until 1942; the mine did not reopen after WWII. Ensearch Exploration Inc. obtained the property in 1979 and did considerable underground work and exploration drilling. A 100-ton-a-day mill was built and about 10,000 tons of ore was milled. Several companies continued exploration into the early 1990s and another 1,000 tons of ore was mined. In 2005, Full Metals Minerals Corp. began intensive exploration of the Lucky Shot (Full Metal Minerals Corp., 2010a). Through 2008, Full Metal Minerals diamond drilled 164 holes; sampled the old dumps and underground workings; rehabilitated, improved, and sampled the old underground workings; and mined a bulk sample for metallurgical testing. In 2009, they drilled another 27 holes with several notable intercepts with 24.14 to 102.00 grams of gold per tonne (Full Metal Minerals Corp., 2010b). In the late Fall of 2009, they finalized an option agreement with Harmony Gold Corporation to continue exploring the property (Full Metal Minerals Corp., 2009). In November 2013, Miranda Gold Corp. (Miranda) entered a lease agreement with Alaska Hardrock Inc. and the following year Miranda completed a resource estimate on the Coleman Zone (Linebarger, 2014).

Production notes:

The Lucky Shot Mine and the adjacent War Baby Mine (AN003) were combined prior to WWII and both mines were simultaneously operated by Willow Creek Mines. Stoll (1997) estimated that the total production to 1951 from the combined mines was about 252,000 ounces of gold.

Reserves:

A National Instrument 43-101 compliant resource estimate on the Coleman Zone was completed by Miranda Gold Corp. in September 2014. The resource was calculated using a 7 gram per tonne gold cutoff grade. The measured resource was calculated to be 11,500 tonnes at 28.5 grams per tonne gold, yielding 10,500 troy ounces. The indicated resource was calculated to be 67,200 tonnes at 23.9 grams per tonne gold, yielding 51,600 troy ounces. The inferred resource was calculated to be 5,300 tonnes at 24.2 grams per tonne gold, yielding 4,100 troy ounces (Linebarger, 2014).

In March 2016, Miranda and Gold Torrent announced an updated resource estimate for the Willow Creek project, including measured and indicated resources of 121,500 ounces of gold averaging 18.3 grams of gold per tonne and 12,100 ounces of silver averaging 1.8 grams of silver per tonne contained in 206,600 tonnes of material. Inferred mineral resources include 59,000 tonnes of material that contain 35,150 ounces of gold averaging18.5 grams of gold per tonne and 2,900 ounces of silver averaging 1.5 grams of silver per tonne (Black and others, 2016a). All estimated resources are based on a cutoff grade of 5.0 grams of gold per tonne, a long-term gold price of $1,265 per ounce, and assumed metallurgical recoveries of 80 percent. Improved understanding of the geologic controls on mineralization resulted in a significant increase in the mineral-resource estimate for the Willow Creek project. In total, mineral resources at the Willow Creek project include eight veins in the Coleman area and two veins in the Lucky Shot area (AN002), and are based on information from 174 drill holes. Potential exists to increase the mineral resources through drilling down-dip extensions of the Coleman and Lucky Shot area, and the exploration targets in the War Baby (AN 003) and Murphy areas along strike to the east (Athey and Werdon, 2017). In July 2016, a newly completed NI 43-101 preliminary feasibility study reported proven and probable mineral reserves of 93,274 ounces of gold contained in 207,000 tonnes of material grading an average of 14.0 grams of gold per tonne (Black and others, 2016b).

The Willow Creek project is currently being developed through a joint-venture partnership between Miranda Gold Corp. and Gold Torrent Inc., with Gold Torrent currently earning a 70 percent equity interest through the funding of the first $10 million in development costs (Athey and Werdon, 2017).

Site name(s): War Baby; Willow Creek Mines Inc.

Site type: Mine

ARDF no.: AN003

Latitude: 61.7811 **Quadrangle:** AN D-7

Longitude: 149.4016

Location description and accuracy:

The War Baby Mine is marked with an adit symbol and the label 'War Baby' on the Anchorage D-7 1:63,360-scale topographic map. It is on the northwest valley wall of Craigie Creek about 5,000 ft east of VABM Box, near the center of section 35, T. 20 N., R. 1 W. The adjacent Lucky Shot Mine (AN002) and the War Baby mine have long been consolidated into a single property which now is referred to as the Lucky Shot.

Commodities:

Main: Au

Other: Cu

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

Located in 1918, The War Baby Mine quickly saw the erection of a small mill. The first production from the mine occurred in 1919 after two short tunnels and a crosscut were driven. Willow Creek Mines took over the property in 1921. The War Baby was mined, with interruptions, from 1919 until 1940. There were over 2,000 ft of underground workings on 3 levels. Ray (1933) reported that production from 1922 through 1927 was from a single stope measuring 175 by 250 ft with a maximum width of 10 to 12 ft. The ore mined through 1927 averaged 2.18 ounces of gold per ton (Ray, 1933). There may have been some copper production. By 1950, the mine had long since closed and the workings were inaccessible (Ray, 1954).

Chapin (1920) reported that four or five parallel quartz veins at the War Baby Mine cut the Late Cretaceous Willow Creek Pluton. The pluton is zoned: the outer part consists of hornblende quartz diorite and lesser hornblende tonalite; the core consists of hornblende-biotite granodiorite, and lesser hornblende-biotite quartz monzodiorite and biotite quartz monzonite. Wallrock alteration is intense within a few inches of the veins but seldom extends more than 10 to 12 inches beyond the veins.

The veins at the War Baby Mine strike N 80 E, and dip 17 to 62 NW; they are found in a 33-feet-wide zone and vary in thickness from 1 to 15 inches. The veins appear to belong to a single system that locally branches in the hanging wall. The footwall is marked by slickensides that separate the lode from fresh country rock. Sericitization and carbonate alteration predominate, but there is some pyritization and chloritization occurs in the outer parts of the alteration zone (Ray, 1954). The veins are a continuation of those at the Lucky Shot mine (AN002) although offset 600 to 700 feet along a prominent fault. The ore mined through 1927 averaged 2.18 oz/ton Au (Ray, 1933).

The War Baby mine was consolidated with the Lucky Shot Mine (CH002) and mined by the same company before 1942. In 2005, Full Metal Minerals Corp. began a intensive exploration that included the Lucky Shot Mine, the War Baby Mine, and adjacent ground beyond either of them. The War Baby is now only a block within that larger deposit that retains the name Lucky Shot. See the description of the Lucky Shot Mine (AN002) for the status of the ground that was once the War Baby.

Alteration:

The wall rocks are intensely altered near the veins. Adjacent to the veins, the wall rock is bleached to a white or gray-green color, with much sericite, clay, and carbonates. There is an outer zone of propylitic alteration.

Age of mineralization:

Late Cretaceous or younger; veins cut the Late Cretaceous Willow Creek Pluton.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

Site name(s): Gold Bullion; New Bullion; Ready Bullion; Willow Creek Mines Inc.

Site type:

Mine

ARDF no.: AN004

Latitude: 61.7898

Quadrangle: AN D-7

Longitude: 149.3292

Location description and accuracy:

Marked by adit symbols and the label 'Gold Bullion Mine' on the Anchorage D-7 1:63,360-scale topographic map. The mine is near the top of the northwestern flank of Bullion Mountain, on the divide between Willow and Craigie Creeks. It is near the southwest corner of section 29, T. 20 N., R. 1 E. of the Seward Meridian.

Commodities:

Main: Au

Other: Cu, Hg

Ore minerals: Chalcopyrite, cinnabar, pyrite, secondary copper minerals

Gangue minerals: Quartz

Geologic description:

The Gold Bullion Mine was developed on one or more quartz veins 1.5 to 14 feet thick that are intermittently exposed over 3,000 feet of strike length and have an average grade of about 1.7 ounces of gold per ton (Capps, 1915). The nearly horizontal quartz veins at the Gold Bullion contain gold, small amounts of pyrite, chalcopyrite, other sulfides, and are stained by copper carbonates. The veins cut tonalite and quartz diorite of the Willow Creek pluton, which has been dated at 73-74 Ma (Stevens, 2010; Madden-Mcguire and others, 1988). At least three normal faults are known to displace the veins (Stevens, 2010). Visible slickensides and gouge are along the vein walls (Katz, 1911). Capps (1915) reported cinnabar along cracks in quartz in one tunnel. According to Chapin (1920), most mining was on one vein that strikes N 10 E, and dips 14 NW. The ore averaged about 1.7 ounces of gold per ton (Ray, 1954). A K-Ar age from muscovite in a quartz-sericite selvage adjacent to a gold-bearing vein nearby was 56 Ma, early Paleocene (Silberman and others, 1978). Wall rock alteration is intense within a few inches of the veins, but seldom extends more than 10 to 12 inches beyond the quartz vein. Sericitization and carbonate alteration predominate, but there is some pyritization, and in the outer parts of the alteration zone the wall rock is chloritized (Ray, 1954).

An adjacent property, the Ready Bullion vein was discovered during mining at the Gold Bullion Mine. Workings were extended to it from the Ready Bullion in 1937 (Roehm, 1938; Stevens, 2010). The Ready Bullion vein was 12 to 18 inches thick and could be traced for three claims. It was considered to be the down-dip extension of the Gold Bullion.

In early 2010, the Gold Bullion Mine was part of a large block of claims that was being explored by the Harmony Gold Corporation (Stevens, 2010). In 2014 Miranda Gold Corp. collected soil samples and vein samples that identified significant anomalies potentially extending the fault limit of the Gold Bullion vein and provided new targets for vein segments between the Murphy and Bullion Mountain veins (Linebarger, 2014).

Alteration:

Probably similar to that at the nearby Lucky Shot Mine (AN002), where the wall rocks are intensely altered near the veins. Adjacent to the veins, the wall rock is bleached white or gray-green, with much sericite, clay, and carbonates. There is an outer zone of propylitic alteration (Ray, 1954).

Age of mineralization:

Early Paleocene based on a 56 Ma K-Ar date frommuscovite in a quartz-sericite selvage adjacent to a gold-bearing vein nearby (Silberman and others, 1978).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Gold Bullion Mine was staked by William Bartholf in 1907 (Capps, 1915). From 1909 to 1927, mine was the second largest producer in the district (Ray, 1933). The first ore from the property was from an open cut on a vein outcrop. The ore was carried by pack horse to the mill 1,600 ft below on Craigie Creek. The 2-stamp mill with a capacity of six tons a day was built in 1909 (Stoll, 1997). A 5-stamp mill was added to the property in 1911, increasing the mill capacity to 21 tons of ore per day. By 1915, a cyanide plant, five tunnels, numerous open cuts, several aerial trams, and other surface improvements were reported (Capps, 1915). According to Capps (1919), there was a total of 5,220 feet of underground workings. The old tailings were cyanided in 1939-1940 and several thousand dollars of gold was recovered (Ray, 1954).

The Ready Bullion was also mined in the mid-1970s by Dan Renshaw (personal communication, 1998). He mined from surface pits along the ridge above the Ready Bullion adits from frozen, near-surface portions of the vein that had been left in place during early mining to protect the underground workings. Several hundred tons were mined that ran 3 to 4 ounces of gold per ton. The ore was trucked to the Gold Cord mill (AN007) on upper Fishhook Creek, where the last of it was milled in 1977. Mining stopped with additional ore in sight when the property was folded into a consolidation of a number of properties when gold was approaching $800 per ounce. Subsequently, the price of gold retreated to a level that curtailed the effort and there was no additional production from the Ready Bullion. Access to the property during this work was by a steep, zigzag road upward from the head of Little Willow Creek.

In early 2010, the Gold Bullion Mine was part of a large block of claims that was being explored by the Harmony Gold Corporation (Stevens, 2010). In November 2013, Miranda Gold Corp. (Miranda) entered a lease agreement with Alaska Hardrock Inc. and collected 234 soil samples and three vein samples in the summer of 2014 that identified significant anomalies potentially extending the fault limit of the Gold Bullion vein and provided new targets for vein segments between the Murphy and Bullion Mountain veins (Linebarger, 2014).

Production notes:

The Gold Bullion Mine produced about 77,000 ounces of gold to 1951, most of it from 1911 to 1927, and it is the 3rd largest gold mine in the Willow Creek district (Stoll, 1997). Dan Renshaw's production is estimated to be about 30 to 40 ounces.

Reserves:

None.

Location description and accuracy:

Because of ambiguities, name changes over time, and the limited information in several source documents, in the initial record for this this site, it and the nearby Gray Eagle property were done individually as different deposits on different veins. Newer information has made it obvious that there is a single deposit on a single vein that has gone through several changes of ownership. The deposit is now the 'Gold Top, Gray Eagle' Mine,ARDF site AN015 and information from this record has been integrated into that record. The ARDF number in this record has been preserved only for accounting purposes.

Site name(s): Gold Top, Gray Eagle

Site type: Mine

ARDF no.: AN015

Latitude: 61.7984 **Quadrangle:** AN D-7

Longitude: 149.3776

Location description and accuracy:

The center of the Gold Top/Gray Eagle vein is about 2.1 miles northeast of VABM Box, near the top of the ridge on the northwest side of Craigie Creek. It is about 0.4 mile north-northwest of the center of section 25, T. 20 N., R. 1 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

The Gray Eagle and Gold Top veins are mentioned in Ray (1954) and Stoll (1997) but the information is limited. Stevens (2010) describes the vein, which probably probably was described previously under different names, in some detail. It has about the same orientation as the veins at the Lucky Shot Mine (AN002) and geologically is probably similar. Free gold is visible in the vein. The vein can be traced in trenches for at least 2,500 feet. It trends N 80 W to S 80 W and dips 50 to 60N. It is 12 inches to 8 feet wide and averages about 4 feet. The Smith tunnel that was driven sometime before 1940, intersected the vein and the workings follow it for about 850 feet. Forty samples were taken; the assays varied from low to 0.7 ounces of gold per ton (Stevens, 2010). In 1940, open cuts exposed the vein, the older trenches were cleaned out, and 2 short adits were driven to reach the vein. The rocks in the area are tonalite to quartz diorite of the Willow Creek pluton, dated at 73-74 Ma (Madden-Mcguire and others, 1989).

Before 1940, Milo Kelly of Knik, Alaska recovered about 60 ounces of gold from a few hundred pounds of ore mined from shallow workings on the Gray Eagle property (Vinal, 1940). The mine is now part of the property being explored by the Harmony Gold Corporation (Stevens, 2010) but in early 2010, there is no indication of any recent work on the Gold Top/Gray Eagle vein.

Alteration:

Probably similar to that at the nearby Lucky Shot Mine (AN002). There the wall rocks are intensely altered near the veins. Adjacent to the veins, the wall rock is bleached white or gray-green, with much sericite, clay, and carbonates. There is an outer zone of propylitic alteration.

Age of mineralization:

Late Cretaceous or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
36a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:
Sometime prior to 1940, there was considerable trenching and an adit intersected the Gold Top/Gray Eagle vein. About 850 feet of drifts exposed the vein. In 1940, more trenches were dug, the old trenches were rehabilitated, and two short adits were driven to the vein. Since 2005, the property has been part of a large block of claims that is being explored by Harmony Gold Corporation, but as of early 2010, there was no evidence of work work on the Gray Eagle/Gold Top vein.

Production notes:
Before 1940, Milo Kelly of Knik, Alaska recovered about 60 ounces of gold from a few hundred pounds of ore mined from shallow workings on the Gray Eagle property.

Reserves:
None.

Site name(s): Nippon; Jap

Site type: Mine

ARDF no.: AN030

Latitude: 61.7903 **Quadrangle:** AN D-7

Longitude: 149.3124

Location description and accuracy:

The Nippon Mine is at elevation of about 4,200 feet in the cirque at the head of Upper Willow Creek. It is about 0.9 mile north-northwest of VABM Pass on Skyscraper Mountain and about 0.4 mile south-southeast of the center of section 29, T. 20 N., R. 1 E. The location is accurate.

Commodities:

Main: As, Au, Cu, Pb

Other:

Ore minerals: Arsenopyrite, galena, gold, pyrite

Gangue minerals: Quartz

Geologic description:

At the Nippon Mine (the Jap Mine in early reports), there are two parallel veins 6 inches to 2 feet thick and about 300 feet apart (Roehm, 1938; Stoll, 1997; Stevens, 2010). Five tunnels exposed the veins in several places for a total length of more than 700 feet. The upper vein is exposed in two short tunnels; the lower vein is exposed in two other tunnels. There is little detailed geologic information about the Nippon veins. But they are probably similar to the other veins in the Willow Creek district and consist of low-sulfide quartz veins with a few percent pyrite, arsenopyrite, and galena; follow shear zones; and free gold is often visible. Elsewhere in the district and probably here, wallrock alteration is intense within a few inches of the veins, but seldom extends more than 10 to 12 inches beyond the quartz. Sericitization and carbonate alteration predominate, but there is some pyritization and chloritization (Ray, 1954). The veins cut tonalite to quartz diorite of the Willow Creek pluton which has been dated at 73-74 Ma (Stevens, 2010, Madden-Mcguire and others, 1988).

The Nippon Mine was discovered between 1909 and 1914 (Roehm, 1938; Stoll, 1997). A single stamp mill was installed before 1915 and there may have been some minor production. According to Brooks (1925), no attempt was made to mine ore that contained less than 4.85 ounces of gold per ton. In 1937, a miner was milling 200 to 300 pounds of high-grade ore from a 10-inch vein. Three vertical diamond drill holes were drilled in 1941; samples contained up to 1.88 ounces of gold per ton.

In the early 1980s, Ensearch Exploration Inc. drilled the upper and lower veins from the old underground workings Stevens, 2010). The work was suspended when the veins to found to be highly fractured. Ensearch's best intercept contained 3.32 ounces of gold per ton. As a result of this limited drilling, Hawley and Visconty (1982) outlined a 6,000-ton block of high grade ore. Yongue (1989) thought there may have been a reserve of 17,100 tons of material in the upper vein with a grade of 0.380 ounce of gold per ton and 2,272 tons of of material in the lower vein with a grade of 0.9 ounce per ton.

Alteration:

Elsewhere in the district and probably here, wallrock alteration is intense within a few inches of the veins, but seldom extends more than 10 to 12 inches beyond the quartz. Sericitization and carbonate alteration predominate, but there is some pyritization and chloritization (Ray, 1954).

Age of mineralization:

Late Cretaceous or younger; veins cuts the Late Cretaceous Willow Creek Pluton.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The workings include five adits and more than 700 feet of drifts on two veins. A small mill was installed in 1915 and there may have been some gold produced. (Capps, 1916). There was minor production in 1937 by one miner and 3 holes were diamond drilled in 1941. Ensearch Exploration Ltd. drilled 7 holes in the early 1980s and sampled and mapped the property.

Production notes:

There was probably a small amount of ore milled in a 2-stamp mill about the time of WWI. A miner produced 200 to 300 pounds of ore a day in 1937 and probably recovered a small amount of gold from it.

Reserves:

As a result of limited diamond drilling in the early 1980s by Ensearch Development Ltd., Hawley and Visconty (1982) outlined a 6,000-ton block of high grade ore. Yongue (1989) thought there may have been a reserve of 17,100 tons of material in the upper vein with a grade of 0.380 ounce of gold per ton, and 2,272 tons of of material in the lower vein with a grade of 0.9 ounce per ton.

Last report date: 2011-03-04

Site name(s): Bornite; Ruby Creek

Site type: Prospect

ARDF no.: AR018

Latitude: 67.0624 **Quadrangle:** AR A-2

Longitude: 156.948

Location description and accuracy:

The Bornite prospect is near the Bornite locality shown on the 1:63,360-scale topographic map. The prospect is near the center of section 8, T. 19 N., R. 9 E., of the Kateel River Meridian, and about 1.6 miles north-northeast of Bannock Mountain. The location is well known and accurate within 500 feet.

Commodities:

Main: Co, Cu

Other: Ag, Au, Ge, Pb, U, Zn

Ore minerals: Bornite, carrollite, chalcocite, chalcopyrite, cymrite, galena, germanite, marcasite, pyrite, pyrrhotite, renierite, sphalerite, tennantite-tetrahedrite

Gangue minerals: Barite, dolomite

Geologic description:

The mineralization at the Bornite prospect consists of sulfide minerals in a matrix of brecciated, intensely folded and faulted dolomite and limestone of the Devonian Bornite marble, a 3000-ft.-thick unit of carbonate rocks (Hitzman and others, 1986). The main ore minerals are bornite and chalcopyrite but carrollite, chalcocite, galena, germanite, renierite, sphalerite, and tennantite-tetrahedrite also occur in smaller amounts. The deposit is structurally and stratigraphically confined to the Devonian dolomite, limestone, and calcareous phyllite along the fault (?) -controlled margin of a carbonate bank adjacent to a shale-filled graben. Hitzman and others believed the deposit to have formed along a rifted continental margin in Late Devonian time. Rigby and others (2011), however, describe Bornite as a copper-cobalt deposit with Mississippi Valley and Olympic Dam affinities.

From the 1950s and into the 1980s, Kennecott Exploration Co. explored the Bornite deposit underground from a shaft and workings on two levels and also extensive surface drilling. In 2011 NovaGold Resources Inc. and the NANA Native Corporation, who owns the land, reached an agreement to explore the deposit (Petsel and others, 2011). NovaGold drilled 6 holes in 2011 totaling about 2,600 meters to verify Kennecott's earlier work and 9 other exploration holes totaling 3,500 meters (NovaGold Resources Inc., 2011a, 2011b). The NovaGold drilling not only verified the earlier data in several high-grade intercepts, it also identified a new South Reef zone that significantly increases the the size of the deposit. Some notable intercepts were: 1) four intervals that totaled 111.3 meters in one hole that averaged 2.1 percent copper; 2) 26.3 meters that averaged 6.7 percent copper; 3) 93.2 meters that averaged 2.1 percent copper, 4) 31.9 meters that averaged 5.4 percent copper; 5) 110.6 meters that averaged 2.6 percent copper; 6) 153.1 meters that averaged 1.2 percent copper, and 7) 178 meters that averaged 4.0 percent copper and this included 59.2 meters that averaged 12.0 percent copper.

Hitzman (1986) estimated Bornite to have a resource of 90 million tons with a grade of 1.2 percent copper.

As reported in 2014, the Bornite Project is estimated to contain 2.16 billion pounds of copper (6.8 million tonnes grading 1.19 percent copper) in the indicated category and 3.3 billion pounds of copper (90.8 million tonnes grading 1.64 percent copper) in the inferred category (Davis and others, 2014).

Alteration:

Dolomitization (Davis and others, 2014).

Age of mineralization:

Late Devonian by analogy with other deposits in the Ambler mineral belt (Davis and others, 2014).

Generic deposit model:

Deposit model:

Mississippi Valley or Olympic Dan similarities? Kipushi Cu-Co deposit? (Cox and Singer, 1986, model 32c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

32c?

Production Status: None

Site Status: Active

Workings/exploration:

From the 1950s into the 1980s, Kennecott Exploration Co. explored the Bornite deposit underground from a shaft and workings on two levels and also by extensive surface drilling. In 2011 NovaGold Resources Inc. and the NANA Native Corporation who own the land reached an agreement to explore the deposit (Petsel and others, 2011). NovaGold drilled 6 holes in 2011 totaling about 2,600 meters to verify the Kennecott's earlier work and 9 other exploration holes totaling 3,500 meters (NovaGold Resources Inc., 2011a, 2011b).

The NovaGold drilling not only verified the earlier data in several high-grade intercepts, it also identified a new South Reef zone that significantly increases the the size of the deposit. Some notable intercepts were: 1) 4 intervals that totaled 111.3 meters in one hole that averaged 2.1 percent copper; 2) 26.3 meters that averaged 6.7 percent copper; 3) 93.2 meters that averaged 2.1 percent copper, 4) 31.9 meters that averaged 5.4 percent copper; 5) 110.6 meters that averaged 2.6 percent copper; 6) 153.1 meters that averaged 1.2 percent copper, and 7) 178 meters that averaged 4.0 percent copper and this included 59.2 meters that averaged 12.0 percent copper.

In 2012, NovaCopper captured extensive physical property data at Bornite including resistivity, chargeability, specific gravity, and magnetic susceptibility data for use in modeling the existing ground induced polarity (IP) and gravity surveys, and the airborne electromagnetic (EM) and magnetic surveys. In general, some broad comments can be made concerning geophysical domains in and around mineralization at Bornite. Mineralization is characterized by low resistivity, less than 20 ohms, ambiguous but elevated, often irregular chargeability highs (greater than 35 milliradians) marginal to the mineralization, and 3 to 5 milligal gravity anomalies. Mineralization appears to lie along the flanks of 20 to 150 nanoteslas long wave magnetic anomalies (Davis and others, 2014).

As reported in 2014, the Bornite Project is now estimated to contain 2.16 billion pounds of copper (6.8 million tonnes grading 1.19 percent copper) in the indicated category and 3.3 billion pounds of copper (90.8 million tonnes grading 1.64 percent copper) in the inferred category (Davis and others, 2014).

Production notes:

None.

Reserves:

As reported in 2014, the Bornite Project is now estimated to contain 179 million pounds of copper (6.8 million tonnes grading 1.19 percent copper) in the indicated category and 3.3 billion pounds of copper (90.8 million tonnes grading 1.64 percent copper) in the inferred category (Davis and others, 2014).

The historic resource estimate from Hitzman (1986) was 90 million tons with an average of 1.2 percent copper (Hitzman and others, 1986).

On April 19, 2016, Trilogy Metals Inc. released an updated resource estimate, and on May 16, 2016, filed

a NI 43-101 technical report for the Bornite deposit (Davis and others, 2016). The updated resource resulted in contained copper in indicated resources increasing from 334 to 913 million pounds, constituting a 173 percent increase in contained metal over the previous resource estimate. Total contained copper in inferred resources decreased from 5,696 to 5,450 million pounds copper (1,768 million pounds in-pit at 0.5 percent copper cut-off grade; 3,683 million pounds below-pit at 1.5 percent copper cut-off grade), which constitutes a 4 percent decrease in contained metal due principally to moving in-pit inferred resources to the indicated category. The resource update incorporated a new, 3D lithology, alteration, and structural model for the Bornite deposit, as well as results from previously un-sampled or partially sampled historical Kennecott drill core. Trilogy continued environmental baseline data collection, but no exploration or drilling was conducted in 2016 at Bornite (Athey and Werdon, 2017).

Last report date: 2017-08-26

Site name(s): Arctic

Site type: Prospect

ARDF no.: AR025

Latitude: 67.174 **Quadrangle:** AR A-1

Longitude: 156.3875

Location description and accuracy:

The Arctic prospect is about 1.2 miles east of VABM 3725 'Riley' on a ridge above the Kogoluktuk River in the Ambler district. The property is shown as a group of prospect symbols on the USGS 1:63,360-scale topographic map in the southeast quarter of section 34, T. 21 N., R. 11 E., of the Kateel River Meridian. The location is well-known and accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Sb

Ore minerals: Arsenopyrite, barite, bornite, chalcocite, chalcopyrite, galena, pyrite, pyrrhotite, sphalerite, stibnite, tennantite-tetrahedrite

Gangue minerals: Calcite, quartz, talc

Geologic description:

Arctic is one of several volcanogenic deposits in the Ambler schist belt along the south flank of the Brooks Range. The deposits may be part of a rifted continental margin (Schmidt, 1981). Arctic is a syngenetic deposit hosted in the Ambler Schist Belt, a thick sequence of Devonian or Mississippian, low to medium-grade metamorphosed basaltic and rhyolitic rocks, submarine ash flow tuffs, volcaniclastic and minor plutonic rocks, and pelitic, carbonaceous, and calcareous metasedimentary rocks. These rocks are part of a large fold structure termed the Kalurivik arch. A Devonian or Mississippi age of mineralization is based both on fossil evidence and on U-Pb radiometric dating (Hitzman and others, 1986).

The Arctic polymetallic, stratabound, volcanogenic deposit consists of tabular bodies of banded massive and disseminated sulfides, one foot to more than 55 feet thick, composed of 20 percent to 90 percent pyrite, chalcopyrite and sphalerite, along with lesser amounts of pyrrhotite, chalcocite, bornite, galena, tennantite-tetrahedrite, arsenopyrite and stibnite (Schmidt, 1988). The sulfides are enclosed in calcareous talcose to quartzose lenses within a metavolcanic (rhyolitic) unit. The deposit is about 3,000 feet by 2,200 feet in area and about 270 feet thick. The massive sulfide occurrences are covered by a small gossan cap 9 to 15 feet deep.

Alteration:

Chlorite-rich rocks in the footwall and surrounding the sulfides form an alteration zone containing a complex assemblage of barium fluorphlogopite, talc, Mg-chlorite, barite, phengite, quartz, and calcite (Schmidt, 1988).

Age of mineralization:

Devonian-Mississippian, the age of the host rocks (Hitzman and others, 1986).

Generic deposit model:

Deposit model:
Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
28a

Production Status: None

Site Status: Active

Workings/exploration:

Kennecott completed 70 drill holes in the Arctic deposit in the 1970s and defined an inferred resource of 36.3 million tons of ore.

NovaGold Resources, Inc. (2007) reached an earn-in agreement with Kennecott Exploration Company and Kennecott Arctic Company (subsidiaries of Rio Tinto PLC) in March 2004. The agreement covers a 35,000 acre area in the Ambler district. Initial exploration by NovaGold in 2004 focused on the Arctic deposit and included new descriptions of existing core, structural geology studies, and drilling 11 infill holes totaling 9,768 feet. These holes confirmed previous drill results and helped refine the three-dimensional geologic model for the Arctic deposit. Some 2004 drill intercepts reported by NovaGold include: 1) hole AR04-80 had 6.5 meters with 3.36 percent copper, 0.91 gram of gold per tonne, 1.90 percent lead, and 7.93 percent zinc; 2) hole AR04-86 had 12.5 meters with 3.76 percent copper, 0.91 gram of gold per tonne, 52.4 grams of silver per tonne, 0.58 percent lead, and 6.01 percent zinc, or an 8.0 percent copper equivalent; 3) hole AR04-87 had 7.4 meters with 9.65 percent copper, 0.73 grams of gold per tonne, 108.2 grams of silver per tonne, 1.64 percent lead, and 10.35 percent zinc, or 16.9 percent copper equivalent.

In 2005, NovaGold drilled about 3,000 meters of core hole and carried out district-scale surface geology, geochemistry, and geophysical surveys (NovaGold Resources, Inc., 2007). In 2006, NovaGold drilled 12 holes to test geophysical anomalies near the Arctic deposit and outlined additional mineralization. They also carried out extensive detailed surface geologic mapping and geochemical surveying. As of May 2011, the deposit has been explored by 119 core holes totaling about 25,000 meters, 96 of which are in mineralization. In 2011, NovaGold commissioned a comprehensive NI 43-101 preliminary economic assessment of the deposit that included a statement of its resources (Rigby and others, 2011).

Assuming a net smelter return of $75 per ton, the deposit has an indicated resource of 16.845 million tons with an average grade of 4.14 percent copper, 6.03 percent zinc, 0.94 percent lead, 0.83 gram of gold per tonne, and 59.62 grams of silver per ton. It has an addition inferred resource of 12.087 million tons with an average grade of 3.53 percent copper, 4.94 percent zinc, 0.79 percent lead, 0.067 grams of gold per tonne, and 48.04 grams of silver per tonne.

In 2016, Trilogy Metals Inc. (formerly NovaCopper Inc.) drilled a total of 3,058 meters in 13 holes at their Arctic volcanogenic massive sulfide deposit. Significant results include: hole AR16-0155, which intersected 3 mineralized intervals, including 36.36 meters of 2.27 percent copper, 0.27 gram of gold per tonne, 25.3 grams of silver per tonne, 0.36 percent lead, and 2.54 percent zinc, and 8.48 meters of 6.14 percent Cu, 1.32 grams of gold per tonne, 96.6 grams of silver per tonne, 1.93 percent lead, and 8.27 percent zinc; hole AR16-0148, which intersected 4 mineralized intervals, including 21.22 meters of 3.79 percent copper, 0.85 gram of gold per tonne, 69.1 grams of silver per tonne, 0.99 percent lead, and 5.78 percent zinc; hole AR16-0150, which intersected 5 mineralized intervals, including 16.60 meters of 5.40 percent copper, 0.20 gram of gold per tonne, 46.0 grams of silver per tonne, 1.23 percent lead, and 6.69 percent zinc; and hole AR16-0153, which intersected 12.59 meters of 2.49 percent copper, 0.86 gram of gold per tonne, 56.6 grams of silver per tonne, 2.17 percent lead, and 9.64 percent zinc. Trilogy plans to complete a prefeasibility study and update the resource estimates for the Arctic deposit in 2017 (Athey and Werdon, 2017).

Production notes:
None.

Reserves:

Kennecott completed 70 drill holes in the Arctic deposit in the 1970s and estimated an inferred resource of 36.3 million tons grading 4.0 percent copper, 5.5 percent zinc, 0.8 percent lead, 0.7 gram of gold per tonne,

and 54.9 grams of silver per tonne, or 8.0 percent copper equivalent (Eakins and others, 1985).

In 2011, NovaGold commissioned a comprehensive NI 43-101 preliminary economic assessment of the deposit that included a statement of its resources (Rigby and others, 2011). Assuming a net smelter return of $75 per ton, the deposit has an indicated resources of 16.845 million tonnes with an average grade of 4.14 percent copper, 6.03 percent zinc, 0.94 percent lead, 0.83 grams of gold per tonne, and 59.62 grams of silver per tonne. It has an addition inferred resource of 12.087 million tons with an average grade of 3.53 percent copper, 4.94 percent zinc, 0.79 percent lead, 0.067 grams of gold per tonne, and 48.04 grams of silver per tonne.

In 2013, NovaGold commissioned a comprehensive Preliminary Economic Assessment report (43-101 compliant). Using a constant net smelter return of $35.01 per tonne milled, they report 1) 23.848 million tonnes indicated with an average grade of 3.26 percent copper, 4.45 percent zinc, 0.76 percent lead, 0.71 gram of gold per tonne, and 53.2 grams of silver per tonne; and 2) 3.368 million tonnes inferred with an average grade of 3.22 percent copper, 3.84 percent zinc, 0.58 percent lead, 0.59 percent gold, and 41.5 percent silver (Wilkins and others, 2013).

As of 2016, the Arctic deposit has a total indicated and inferred resource of 27.2 million tonnes with 3.25 percent copper, 4.37 percent zinc, an in situ lead grade of 0.74 percent, 0.02 ounce of gold per tonne, and 1.51 ounces of silver per tonne, for contained metals of 1,952 million pounds of copper, 2.623 million pounds of zinc, 444 million pounds of lead, 610,000 ounces of gold, and 45.3 million ounces of silver (Wilkins and others, 2013).

Last report date: 2017-08-26

Site name(s): Horse Creek; Cliff; Dh; Lost

Site type: Prospect

ARDF no.: AR029

Latitude: 67.31 **Quadrangle:** AR B-2

Longitude: 156.7

Location description and accuracy:

Located north of VABM Ruby on ridge between Ambler and Shungnak Rivers in Sec. 17, T. 22 N., R. 10 E., of the Kateel River Meridian. Shown as locality 39 in Mayfield and Grybeck (1978) and accurate to within 1000 ft. (600m).

Commodities:

Main: Cu, Pb, Zn

Other: Ag

Ore minerals: Bornite, chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Calcite, muscovite, quartz, sericite

Geologic description:

Pyrite, chalcopyrite, bornite, galena and sphalerite form lenses, stringers, disseminations, and locally massive pods in metamorphosed Devonian-Mississippian volcanic, volcaniclastic, and sedimentary rocks. Sulfide lenses are complexly folded and faulted. Country rocks are interbedded porphyroblastic quartz-muscovite-calcite schist, graphitic schist, greenstone, (some have pillow structure, and some occur as plugs and sills throughout the section), and weakly metamorphosed semischistose graywacke (Nana Development Corp., written communication, 1997). Deposit is reported similar to Arctic deposit (AR025). Horse Creek it is a highly complex deformed sequence of predominantly country rock schists and greenstones. Exposures are found along a prominent north-south trending cliff. Two inter-layered sequences of 'package' rocks have been identified; and contain the Cliff North/Horse Creek mineral showings. The Horse Creek occurrence is on the north limb of an overturned syncline and the Cliff North (described in more detail separately) occurrence is on the south limb (Ellis, 1980).

Alteration:

Quartz, chlorite, calcite, and sericite alteration is associated with mineralization; there is also sericite-altered quartz -muscovite-schist (Ellis, 1980).

Age of mineralization:

Devonian, based on age of host rock (Ellis, 1980).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Initial exploration efforts started in the early 1970s. Exploration efforts include geochemical surveys such as rock, soil, and stream sediment sampling, hand trenching, geologic mapping, geophysical surveys that included induced polarity (IP) and electromagnetic (EM) surveys, and diamond core drilling of eight drill holes. The majority of this work was completed between 1976 and 1980 (Ellis, 1980).

Production notes:

None.

Reserves:

None.

Additional comments:

This massive sulfide prospect is in the Ambler schist belt. Nana Development Corporation information based on a 1984 unpublished Bear Creek Exploration report.

Cliff North and Cliff South are referred to in this record generally as 'Cliff'. In 2014, Cliff North and Cliff South were created as a separate records from Horse Creek since both are on separate parts of a large overturned syncline and the prospects are separated by about a mile from Horse Creek (W.T. Ellis, Vice President, Alaska Earth Sciences, Inc., oral commun., 2014).

Last report date: 2014-03-11

Site name(s): Smucker; Charlie; Patti; Puzzle; Ambler 4-B

Site type: Prospect

ARDF no.: AR033

Latitude: 67.298 **Quadrangle:** AR B-3

Longitude: 157.1609

Location description and accuracy:

Located on ridge east of VABM Sleet in NW1/4 NW1/4, 0.6 mile from the center of section 20, T. 22 N., R. 8 E., of the Kateel River Meridian. Prospect at approximately 1,400 ft in elevation. Accurately located to within 300 ft.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Au

Ore minerals: Chalcopyrite, galena, owyheeite, pyrite, sphalerite

Gangue minerals: Calcite, chlorite, muscovite, quartz, sericite

Geologic description:

Layered sulfide zone 9 ft to 27 ft. (3 m to 9 m) thick, continuos for at least 6000 ft (2000 m) along strike, consists of banded, fine to medium grained pyrite, sphalerite, galena, chalcopyrite and minor owyheeite in a silica-calcite-pyrite matrix. The country rocks are characteristic of the Devonian-Mississippian Ambler sequence and consist dominantly of well-foliated porphyroblastic quartz-feldspar-muscovite-chlorite schist interlayered with quartz-muscovite-chlorite phyllite, graphitic phyllite, calcite-mica schist and marble. Mineralized zone is repeated by complex folding (Nana Development Corp., written communication, 1997).

Alteration:

No hydrothermal alteration of wall rock evident (Hitzman and others, 1986).

Age of mineralization:

Devonian (Hitzman and others, 1986).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active?

Workings/exploration:

Surface geologic mapping, geochemical sampling (soil grids), electromagnetic measurements, magnetometer measurements, and eight drill holes by 1984 (Nana Development Corp., written communication, 1997). According to Mayfield and Grybeck (1978) two drill samples 2400 ft (820 m) apart intersected layered sulfide zones 9 ft. to 27 ft. (3 m to 9 m) thick assaying 100 g/ton Ag, 2-8 percent Zn and 1-1.6 percent Pb. Grades from drill samples indicated 3.8 percent Zn, 1.2 to 1.6 percent Pb, 69-514 g/ton Ag.

Production notes:

None.

Reserves:

Hitzman and others (1986) report greater than eight million metric tons grading 0.8 percent Cu, 6.8 percent Zn, 2.3 percent Pb, 200 g/ton Ag. Bundtzen (1996) reported 'significant' tonnage grading 1.5 percent Pb, 5 percent-10 percent Zn, 103-343 g/ton Ag, and minor Au.

Additional comments:

Excellent example of stratiform volcanogenic sulfide deposit typical of the Ambler sequence in the southern Brooks Range. This is the westernmost known occurrence of this type deposit in the southern Brooks Range. All available data suggest Smucker to be relatively significant in size (Hitzman and others, 1986).

This location was changed in 2014 from the 1997 version of this record. The 1997 version was mislocated (W.T. Ellis, Vice President, Alaska Earth Sciences, Inc., oral commun., 2014).

Last report date: 2014-03-11

Site name(s): Kogo

Site type: Prospect

ARDF no.: AR066

Latitude: 67.241 **Quadrangle:** AR A-1

Longitude: 156.411

Location description and accuracy:

The prospect is equidistant between the Shungnak and Kogoluktuk Rivers in the NW1/4 Section 10, T. 21 N., R. 11 E., of the Kateel River Meridian. The prospect is at an approximate elevation of 2,600 ft. The location is accurate within 1000 feet.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, graphite, quartz, sericite, talc

Geologic description:

The Kogo prospect can be divided into two distinct sequences. The north and east rocks consist predominantly of metasediments and metavolcanics (greenstone). To the south and west a sequence exists consisting of metasediments, carbonate schists, black schists, white schists, marbles, rhyolites. The mineralized occurrence is semi-massive to disseminated sulfides in the metavolcanic schists. The greenstone host rock has been complexly folded and faulted (Ellis, 1980).

The deposit was first discovered in 1974 as a hydrogeochemical anomaly; a copper-precipitating spring was reported to Sunshine Mining Company by R.R. Walters. A white precipitate coated rocks downstream from the spring (Ellis, 1980).

Alteration:

Quartz, sericite, and pyrite alteration is associated with mineralization (Ellis, 1980).

Age of mineralization:

Devonian, based on age of host rock (Ellis, 1980).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Workings/exploration:

Initial exploration efforts started in the mid-1970s. Exploration efforts included geochemical surveys such as rock, soil, and stream sediment sampling, mapping, geophysical induced polarity (IP) survey, and two shallow exploration diamond core holes. This work was done to determined the cause of the anomalous stream sediments, which was speculated to derive from a deeply buried metalized source. Despite the geophysical work, a mineralized source was not found. A 50 foot mineralized drill section averaged about 0.02 percent silver, 0.05 percent zinc, 0.1 percent copper, and 0.4 percent lead in hole Kogo-1. The majority of this work was completed between 1976 and 1980 by Sunshine Mining Company (Ellis, 1980).

Production notes:

None.

Reserves:

None.

Site name(s): Cliff North

Site type: Prospect

ARDF no.: AR067

Latitude: 67.295 **Quadrangle:** AR B-2

Longitude: 156.706

Location description and accuracy:
Located equidistant between the Ambler and Shunghak Rivers, section 22 T. 22 N., R. 10 E., of the Kateel River Meridian at approximately 3,500 ft in elevation. The coordinates are accurate to within 500 ft.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Calcite, quartz, sericite

Geologic description:
The Cliff South prospect is in a highly complex deformed sequence of predominantly country rock schists and greenstones. Exposures are found along a prominent north-south trending cliff. Two inter-layered sequences of metamorphosed Devonian-Mississippian volcanic, volcaniclastic, and sedimentary rocks have been identified; these contain the Cliff North/Horse Creek and Cliff South mineral showings. The structure is very complicated and all three prospects are different parts of a larger structure. The Horse Creek (AR029) occurrence is on the north limb of an north-dipping overturned syncline, the Cliff North occurrence is on the south limb of the overturned syncline, while Cliff South is on the open south limb of a corresponding overturned anticline between Cliff South and Cliff North (Ellis, 1980).
Mineralization is characterized by copper, lead, zinc, and silver occurring as massive, semi-massive, and disseminates sulfide found in outcrop and by diamond drilling. Detailed mapping of this zone indicated that the mineral horizons contain widespread mineralization, with locally calcareous lenses of massive sulfides up to 8 feet thick (Ellis, 1980).

Alteration:
Strong sulfide oxidation. Quartz, chlorite, calcite, and sericite alteration is associated with mineralization; there is also sericite-altered quartz -muscovite-schist (Ellis, 1980).

Age of mineralization:
Devonian, based on age of host rock (Ellis, 1980).

Generic deposit model:

Deposit model:
Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Initial exploration efforts started in the early 1970s. Exploration efforts to date includes geochemical surveys such as rock, soil, and stream sediment sampling, hand trenching, geophysical surveys that included induced polarity (IP) and electromagnetic (EM) surveys, and diamond core drilling. Most of the drill holes contained two mineralized zones that averaged 8 to 14 feet thick. They averaged from 0.3 to 1.4 percent copper, 0.6 to 1.9 percent lead, 2.5 to 5.5 percent zinc, and 0.5 to 2.0 ounces per ton silver. Rock chip samples have assayed as high as 2.7 percent copper, 3.9 percent lead, 8,4 percent zinc, and 4.6 ounces per ton silver. A high conductive geophysical anomaly correlates with anomalous geochemical samples. The majority of this work was completed between 1976 and 1980 by Sunshine Mining Company (Ellis, 1980).

Production notes:

None.

Reserves:

In 1980, Sunshine Mining Company estimated a geologic reserve of 6.5 million tons ore grading 0.5 percent Cu, 1.0 opt Ag, 0.9 percent Pb, and 2.5 percent Zn (ELlis, 1980).

Additional comments:

Cliff North is referred to under Horse Creek (AR029) generally as 'Cliff'. In 2014, Cliff North was created as a separate record from Horse Creek since both are on separate parts of a large overturned syncline and the prospects are separated by about a mile (W.T. Ellis, Vice President, Alaska Earth Sciences, Inc., oral communication, 2014).

Site name(s): Bud

Site type: Prospect

ARDF no.: AR069

Latitude: 67.219 **Quadrangle:** AR A-2

Longitude: 156.68

Location description and accuracy:

The Bud prospect is located in section 16, T. 21 N., R. 10 E., of the Kateel River Meridian, at an elevation of approximately 2,600 ft. This location is accurate to within 1000 feet.

Commodities:

Main: Ag, Cu, Zn

Other: Au, Pb

Ore minerals: Chalcopyrite, galena, gold, pyrite, silver, sphalerite

Gangue minerals: Calcite, quartz, sericite

Geologic description:

The Bud Prospect hosted in Ambler sequence of metamorphosed Devonian and Mississippian volcanic, volcaniclastic, and sedimentary rocks. Ore minerals are concentrated in a felsic tuffaceous sedimentary section of rocks containing numerous basalt sills and flows immediately above a basal carbonate section (Hitzmann and others, 1986).

The local stratigraphy at Bud include over 700 feet of white-green quartz mica schist, non-porphyritic white rhyolite, button schist, porphyroblastic white schist, graphite schist, and varieties of mafic metacarbonate and greenstone. Both footwall and hanging wall units are composed of quartz-chlorite-muscovite schist. In general, the entire sequence has an average strike of on N 70 W, and dips southward at 35 to 50 degrees. The mineralized horizon at Bud is stratigraphically the same as the Sunshine Creek (AR028), prospect approximately 1 mile to the east (Ellis, 1984).

Alteration:

Quartz, chlorite, calcite, and sericite alteration is associated with mineralization (Ellis, 1980).

Age of mineralization:

Devonian, based on age of host rock (Ellis, 1984).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active?

Workings/exploration:

Initial exploration efforts started in the mind 1970s and includes surveys such as soil, stream sediment, and rock sampling, hand trenching, geologic mapping, geophysical surveys, and 3,670 ft of diamond core drilling in seven holes. Exploration was completed by Sunshine Mining Company in 1974 and subsequent exploration through drilling was completed Anaconda Copper Company. The discovery gossan contains 0.05 to 0.25 ounces per ton gold. Drill hole Bud 87-03 assayed 1.7 percent copper, 0.41 percent lead, 1.5 percent zinc 2.0 ounce per tonne silver and 0.017 ounce per ton gold (Ellis, 1984).

Last report date: 2014-03-11

Site name(s): Ambler

Site type: Prospect

ARDF no.: AR070

Latitude: 67.277 **Quadrangle:** AR B-3

Longitude: 157.048

Location description and accuracy:

The Ambler prospect is located 2.0 miles east of Kaluriuik Creek at an elevation of 1,900 feet; in section 26, T. 22 N., R. 8 E., of the Kateel River Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Zn

Other: Au, Cu, Pb

Ore minerals: Galena, pyrite, silver, sphalerite

Gangue minerals: Calcite, quartz, sericite

Geologic description:

The Ambler prospect consists of a rhyolite dome approximately 1000 feet thick, overlain by 500 feet of layered schistose rhyolites and quartz latites, which include ignimbrites and sedimentary equivalents. The rhyolite dome footwall contact is with a calc mica schist sequence, with numerous marble and graphitic schist interbeds and thin cherty semi- to massive-sulfides. The footwall of the calc-schist unit consists of quartz-chlorite-muscovite schist, which extends for several miles to the north. The hanging wall of the rhyolite sequence consists of interbedded greenstone, calc-schist, black graphitic schist and gossanous quartz-muscovite schist. These rocks dip gently to the south and are overlain by massive greenstone and quartz-chlorite-muscovite country rock schist. At the top of the layered rhyolite sequence is a gossan vent about 40 feet thick, which has been interpreted to be an inactive degassing zone from a local fumarolic center, supported by a fragmental to vuggy rock texture and local silicification (Modroo,1983).

Mineralization consists of sulfide accumulations that are interpreted to be associated with the vent degassing area. They occur as banded base metal sulfides associated with massive chert units (Modroo, 1983).

Drill holes were completed on adjacent claims (to the south and east) by Cominco, which reported 3 to 15 feet thick silver bearing massive sulfides. Assays from an outcropping massive sulfide lens with cherty interbeds ran as high as 0.006 ounce of gold per ton, 4.96 ounces of silver per ton, 10 percent zinc, 0.78 percent lead, and 0.30 percent copper (Modroo,1983).

Alteration:

Quartz, chlorite, calcite, and sericite alteration is associated with mineralization (Modroo, 1983).

Age of mineralization:

Devonian, based on age of host rock (Modroo,1983).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Anaconda Minerals Company explored the Ambler prospect claims from 1975 to 1982; past work consisted of geologic mapping, geochemical and geophysical surveys, and 2,981 feet of diamond drilling in six holes by Anaconda Copper Company. Additional drill holes have been completed on adjacent claims (to the south and east) by Cominco, which reported 3 to 15 feet thick silver bearing massive sulfides. Assays from an outcropping massive sulfide lens with cherty interbeds ran as high as 0.006 ounce of gold per ton, 4.96 ounces of silver per ton, 10 percent zinc, 0.78 percent lead, and 0.30 percent copper (Modroo,1983).

Production notes:

None.

Reserves:

None.

Additional comments:

This record was created to give Ambler a separate record from Arctic (AR025). As of 2012, the two prospects were grouped together despite that they are separate prospects and Ambler is located 19 miles from the Arctic deposit. Both sites are in the Ambler district.

Last report date: 2016-03-15

Site name(s): South Reef

Site type: Prospect

ARDF no.: AR071

Latitude: 67.065 **Quadrangle:** AR A-2

Longitude: 156.91

Location description and accuracy:

Approximately 3,500 feet east southeast of Bornite (AR018) at an elevation of 1,200 feet; section 9, T. 19 N., R. 9 E., of the Kateel River Meridian. This location is accurate to within 500 feet.

Commodities:

Main: Cu

Other: Ag, Co, Zn

Ore minerals: Bornite, chalcocite, chalcopyrite

Gangue minerals: Barite, dolomite

Geologic description:

The geology of the South Reef deposit is composed of alternating beds of carbonate rocks (limestone and dolostone) and calcareous phyllite. Limestone transitions laterally into dolostone, which hosts the majority of the mineralization and is considered to be hydrothermal in origin. Spatial relationships and petrographic work establish dolomitization as genetically related to early stages of the copper mineralizing system (Hitzman, 1986).

Copper mineralization in the South Reef zone consists of one to three mineralized intervals (at a 0.5 percent cut-off) coalescing into a crudely stratiform body hosted in secondary dolomite developed at or near the Iron Mountain structure. The body, which is 250 to 300 meters wide and 750 meters long varies in true thickness from roughly 10 meters to as much as 170 meters (Davis and others, 2014).

The South Reef deposit is located within the Arctic Alaska Terrane, a sequence of mostly Paleozoic continental margin rocks that make up the Brooks Range and North Slope of Alaska (Moore, 1992). It is within the Phyllite Belt geologic subdivision, which together with the higher-grade Schist Belt, stretches almost the entire length of the Brooks Range and is considered to represent the hinterland of the Jurassic Brooks Range orogeny. The southern margin of the Phyllite Belt is marked by melange and low angle faults associated with the Kobuk River fault zone, while the northern boundary is thought to be gradational with the higher-grade metamorphic rocks of the Schist Belt (Till and others, 2008).

Alteration:

Dolomitization (Davis and others, 2014).

Age of mineralization:

Sulfide mineralization (chalcopyrite, pyrite, and bornite) from Bornite (Ruby Creek) was dated by Re-Os techniques (Selby and others, 2009), producing an age of 384 ± 4.2 Ma for main stage copper mineralization.

Generic deposit model:

Deposit model:

Mississippi Valley or Olympic Dam similarities? Kipushi Cu-Co deposit? (Cox and Singer, 1986, model 32c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

32c?

Production Status: Undetermined

Site Status: Active

Workings/exploration:

South Reef was discovered during recent work (2006-2012) near the Bornite (AR018) prospect by NovaCopper. Twenty one drill holes have been completed at the South Reef deposit as of winter 2014. The 2012 drilling defined an approximately 250 to 300 meters wide by 750 meters long zone of mineralization at South Reef. Based on the drilling results, using a 1 percent copper cut-off, there is an inferred resource of 43.1 million tonnes of 2.54 percent copper (Davis and others, 2014).

Production notes:

None.

Reserves:

The 2012 drilling defined an approximately 250 to 300 meters wide by 750 meters long zone of mineralization at South Reef. Based on the drilling results, using a 1 percent copper cut-off, there is an inferred resource of 43.1 million tonnes of 2.54 percent copper (Davis and others, 2014).

Site name(s): Huff; Spud

Site type: Prospect

ARDF no.: BC001

Latitude: 56.4843 **Quadrangle:** BC B-6

Longitude: 131.9864

Location description and accuracy:

The mineralization at this prospect occurs for about 300 feet along a north-northwest trending band of gneiss and marble. The center of the mineralization is just east of the toe of the Nelson Glacier about 0.3 mile northeast of the center of section 21, T. 62 S., R. 86 E., of the Copper River Meridian. The location is accurate. Still and others (2002) include a detailed map of the prospect.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrrhotite, sphalerite

Gangue minerals: Fluorite, quartz

Geologic description:

This prospect was first located by Bill Huff in 1963 (Race, 1963, Still and others, 2002). From 1965 to 1992 it was optioned to a succession of companies: Bunker Hill Mining Company; Humble Oil and Refining Company; Watts, Griffis, and McQuatt; AMAX Exploration Company, and El Paso National Gas Company who mapped and sampled the prospect, did a geophysical survey, and drilled two holes, 99 and 149 feet long.

The country rocks in the general area of this prospect are Mesozoic or Paleozoic pelitic schist and paragneiss, with subordinate amphibolite and marble (Koch, 1996, 1997, Gault and others, 1953; George and Wyckoff, 1973). The mineralization occurs in a marble bed about 30 feet thick that is mineralized for about 300 feet (Still and others, 2002). Irregular masses and bands of pyrrhotite, galena, sphalerite, and chalcopyrite 0.5 to 15 feet thick replace the marble in the hanging wall. These sulfides and the mineralized marble are cut by thin, cross fractures that pinch and swell and locally contain vuggy fluorite-quartz pods and lenses with some galena and sphalerite. These fractures may be the conduits for the fluids that formed the sulfide replacements in the marble. The mineralization is probably related to a nearby 16.2 Ma biotite granite (see PE040).

Still and others (2002) collected 5 samples across the massive, replacement mineralization. They contained 46.7 parts per million (ppm) to 4.6 ounces of silver per ton, 2.688 to 7,330 ppm copper, 3.28 to 20.08 percent lead, and 6.9 to 22.68 percent zinc. Three, 4- to 6-foot samples collected by El Paso across this mineralization contained 3.09 to 19.69 ounces of silver per ton, 0.7 to 1.2 percent copper, 15.9 to 24.9 percent lead, and 7.1 to 9.3 percent zinc (George and Wyckoff, 1973). A geophysical survey by El Paso identified a large conductor over the exposed mineralization that suggests more extensive mineralization at depth. A 149-foot hole into this anomaly cut 7 feet of mineralization at a depth of about 85 feet that contained 1.40 ounce of silver per ton, 0.3 percent copper, 7.40 percent lead, and 4.30 percent zinc. Still and others (2002) also collected several samples of the cross fractures with fluorite with vuggy fluorite and quartz from 150 to 2,400 feet away from the main galena-sphalerite replacement deposits in the marble. The best contained 2,166 ppm gold, 228.40 ounces of silver per ton, 6.24 percent lead, and 4.40 percent zinc.

Alteration:

Age of mineralization:

Probably related to a nearby 16.2 Ma biotite granite pluton as are other deposits in the Groundhog Basin area.

Generic deposit model:

Deposit model:

Lead-zinc replacement deposit in marble; cut by fractures with pods and lenses of vuggy fluorite and quartz with minor galena and sphalerite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

This prospect was first located by Bill Huff in 1963 (Race, 1963; Still and others, 2002). From 1965 to 1992 it was optioned to a succession of companies: Bunker Hill Mining Company; Humble Oil and Refining Company; AMAX Exploration Company; and El Paso National Gas Company. The El Paso National Gas Company who mapped and sampled the prospect, did geophysical surveys and drilled two holes, 99 and 149 feet long.

Production notes:

None.

Reserves:

None.

Site name(s): Copper King

Site type: Prospect

ARDF no.: BC002

Latitude: 56.4404 **Quadrangle:** BC B-6

Longitude: 131.9644

Location description and accuracy:

The Copper King prospect is 1.5 mile southeast of Berg Mountain at an elevation of about 1,300 feet about 0.6 mile northeast of the center of section 3, T 63 S., R, 80 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The country rocks in the general area of the Copper King prospect are Mesozoic or Paleozoic pelitic schist and paragneiss and subordinate amphibolite and marble (Koch, 1996, 1997). As mapped by George and Wyckoff (1973), the rocks have been metamorphosed to upper greenschist of lower amphibolite facies quartz-mica schists and hornblende-biotite-pyroxene-feldspar gneiss; rhyolite sills parallel the foliation.

The Copper King prospect was staked in 1906 and restaked in 1951 (Chapin, 1916; Chapin, 1918, Berg and Cobb, 1967). Williams (1957) described the deposit as a 4.5-foot-thick quartz vein with sulfides that is exposed for about 45 feet along a small creek and in a 9-foot-deep shaft. A sample from the dump of the shaft contained 3.3 percent zinc and a trace of copper. Still and others (2002) located a quartz vein in place that contains sphalerite, chalcopyrite, and pyrite. A 0.7-foot sample across the vein contained 18.9 parts per million (ppm) silver, 5,639 ppm copper, and 2.1 percent zinc. A sample from the dump of the shaft contained 12 ppm silver, 4,694 ppm copper, and 1.9 percent zinc. They also located a quartz vein about 750 feet northwest of the shaft along a small creek. A 1.6-foot sample contained 679 parts per billion gold.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Quartz vein with sulfides.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

The Copper King prospect was staked in 1906 and restaked in 1951 (Chapin, 1916; Chapin, 1918, Berg and Cobb, 1967). Williams (1957) described the deposit as a 4.5-foot-thick quartz vein with sulfides that is exposed for about 45 feet along a small creek and in a 9-foot-deep shaft. Site type: Prospect

ARDF no.: BC003

Latitude: 56.3967 **Quadrangle:** BC B-6

Longitude: 131.9435

Location description and accuracy:

This prospect is said to consist of claims that were staked as early as 1907 on the north side of Berg Basin somewhere between the mouths of Berg Creek and Aaron Creeks. The location is poorly known and the propect may easily be a mile or more from the coordinates in section 23, T. 65 S., R. 86 E., of the Copper River Meridian. However, there is little information about the Berg prospect. Early reports describing it (Chapin, 1916, p. 78; 1918, p. 75) include references to the Copper King prospect (BC002). Parts of some of the early descriptions of the Berg prospect are ambiguous and may actually refer to a deposit in Berg Basin to the west in the adjoining Petersburg quadrangle.

Commodities:

Main: Au?

Other:

Ore minerals: Gold?

Gangue minerals:

Geologic description:

The country rocks in the general area of the Berg prospect (Koch, 1996, 1997) are Mesozoic or Paleozoic pelitic schist and paragneiss, and subordinate amphibolite and marble. Ambiguous early descriptions suggest that the prospect is an auriferous lode deposit. No other geological information about this property has been made public. Still and others (2002) investigated the area and did some sampling but found no evidence of mineralization.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

There is little evidence of workings in the vicinity other than claim records that date back to before WWI.

Production notes:

None.

Reserves:

None.

Site type: Prospect

ARDF no.: BC004

Latitude: 56.514 **Quadrangle:** BC C-6

Longitude: 131.735

Location description and accuracy:

This prospect is about 1.0 mile south-southwest of Cone Mountain; it is at an elevation of about 3,000 feet near the northeast corner of T. 62 S., R. 88 E., of the Copper River Meridian. The location is probably accurate within about a quarter of a mile.

Commodities:

Main: U?

Other: Ce, La, Mo, Nd, Th

Ore minerals: Unspecified radioactive minerals

Gangue minerals:

Geologic description:

The country rocks in the general area of the Cone Mountain prospect are a Miocene (?) alkali feldspar granite stock and associated quartz-porphyritic rhyolite dikes (Koch, 1996, 1997). The prospect is on the western margin of the stock, which intrudes Eocene granodiorite and quartz monzonite plutons and Mesozoic or Paleozoic pelitic schist and paragneiss. A group of 145 claims was staked in 1976, presumably for uranium-bearing and related minerals (Elliott and Koch, 1981, loc. 4; Koch and others, 1981; U. S. Geological Survey, 1979). Geochemical surveys [(Koch and Elliott, 1981 (OFR 81-728C-K)] show high values of silver, beryllium, molybdenum, niobium, lead, tin, yttrium, rare earth elements, and zinc in rock, stream-sediment and heavy-mineral concentrate samples from the immediate area of the stock. Differentiation enrichment of these elements in such a highly-evolved silicic magma may account for most of the values reported, but a few high lead and zinc values suggest local sulfide deposition.

In 1976, Pacific Coastal Minerals staked 176 claims in the area; they held them several years and did some drilling. Still and others (2002) collected samples of granite at two localities between Cone Mountain and Black Crag; they contained up to 140 parts per million (ppm) cerium, 75 ppm lanthanum, 48 ppm neodymium, and 66.9 ppm thorium. They also collected 8 samples of a variety of felsic volcanic and intrusive rocks. The highest values were in a sample of molybdenite-bearing rhyolite breccia that contained 1,740 ppm cerium, 954 ppm lanthanum, 440 ppm neodymium, 60 ppm samarium, 72.6 ppm thorium, and 2,098 ppm molybdenum.

Alteration:

Age of mineralization:

Miocene?

Site name(s): North Bradfield River; Ptarmigan

Site type: Prospect

ARDF no.: BC009

Latitude: 56.4012 **Quadrangle:** BC B-5

Longitude: 131.4084

Location description and accuracy:

The coordinates mark the approximate center of a group of pods and lenses of mineralization that are scattered along a northwest-trending belt about 2 miles long and 0.5 mile wide. The center of the prospect is near the northeast corner of section 29, T. 63 S., R. 90 E., of the Copper River Meridian, about 9 miles southwest of Mount Pounder. Figure 33 of Still and others (2002) is a map of the deposit. The location is accurate.

Commodities:

Main: Cu, Fe

Other: Ag, Au, Mo, Zn

Ore minerals: Chalcopyrite, hematite, magnetite, malachite, pyrrhotite

Gangue minerals: Calcite, calc-silicate minerals

Geologic description:

The North Bradfield Canal prospect was discovered by Ken Eichner in 1955 and by 1958 was covered by 41 claims (Eichner, 2002; Still and other, 2002). Takahashi, C.T., and Co. optioned the property until 1959; they mapped it, flew a aeromagnetic survey over it, and drilled 14 shallow holes. From 1960 to 1962, it was held by Utah Construction who did more surface work and drilled at least 460 feet of hole (Utah Construction, 1962). MacKevett and Blake (1963) of the U.S.G.S. mapped the geology in detail and Still and others (2002) of the U.S. Bureau of Land Management did some additional surface and geochemical sampling. Still and others (2002) revisited the prospect as part of a regional mineral assessment and did some sampling that largely confirmed the earlier work.

The North Bradfield River prospect (MacKevett and Blake, 1963, p. D1-D21) consists chiefly of metasomatic, magnetite-skarn deposits at the northwest end of a large roof pendant of gneiss, granulite, schist, marble, and skarn in quartz monzonite of the Coast Range Batholith, which in turn is cut by dikes of quartz diorite, aplite, and alaskite. The metamorphic bedded rocks are complexly folded. MacKevett and Blake interpret the general structure of the pendant as an overturned syncline that probably extends for many miles to the southeast. Sonnevil (1981, p. B117), on the other hand, interprets the dominant structure in the area as a homocline that dips northwest to northeast. Koch (1997, p. 24) reports that the pendant is marked by an aeromagnetic trough that roughly parallels its outcrop (U. S. Geological Survey, 1979). The deposit is in marble layers of the roof pendant and consists of calc-silicate skarn that is partly replaced by massive magnetite with interstitial pyrrhotite; the magnetite is cut by veinlets of chalcopyrite. This ore contains subordinate amounts of hematite, limonite, and malachite. The orebodies, of which at least 15 are exposed, are crudely stratiform and apparently discontinuous; they range in strike length from 50-350 feet and in thickness from 2-40 feet. They occur in a belt about 2 miles long and 0.5 mile wide. Koch (1997, p. 24-25) suggests that at least some of the metal concentration in these deposits is related to the emplacement of an Eocene quartz monzonite and granodiorite stock, near the contact with the Mesozoic or Paleozoic metamorphic bedded rocks that host the deposits (Elliott and Koch, 1981; Koch, 1996). Koch (1997, p. 24, 25) and Elliott and Koch (1981, p. 8, loc. 9) also report anomalous amounts of silver, gold, molybdenum, and zinc in rock samples collected at and near the North Bradfield River deposits.

As a result of their surface work and drilling, Utah Construction (1962) estimated that the 9 magnetite-copper bodies that they identified contain about 1,000,000 tons of proven and probable resources and 4,481,000 tons of possible resources with a estimated grade of 35 to 40 percent iron, 0.2 to 0.3 percent copper, and 3 to 4 percent sulfur.

Alteration:

Calc-silicate skarn is developed in marble units adjacent to the orebodies.

Age of mineralization:

Probably Eocene based on a nearby intrusive that probably is genetically related to the deposit.

Generic deposit model:

Deposit model:

Cu-Fe skarn (Cox and Singer, 1986; model 18d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18d

Production Status: None

Site Status: Probably inactive

Workings/exploration:

The Bradfield Canal prospect was discovered by Ken Eichner in 1955 and by 1958 was covered by 41 claims (Eichner, 2002; Still and other, 2002. Takahashi, C.T., and Co. optioned the property until 1959; they mapped it, flew an aeromagnetic survey over it, and drilled 14 shallow holes. From 1960 to 1962, it was held by Utah Construction who did more surface work and drilled at least 460 feet of hole (Utah Construction, 1960). MacKevett and Blake (1963) of the U.S.G.S. mapped the geology in detail and Still and others (2002) of the U.S. Bureau of Land Management did some additional surface and geochemical sampling.

Production notes:

None.

Reserves:

As a result of their surface work and drilling, Utah Construction (1962) estimated that the 9 magnetite-copper bodies that they identified contain about 1,000,000 tons of proven and probable resources and 4,481,000 tons of possible resources with a estimated grade of 35 to 40 percent iron, 0.2 to 0.3 percent copper, and 3 to 4 percent sulfur.

Additional comments:

Elliott and Koch (1981) also apply the name 'Ptarmigan' to the North Bradfield River prospect. Still and others (2002) indicated that there were no active claims on the property at the time of their work.

Site name(s): Craig

Site type: Prospect

ARDF no.: BC010

Latitude: 56.4652 **Quadrangle:** BC B-4

Longitude: 131.2605

Location description and accuracy:

This prospect consists of about 60 claims staked in 1977 about 4 miles west-northwest of Mt. Pounder. Their location is not well known and somewhat arbitrarily, the center of the claims is plotted about 0.5 mile east of the center of section 30, T. 62 S., R. 91 E., of the Copper River Meridian. This location may be a mile or more from the center of the claims.

Commodities:

Main: Cu

Other:

Ore minerals: Chalcopyrite, magnetite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

Sixty 'Craig' claims were staked here in 1977 but were allowed to lapse after two years; there apparently has been no activity since.

The country rocks in the general area of the Craig occurrence are Mesozoic or Paleozoic metasedimentary rocks, locally including marble, and subordinate metavolcanic rocks (Elliott and Koch, 1981; Koch, 1996).

As described by Elliott and Koch (1981), the mineralization consists of chalcopyrite, pyrite, and pyrrhotite disseminated in the metasedimentary rocks; the chalcopyrite also occurs in thin veinlets. Skarn float at or near the prospect contains magnetite and minor chalcopyrite. Still and others (2002) sampled rubblecrop from talus in the area. Several samples contained layered and disseminated sulfides, mainly pyrite; with disseminated chalcopyrite. A sample of hornblendite (skarn?) with 25 percent sulfides, mainly pyrite and pyrrhotite, contained 5,706 parts per million (ppm) copper and 3.1 percent zinc. Sample with layered and disseminated pyrite contained negligible base metal values and the highest gold value in the 7 samples that were selected for analysis was only 30 parts per billion gold.

Alteration:

Age of mineralization:

Mesozoic or Paleozoic (?).

Generic deposit model:

Deposit model:

Layered and disseminated sulfides in metamorphic rocks and skarn.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Sixty 'Craig' claims were staked here in 1977 but were allowed to lapse after two years; there apparently has been no activity since. Limited sampling by the U.S.G.S. and Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Last report date: 2008-03-04

Site name(s): Unnamed (near Black Crag)

Site type: Prospect

ARDF no.: BC090

Latitude: 56.5367 **Quadrangle:** BC C-6

Longitude: 131.6992

Location description and accuracy:

This unnamed site is about a mile southeast of Black Crag near the Alaska-British Columbia boundary in section 36, T. 61 S., R. 88 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Mo, Zn

Other: Ce, La, Nd, Sm, Th, U

Ore minerals: Chalcopyrite, molybdenite, pyrite

Gangue minerals:

Geologic description:

Still and others (2002) found possible evidence of claim staking here and were told of drilling for molybdenum in the 50s but there is no information about exploration here prior to their work. They briefly examined the area and collected several mineralized samples as part of a regional mineral assessment for the Bureau of Land Management. The site might be part of the prospect several miles to the southwest (BC004) that was explored in the 1970s.

The country rocks in the general area of Black Crag are a Miocene (?) alkali-feldspar granite stock and associated quartz-porphyritic rhyolite dikes (Koch, 1996). The prospect is near the margin of the stock, which intrudes Eocene granodiorite and quartz monzonite plutons and Mesozoic or Paleozoic pelitic schist and paragneiss.

On the east side of the valley, Still and others (2002) collected several samples of float that consisted of: 1) quartz porphyry with molybdenite along fractures; 2) fine-grained silicified felsite cut by a 0.1-foot-thick seam of molybdenite; and 3) silicified granite with pyrite and chalcopyrite. Samples of the molybdenite-bearing rocks contained 735 and 1,348 parts per million (ppm) molybdenum and the copper-bearing sample contained 1,508 ppm copper. A sample of silicified breccia cemented by pyrrhotite contained 93 parts per billion gold, 43.5 ppm silver, and 558 ppm zinc. At the head of the valley under a hanging glacier, volcanic rock with molybdenite along fractures is abundant. Samples contained 23 to 2,529 ppm molybdenum, 119 to 713 ppm zinc, and up to 1,740 ppm cerium, 954 ppm lanthanum, 440 ppm neodymium, 60 ppm samarium, 72.6 ppb thorium, and 16 ppm uranium.

Alteration:

Mineralized rocks are silicified.

Age of mineralization:

Tertiary or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Porphyry Cu-Mo (Cox and Singer, 1986; model 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
21a

Production Status: None

Site Status: Undetermined

Workings/exploration:

Still and others (2002) found possible evidence of claim staking here and were told of drilling for molybdenum in the 1950s but there is no information about exploration here prior to their work. They briefly examined the area and collected several mineralized samples as part of a regional mineral assessment for the Bureau of Land Management. Last report date: 2008-03-04

Site name(s): Unnamed (west of the terminus of Nelson Glacier)

Site type: Occurrence

ARDF no.: BC091

Latitude: 56.4788 **Quadrangle:** BC B-6

Longitude: 131.999

Location description and accuracy:

This occurrence is just west of the terminus of the Nelson Glacier near the center of section 21, T. 62 S. R. 86 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, As, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

This occurrence is in an area that was covered by a large blocks of claims that were variously held from 1965 to 1981 by Bunker Hill Mining Company, Humble Oil and Refining Company, El Paso Natural Gas Company, and AMAX Exploration (Still and others, 2002). There apparently was no exploration of these particular occurrences by these companies beyond areal mapping and sampling, or at least there is no notable record of any.

The country rocks in the area of the prospects include Tertiary to Cretaceous biotite schist, biotite-garnet-quartz schist, quartzofeldspathic gneiss, and minor marble and calc-silicate gneiss metamorphosed from Mesozoic to Paleozoic protoliths (George and Wyckoff, 1973; Brew, 1997). The metamorphic rocks near the prospect are cut by several large Tertiary felsic dikes and sills that have been dated nearby at about 16.2 Ma (see PE043), and by a large Cretaceous tonalite pluton that intrudes the metamorphic section just to the east.

Still and others (2002) briefly examined the ridge west of the terminus of the Nelson Glacier and identified a 2-foot-wide vuggy, silicified zone that cuts gneiss. The silicified zone extends for about 80 feet and locally contains pyrite, chalcopyrite, galena, and sphalerite. A 0.2-foot-thick chip sample across what appeared to be the most mineralized section of the zone contained 4.39 ounces of silver per ton, 2.70 percent lead, 9, 577 parts per million (ppm) zinc, and 8.63 ppm arsenic. (The mineralization is similar to or an extension of the mineralization in the prospect about 0.3 mile to the northeast across the terminus of the Nelson Glacier (BC001)).

Alteration:

Age of mineralization:

Probably related to a nearby 16.2 Ma biotite granite as are other deposits in the Groundhog Basin area.

Generic deposit model:

Deposit model:

Vuggy silicified zone in gneiss.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

This occurrence is on a large block of claims that were variously held from 1965 to 1981 by Bunker Hill Mining Company, Humble Oil and Refining Company, El Paso Natural Gas Company, and AMAX Exploration (Still and others, 2002). There apparently was no exploration of these occurrences by these companies beyond areal mapping and sampling. Still and others (2002) examined these occurrences as part of a regional mineral assessment by the Bureau of Land Management.

Last report date: 2008-03-04

Site name(s): Unnamed (Near Mt. Lewis Cass)

Site type: Occurrence

ARDF no.: BC092

Latitude: 56.3895 **Quadrangle:** BC B-4

Longitude: 131.1119

Location description and accuracy:

This occurrence is about 1.5 miles southwest of Mt. Lewis Cass; the mineralization appears to extend from about 2,400 to 4,100 feet in elevation and was sampled in outcrop at about 2,500 feet. It is about 0.2 mile southeast of the center of section 19, T 63 S., R. 92 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Mo

Other:

Ore minerals: Chalcopyrite, magnetite, molybdenite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The Mount Lewis Cass occurrence was discovered by Still and others (2002). The mineralization is near the contact of Eocene granodiorite and Mesozoic and/or Paleozoic metasedimentary and metavolcanic rocks and marble. The granodiorite contains molybdenite in narrow quartz stringers, in knots, and as disseminations. Several samples contained 1,240 and 1,558 parts per million (ppm) molybdenum. Iron-stained silicified metasedimentary and metavolcanic rocks in float on the south side of the valley contain pyrrhotite, pyrite, and chalcopyrite. Chalcopyrite-bearing samples contained 1.832 ppm to 1.35 percent copper, 289 parts per billion gold, and 17.6 ppm silver.

Alteration:

Silicification.

Age of mineralization:

At least some is Eocene or younger based on the age of the granodiorite host rock.

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Discovered by Still and others (2002) during a regional mineral assessment for the Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Last report date: 2008-03-04

Site name(s): Unnamed (east of Upper Marten Lake)

Site type: Occurrence

ARDF no.: BC093

Latitude: 56.2889 **Quadrangle:** BC B-6

Longitude: 131.7921

Location description and accuracy:

This occurrence is in a saddle at an elevation of 2,600 feet; it is about 1.1 mile east-southeast of the southeast end of Upper Marten Lake near the center of section 26, T. 64 S., R. 86 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Pb

Other:

Ore minerals: Pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

This occurrence was first described by Still and others (2002) in an area with little previous indication of mineralization. It is along a fault zone that strikes 330 degrees and dips 75 degrees to the northeast. The fault cuts Mesozoic and/or Paleozoic schist and paragneiss near the contact with Cretaceous diorite (Elliot and Koch, 1981). The occurrence is about 2 miles west of the Coast Range megalineament (Brew and Ford, 1978), and the 'Great Tonalite Sill' (Brew and Morrell, 1983). Quartz stringers and clay gouge are common in the fault zone. Some of the quartz stringers contain pyrite, pyrrhotite, and other sulfides. Four samples of iron-stained quartz were collected along the fault; one contained 475 parts per billion gold, 86.9 part per million (ppm) silver, and 1,218 ppm lead.

Another quartz vein about 0.2 to 1 foot thick about 2 miles north of the main occurrence contains only minor pyrite and assayed 517 ppb gold.

Alteration:

No information other than along a fault zone with clay gouge.

Age of mineralization:

Generic deposit model:

Deposit model:

Gold-quartz veinlets along a regional fault.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only a few samples collected by Still and others (2002) during a regional mineral assessment by the Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Last report date: 2008-03-04

Site name(s): Unnamed (near mouth of Harding River)

Site type: Prospect

ARDF no.: BC094

Latitude: 56.2025 **Quadrangle:** BC A-5

Longitude: 131.6379

Location description and accuracy:

This prospect is at an elevation of about 40 feet on the west side of a small bight about 0.7 mile west-southwest of the mouth of the Harding River on Bradfield Canal. It is about 0.3 mile southwest of the center of section 27, T. 69 S., R. 89 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

As first described by Roehm (1942) and sampled by Still and others (2002), this prospect is an old opencut and probably the best mineralization in the several shear zones along Bradfield Canal in this area. The prospect is near the contact zone between the Eocene Coast Mountains batholith and metamorphic rocks. As described by Roehm (1942), the shear zone at this open cut has a hanging wall of mica schist or gneiss and a footwall of marble. A quartz vein about 0.5 to 1 foot thick occurs along the shear for about 20 feet of the opencut. The vein contains 1 to 2 percent sulfides, mainly pyrrhotite with pyrite and chalcopyrite. Still and others (2002) collected several samples; the highest values were 17 parts per billion gold, 1.8 part per million (ppm) silver, 197 ppm copper, and 235 ppm zinc.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Quartz vein with low values of gold, silver, copper, and zinc.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

A short opencut was dug before 1942 and there was limited sampling by government geologists about 2000.

Production notes:

None.

Reserves:

None.

Site name(s): Blue Lead; Blue Lead Extension; Rob

Site type: Mines

ARDF no.: BD003

Latitude: 64.3603 **Quadrangle:** BD B-1

Longitude: 144.20323

Location description and accuracy:

The Blue Lead and Blue Lead Extension Mines are about 2 miles north of the north peak '5080' of Black Mountain. They are at an elevation of about 3,790 feet at the head of Johnson Creek, near the southeast corner of section 29, T. 6 S., R. 17 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Sb

Other: Cu, Pb, Te, W

Ore minerals: Arsenopyrite, covellite, digenite, gold, jamesonite, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. By the winter of 1936, the first underground workings were begun. A 450-foot tunnel was driven following a small vein, termed the Blue Lead Extension. After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the nearby Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). The Blue Lead and Blue Lead Extension have approximately 775 feet of underground workings. There was limited exploration in the 1970s.

From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM Inc.) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling in 26 holes. The location of the holes is vague but they drilled at least 3 holes at the Blue Lead prospect (Flanders, 2010). In 2002, Freegold Ventures optioned a large block of claims that covered the Blue Lead and several other nearby deposits that are described separately: the Grizzly Bear (BD003), Michigan Lode (BD025), Gray Lead (BD017), Wolverine (BD057), Upper Trench, Lower Trench (BD058) and O'Reely (BD059). Freegold has continued the exploration through early 2012 as the Rob project (Flanders, 2010; Freegold Ventures Ltd., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. Freegold commissioned a comprehensive NI 43-101 report that summarized their and previous work (Freeman, 2004). The report was updated in 2010 (Flanders, 2010).

The Blue Lead Mine produced 132 ounces of gold and 25 ounces of silver from approximately 150 tons of ore (Thomas, 1970).

As interpreted by Bailey (2001), Freeman (2004), and Flanders (2010) this and the several other similar deposits in the area are near the contact of a large Cretaceous biotite granodiorite pluton and a mixed unit of Paleozoic biotite gneiss, feldspar-biotite augen gneiss, and quartzite that form a large gneiss dome. Locally the granodiorite is cut by hornblende, andesite porphyry dikes. The rocks are locally intensely sheared and this and the nearby Gray Lead (BD017), Grizzly Bear (BD018) and Michigan Lode (BD025) Mines are aligned along the northeast-trending Gray Lead fault. This shearing is observed in the underground

workings and also at the surface where it is marked by pronounced saddle-like depressions across the spurs separating the westward-flowing tributaries of Tibbs Creek.

The lode deposits in the area are gold-bearing quartz veins in shear zones in the metamorphic and igneous rocks. The quartz veins contain gold +/- base metal +/- silver and a variable combination of sulfides, including arsenopyrite, covellite, digenite, jamesonite, pyrite, and stibnite. Typically, the gold content decreases as sulfides increase. The veins are commonly 2 to 3 feet in width but some are as wide as 8 feet (Thomas, 1970). When gold is present, it is usually extremely fine grained. However, veins at the nearby Grizzly Bear Mine (BD018) contain relatively coarse gold, which is easily visible in hand specimen. The Blue Lead Mine is centered on a 2.5-foot-wide quartz vein with jamesonite and minor pyrite (Menzie and Foster, 1979). In the underground workings, the vein is nearly flat lying or dips gently to the north (Reed, 1937). Glover (1950) reports a range in gold fineness of 724.4 to 773.7 for the Blue Lead Mine. Freeman (2004) and Flanders (2010) classified the Blue Lead as a 'intrusion-hosted, probably intrusion-related gold vein with variable silver, tungsten, and bismuth'.

Freeman (2004) indicated the nine holes have been drilled on the Blue Lead, Blue Lead Extension, and Grizzly Bear (BD018) deposits, presumably during the joint-venture exploration from 1995 to 1999. The highest gold value was a 1.0-foot interval that contained 0.92 ounce of gold per ton, 28.2 parts per million (ppm) silver, and 4,650 ppm arsenic.

Alteration:

Not described in detail but alteration is associated with the veins.

Age of mineralization:

Probably genetically related to a nearby Cretaceous granodiorite intrusive.

Generic deposit model:

Deposit model:

Silver-gold-quartz veins and stockwork, +/- arsenic, copper, lead, antimony, tellurium, and tungsten (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. By the winter of 1936, the first underground workings were begun. A 450-foot tunnel was driven following a small vein, termed the Blue Lead Extension. After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the nearby Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). The Blue Lead and Blue Lead Extension have approximately 775 feet of underground workings. There was limited exploration in the 1970s.

From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling. In 2002, Freegold Ventures optioned a large block of claims that covered the Blue Lead and several other nearby deposits that are described separately: the Grizzly Bear (BD003), Michigan Lode (BD025), Gray Lead (BD017), Wolverine (BD057), Upper Trench, Lower Trench (BD058) and O'Reely (BD059); and explored them as the Rob project. Through early 2012, Freegold has continued to explore them (Flanders, 2010; Freegold Ventures Inc., 2012).

Freeman (2004) states that 9 holes have been drilled on the Blue Lead, Blue Lead Extension, and Grizzly Bear (BD018) deposits, apparently during the 1995-1999 joint venture.

Production notes:

The Blue Lead Mine produced 132 ounces of gold and 25 ounces of silver from approximately 150 tons of ore (Thomas, 1970).

Reserves:

None.

Site name(s): May's Pit; Campbell-Monroe; Campbell

Site type: Mine

ARDF no.: BD007

Latitude: 64.3008 **Quadrangle:** BD B-5

Longitude: 146.3002

Location description and accuracy:

May's Pit, as the mine is now commonly known, is on a large flat, now-barren saddle on the divide between the head of Tenderfoot Creek and lower Buckeye Creek. It is about 1.6 miles northeast of Richardson on the Richardson Highway and near the center of the southern boundary of section 14, T. 7 S., R. 7 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the mineralized quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

The May's Pit residual placer was found in 1908 by Fred Campbell but mining was stymied for 40 years because of the lack of water. Campbell transported ore downhill to Hinkley Gulch for processing (Olson and others, 1985; May, 2005, Freeman, 2011). In 1948 or 1949, Campbell leased the ground to Gib Martin who mined the property as an open pit with a dozer. As related by Freeman (2011), another miner said that he had seen an estimated 4,500 ounces of gold that came from the final cleanup of Martin's mining. Subsequently, the ground was leased to Gil Monroe and Erick Erickson who mined the property until 1978. In 1979, Don May of Polar Mining acquire the property. He worked the property as an open pit with a dozer from 1979 to 1981 and recovered 8,000 ounces of gold.

In 1988, Asarco drilled a hole at least 330 feet deep in the center of May’s pit (Applegate, 1988). Most of the hole was in biotite-muscovite schist and biotite-feldspar-quartz gneiss; a quartz-feldspar-porphyry dike about 5 feet thick was cut and the hole bottomed in mylonite. The hole intersected a few thin quartz veins with pyrite selvages but no sample from the hole produced as much as 0.002 ounce of gold per ton. In 2005, an extensive soil sampling program that extended over the property into upper Tenderfoot Creek defined several areas that were anomalous in gold, silver, arsenic, bismuth, tin, tungsten, copper, lead, and zinc (Noyes and others, 2006). The anomalies were less pronounced over May’s Pit. Freeman (2011) suggests

that May’s Pit may be above a distal intrusion-related gold deposit similar to the one at the Democrat Mine (BD014).

Alteration:

Possible alteration of intrusive and/or schistose host rocks to kaolinite (Swainbank and others, 1984).

Age of mineralization:

Quaternary?

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Residual gold placer, possibly above or near an intrusion-related gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

The May's Pit residual placer was found in 1908 by Fred Campbell but mining was stymied for 40 years because of the lack of water. Campbell transported ore downhill to Hinkley Gulch for processing (Olson and others, 1985; May, 2005; Freeman, 2011). In 1948 or 1949, Campbell leased the ground to Gib Martin who mined the property as an open pit with a dozer. Subsequently, the ground was leased to Gil Monroe and Erick Erickson who mined the property until 1978. In 1979, Don May of Polar Mining acquired the property and he mined an open pit with a dozer from 1979 to 1981. In 1988, Asarco drilled a hole at least 330 feet deep in the center of May’s pit (Applegate, 1988). In 2005, an extensive soil sampling program covered the mine and extended into upper Tenderfoot Creek.

Production notes:

Production of 8,000 ounces of gold from 1979 to 1981 is documented. Another 4,500 ounces reportedly was produced and there may have been significantly more.

Reserves:

Unknown.

Site type:

Mine

ARDF no.: BD014

Latitude: 64.3341 **Quadrangle:** BD B-5

Longitude: 146.3553

Location description and accuracy:

The Democrat Mine is located at the head of Banner Creek (BD001), which has been placer mined for several miles below the Democrat Mine. The mine is centered about 3.5 miles north of the town of Richardson and about 0.5 mile east-southeast of the center of section 4, T. 7 S., R. 7 E., of the Fairbanks Meridian. Several unimproved roads provide access to the mine. It consists of a open cut in the hillside along Banner Creek. Some contiguous workings that are usually described with the Democrat Mine are sometimes called the Camp Pit. The location is accurate.

Commodities:

Main: Ag, As, Au, Sb

Other: Cu, Bi, Hg, Mo, Pb, U, Zn

Ore minerals: Acanthite, boulangerite, enargite, freibergite, gold, owyheeite, pyrargyrite, stephanite, stibnite, stetefeldtite, tetrahedrite

Gangue minerals: Ankerite, carbonate, quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma felsic to intermediate dikes and plugs, notably the quartz-feldspar porphyry at this site.

The Democrat Mine has been the focus of most of the recent work in the Richardson district (Freeman, 2011). The Democrat Mine was the first lode prospect discovered in the Richardson district in 1913. By 1921, three short adits, and two shafts had been driven on the property and a small arastra mill produced an unknown but probably small amount of gold (Brooks, 1923). Modern work in the area was initiated by Bundtzen and Reger (1977), and Swainbank and others (1984), who identified several areas of mineral potential and defined the general geology and geochemistry of the district. The first detailed work on the Democrat Mine was by John Mitchell in the late 1980s, and in 1987, the Tri-Valley Corporation (now Select Resources Corporation, Inc.) acquired the property and have retained it through the end of 2011.

Tri-Valley drilled one reverse circulation hole 101.5 feet deep in 1987 and collected many rock samples from the quartz-feldspar porphyry dike that hosts the mineralization; the hole averaged 0.013 ounce of gold per ton. In 1988, Tri-Valley and Asarco Inc. in a joint venture drilled 17 diamond drill holes that totaled 4,462 feet. The drilling was at 8 locations along about 3,400 feet of the quartz-feldspar porphyry dike. Some

notable intercepts were 85 feet that averaged 0.032 ounce of gold per ton, 130 feet that averaged 0.185 ounce of gold per ton, and 175 feet that averaged 0.032 ounce of gold per ton. The highest grades were near the surface. Many (most?) of the investigators who subsequently reviewed the drill data concluded that the gold values were underestimated. Asarco terminated their agreement in late 1988. Later in 1988 and in 1989, Tri-Valley collected several large bulk samples on the surface of the deposit to prove that the Asarco drilling had underestimated the grade of the deposit. As a result of one of these episodes of bulk sampling, Mitchell (1989) estimated that the zone from which a large bulk sample was taken contained 18,750 tons of material that averaged 0.439 ounce of gold per ton. From another bulk-sample, Stearns (1989) identified four areas within the quartz porphyry dike that was estimated to contain 250,000 tons of material that averaged 0.07 ounces of gold per ton, or about 17,500 ounces of gold. Some (Freeman, 2011) considered the bulk sampling to be flawed. The bulk-sampling at the Democrat Mine in the 1980s produced 2,357 ounces of gold, the only lode gold produced in the district.

In 1991, Tri-Valley began working with TSNIGRI (Research Center of the Institute for Geological Exploration of Base and Precious Metals), of the Russian Ministry of Geology, and carried out geologic mapping, geophysics, and geochemical surveys at and around the Democrat Mine; the work continued to 2001. In 1997, Tri-Valley drilled 7 reverse-circulation holes at the Democrat property, completed several ground-geophysical grids, dug at least one trench, and collected numerous rock samples. The drilling was in the same general area as the 1987 and 1988 drilling. A report by Bright (1998) using drilling, and 1997 channel sampling estimated that 4 blocks of material 80-feet thick contained 141,539 tons of material with an average grade of 0.106 ounce of gold per ton (15,074 ounces). Freeman (2011) reported that an area about 1,200 feet long, 300-600 feet wide, and 200 feet thick averaged 0.65 part per million gold. In 2005, Select Resources (a subsidiary of Tri-Valley) compiled the previous information, sampled soils, and drilled 8 holes that totaled 930 meters. In 2010, Select collected fifteen, 25-kilogram samples for analysis.

The gold mineralization at the Democrat Mine is concentrated in the Democrat dike, which is up to 600 feet thick in the mine area. The dike has intruded along a northwest-trending, steeply-northeast-dipping structure (Freeman, 2011). The hanging wall is paragneiss; the footwall is lower-greenschist-facies rocks. The gold mineralization does not extend into the wall rocks. Locally, the dike thickens at flexures and is disrupted by northeast trending faults. The mineralization commonly is in quartz veins but the ore minerals are also disseminated in the dike rock. Locally, the ore is very rich, with a diverse suite of minerals including acanthite, freibergite, pyrargyrite, stephanite, stetefeldite, and owyheeite, boulangerite, stibnite, and enargite (Bundtzen, 2004). A suite of rich samples contained up to 28.323 ounces of gold per ton, 2,450 parts per million (ppm) copper, 5,320 ppm arsenic, 10,200 ppm antimony, 15,600 ppm lead, 28.1 ppm mercury, 56 ppm molybdenum, 88 ppm uranium, and more than 1 percent zinc. There is some indication of supergene enrichment. Geochemically, the gold is closely associated with silver, arsenic, copper, molybdenum, tungsten, and tin (Freeman, 2011).

McCoy and others (1997) describe several stages of alteration at the Democrat Mine. An early stage of alteration consists of quartz-tourmaline-muscovite +/- biotite +/- K-spar +/- clinozoisite. The stage more commonly associated with gold is an assemblage of quartz-white mica +/- ankerite +/- carbonaceous material. Locally, the plagioclase and K-spar phenocrysts are weathered to montmorillonite and kaolinite, respectively (D.J. Szumigala, oral communication, 1998). Albite is present in veins with quartz (R.J. Newberry, oral communication, 1998). In addition, the surrounding gneiss displays evidence of hornfelsing (K. Ausburn, oral communication, 1998).

In a recent synthesis of the many years of work at the property, Freeman (2011) proposes that the Democrat Mine is part of a structurally controlled, pluton related, boron enriched, gold-silver-tin-polymetallic hydrothermal system. McCoy and others (1977) include the Democrat Mine in their comprehensive article on the plutonic-related gold deposits of Interior Alaska.

Alteration:

McCoy and others (1997) describe several stages of alteration at the Democrat Lode. An early stage of alteration consists of quartz-tourmaline-muscovite +/- biotite +/- K-spar +/- clinozoisite. The stage more commonly associated with gold is an assemblage of quartz-white mica +/- ankerite +/- carbonaceous material. Locally, the plagioclase and K-spar phenocrysts are weathered to montmorillonite and kaolinite, respectively (D.J. Szumigala, oral communication, 1998). Albite is present in veins with quartz (R.J. Newberry, oral communication, 1998). In addition, the surrounding gneiss displays evidence of hornfelsing (K. Ausburn, oral communication, 1998).

Age of mineralization:

Most of the mineralization is about 90 Ma (as are many of the intrusion-related gold deposits in central Alaska).

Generic deposit model:

Deposit model:

Intrusion-related gold deposit; part of a structurally controlled, boron-enriched, gold-silver-tin-polymetallic hydrothermal system.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Democrat Mine has been the focus of most of the recent work in the Richardson district (Freeman, 2011). The Democrat Mine was the first lode prospect discovered in the Richardson district in 1913. By 1921, three short adits, and two shafts had been driven on the property and a small arrastra mill produced an unknown but probably small amount of gold (Brooks, 1923). Modern work in the area was initiated by Bundtzen and Reger (1977), and Swainbank and others (1984), who identified several areas of mineral potential and defined the general geology and geochemistry of the district. The first detailed work on the Democrat Mine was by John Mitchell in the late 1980s, and in 1987, the Tri-Valley Corporation (now Select Resources Corporation, Inc.) acquired the property and have retained it through the end of 2011.

Tri-Valley drilled one reverse circulation hole 101.5 feet deep in 1987 and collected many rock samples from the quartz-feldspar porphyry dike that hosts the mineralization. In 1988, Tri-Valley and Asarco Inc. in a joint venture drilled 17 diamond drill holes that totaled 4,462 feet. The drilling was at 8 locations along about 3,400 feet of the quartz-feldspar porphyry dike. Asarco terminated their agreement in late 1988. Later in 1988 and in 1989, Tri-Valley collected several large bulk samples on the surface of the deposit to prove that the Asarco drilling had underestimated the grade of the deposit.

In 1991, Tri-Valley began working with TsNIGRI (Research Center of the Institute for Geological Exploration of Base and Precious Metals), of the Russian Ministry of Geology, and carried out geologic mapping, geophysics, and geochemical surveys at and around the Democrat Mine; the work continued to 2001. In 1997, Tri-Valley drilled 7 reverse-circulation holes at the Democrat property, completed several ground-geophysical grids, dug at least one trench, and collected numerous rock samples. The drilling was in the same general area as the 1987 and 1988 drilling. In 2010, Select collected fifteen, 25-kilogram samples for analysis.

In 2016, Northern Empire Resources Corp. conducted exploration on their Richardson property, which hosts multiple intrusion-related as well as low- and high-angle fault-hosted lode gold prospects with gold ± silver ± arsenic ± antimony ± bismuth geochemical signatures. The project area includes the historical Democrat lode gold mine. In 2016, Northern Empire Resources Corp. collected rock chip-channel samples at 1-m intervals across 130 meters of the exposed face at Democrat. One 32-meter-long sample returned 5.73 grams of gold per tonne and 29.8 grams of silver per tonne, including 6 meters of 18.33 grams of gold per tonne and 48.95 grams of silver per tonne. Another sample collected about 61 meters away returned 2.57 grams of gold per tonne and 39.3 grams of silver per tonne across 6 m. Northern Empire also collected 1,298 geochemical samples across the Richardson property and conducted trenching, prospecting, 277 line-km of ground-magnetic geophysical surveys, identified structures in airborne geophysics, re-logged historical core holes, and delineated future drill targets. Work to date has identified a 2,000-meter-long, north–northeast-trending, gold-in-soil anomaly with a coincident geophysical structural signature. Additionally, 2,000 meters of the geophysical signature is poorly covered by soil data. A second northwest-trending mineralized structure was identified, with coincident elevated gold-in-soils over a 1,000-m strike length, with an additional 1,000 meters remaining to be evaluated by geochemical sampling (Athey and

Werdon, 2017).

Production notes:

There probably was a small but undocumented amount of gold produced from 1913 to 1922 from a small arrastra mill. The only other production was 2,357 ounces of gold that was recovered in 1988 and 1989 during the processing of several large bulk samples collected at the surface.

Reserves:

Since 1988, there have been several attempts to estimate the gold resources of the Democrat Mine. However, different criteria have been used, there has been some uncertainty about the accuracy of the data, and the samples do not necessarily overlap geographically. Mitchell (1989) estimated that a zone from which a large bulk sample was taken contained 18,750 tons of material that averaged 0.439 ounce of gold per ton. In another bulk-sampling effort, Stearns (1989) identified four areas in the quartz-feldspar porphyry dikes that were estimated to contain 250,000 tons of material that averaged 0.07 ounce of gold per ton, or about 17,500 ounces of gold. Based mainly on drilling and surface sampling to 1998, Bright (1998) estimated that 4 blocks of material 80-feet thick contained 141,539 tons of material with an average grade of 0.106 ounce of gold per ton (15,074 ounces). Freeman (2011) estimated that an area about 1,200 feet long, 300-600 feet wide, and 200 feet thick averaged 0.65 part per million gold.

Additional comments:

In his synthesis of more than 25 years of the work on the Democrat Mine and the surrounding area, Freeman (2011) lists and cites data that he had access to from a voluminous body of unpublished, internal reports done for the Tri-Valley Corporation and other companies. Some of Freeman's references not included in the reference list that follows may only peripherally relate to this deposit and most are not available publicly.

This site is part of the Richardson project (as of 2016).

Last report date: 2017-08-26

Site name(s): Gray Lead; Grey Lead; Hilltop; Rob

Site type: Prospect

ARDF no.: BD017

Latitude: 64.3445 **Quadrangle:** BD B-1

Longitude: 144.2523

Location description and accuracy:

The Gray Lead prospect is along a ridge at an elevation of about 4,070 feet, about 1.3 mile northwest of the north peak (5080) of Black Mountain. It is about 0.5 mile south of the center of section 31, T. 6 S., R. 18 E., of the Fairbanks Meridian. The location is accurate, though degree of accuracy not reported.

Commodities:

Main: Ag, As, Au, Sb

Other: Cu, Pb, Te, W

Ore minerals: Arsenopyrite, bismuthinite, covellite, digenite, gold, jamesonite, pyrite, stibnite

Gangue minerals: Quartz, sericite

Geologic description:

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. The first underground workings were driven in the winter of 1936. A 450-foot tunnel was driven following a small vein, termed the Blue Lead Extension (BD003). After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the nearby Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). The Gray Lead prospect was also probably discovered about this time. From 1939 to 1941, approximately 1,300 feet of surface and subsurface workings were completed at the Gray Lead prospect (Thomas, 1970). Over 300 feet of the vein was traced at the surface (Joesting, 1938). There was limited exploration reported in the 1970s.

From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM Inc.) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling in 26 holes. The details of the drilling are vague but at least 4 holes were drilled at the Gray Lead prospect. Surface rock samples contained up to 4.93 ounces of gold per ton. The best intercept in the drilling was 13.5 feet that averaged 0.92 ounce of gold per ton (Flanders, 2010).

In 2002, Freegold Ventures Ltd. optioned a large block of claims that covered the Gray Lead land several other nearby deposits that are described separately: the Grizzly Bear (BD018), Michigan Lode (BD025), Wolverine (BD057), Upper Trench, Lower Trench (BD058), and O'Reely (BD059). Freegold has continued the exploration through early 2012 as the Rob project. (Flanders, 2010; Freegold Ventures Ltd., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. In 2004, Freegold commissioned a comprehensive NI 43-101 report (Freeman, 2004) that summarized their and previous work. The 2004 report was updated by Flanders (2010) No ore has been mined from the Gray Lead prospect although 20 holes have been drilled on it since 1995.

As interpreted by Bailey (2001), Freeman (2004), and Flanders (2010), this and the several other similar deposits in the area are near the contact of a large Cretaceous biotite granodiorite stock with a mixed unit of Paleozoic biotite gneiss, feldspar-biotite augen gneiss, and quartzite that form a large gneiss dome. The

granodiorite is cut by hornblende, andesite porphyry dikes. The rocks are locally intensely sheared and Grizzly Bear (BD018) and Michigan Lode (BD025) are aligned along the northeast-trending Gray Lead fault. This fault is observed in the underground workings of the Gray Lead prospect and also at the surface where it is marked by pronounced saddle-like depressions across the spurs separating the westward-flowing tributaries of Tibbs Creek.

The lode deposits in the area are gold-bearing quartz veins in shear zones in the metamorphic and igneous rocks. The quartz veins contain gold +/- base metal +/- silver and a variable combination of sulfides, including arsenopyrite, covellite, digenite, jamesonite, pyrite, and stibnite. Typically, the gold content decreases as sulfides increase. Veins are commonly 2 to 3 feet in width but some are as wide as 8 feet (Thomas, 1970). When gold is present, it is usually extremely fine grained. However, veins at the nearby Grizzly Bear mine (BD018) contain relatively coarse gold which is easily visible in hand specimen (Freeman, 2004).

The Gray Lead prospect is on a quartz vein 2 feet in width. In the underground workings, the vein dips steeply west (Joesting, 1938). Freeman (2004) cites numerous grab samples from veins at the Gray Lead prospect that contain up to 2.105 ounces of gold per ton, up to 43.50 parts per million (ppm) silver, more than 1 percent arsenic, up to 1,610 ppm bismuth, up to 415 ppm lead, more than 1 percent antimony, up to 180.50 ppm tellurium, and up to 97.2 ppm tungsten. The many surface samples of veins and altered granite collected in subsequent years varied greatly in their relative and specific metal content but they essentially have the same association of metals. Freeman (2004) classifies the Gray Lead deposit as a quartz vein hosted in gneiss and/or high-grade schist near an intrusion that was the source of the mineralization.

In 2007, Freegold Ventures Ltd. (2007) drilled 8 holes on the Gray Lead vein that totaled 1,529 feet. All of the holes intersected the vein which is in biotite, augen paragneiss. The mineralization consisted of sugary textured quartz with fine-grained bismuthinite and arsenopyrite. The width of the vein varies but probably averages more than 10 feet thick.

Alteration:

Alteration has been reported as pervasive quartz- sericite- sulfide alteration occurring adjacent to veins and extending for up to one mile from the source structure (Flanders, 2010).

Age of mineralization:

Genetically related to a nearby Cretaceous granodiorite intrusive.

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active?

Workings/exploration:

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. The first underground workings were driven in the winter of 1936. A 450-foot tunnel was driven following a small vein, termed the Blue Lead Extension (BD003). After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the nearby Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). The Gray Lead vein was also probably discovered about this time. From 1939 to 1941, approximately 1,300 feet of surface and subsurface workings were completed at the Gray Lead prospect

(Thomas, 1970). Over 300 feet of the vein could be traced at the surface (Joesting, 1938). There was limited exploration reported in the 1970s. From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling in 26 holes. The details of the drilling are vague but one or more probably was drilled at the Gray Lead prospect.

In 2002, Freegold Ventures optioned a large block of claims that covered the Gray Lead lode and several other nearby deposits that are described separately: the Grizzly Bear (BD003), Michigan Lode (BD025), Wolverine (BD057), Upper Trench, Lower Trench (BD058) and O'Reely (BD059). Freegold has continued the exploration through early 2012 as the Rob project. (Flanders, 2010; Freegold Ventures Ltd., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. In 2007, Freegold Ventures Ltd. (2007) drilled 8 holes on the Gray Lead prospect that totaled 1,529 feet. Some of the notable intercepts in these holes were: 16.5 feet that contained 0.197 ounce of gold per ton, 13.5 feet that contained 0. 586 ounce of gold per ton, 13.0 feet that contained .841 ounces of gold per ton, 14.0 feet that contained 0.230 ounce of gold per ton, and 6.5 feet that contained 0.677 ounce of gold per ton. In 2008, they drilled 12 more holes that totaled 3,144.2 feet. In addition, 14 grab rock samples were submitted for geochemical analysis, and IP and resistivity surveys were conducted (Flanders, 2010). Highlights of the results of 2008 drilling are 4.5 meters of 18 g/t gold and 2. meters of 62 g/t gold (Freegold Ventures Ltd, 2008).

Production notes:

None.

Reserves:

None.

Site name(s): Grizzly Bear; Yellow Jacket

Site type: Mine

ARDF no.: BD018

Latitude: 64.3512 **Quadrangle:** BD B-1

Longitude: 144.2093

Location description and accuracy:

The Grizzly Bear mine is situated on a ridge of Black Mountain separating the headwaters of Antimony Creek, a tributary of Tibbs Creek (BD040), and Summit Creek, a tributary of Boulder Creek (BD004). The mine is about 0.3 mile east of the center of section 32, T. 6 S., R. 18 E., of the Fairbanks Meridian. The Yellow Jacket deposit is nearby (The Grizzly Bear Mine is misplaced on the USGS 1:63,360-scale topographic map.).

Commodities:

Main: Ag, As, Au, Sb

Other: Cu, Pb, Te, W

Ore minerals: Arsenopyrite, covellite, digenite, gold, jamesonite, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

The Grizzly Bear mine and Yellow Jacket deposit are situated the ridge of Black Mountain that is largely underlain by Cretaceous granodiorite (Weber and others, 1978). Augen gneiss, gneissic schist, and schist are the west of Black Mountain. There is intense shearing and faulting in the contact between the metamorphic and intrusive rocks. This shearing is observed in the underground workings and at the surface as pronounced saddle-like depressions across the spurs separating the westward-flowing tributaries of Tibbs Creek. This shear zone trends roughly N 15 E and dips 65 degrees NW. The lode deposits in the area are mostly gold-bearing quartz veins in the shear zone, although some are in the granodiorite. The veins contain gold and a variable assemblage of sulfides, including arsenopyrite, covellite, digenite, jamesonite, pyrite, and stibnite. Typically, gold content decreases as sulfides increase. Veins are commonly 2 to 3 feet in width, with some as wide as 8 feet (Thomas, 1970). When gold is present, it is usually extremely fine grained. However, other near veins such as in the Blue Lead Mine (BD003) contain relatively coarse gold, which is easily visible in hand specimen.

The Grizzly Bear Mine was developed on an 18-inch-wide quartz vein. Based on underground workings, the vein dips steeply to the south (Reed, 1937). Much of the ore is on the hanging wall (Thomas, 1970). Thomas (1970) shows the Yellow Jacket prospect as a vein exposed at the surface approximately one third of a mile southwest of the Grizzly Bear Mine. Glover (1950) reported a range in gold fineness of 766 to 780 for the Grizzly Bear Mine.

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. By the winter of 1936, the first underground workings were being installed. A 450-foot tunnel was driven following a small vein, termed the Blue Lead Extension (BD003). After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). There was limited exploration in the 1970s. The mill was still on site and the mine shaft was accessible in 1970, but blocked by ice (Thomas, 1970). It is reported that 350 tons of ore was produced from

the Grizzly Bear mine and processed at the mill at the Blue Lead mine. Another 150 tons was produced from the Blue Lead mine (Reed, 1937). No ore was mined from the Yellow Jacket vein (Thomas, 1970).

From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics. They drilled 26 holes in the area that totaled 16,215 feet in 26 holes. The location of the holes is vague but one or more of these holes was at the Grizzly Bear Mine.

In 2002, Freegold Ventures optioned a large block of claims that covered the Grizzly Bear Mine and several others deposits nearby that are described separately: the Blue Lead (BD003), Michigan Lode (BD025), Gray Lead (BD017), Wolverine (BD057), Upper Trench/ Lower Trench (BD058) and O'Reely (BD059). Freegold has continued the exploration through early 2012 as the Rob project. (Flanders, 2010; Freegold Ventures Ltd., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys.

Freeman (2004) and Flanders (2010) consider the deposit to be Au ± base metal, ± Ag ± W ± Bi intrusion-hosted mineralization with a possible genetic relationship between the precious metal mineralization and the emplacement of the intrusion.

Alteration:

Age of mineralization:

Probably genetically related to a nearby Cretaceous granodiorite intrusive.

Generic deposit model:

Deposit model:

Silver-gold-quartz veins and stockwork, +/- arsenic, copper, lead, antimony, tellurium, and tungsten (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. By the winter of 1936, the first underground workings were driven. A 450-foot tunnel was driven following a small vein called the Blue Lead Extension. After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). The mill was still on site and the mine shaft openings were accessible in 1970, but blocked by ice (Thomas, 1970).

From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling. They drilled 26 holes; one or more of these hole may have been at the Grizzly Bear Mine but the details are obscure. In 2002, Freegold Ventures optioned a large block of claims that covered the Grizzly Bear and several other nearby deposits that are described separately: the Blue Lead (BD003), Michigan Lode (BD025), Gray Lead (BD017), Wolverine (BD057), Upper Trench/ Lower Trench (BD058) and O'Reely (BD059). They continued to explore them as a unit as the Rob project through early 2012 (Flanders, 2010; Freegold Ventures Ltd., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys.

Production notes:

The Grizzly Bear Mine has produced 350 tons of ore and processed them at the mill at the Blue Lead mill (Reed, 1937). No ore was mined from the Yellow Jacket vein (Thomas, 1970).

Reserves:

None.

Reporter(s): Cameron S. Rombach (ADGGS); D.J. Grybeck (Contractor, USGS)

Last report date: 2012-04-01

Site name(s): Hinkley Gulch

Site type: Mines

ARDF no.: BD019

Latitude: 64.3061 **Quadrangle:** BD B-5

Longitude: 146.313

Location description and accuracy:

Hinkley Gulch is a small northwest flowing tributary to lower Banner Creek. The gulch is not labeled on the USGS topographic maps but 'Hinkley Gulch' has long been used locally and in various mining-related publications. The mine is about 1.6 miles north-northeast of Richardson on the Richardson Highway, in the southwest corner of section 14, T. 7 S., R. 7 E., of the Fairbanks Meridian.

Commodities:

Main: Au

Other: Ag, As, Bi, Cu, Pb, Sb, Sn, U, W, Zn

Ore minerals: Gold

Gangue minerals:

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the mineralized quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

Placer gold was discovered nearby on Tenderfoot Creek (BD039) in 1905 and Hinkley Gulch was probably mined soon after. Ellsworth and Parker (1911) noted mining in Hinkley Gulch in open cuts and by drifting. There was at least one episode of mining after WWII. Don May (oral communication, 1998) said that Terry Anderson recovered 3,000 ounces of gold from Hinkley Gulch, but details are lacking. In recent years, there has been considerable production from a residual gold placer at May's Pit (BD007) about a half mile to the southeast on the saddle at the head of Hinkley Gulch and there has been speculation that the gold in the placers at May's Pit and Hinkley Gulch share a common origin (Freeman, 2011). Glover (1950) reported that the gold from Hinkley Gulch was 677 to 680 fine and Bundtzen and Reger (1977) said it averaged 670 fine.

Since the late 1980s there has been intermittent but extensive exploration in the Richardson district for lode gold deposits and some of that work has overlapped or involved sampling and mapping along Hinkley Gulch. Swainbank and others (1984) mapped highly altered rocks exposed along Hiinkley Gulch. Intervals up to 60 feet wide consist of sheared and oxidized epidote-amphibolite and garnet-amphibole skarn. A breccia exposed along the gulch that consists of clasts of quartz-feldspar porphyry, schist, quartzite and gneiss could be traced northeast for about 1,500 feet. A chip sample of porphyry contained 0.30 parts per

million (ppm) gold, and low levels of copper, lead, zinc, antimony, and uranium. In 2005, an extensive soil sampling program defined several areas over or near Hinkley Gulch that were anomalous in gold, silver, arsenic, bismuth, tin, tungsten, copper, lead, and zinc (Noyes and others, 2006). In view of the altered rocks and the geochemical anomalies, Freeman (2011) suggests that the Hinkley Gulch may be over or near a distal intrusion-related gold deposit similar to the one at the Democrat Mine (BD014).

Alteration:

Rock in the vicinity of the placer on Hinkley Gulch are locally highly altered, sheared, oxidized, and brecciated.

Age of mineralization:

Quaternary placer and a 90 Ma intrusion-related gold deposit.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Placer gold was discovered nearby on Tenderfoot Creek (BD039) in 1905 and Hinkley Gulch was probably mined soon after. Ellsworth and Parker (1911) noted mining in Hinkley Gulch in open cuts and by drifting. There was at least one episode of mining after WWII. Since the late 1980s there has been intermittent but extensive exploration in the Richardson district for lode gold deposits and some of that work has overlapped or involved sampling and mapping along Hinkley Gulch. In 2005, an extensive soil sampling program defined several anomalous areas over or near Hinkley Gulch.

Production notes:

There is little document production from Hinkley Gulch but 3,000 ounces of gold reportedly was produced some time after was WWII.

Reserves:

Unknown.

Site name(s): Junction Creek

Site type: Mines

ARDF no.: BD021

Latitude: 64.333 **Quadrangle:** BD B-5

Longitude: 146.403

Location description and accuracy:

Junction Creek, a tributary of Redmond Creek, is approximately 3.5 miles north of the town of Richardson on the Richardson Highway. This site is approximately at the center of the mining at the head of the creek in the lower half of section 5, T. 7 S., R. 7 E., of the Fairbanks Meridian. There was also drilling after WWII about 2 and 5 miles downstream; see the Geologic Description field for details.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

There is little information on placer mining on Junction Creek although it was probably prospected soon after gold was discovered in the Richardson District in 1905. Metz (1991) described early drift mine and surface tailings in the Junction Creek. Most of the mining apparently took place at the head of Junction Creek in the lower half of section 5, T. 7 S., R. 7 E., but it may be more extensive. The Alaska Division of Mining Kardex file system records active claims on Junction Creek as recent as 1984.

Based on oral communications with Dan Cobin, a prospector in the area, Freeman (2011) notes that Cobin drilled one hole near the junction of Democrat Creek and Junction Creek, probably after WWII; only low gold values were found. Cobin also drilled another hole about 3 miles downstream, probably near the center of section 33, T. 6 S., R. 6 E.; no further work was done although 'good pay' was found.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

There is little information on placer mining on Junction Creek although it was probably prospected soon after gold was discovered in the Richardson District in 1905. Metz (1991) described early drift mine and surface tailings in the Junction Creek. Most of the mining apparently took place at the head of Junction Creek in the lower half of section 5, T. 7 S., R. 7 E., but it may be more extensive. Site name(s): Michigan; Michigan Lode; Michigan Lead; Rob

Site type: Prospect

ARDF no.: BD025

Latitude: 64.3624 **Quadrangle:** BD B-1

Longitude: 144.1979

Location description and accuracy:

The Michigan prospect about 2.1 miles north-northwest of the north(5080) peak of Black Mountain and about 0.4 mile southwest of the center of section 28, T. 6 S., R. 18 E, of the Fairbanks Meridian. Although sometimes described as a separate deposit, it may be a continuation of the mineralization at the Blue Lead prospect (BD003) and Grizzly Bear Mine (BD018) just to the south. The location is accurate within 500 feet.

Commodities:

Main: Ag, As, Au, Sb

Other: Bi, Cu, Pb, Te, W

Ore minerals: Arsenopyrite, covellite, digenite, gold, jamesonite, pyrite, stibnite

Gangue minerals: Quartz, sericite

Geologic description:

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. By the winter of 1936, the first underground workings were begun. A 450-foot tunnel was driven following a small vein, termed the Blue Lead Extension (BD003). After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the nearby Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). The Michigan Lode was also probably discovered about that time. No ore has been mined from the Michigan Lode (Thomas, 1970) and the only workings are trenches.

From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling. The joint venture drilled 26 holes but details on their location is largely lacking. Apparently no holes were drilled on the Michigan prospect. In 2002, Freegold Ventures optioned a large block of claims that covered the Michigan Lode and several other nearby deposits that are described separately: Gray Lead (BD017), the Grizzly Bear (BD018), Wolverine (BD057), Upper Trench, Lower Trench (BD058) and O'Reely (BD059). Through early 2012, Freegold has been exploring them as a unit under the name Rob (Flanders, 2010; Freegold Ventures Inc., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. In 2004, Freegold commissioned a comprehensive NI 43-101 report (Freeman, 2004) that summarized their and previous work. That report was updated in 2010 (Flanders, 2010).

As interpreted by Bailey (2001), Freeman (2004), and Flanders (2010) this and several other similar prospects in the area are near the contact of a large Cretaceous biotite granodiorite pluton that intrudes a mixed unit of Paleozoic biotite gneiss, feldspar-biotite augen gneiss, and quartzite that forms a large gneiss dome. The granodiorite is cut by hornblende, andesite porphyry dikes. The rocks are intensely sheared locally and this and the nearby Gray Lead (BD017), Blue Lead (BD003), and Grizzly Bear (BD018) deposits are aligned along the northeast-trending Gray Lead fault. This shearing is observed in the

underground workings and at the surface as saddle-like depressions across the spurs separating the westward-flowing tributaries of Tibbs Creek.

The lode deposits in the area are gold-bearing quartz veins in shear zones in the metamorphic and igneous rocks. The quartz veins contain gold +/- base metal +/- silver and a variable combination of sulfides, including arsenopyrite, covellite, digenite, jamesonite, pyrite, and stibnite. Typically, the gold content decreases as sulfides increase. The veins commonly are 2 to 3 feet in width but some are as wide as 8 feet (Thomas, 1970). When gold is present, it is usually extremely fine grained. However, veins at the nearby Grizzly Bear mine (BD018) contain relatively coarse gold, which is easily visible in hand specimen.

Thomas (1970) describes the Michigan Lode as a vein. Samples from vein quartz with a blue hue contain 0.10 ounce of gold per ton; some Fe-stained quartz sampled contained 0.42 ounce of gold per ton and 0.08 ounce of silver per ton. A sample containing cryptocrystalline quartz with a blue cast contained 8.76 ounces of gold per ton and 3.26 ounces of silver per ton (Thomas, 1970). Freeman (2004) and Flanders (2010) classified the Michigan Lode as a 'stockwork-shear deposit with anomalous bismuth, tellurium, and tungsten, in a porphyritic, intermediate to felsic intrusion that may be genetically related to the deposit'. Flanders (2010) cites grab samples of vein and altered granite that contain up to 28.83 ounces of gold per ton, up to 9.50 parts per million (ppm) silver, more than 1 percent arsenic, up to 0.83 ppm bismuth, up to 40 ppm lead, up to 776 ppm antimony, up to 0.30 ppm tellurium, and up to 0.05 ppm tungsten.

Alteration:

Alteration varies from flood silica to intense sericite alteration that leaves the host rock soft and easily broken with bare hands (Flanders, 2010).

Age of mineralization:

Probably genetically related to a nearby Cretaceous granodiorite intrusive.

Generic deposit model:

Deposit model:

Silver-gold-quartz veins and stockwork, +/- arsenic, copper, lead, antimony, tellurium, and tungsten (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active?

Workings/exploration:

The Goodpaster region was first explored for placer gold in 1915. In the early 1930s, gold-bearing quartz veins were discovered in the upper Tibbs Creek area. By the winter of 1936, the first underground workings were begun. A 450-foot tunnel was driven following a small vein, termed the Blue Lead Extension. After disappointing results, the work was stopped. In the summer of 1936, five men drove a 300-foot tunnel at the outcrop of the Blue Lead vein (Reed, 1937). During the winter of 1937, a 300-foot tunnel was driven at the nearby Grizzly Bear Mine (BD018) and a 50-ton mill was constructed. In the summer of 1938, the mill was moved to the Blue Lead Mine and operated for a year and a half until the fall of 1939 (Joesting, 1938). The Michigan Lode was also probably discovered about this time. No ore has been mined from the Michigan Lode (Thomas, 1970).

From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling. The work has included extensive

mapping, surface sampling, and geochemical and geophysical surveys. Through 2004, Ventures spent more than $1 million exploring the Rob property and in 2004 commissioned a comprehensive NI 43-101 report (Freeman, 2004); an update was done in 2010 (Flanders, 2010). Freegold drilled 3 holes in 2011.

The 2011 drilling was the first drilling done at Michigan; 2,984 feet was drilled in order to evaluate the bulk tonnage potential of the prospect. Highlights of the results of 2011 drilling are 57 gpt gold for over five feet, and 7 gpt gold for over 11.5 feet (Avalon Development Corporation, 2014).

Production notes:

None.

Reserves:

None.

Site name(s): Pogo

Site type: Mine

ARDF no.: BD033

Latitude: 64.4526 **Quadrangle:** BD B-2

Longitude: 144.9136

Location description and accuracy:

The center of the Liese zone of the Pogo Mine that was the focus of mining as of early 2012 is just east of the Goodpaster River about 1.7 miles south of the mouth of Indian Creek. It is near the center of section 26, T. 5 S., R. 14 E, of the Fairbanks Meridian. Lamier and Puchlik (2011) have an image looking down on the mine and the zones of mineralization.

Commodities:

Main: Au

Other: Ag, As, Bi, Cu, Mo, Pb, Te, Zn

Ore minerals: Arsenopyrite, bismuth, bismuthinite, chalcopyrite, gold, loellingite, maldonite, pyrite, pyrrhotite, sphalerite, tetradymite

Gangue minerals: Biotite, dolomite, feldspar, quartz, sericite

Geologic description:

The Goodpaster region was first explored for placer gold in 1915. Thomas (1970) reports a stampede of prospectors that quickly ended when little gold was found. In 1991, a regional stream sediment sampling program identified gold, arsenic, and tungsten anomalies in Liese Creek and Pogo Creek. From 1991 to 1994, exploration consisted of soil sampling, minor prospecting, and geophysics. The Pogo deposit underlies a 1-square-mile area that contains more than 100 parts per billion (ppb) gold in soils. Three core drill holes were completed on Liese Creek in 1994; 13 additional core holes were drilled in 1995. These holes identified the Liese L1 zone. Work in 1996 consisted of 22 drill holes that further defined the zone. From 1991 to 1996, the exploration program drilled a total of 36,703 feet of core with 4,142 core samples and 3,520 geochemical samples. An additional 41 drill holes in 1997 enlarged the deposit and found the lower Liese L2 zone. Drilling in 1998 focused on better defining the L1 and L2 and the Liese L3 zone that was first identified in 1991. As of 1999, a total of 91,263 feet of drilling had been completed and 3,404 core samples and 1,500 geochemical samples were collected (M. Smith, oral communication, 1999). Extensive exploration continued through 2011 when three new ore bodies outside the Liese zone were announced (Lamier and Puchlik, 2011).

All the permits for the mine were received by the middle of 2004 (Szumigala and Hughes, 2005). By January 2006, the deposit had been fully developed with a large permanent camp, ore processing facilities, water treatment plant, power transmission lines, provisions for tailings disposal, and underground workings (Szumigala and Hughes, 2007). The first ore arrived at the mill on January 12, 2006 and the first gold pour was on February 12, 2006. Until 2009, the Pogo project was a joint venture of the Teck Resources Corporation, Sumitomo Metal Mining, and Sumitomo Corporation, with Teck as the operator. In July, 2009, Teck sold their interest in the mine and it is now fully owned by Sumitomo (Szumigala and others, 2011).

The rocks in the area are high grade gneiss intruded by Cretaceous granitic bodies. The area is cut by prominent northwest-trending high-angle faults but there are other high-angle faults with various orientations. To the north, the region is intruded by the Cretaceous Goodpaster batholith. At the Pogo deposit the host rock is predominantly amphibolite-grade biotite-quartz-feldspar gneiss. In the Liese Creek drainage, a series of granodiorite dikes intrude the gneiss. These dikes are interpreted to be apophyses of the

batholith. The youngest geologic unit in the area is a northwest-trending, steeply dipping, diorite dike situated in Liese Creek. This dike partly cuts off mineralization on the northeast edge of the deposit (Teck Resources Inc., 1998).

Geochronology studies have focused on the granodiorite and diorite dikes in the Liese Creek drainage. The diorite dike has an 40Ar/39Ar biotite age of 94 Ma, and a U-Pb zircon age of 94 Ma. The granodiorite dike has a 40Ar/39Ar biotite age of 91.7 Ma, a 40Ar/39Ar white mica age of 91.2 Ma, and a U-Pb monazite age of 107 Ma (M. Smith, oral communication, 1999). Lamier and Puchlik (2011) suggest similarities of the Pogo deposit to other intrusion-related gold deposits in interior Alaska, e.g., the Fort Knox Mine (ARDF FB112). The mineral assemblages suggest deposition from rapidly-changing pulses of magmatic fluids rather than from a metamorphic source.

As of early 2012, mining is centered on the Liese zone that consists of at least three flat-lying, subparallel, stacked tabular bodies of massive quartz, he L1, L2, and L3. The Pogo deposit is marked by a flexure point with an almost sinusoidal wave shape. The west portion of the deposit strikes northeast and dips northwest about 30 degrees. The east portion of the deposit strikes east and dips north about 30 degrees. The upper Liese zone (L1) is the largest and shallowest; it is at least 4,000 by 2,000 feet in area and varies from 0 to 65 feet thick. The lower Liese zone (L2) lies 300 to 500 feet below the L1. It is generally thinner, but higher grade than the L1. The L3 zone is approximately 800 feet below L1 (Smith, 1999). Although there are no mappable thrust faults, the Liese zones intersect the foliation of the host rock at an angle of about 5 degrees and apparently mark low angle structures.

The mineralized layers in the Liese zone are predominantly quartz with about 3 percent sulfides. The ore minerals in the quartz include arsenopyrite, bismuth, bismuthinite, chalcopyrite, gold, loellingite, maldonite, pyrite, pyrrhotite, sphalerite, and tetradymite (Smith, 1999). The gold occurs as 1 to 25 micron grains in arsenopyrite along fractures, and as inclusions in bismuth, tetradymite, and other gold-lead-bismuth-tellurium minerals. Geochemical data suggest a strong correlation between gold and bismuth, and a weaker correlation between gold and other lithophile elements (Smith, 1999).

The Liese zones are all display vein and replacement textures. The veining textures are characterized by two styles of quartz veins and alteration assemblages. The early veins are characterized by white quartz with arsenopyrite, chalcopyrite, pyrite, pyrrhotite and loellingite, and secondary biotite in selvages up to 1 meter wide (Smith, 1998). The later veins are characterized by gray quartz in stockwork veins and replacement selvages. They contain arsenopyrite and pyrite, with secondary disseminated sericite and dolomite that often overprints earlier secondary biotite. Some silica flooding is observed in the gneiss and intrusive rocks (M. Smith, oral communication, 1999).

Work in the late 2000s and into 2011 identified three other areas of mineralization peripheral to the Liese zone (Lamier and Puchlik (2011). A North zone consists of three, steeply dipping quartz veins that strike northwest. they intersect the Liese zone and radiate out from it; they may be the feeder to it. The East Deep zone about 1,000 feet northeast of the Liese zone was the main focus of drilling in 2011. A 95 Ma post-mineral dike separates it from the Liese zone which it resembles in orientation and mineral assemblages. The 4021 target is about 2.5 miles southeast of the Liese Zone. It consists of two, stacked, shallow-dipping quartz veins in granitic gneiss. It possibly is a distal extension of the Liese Zone.

In 2011, the Pogo Mine produced 385,000 ounces of gold (Puchlik and others, 2012).

In 2016, the Pogo Mine produced 269,342 ounces of gold from 1,515,117 tons of ore and waste materials mined; 941,856 tons were milled, and 12,812,069 cubic feet of paste fill was placed back in the underground workings (Athey and Werdon, 2017).

At least five high-grade gold zones (Liese, East Deep, North, Fun, and South Pogo) have been discovered within 1 mile of the mill; these zones are currently contributing ore to the mill, or are expected to in the near future (Athey and Werdon, 2017).

Alteration:

The Liese Zones all are associated with vein and replacement type textures. The veining textures are characterized by two styles of quartz veins and alteration assemblages. The early veins are typified by white quartz containing arsenopyrite, chalcopyrite, pyrite, pyrrhotite and loellingite with secondary biotite in selvages up to 1 meter in width. The later veins are typified by gray quartz as stockwork veins and replacement selvages containing arsenopyrite and pyrite, with secondary disseminated sericite and dolomite. It is common to find the sericite-dolomite alteration overprinted upon the earlier secondary biotite. Some silica flooding is observed in the gneiss and intrusive (M. Smith, oral communication, 1999).

Age of mineralization:

Mineralization at the Pogo deposit is thought to be plutonic-related. Geochronology studies have focused on the granodiorite and diorite dikes in the Liese Creek drainage. A diorite dike has an 40Ar/39Ar biotite age of 94 Ma, and a U-Pb zircon age of 94 Ma. A granodiorite dike has an 40Ar/39Ar biotite age of 91.7 Ma, an 40Ar/39Ar white mica age of 91.2 Ma, and a U-Pb monazite age of 107 Ma. (M. Smith, oral communication, 1999).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins? (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a?

Production Status: Yes; large

Site Status: Active

Workings/exploration:

The Goodpaster region was first explored for placer gold in 1915. Thomas (1970) reports a stampede of prospectors that quickly ended when little gold was found. In 1991, a regional stream sediment sampling program identified gold, arsenic, and tungsten anomalies in Liese Creek and Pogo Creek. From 1991 to 1994, exploration consisted of soil sampling, minor prospecting, and geophysics. The Pogo deposit underlies a 1-square-mile area that contain more than 100 parts per billion (ppb) gold in soils. Three core drill holes were completed on Liese Creek in 1994; 13 additional core holes were drilled in 1995. These holes identified the Liese L1 zone. Work in 1996 consisted of 22 drill holes that further defined the zone. From 1991 to 1996, the exploration program drilled a total of 36,703 feet of core with 4,142 core samples and 3,520 geochemical samples. An additional 41 drill holes in 1997 enlarged the deposit and found the lower Liese L2 zone. Drilling in 1998 focused on better defining the L1 and L2 and the Liese L3 zone that was first identified in 1991. As of 1999, a total of 91,263 feet of drilling had been completed and 3,404 core samples and 1,500 geochemical samples were collected (M. Smith, oral communication, 1999). Extensive exploration continued through 2011 when three new ore bodies outside the Liese zone were announced (Lamier and Puchlik, 2011).

All the permits for the mine were received by the middle of 2004 (Szumigala and Hughes, 2005). By January 2006, the deposit had been fully developed with a large permanent camp, ore processing facilities, water treatment plant, power transmission lines, provisions for tailings disposal, and underground workings (Szumigala and Hughes, 2007). The first ore arrived at the mill on January 12, 2006 and the first gold pour was on February 12, 2006. Until 2009, the Pogo project was a joint venture of the Teck Resources Corporation, Sumitomo Metal Mining, and Sumitomo Corporation, with Teck as the operator. In July, 2009, Teck sold their interest in the mine and it is now fully owned by Sumitomo (Szumigala and others, 2011).

In 2012, surface exploration included four surface drills. Underground drilling included four drills with over 100,000 feet drilled as of late 2012. The areas of focus were definition drilling of Liese Zone, and East Deep, the latter of which also had underground exploration drilling performed. Geotechical and hydrological drilling programs were also undertaken. Twenty more prospects were identified by gold geochemical anomalies, geophysical data, and quartz vein outcrops (Puchlik and others, 2012).

To ensure continued mining into the future, Sumitomo Metal Mining Pogo LLC invested $10 million in exploration at Pogo mine in 2016, following $15 million in 2015. At least five high-grade gold zones (Liese, East Deep, North, Fun, and South Pogo) have been discovered within 1 mile of the mill; these zones are currently contributing ore to the mill, or are expected to in the near future (Athey and Werdon, 2017).

Production notes:

In 2010, the Pogo Mine mined 900,585 tons of ore from which 383,434 ounces of gold was produced with a recovery rate of 89.6 percent (Szumigala and others, 2011). The total production of the Pogo Mine from

2006 when mining began to 2010 was 1,483,645 ounces of gold.
In 2011, the Pogo Mine produced 385,000 ounces of gold (Puchlik and others, 2012).
Pogo mine celebrated its 10th anniversary of production in 2016, producing 269,342 ounces of gold from 1,515,117 tons of ore and waste materials mined; 941,856 tons were milled, and 12,812,069 cubic feet of paste fill was placed back in the underground workings (Athey and Werdon, 2017).

Reserves:

As of December 31, 2011, the Pogo Mine has a total reserve and resource of 13.594 million tons with an average grade of 0.366 ounces of gold per ton (or 4.973 million ounces of gold) (Sumitomo Metal Mining Co., Ltd., 2012). This total included 1.283 million ounces of gold in the East Deep target that was identified in 2011.

Site name(s): Shamrock; Shamrock/Buck; Buck

Site type: Prospects

ARDF no.: BD038

Latitude: 64.3816 **Quadrangle:** BD B-5

Longitude: 146.4323

Location description and accuracy:

The Shamrock prospect covers a considerable area on the west side of 'Buck Mountain', the hill under VABM 3026 'Buck'. But the coordinates are at the center of the considerable trenching on it about 1 mile west of the top of the hill. The prospect is about 7.2 miles northwest of Richardson on the Richardson Highway and about 0.1 mile northeast of the center of section 19, T. 6 S., R. 7 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Bi, Pb, Sb

Ore minerals: Arsenopyrite, bismuthinite, chalcopyrite, gold, pyrite, sphalerite, tetrahedrite

Gangue minerals: Ankerite, quartz, siderite

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014). The country rocks around the Shamrock prospect are mainly unaltered quartz-biotite-feldspar-hornblende gneiss (Freeman, 2011).

The Shamrock prospect was first identified in 1991 during regional reconnaissance exploration and geochemical surveys (Vartanyan and others, 1991; Freeman, 2011). Panned concentrate samples containing visible gold, as well as notable pyrite, tourmaline, biotite, pyroxene, and magnetite were found widely in the area west of VABM Buck. In 1992, the area was mapped, three long road cuts and trenches were dug west of VABM Buck, and 582 grab and channel samples were collected in them (Vartanyan and others, 1992; Freeman, 2011). The samples contained up to 6,351 parts per billion (ppb) gold, up to 364 parts per million (ppm) silver, up to more than 2,000 ppm arsenic, up to 379 ppm bismuth, up to 2,866 ppm lead, and up to more than 2,000 ppm antimony. Channel samples up to 15 meters long contained more than 500 ppb gold; the highest grade was 1.5 meters that averaged 6,351 ppb gold; the longest was 12 meters that averaged 1,997 ppb gold. Aushburn (1998 [Redstar]) check sampled some of the trenches but could not duplicate the high values of the 1997 work.

Freeman (2011) identified three types of mineralization: 1) quartz-limonite breccia, 2) pyrite-arsenopyrite-tourmaline-quartz veins, and pyrite-arsenopyrite-quartz veinlets. The quartz-limonite breccia is widespread.

The pyrite-arsenopyrite-tourmaline-quartz veins form linear zones up to 40 centimeters thick. They commonly also contain sphalerite, chalcopyrite, tetrahedrite, and rare bismuthinite. The pyrite-arsenopyrite-quartz veinlets are closely-spaced and feature cockscomb textures; fluid inclusion work indicates that they formed at 150-280 degrees C. These veins contain no silver, lead, bismuth, or antimony minerals but they average 1,201 ppb gold and 1,350 ppm arsenic. Pervasive quartz-sericite and quartz-sericite-muscovite flooding in the gneiss host rock form alteration envelopes around the gold-bearing zones. The alteration and mineralization trends north, varies from 20 to 50 meters wide, and extends for 200 to 4,000 feet along strike.

In 1997, the Tri-Valley Corporation collected more rock samples, drilled 4 core holes that totaled 641.5 meters, and dug or re-dug 12,950 feet of trenches (Aushburn, 1998 [Executive summary]). The best intercept in the drilling was 20 feet that averaged 1.77 grams of gold per tonne. Noyes and others (2006) reexamined the 1997 core with results that differed only in detail.

In 1999, Placer Dome (USA) sampled the soils on bedrock on a 200-meter grid and found that the gold is associated with arsenic and antimony (Rogers and others, 1999). They also collected 59 rock samples; they contained up to 2,200 ppb gold, 14.4 ppm silver, 10,000 ppm arsenic, 110 ppm bismuth, 46,600 ppm lead, and 10,000 ppm antimony.

After synthesizing the considerable analytical and geologic data on the Shamrock deposit, Freeman (2011) concluded that it is distal Intrusion-related gold deposit.

Alteration:

Pervasive quartz-sericite and quartz-sericite-muscovite flooding in the gneiss host rock form alteration envelopes around the gold-bearing zones.

Age of mineralization:

Probably about 90 Ma as are most of the gold deposits in the Richardson District and many in central Alaska.

Generic deposit model:

Deposit model:

Distal, intrusion-related gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Shamrock prospect was first identified in 1991 during regional reconnaissance exploration and geochemical surveys (Vartanyan and others, 1991; Freeman, 2011). In 1992, the area was mapped, three long road cuts and trenches were dug west of VABM Buck, and 582 grab and channel samples were collected (Vartanyan and others, 1992; Freeman, 2011). In 1997, the Tri-Valley Corporation collected more rock samples, drilled 4 core holes that totaled 641.5 meters, and dug or re-dug 12,950 feet of trenches (Aushburn, 1998 [Executive summary]). Noyes and others (2006) reexamined the 1997 core. In 1999, Placer Dome (USA) sampled the soils on bedrock on a 200-meter grid over the prospect.

Production notes:

None.

Reserves:

None.

Site name(s): Tenderfoot Creek

Site type: Mines

ARDF no.: BD039

Latitude: 64.275 **Quadrangle:** BD B-5

Longitude: 146.2299

Location description and accuracy:

Tenderfoot Creek parallels the Richardson Highway from near its headwaters to its mouth on the Tanana River about 5 miles east-southeast of the the town of Richardson. About 4 miles of the creek above its mouth has been mined and the coordinates are at about the center of the mining in the southeast quarter of section 30, , T. 8 S., R. 8 E., of the Fairbanks Meridian.

Commodities:

Main: Ag, Au

Other: Pb

Ore minerals: Galena, gold

Gangue minerals:

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the mineralized quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

Tenderfoot Creek has been the largest gold producer in the Richardson district. Placer gold was discovered in the Richardson District on Tenderfoot Creek in 1905 and mining has continued intermittently to 2010. The depth to bedrock along most of the creek that was mined before WWII varied from 30 feet to 155 feet near its mouth and the early mining was largely by underground drifting (Ellsworth and Parker, 1911). The peak year of early mining was 1908. Mining then declined until a bench on the north side of the creek was discovered that led to a resurgence of mining until 1916 (Olson and others, 1985). Mining probably continued now and then in subsequent years but documentation is sparse. Wedow and others (1954) reported that the only placer mine in operation on Tenderfoot Creek in 1946 was on 13 Below Discovery. In 2012, A large area of tailings barren of vegetation at the head of the creek can be easily seen on satellite imagery available on the internet; it probably represents fairly recent open-pit mining with earth-moving equipment. Szumigala and others (2011) reports that two miners produced gold from an open pits on Tenderfoot Creek in 2010.

There are several determinations of the fineness of the gold from Tenderfoot Creek. Bundtzen and Reger (1977) reported the gold to be 670 fine. Metz and Hawkins (1981) reported the gold to average 901 fine and Glover (1950) reported that the gold varies from 622 to 735 fine. Chapin (1914) reported that a piece of

gold-bearing galena float was recovered during mining operations; the source has not been found.
The Richardson District produced about 95, 000 ounces of gold and 24, 000 ounces of silver from 1905 to 1921 (Bundtzen and Reger, 1977). Much if not the great majority of that gold came from Tenderfoot Creek. No data is available for later production.

Alteration:

Age of mineralization:
Quaternary.

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; medium

Site Status: Inactive

Workings/exploration:
Placer gold was discovered in the Richardson district in 1905. Mining initially occurred on Tenderfoot Creek and expanded to nearby Banner Creek (BD001) and associated tributaries. Because the depth to bedrock in the drainage is 30 to 155 feet, early mining on Tenderfoot Creek was largely by drifting methods (Ellsworth and Parker, 1911). In recent years, surface mining, utilizing earth moving equipment, has taken place at the head of Tenderfoot Creek.

Production notes:
From 1905 through 1921, the Richardson District produced about 95,000 ounces of gold and 24,000 ounces of silver (Bundtzen and Reger, 1977). Most of this was from placers on Tenderfoot Creek. Since 1980, the district has produced approximately 10,000 additional ounces of gold from intermittent mining; an unknown portion of this came from Tenderfoot Creek (Olson and others, 1985).

Reserves:
None.

Last report date: 2012-04-01

Site name(s): Wide Zone

Site type: Prospect

ARDF no.: BD046

Latitude: 64.3214 **Quadrangle:** BD B-5

Longitude: 146.3325

Location description and accuracy:

The Wide Zone prospect is about 2.6 miles north of Richardson on the Richardson Highway. It includes most of the section 10, T. 7 S., R. 7 E., of the Fairbanks Meridian, northeast of the mouth of Buckeye Creek and the coordinates are near the center of the section.

Commodities:

Main: Au

Other: Ag, As, Pb, Sb, Zn

Ore minerals: Arsenopyrite, galena, gold, pyrite, stibnite, lead-antimony sulfosalts

Gangue minerals: Quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

The rocks at the Wide Zone prospect are mainly quartz- muscovite schist cut by faulted or pinched-out bodies of quartz-feldspar porphyry similar to the 90 Ma porphyry that is associated with the mineralization at the Democrat Mine (BD014) about a mile to the northwest. Reconnaissance geochemical sampling in 1991 and 2005 identified numerous areas anomalous in gold, arsenic, bismuth, lead, antimony, and tungsten (Vartanyan and others, 1991; Noyes, 2006). The geochemical data and the presence of the characteristic quartz-feldspar porphyry associated with mineralization in the area suggests that the prospect hosts a distal intrusion-related gold deposit (Freeman, 2011). The prospect may be in a down-dropped block of mineralized ground that fills the gap from the mineralization at the Democrat Mine (BD014) to the mineralization at Hinkley Gulch (BD019) and May's Pit (BD007).

Alteration:

Age of mineralization:

Probably 90 Ma as is other mineralization of the same type in the immediate area.

Generic deposit model:

Deposit model:
Intrusion-related gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Production notes:
None.

Reserves:
None.

Site name(s): Buckeye; Buckeye Pup

Site type: Prospects

ARDF no.: BD048

Latitude: 64.334 **Quadrangle:** BD B-5

Longitude: 146.253

Location description and accuracy:

The Buckeye prospect is on the hillside on the north side of Banner Creek about 3.5 miles above its mouth. It is about 4.2 miles northeast of Richardson on the Richardson Highway and about 0.6 mile west-southwest of the center of section 6, T. 7 S., R. 8 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Bi, Pb, Sb, Te

Ore minerals: Arsenopyrite, bismuth, galena, gold, lead-antimony sulfosalts, pyrite, pyrrhotite, stibnite

Gangue minerals: Limonite, quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

The Buckeye prospect was discovered by the Tri-Valley Corporation during reconnaissance exploration in 1998 when they found 10 float samples of quartz that contained 0.35 to 1.54 ounces of gold per ton; the samples also contained up to 846 parts per million (ppm) bismuth and up to 127 ppm tellurium (Vantanyan and others, 1998). In late 1998, the Tri-Valley Corporation and Placer Dome (USA) formed a joint venture that initially concentrated on the headwaters of Banner Creek, an area that included the over the Buckeye prospect and the Bald Knob prospect (BD073) about a mile and a half to the north. In 1999, Placer Dome collected 1,037 soil samples on bedrock, collected 136 rock samples, and drilled three hole that totaled 516.5 meters (Rogers and others 1999). The soil samples defined a strong gold-bismuth-tellurium anomaly over the Buckeye and Bald Knob prospects. One drill hole was at the Buckeye prospect, the other two were at the Bald Knob prospect. Placer Dome did more soil and rock sampling in 2000 and drilled three more holes (Graham, 2002; Noyes and others, 2006). Intercepts with more than 100 parts per billion gold were seen in the six holes drilled in 1999 and 2000. The high gold values correlate with high bismuth and tellurium but the drill core showed no correlation of gold with such pathfinder elements as silver, arsenic, antimony, copper, lead, or zinc. The higher gold values are in narrow quartz veins that cut otherwise unaltered gneiss. Additional soil sampling in 2005 added little to the extent of the previous anomalies. The source of the rich gold-bismuth-tellurium-quartz samples found at the surface near the Buckeye prospect in 1998 remains unknown. In his synthesis of the previous work on the gold mineralization of the Richardson

district Freeman (2011) suggests that the mineralization at the Buckeye prospect is a distal intrusion-related gold deposit.

Alteration:

Notable lack of alteration in the gneiss host rock.

Age of mineralization:

Probably 90 Ma as are most of the gold deposits in the district.

Generic deposit model:

Deposit model:

Distal intrusion-related gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Three generations of sampling soil on bedrock from 1998 to 2005. Numerous rock samples collected and analyzed. Six holes were drilled on similar mineralization in 1999 and 2000 on this and the nearby Bald Knob prospect (BD073).

Production notes:

None.

Reserves:

None.

Site name(s): Money Rock; Money-Rock; Rainbow; Aurora; Indian

Site type: Prospect

ARDF no.: BD054

Latitude: 64.4614 **Quadrangle:** BD B-2

Longitude: 145.0272

Location description and accuracy:

This property consists of three blocks of State of Alaska claims that are contiguous or close by; they cover much of sections 8-10, 16-17, 19-20, and 29-30 of T. 5 S., R. 14 E., of the Fairbanks Meridian. The coordinates are at about the center of the samples with the best gold values. The outlines of the claim boundaries are shown on figure 1 of Schaefer (2006) and Alix Resources Corp. (2010). The claims are about 3 miles northwest of the Pogo Mine (BD033) and about 3 miles west of the junction of Indian Creek and the Goodpaster River. The location is accurate to 500 feet.

Commodities:

Main: Au

Other: As, Bi, Te

Ore minerals: Arsenopyrite, gold, pyrite

Gangue minerals: Dolomite, quartz, sericite

Geologic description:

The rocks in the area consist primarily of pre-Mississippian paragneiss and orthogneiss and lesser schist and quartzite; the metamorphic rocks are intruded by several Cretaceous granitic plutons (Werdon and others, 2004). The Aurora claim block is underlain by paragneiss, schist, quartzite and minor orthogneiss that are cut by several Tertiary basaltic dikes. The Indian claim block is mainly underlain by orthogneiss similar to that at the nearby Pogo mine (BD033) and Cretaceous granodiorite of the Goodpaster Batholith to the north. The Rainbow claim block is mainly paragneiss in contact with Cretaceous (96.6-99 Ma) tonalite; hornfels is developed at the contact. The Rainbow claim block is cut by a small Cretaceous(?) granodiorite/quartz monzonite dike that is moderately altered to sericite and carbonate. Locally, the gneiss is moderately to strongly silicified with the development of sericite+/-carbonate (Schaefer, 2006). Airborne geophysical surveys (Burns and others, 2000; 2005) show a strong magnetic anomaly over the hornfels adjacent to the Cretaceous tonalite at the Rainbow claim block; a similar highly magnetic anomaly over the north half of the Aurora claim block suggests hornfels adjacent to a buried intrusive.

Quartz veins with disseminated arsenopyrite have been found in float on the Rainbow claim block near the contact between gneiss and the Cretaceous tonalite (Schaefer, 2006; Alix Resources Corp., 2010). Rock float samples contain up to 2.4 grams of gold per ton and more than 10,000 parts per million arsenic and anomalous bismuth. Scattered soil samples from the area are also generally anomalous in gold and arsenic, and locally anomalous in bismuth and tellurium.

The Rainbow, Aurora, and Indian claim blocks were first located by three prospectors, beginning in 1999. In 2002, they were leased to the Anglo-Gold Corporation who did only limited work, mainly soil sampling on the ridges, as part of a larger effort in the area. In 2006, the claims were leased to Tonogold Resources Inc. (2008). In 2010, the property was held by the Alix Resources Corp. (2010) and in the summer of 2010 they signed an option agreement with the Precious Metals Exploration Company to explore the property.

As of 2012, Alix refers to this property as Money Rock. In summer 2012, Alix performed a two-hole drill program designed to test the subsurface expression of a surface rock and soil gold anomaly. Both drillholes encountered alternating intervals of paragneiss and orthogneiss. Gold in both holes occurs in quartz-

arsenopyrite-pyrite veins associated with broad zones of patchy sericite-dolomite-silica alteration. Results from MR-12-01 are 0.48 gram of gold per tonne from 48.0 to 53.0 meters, 0.47 gram of gold per tonne from 111.0 to 112.4 meters, and 1.67 grams of gold per tonne from 199.0 to 200.6 meters. Results from MR-12-02 are 0.53 gram of gold per tonne from 395.3 to 396.8 meters (Alix Resources Corp., 2012a, 2012b).

Alteration:

Sericite-carbonate-silica alteration with arsenopyrite and other sulfides in veins and as disseminations (Alix Resources Corp., 2012a).

Age of mineralization:

May be related to nearby Cretaceous (96.6-99 Ma) plutons (Werdon and others, 2004).

Generic deposit model:

Deposit model:

Arsenopyrite-gold-quartz veins; polymetallic veins? (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

The Rainbow, Aurora, and Indian claim blocks were first located by three prospectors, beginning in 1999. In 2002, they were leased by the Anglo-Gold Corporation who did limited work, mainly soil sampling on the ridges, as part of a larger effort in the area. In 2006, the claims were leased to Tonogold Resources Inc. In 2010, the property was optioned by the Precision Metals Exploration Company from Alix Resources Corp. (2010).

As of 2012, Alix refers to this property as Money Rock. In summer 2012, Alix performed a two-hole drill program designed to test the subsurface expression of a surface rock and soil gold anomaly. Both drillholes encountered alternating intervals of paragneiss and orthogneiss. Gold in both holes occurs in quartz-arsenopyrite-pyrite veins associated with broad zones of patchy sericite-dolomite-silica alteration. Results from MR-12-01 are 0.48 gram of gold per tonne from 48.0 to 53.0 meters, 0.47 gram of gold per tonne from 111.0 to 112.4 meters, and 1.67 grams of gold per tonne from 199.0 to 200.6 meters. Results from MR-12-02 are 0.53 gram of gold per tonne from 395.3 to 396.8 meters (Alix Resources Corp., 2012a, 2012b). Money Rock is currently operated by Aurora Exploration Company (Wright, 2013).

In October 2016, Millrock Resources Inc. announced that, through a series of purchase and option agreements and claim staking, it has assembled a 39,159-acre land position covering high-potential gold targets (ARDF numbers BD054, BD055, and BD060) in the Goodpaster Mining District near the Pogo gold mine (BD033). The claims cover soil geochemical anomalies, many of which are untested. On several sites there are intersections obtained through drilling by prior operators that are anomalous in gold. Millrock conducted core re-logging, surface geologic mapping, and soil and rock sampling in 2016; this work defined a northeast–southwest-trending corridor of anomalous gold values and several east–west-trending quartz vein systems as well as a small low-angle, northwest-dipping quartz vein with similar characteristics to the tabular bodies at Pogo (BD033). Millrock also collected short-wave infrared spectra from both core and surface samples (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Last report date: 2017-08-26

Site name(s): West Pogo; ER

Site type: Prospect

ARDF no.: BD055

Latitude: 64.4486 **Quadrangle:** BD B-3

Longitude: 145.0867

Location description and accuracy:

The West Pogo prospect consists of 17 square kilometers of State of Alaska claims. The coordinates are at about the center of the claims, about 5.1 miles west-southwest of the junction of the Goodpaster River and Indian Creek. The prospect is about 0.3 mile southwest of the center of section 27, T. 5 S., R. 13 E., of the Fairbanks Meridian. The prospect adjoins the claims of the Rainbow prospect (BD054); the location is accurate within 500 feet.

Commodities:

Main: Ag, Au, Bi, Te

Other:

Ore minerals: Arsenopyrite, gold, pyrite, silver

Gangue minerals: Dolomite, quartz, sericite

Geologic description:

In 2008, the West Pogo prospect was being explored by International Tower Hill Mines, Inc. (ITH) (2008) after they acquired it from AngloGold Ashanti (USA) Exploration, Inc. The rocks in the area are similar to those at the Pogo Mine (BD033) about 5 miles to the east, where biotite-quartz feldspar orthogneiss is intruded by a 100 Ma diorite. The West Pogo prospect is marked by an east-trending gold anomaly in the soils, which parallels a prominent fault zone. ITH drilled one hole in 2008 near the western margin of the pluton. The hole missed its intended target and remained in the pluton for its entire length; the best interval in the hole was 2 meters that contained 0.3 gram of gold per ton. The geochemistry suggests that the best mineralization is west of the hole.

First Star Resources optioned the property in 2010 and collected several 6-meter-long chip samples across 40 meters of mineralized rubble crop. The samples contained 3.79 to 6.53 grams of gold per tonne and 0.73 to 13.05 grams of silver per tonne (First Star Resources Inc., 2010).

Prior to 2010, ITH collected samples at the surface, mapped the geology, and completed a geochemical soil survey. In 2010, ITH formed a new company, Corvus Gold Inc., to take over many of their properties including West Pogo. They optioned the prospect to First Star Resources who did a 3D Induced Polarization survey, mapped the geology, and sampled in 2011. First Star returned the property to Corvus in December, 2011 and Corvus optioned the property to Alix Resources Corp. in March, 2012 (Corvus Gold Inc., 2012a, 2012b).

The mineralization at the West Pogo prospect occurs mainly as quartz veins similar to those at the Pogo Mine (BD033) about 5 miles to the east (Corvus Gold Inc., 2012b). The work in 2011 identified a new area of mineralization a kilometer long along a regional east-trending structure at the margin of the Cretaceous stock. Samples of altered granite and quartz veins contained up to 118 grams of gold per tonne and elevated bismuth and tellurium.

In summer 2012, Alix executed a discovery-phase drill program consisting of two NQ core drill holes of cumulative total length of 610 meters (2,002 feet). The purpose was to test the subsurface expression of a surface rock and soil gold anomaly, and both holes encountered orthogneiss with sericite-altered, iron-stained zones of brecciation and veining with arsenopyrite +/- pyrite that appeared to increase with depth

(Alix Resources Corp., 2012a).

The results for drill hole WP-12-01 are 0.67 gram of gold per tonne from 243.7 to 249.3 meters including a 2.4 meter interval containing 1.74 grams of gold per tonne. The results for drill hole WP-12-02 are 1.10 grams of gold per tonne from 74.5 to 77.7 meters. The gold intercepts lie within a 95 meter (311 feet) zone of dolomite-sericite alteration overprinted by iron oxides after sulfides. Gold occurs with quartz, surrounded by iron oxide alteration that occurs intermittently throughout the entire drillhole (Alix Resources Corp., 2012b).

Alteration:

Dolomite-sericite overprinted by iron oxides after sulfides (Alix Resources Corp., 2012a).

Age of mineralization:

100 Ma based on the diorite pluton at the center of the prospect (Alix Resources Corp., 2012a).

Generic deposit model:

Deposit model:

Gold-quartz veins that contain bismuth and tellurium (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Prior to 2010, International Tower Hill (ITH) collected samples at the surface, mapped the geology, and completed a geochemical soil survey. As of 2010, ITH formed a new company, Corvus Gold Inc., to take over many of their properties including West Pogo. They optioned the prospect to First Star Resources who did a 3D Induced Polarization survey, mapped the geology, and sampled in 2011. First Star returned the property to Corvus in December, 2011 and Corvus optioned the property to Alix Resources Corp. in March, 2012 (Corvus Gold Inc., 2012a, 2012b).

In summer 2012, Alix executed a discovery-phase drill program consisting of two NQ core drill holes of cumulative total length of 610 meters (2,002 feet). The purpose was to test the subsurface expression of a surface rock and soil gold anomaly, and both holes encountered metagranite with sericite-altered, iron-stained zones of brecciation and veining with arsenopyrite +/- pyrite that appeared to increase with depth (Alix Resources Corp., 2012a).

The results for drill hole WP-12-01 are 0.67 gram of gold per tonne from 243.7 to 249.3 meters including a 2.4 meter interval containing 1.74 grams of gold per tonne. The results for drill hole WP-12-02 are 1.10 grams of gold per tonne from 74.5 to 77.7 meters. The gold intercepts lie within a 95 meter (311 feet) zone of dolomite-sericite alteration overprinted by iron oxides after sulfides. Gold occurs with quartz, surrounded by iron oxide alteration that occurs intermittently throughout the entire drillhole (Alix Resources Corp., 2012b).

In October 2016, Millrock Resources Inc. announced that, through a series of purchase and option agreements and claim staking, it has assembled a 39,159-acre land position covering high-potential gold targets (ARDF numbers BD054, BD055, and BD060) in the Goodpaster Mining District near the Pogo gold mine (BD033). The claims cover soil geochemical anomalies, many of which are untested. On several sites there are intersections obtained through drilling by prior operators that are anomalous in gold. Last report date: 2017-08-26

Site name(s): LMS

Site type: Prospect

ARDF no.: BD056

Latitude: 64.2036 **Quadrangle:** BD A-4

Longitude: 145.5353

Location description and accuracy:

The LMS prospect is on a large block of 92 State of Alaska claims that cover about 25 square miles. The drilling on the prospect extends for about 2 miles along a north-northeast trending ridge that is southeast of the head of Progressive Creek in sections 22 and 27, T. 8 S., R. 11 E., Fairbanks Meridian. The center of the drilling is near VABM Liscum. The location is accurate within 400 m.

Commodities:

Main: Au

Other: As, Pb

Ore minerals: Arsenopyrite, galena, gold, pyrite

Gangue minerals: Quartz

Geologic description:

The LMS gold prospect was discovered by AngloGold Ashanti (USA) Exploration Company in the search for the source of stream sediment and soil anomalies. In 2005, they drilled 3200 meters at 17 locations with encouraging results. International Tower Hill Mines Ltd. (ITH) then explored the property in a joint venture with AngloGold (Klipfel and Giroux, 2008). In 2006, ITH drilled another 6,329 meters in 20 holes. and in 2008 published a comprehensive NI 43-101 report on the property (Klipfel and Giroux, 2008). Corvus Gold Inc. inherited the property from ITH and they optioned the property to First Star Resources in 2010 and 2011. The property reverted to Corvus in late 2011.

The gold mineralization is in a large accretionary complex of igneous and sedimentary rocks that have been metamorphosed to greenschist and amphibolite grade. There is little outcrop in the area and what rocks are exposed on the high ridges consist of middle to early Paleozoic and(or) Late? Proterozoic quartz and pelitic schist and Mississippi and(or) Devonian? augen gneiss (Wilson and others, 1998).

The gold mineralization usually is in strongly silicified and brecciated zones that are associated with low-angle faults marginal to schist units (Klipfel and Giroux, 2008). The ore contains abundant pyrite and minor galena, arsenopyrite, and graphite. The mineralization is accompanied by a silicified zone about 30 meters thick that dips gently west. The low-angle mineralized zones are cut by a series of high-angle, possibly mesothermal quartz veins along an east-west trend of foot- and hanging-wall stockworks.

The Camp zone is one of the better known mineralized targets drilled (Corvus Gold Inc., 2011). As known in early 2012, a gold-bearing, black breccia horizon extends for nearly a kilometer down dip, is 200 to 400 meters wide and continues to the limit of the drilling. The gold in the mineralized horizon appears to be related to a large, through-going sheared zone similar to a structures at the nearby Pogo Mine (BD033).

Some of the notable intercepts in the 2005, ITH drill holes are: 1) 30.48 meters that averaged 1.10 part per million (ppm) gold; 2) 3.04 meters that averaged 1.51 ppm gold; 3) 4.57 meters that averaged 1.12 ppm gold; 4) 25.91 meters that averaged 1.18 ppm gold; 5) 15.39 meters that averaged 3.43 ppm gold; 6) 3.38 meters that averaged 21.52 ppm gold; 7) 4.58 meters that averaged 4.00 ppm gold; 8) 1.53 meters that averaged 1.81 ppm gold; 9) 0.8 meters that averaged 1.95 ppm gold; and 10) 4.17 meters that averaged 1.95 ppm gold.

In 2010, First Star Resources optioned the LMS prospect and drilled three holes totaling 1,103 meters on

the Camp zone to intersect black gold-bearing graphitic quartzite breccia and to test a northeast-striking structure known to contain high grade gold mineralization (First Star, 2010 [LMS]; First Star, 2010 [High grade]). Some notable intercepts in the black, graphitic quartzite breccia were: 19.05 meters with 2.51 grams of gold per tonne and 9.84 grams of silver per tonne; and 9.14 meters with 1.65 grams of gold per tonne, and 15.38 grams of silver per tonne. The holes in the NE-striking structure intersected 0.76 meter with 43.9 grams of gold per tonne and 5.34 grams of silver per tonne; 1.68 meters with 6.12 grams of gold per tonne; 0.76 meter with 95.20 grams of silver per tonne; and 1.52 meters with 4.36 grams of gold per tonne and 9.26 grams of silver per tonne.

In 2011, First Star drilled 11 holes in the black breccia and feeder veins. Some notable intercepts were: 1) 2.9 meters that averaged 12.5 grams of gold per tonne; 2) 13.4 meters that averaged 2.5 grams of gold per tonne and 12.4 grams of silver per tonne; 3) 23.3 meters that averaged 5.2 grams of gold per tonne and 11.9 grams of silver per tonne; and 4) 1.98 meters that averaged 2.7 grams of gold per tonne and 41.7 grams of silver per tonne.

In early 2008 (before the First Star 2010-2011 drilling), International Tower Hill Mines (Klipfel and Giroux, 2008) announced that at a cut-off grade of 0.3 gram of gold per tone, the LMS deposit contains 5.86 million tones of material with an average grade of 0.89 gram of gold per tonne, or 167,000 ounces of gold.

Although no exploration activities were conducted on the LMS property in 2016, Gold Reserve Inc. released a new NI43-101 technical report for the LMS gold project in February (Hunter and Giroux, 2016). In March 2016, Gold Reserve Inc. completed a purchase-and-sale agreement with Raven Gold Alaska Inc., a wholly-owned subsidiary of Corvus Gold Inc., to acquire the LMS Gold Project in the Goodpaster District for $350,000. Raven retains a royalty interest with respect to precious metals produced and recovered equal to 3 percent of net smelter returns, and base metals produced and recovered equal to 1 percent of net smelter returns. Gold Reserve Inc. has the option, for a period of 20 years from the date of closing of the acquisition, to buy back a one-third interest (that is, 1 percent) in the precious-metals royalty for $4 million (Athey and Werdon, 2017).

Alteration:

Associated with a silicified breccia zone about 30 meters thick that dips west in metamorphic rocks (Klipfel and Giroux, 2008).

Age of mineralization:

Paleozoic or younger based on the age of the host rocks (Wilson and others, 1998).

Generic deposit model:

Deposit model:

Gold-quartz mineralization in a thick, silicified breccia zone in quartzite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The LMS prospect was discovered by AngloGold Ashanti (USA) Exploration Company in the search for the source of anomalous stream sediment and soil samples. In 2005, they diamond drilled a total of 3,200 meters 17 locations with encouraging results. In 2008, International Tower Hill Mines Ltd. explored the property in a joint venture with AngloGold. In 2010, First Star Resources optioned the LMS prospect; they drilled 3 holes totaling 1,103 meters in 2010 and 10 more holes in 2011.

Production notes:

None.

Reserves:

In early 2008, International Tower Hill Mines (Klipfel and Giroux, 2008) announced that at a cut-off grade of 0.3 gram of gold per tone, the LMS deposit contains 5.86 million tones of material with an average grade of 0.89 gram of gold per tonne, or 167,000 ounces of gold.

The Camp Zone, part of the encompassing LMS property, contains an inferred resource, at a cut-off grade of 0.5 gram of gold per tonne, of 8.32 million tonnes of material estimated to contain 267,000 ounces of Au at an average grade of 1.00 gram of gold per tonne (Hunter and Giroux, 2016). The effective date for this resource estimate is March 26, 2014. The Camp Zone remains open along strike and at depth, and is situated at the southeast end of a 6-kilometer-long, northwest-trending zone of aligned surface geochemical samples containing anomalous gold, arsenic, and lesser silver and copper.

Additional comments:

The 04/01/2012 record update of this prospect misspelled the name as LWM instead of LMS in all text and references.

Last report date: 2017-08-26

Site name(s): Wolverine; Rob

Site type: Prospect

ARDF no.: BD057

Latitude: 64.3855 **Quadrangle:** BD B-1

Longitude: 144.227

Location description and accuracy:

The Wolverine prospect is on the ridge north of Wolverine Creek, about 2.8 miles north of the north '5080' peak of Black Mountain. It is at an elevation of about 3,300 feet, about 0.5 mile north-northeast of the center of section 20, T. 6 S., R. 18 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Sb

Other: Cu, Pb, Te, W

Ore minerals: Arsenopyrite, gold, jamesonite, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

Although several mines and prospects have been known since the 1930s within a mile of this prospect, the Wolverine prospect was first described by name by Freeman in 2004. From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM Inc.) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling. They drilled 26 holes but the details of their location are vague. They may have drilled at the Wolverine prospect.

In 2002, Freegold Ventures optioned a large block of claims that covered this prospect and several other nearby deposits that are described separately: the Grizzly Bear (BD003), Michigan Lode (BD025), and Upper Trench, Lower Trench (BD058). Freegold Ventures explored them as a unit under the name Rob. Freegold continued to explore the property through 2011 (Freegold Ventures Ltd., 2011). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. Through 2004, Freegold spent more than $1 million exploring the Rob property and in 2004 they commissioned a comprehensive NI 43-101 report (Freeman, 2004) that summarized their and previous work. That report was updated in 2010 (Flanders, 2010).

As interpreted by Bailey (2001) and Freeman (2004), this and several other similar prospects in the area are near the contact of a large Cretaceous granodiorite stock that intrudes a large dome of Paleozoic biotite gneiss, feldspar-biotite augen gneiss, and quartzite. Locally the granodiorite is cut by hornblende andesite-porphyry dikes. The rocks are locally intensely sheared and this and the nearby Michigan Lode (BD025), Blue Lead (BD003), and Grizzly Bear (BD018) deposits are aligned along the northeast-trending Gray Lead fault. The Wolverine prospect is entirely within a Cretaceous granodiorite pluton that is cut by several Cretaceous, andesite porphyry dikes; it is associated with the northeast-trending 'Double Bear' fault.

The Wolverine prospect is probably similar to the other mines and prospects in the immediate area in that it is probably a gold -quartz vein along a shear zone. The quartz veins typically contain gold +/- base metal +/- silver and a variable combination of sulfides, including arsenopyrite, jamesonite, pyrite, and stibnite. The veins are commonly 2 to 3 feet in wide but some are as wide as 8 feet (Thomas, 1970). Samples collected by Freegold (Flanders, 2010) contained up to 1.47 ounces of gold per ton, 22.8 parts per million (ppm) silver, and 1.85 percent arsenic. Freeman (2004) and Flanders (2010) classifies the deposit as 'stockwork-shear style mineralization hosted in porphyritic intermediate to felsic intrusive rocks'.

Alteration:

Not specified but the intrusive rocks are altered.

Age of mineralization:

Probably genetically related to a nearby Cretaceous granodiorite intrusive.

Generic deposit model:

Deposit model:

Silver-gold-quartz veins and stockwork, +/- arsenic, copper, lead, antimony, tellurium, and tungsten (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Site name(s): Upper Trench/ Lower Trench; Rob

Site type: Prospect

ARDF no.: BD058

Latitude: 64.3747 **Quadrangle:** BD B-1

Longitude: 144.2168

Location description and accuracy:

The Upper Trench/ Lower Trench prospect is on the ridge south of Wolverine Creek, about 2.5 miles north of the north peak '5080' of Black Mountain. It is at an elevation of about 3,300 feet about 0.4 mile south-southeast of the center of section 20, T. 6 S., R. 18 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Sb

Other: Cu, Pb, Te, W

Ore minerals:

Gangue minerals: Quartz

Geologic description:

Although several mines and prospects have been known since the 1930s within a mile of this prospect, the Upper Trench/ Lower Trench prospect was first described by Freeman in 2004. From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM Inc.) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling. The joint venture drilled 26 but their location is vague. They probably drilled one or more holes at the Upper Trench/Lower Trench prospect and did considerable trenching.

In 2002, Freegold Ventures optioned a large block of claims that covered this prospect and several other nearby deposits that are described separately, the Grizzly Bear (BD003), Michigan Lode (BD025), and Wolverine (BD057). Freegold Ventures explored them as a unit under the name Rob. They continued the work through early 2012 (Freegold Ventures Ltd., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. Through 2004, Freegold spent more than $1 million exploring the Rob property and in 2004 commissioned a comprehensive NI 43-101 report (Freeman, 2004) that summarized their and previous work. That report was updated in 2010 (Flanders, 2010).

As interpreted by Bailey (2001) and Freeman (2004), this and the several other similar prospects in the area are near the contact of a large Cretaceous granodiorite stock that intrudes a large dome of Paleozoic biotite gneiss, feldspar-biotite augen gneiss, and quartzite. Locally the granodiorite is cut by hornblende andesite-porphyry dikes. The rocks are locally intensely sheared and this and the nearby Michigan Lode (BD025), Blue Lead (BD003), and Grizzly Bear (BD018) deposits are aligned along the northeast-trending Gray Lead fault. The Upper Trench/Lower Trench prospect is entirely within a Cretaceous granodiorite pluton which is cut by several Cretaceous andesite porphyry dikes.

The Upper Trench/Lower Trench prospect is probably similar to the other mines and prospects in the immediate area in that is is a gold -quartz vein along a shear zone. The quartz veins typically contain gold +/- base metal +/- silver and a variable combination of sulfides, including arsenopyrite, jamesonite, pyrite, and stibnite. The veins are commonly 2 to 3 feet in width but some are as wide as 8 feet (Thomas, 1970). There is little specific information on this prospect but Freeman (2004) and Flanders (2010) cite grab samples in the trenches that contain up to 2.04 ounces of gold per ton, 43.6 parts per million (ppm) silver,

1.35 percent arsenic and 17.6 percent antimony. Verification samples collected in 2002 contained up to 22.29 grams of gold per ton, up to 15.75 ppm silver, more than 10,000 ppm arsenic, up to 11.25 ppm bismuth, up to 1,925 ppm lead, more than 10,000 ppm antimony, and up to 1.0 ppm tellurium. Freeman (2004) and Flanders classifies the deposit as 'stockwork-shear style mineralization hosted in porphyritic intermediate to felsic intrusive rocks'.

Alteration:

Not specified.

Age of mineralization:

Probably genetically related to a nearby Cretaceous granodiorite pluton.

Generic deposit model:

Deposit model:

Silver-gold-quartz veins and stockwork, +/- arsenic, copper, lead, antimony, tellurium, and tungsten (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Although several mines and prospects have been known within a mile of this prospect since the 1930s, the Upper Trench/Lower Trench prospect was first publicly described by Freeman in 2004. From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Mining and WGM Inc.) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling. In 2002, Freegold Ventures optioned a large block of claims that covered this prospect and several other nearby deposits that are described separately: the Grizzly Bear (BD003), Michigan Lode (BD025), and Wolverine (BD057). Freegold Ventures explored them as a unit under the name Rob. The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. Freegold continued their exploration into early 2012 (Flanders, 2010; Freegold Ventures Inc., 2012).

Production notes:

None.

Reserves:

None.

Site name(s): O'Reely; Oreely; Rob

Site type: Prospect

ARDF no.: BD059

Latitude: 64.3404 **Quadrangle:** BD B-1

Longitude: 144.2148

Location description and accuracy:

The O'Reely prospect is near the head of Tibbs Creek, about 0.5 mile north of the north peak (5080) of Black Mountain. It is about 0.3 mile north-northeast of the center of section 5, T. 6 S., R. 18 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Sb

Other: Cu, Pb, Te, W

Ore minerals: Arsenopyrite?, gold?, jamesonite?, pyrite?, stibnite?

Gangue minerals: Quartz

Geologic description:

Although several mines and prospects have been known since the 1930s within a mile or so of this prospect, the O'Reely vein was first described by Freeman in 2004. From 1995 to 1999, The Stone Boy Joint Venture (Sumitomo Metal Metal Mining and WGM Inc.) spent more than $1.3 million exploring in the area; they did extensive surface mapping and sampling, surface and airborne geophysics, and 16,215 feet of diamond drilling in 26 holes. They did not drill the O'Reely prospect.

In 2002, Freegold Ventures optioned a large block of claims that covered the O'Reely vein and the several other nearby deposits that are described separately: the Grizzly Bear (BD003), Michigan Lode (BD025), Wolverine (BD057), and Upper Trench/ Lower Trench (BD058). Freegold has continued the exploration through early 2012 as the Rob project. (Flanders, 2010; Freegold Ventures Ltd., 2012). The work has included extensive geologic mapping, surface sampling, and geochemical and geophysical surveys. Freegold commissioned a comprehensive NI 43-101 report in 2004 that summarized their and previous work (Freeman, 2004). The O'Reely vein was first mentioned in it. The 2004 report was updated in 2010 by Flanders (2010).

As interpreted by Bailey (2001) and Freeman (2004), this and the several other similar prospects in the area are near the contact of a large Cretaceous biotite granodiorite pluton that intrudes a large dome of Paleozoic biotite gneiss, feldspar-biotite augen gneiss, and quartzite. The granodiorite is cut by hornblende andesite-porphyry dikes. The rocks are locally intensely sheared and the nearby Michigan Lode (BD025), Blue Lead (BD003), and Grizzly Bear (BD018) deposits are aligned along the northeast-trending Gray Lead fault. The O'Reely vein is in the granodiorite near the contact with Paleozoic gneiss near a similar fault.

The O'Reely vein is probably similar to the other mines and prospects in the immediate area in that it is a gold -quartz vein along a shear zone. The quartz veins typically contain gold +/- base metal +/- silver and a variable combination of sulfides, including arsenopyrite, jamesonite, pyrite, and stibnite. The veins are commonly 2 to 3 feet in wide but some are as wide as 8 feet (Thomas, 1970). The O'Reely vein strikes northeast and can be traced for about 1,500 feet. Freeman (2004) describes the O'Reely vein as a 'polyphase hydrothermal breccia'. Two samples contained 8.04 and 8.38 grams of gold per ton, 16.10 and 53.70 parts per million (ppm) silver, 1,065 and 1,985 ppm arsenic, 15.35 and 39.70 ppm bismuth, 1,800 and 4,210 ppm lead, and 761,1,000 ppm antimony, and anomalous bismuth and tellurium (Freeman 2004). Other surface samples of veins and altered granite collected in subsequent years varied greatly in their relative and specific

metal content but they have essentially the same association of metals.

In 2007, Freegold drilled 9 holes on the O'Reely vein (Freegold Ventures Ltd., 2007). All of the holes cut the vein in mineralized intercepts from 5 to 20 feet wide. Of the 128 intervals that were assayed, 31 contained over 0.2 gram of gold per tonne; the highest was 2.1 grams of gold per tonne across 3 feet. The drilling indicated that the vein is continuous for at least 750 feet horizontally and does not have any structural offsets.

Alteration:

Not described in detail but alteration is associated with the veins.

Age of mineralization:

Probably genetically related to a nearby Cretaceous granodiorite pluton.

Generic deposit model:

Deposit model:

Silver-gold-quartz veins and stockwork, +/- arsenic, copper, lead, antimony, tellurium, and tungsten (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Although several mines and prospects have been known since the 1930s within a mile or so of this prospect, the O'Reely vein was first described by Freeman in 2004. Site name(s): ER-Ogo-Fire

Site type: Prospect

ARDF no.: BD060

Latitude: 64.4433 **Quadrangle:** BD B-3

Longitude: 145.1239

Location description and accuracy:

This prospect is in on the divide between the headwaters of the Goodpaster River and Shaw Creek, about a mile southeast of hill 3750. The coordinates are at about the center of an area with several drill holes on a block of claims outlined by Baknes (2008). It is about 0.6 mile northwest of the center of section 35, T. 5 S., R. 13 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Bi, Sb

Other:

Ore minerals: Chalcopyrite, jamesonite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The rocks in the area are part of the Yukon-Tanana Terrane of the northern Cordillera; they consist largely of late Paleozoic to Devonian medium- to high-grade metamorphic rocks that have been intruded by Cretaceous and Tertiary granitic stocks and batholiths (Baknes, 2008; Wilson and others, 1998). The metamorphic rocks are structurally complex with an older, middle to early Paleozoic and/or late Proterozoic unit that consists of gneiss, schist, quartzite, and amphibolite and a younger, Mississippian and/or Devonian unit that consists largely of augen gneiss that locally forms domal structures. The metamorphic rocks are intruded by 55 Ma to 107 Ma, granitic plutons. The structure of the area is complex and difficult to determine because of poor exposure but several major thrust fault have been identified as well as a series of northeast-trending, northwest-dipping high-angle faults.

The dominant mineralization in the area and the target of most of the exploration are deposits related to Cretaceous intrusions, several classic examples being the Fort Knox Mine (FB115) near Fairbanks and the nearby Pogo Mine (BD033). These deposits are characterized by an association with moderately reduced, I- and S- type granitic intrusions and a lithophile, gold-bismuth-tungsten-arsenic-tellurium-molybdenum(-tin-copper-lead-antimony) suite of elements. The deposits vary from low-sulfide, sheeted or stockwork deposits in the intrusions to replacement deposits, veins, and stockworks in the country rock. The mineralization at the nearby Pogo deposit is the model used in exploring this and other prospects in the area. The mineralization at Pogo consists of thick gently-dipping quartz veins that grade laterally into pegmatite dikes related to 107 Ma syenite and monzonite intrusions. The quartz veins contain about 3 percent sulfides, mainly arsenopyrite, pyrite, pyrrhotite, loellingite, chalcopyrite, bismuthinite, native bismuth and native gold. The veins are associated with biotite alteration overprinted by sericite-dolomite-chlorite-quartz alteration, that extends into the country rock for several meters.

Soon after the recognition of nearby Pogo as a major, economically attractive deposit in 1998, Rimfire Minerals Corporation in conjunction with several joint-venture partners began work in the area and identified this deposit. In 2008, they entered into a joint venture with Rubicon Minerals Corporation and commissioned a thorough technical report on their properties in the Goodpaster District (Baknes, 2008), which is the source of most of the information on this prospect.

The rocks at the ER-Ogo-Fire prospect are Paleozoic augen gneiss interlayered with quartz-feldspar-

biotite paragneiss, and Cretaceous granitic intrusions. Felsic dikes that vary in texture from aplite to pegmatite are common. Scattered occurrences of pyrrhotite and pyrite occur in the vicinity of the prospect and an occurrence of pyrrhotite, pyrite, and chalcopyrite is at the contact between quartz-feldspar and biotite-feldspar schist. Quartz veins are common at the surface but few contain sulfides. Four samples of quartz veins collected at the surface (one of which has jamesonite) contained 15 to 1,521 parts per billion (ppb) gold, less than 0.2 to 0.9 parts per million (ppm) silver, 484 to 2,833 ppm arsenic, up to 0.76 ppm bismuth, 7 to 286 ppm lead, and 13 to 68 ppm antimony. Nine holes were drilled by Anglo-Gold Ashanti (USA) in 2003 and 2004. The drilling cut numerous intercepts up to 3.6 meters long of quartz veins and breccia with arsenopyrite, pyrite, and pyrrhotite. The quartz veins and breccia appear to occur along faulted contacts and are often associated with extensive quartz-sericite-pyrite alteration. There is also post-mineralization, silica-dolomite(-pyrite) alteration associated with re-brecciation of the mineralization. The best of the mineralized intercepts contained 9.0 to 5,310 ppb gold, 0.1 to more than 1 ppm silver, 1,535 to more than 1 percent arsenic, 0.06 to 11.80 ppm bismuth, and 19 to more than 1,000 ppm stibnite.

Alteration:

The quartz veins and breccia intersected in the drill holes are often associated with extensive quartz-sericite-pyrite alteration. There is also post-mineralization, silica-dolomite(-pyrite) alteration associated with re-brecciation of the mineralization.

Age of mineralization:

Probably about 107 Ma based on similarities with the nearby Pogo Mine.

Generic deposit model:

Deposit model:

Quartz veins and breccia related to nearby Cretaceous intrusions.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Extensive surface sampling, and geochemical and geophysical surveys beginning in 1999 and continuing through 2007. Nine holes drilled by AngloGold Ashanti (USA) in 2003 and 2004 totaled 3,158.2 meters.

In October 2016, Millrock Resources Inc. announced that, through a series of purchase and option agreements and claim staking, it has assembled a 39,159-acre land position covering high-potential gold targets (ARDF numbers BD054, BD055, and BD060) in the Goodpaster Mining District near the Pogo gold mine (BD033). The claims cover soil geochemical anomalies, many of which are untested. On several sites there are intersections obtained through drilling by prior operators that are anomalous in gold. Millrock conducted core re-logging, surface geologic mapping, and soil and rock sampling in 2016; this work defined a northeast–southwest-trending corridor of anomalous gold values and several east–west-trending quartz vein systems as well as a small low-angle, northwest-dipping quartz vein with similar characteristics to the tabular bodies at Pogo (BD033). Millrock also collected short-wave infrared spectra from both core and surface samples (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Location description and accuracy:

The Eagle prospect is about 1.8 mile west of the top of Shaw Creek Dome. The coordinates are at about the center of an area with several drill holes in a block of claims outlined by Baknes (2008). The prospect is about 0.6 mile south-southwest of the center of section 20, T. 7 S., R. 12 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Bi, Sb

Other: Cu, Pb

Ore minerals: Chalcopyrite, molybdenite, pyrite

Gangue minerals: Albite, calcite, quartz

Geologic description:

The rocks in the area are part of the Yukon-Tanana Terrane of the northern Cordillera; they consist largely of late Paleozoic to Devonian medium- to high-grade metamorphic rocks that have been intruded by Cretaceous and Tertiary granitic stocks and batholiths (Baknes, 2008; Wilson and others, 1998). The metamorphic rocks are structurally complex with an older, middle to early Paleozoic and/or late Proterozoic unit that consists of gneiss, schist, quartzite, and amphibolite and a younger, Mississippian and/or Devonian unit that consists largely of augen gneiss that locally forms domal structures. The metamorphic rocks are intruded by 55 Ma to 107 Ma, granitic plutons. The structure of the area is complex and difficult to determine because of poor exposure but several major thrust fault have been identified as well as a series of northeast-trending, northwest-dipping high-angle faults.

The dominant mineralization in the area and the target of most of the exploration are deposits related to Cretaceous intrusions, several classic examples being the Fort Knox Mine (FB115) near Fairbanks and the nearby Pogo Mine (BD033). These deposits are characterized by an association with moderately reduced, I- and S- type granitic intrusions and a lithophile, gold-bismuth-tungsten-arsenic-tellurium-molybdenum(-tin-copper-lead-antimony) suite of elements. The deposits vary from low-sulfide, sheeted or stockwork deposits in the intrusions to replacement deposits, veins, and stockworks in the country rock. The mineralization at the nearby Pogo deposit is the model used in exploring this and other prospects in the area. The mineralization at Pogo consists of thick gently-dipping quartz veins that grade laterally into pegmatite dikes related to 107 Ma syenite and monzonite intrusions. The quartz veins contain about 3 percent sulfides, mainly arsenopyrite, pyrite, pyrrhotite, loellingite, chalcopyrite, bismuthinite, native bismuth and native gold. The veins are associated with biotite alteration overprinted by sericite-dolomite-chlorite(-quartz alteration, that extends into the country rock for several meters.

Soon after the recognition of nearby Pogo as a major and economically attractive deposit in 1998, Rimfire Minerals Corporation in conjunction with several joint-venture partners began work in the area and identified this deposit. In 2008, they entered into a joint venture with Rubicon Minerals Corporation and commissioned a thorough technical report on their properties in the Goodpaster District (Baknes, 2008), which is the source of most of the information on this prospect.

The rocks in the vicinity of the Eagle prospect are dominantly irregularly-shaped, multiphase granite to

granodiorite intrusions surrounded by orthogneiss. The geology is poorly exposed but several lineaments roughly parallel soil-geochemical anomalies. Several samples with disseminated pyrite and trace chalcopyrite and one with molybdenite were identified on the surface and numerous samples were collected. Nine of the samples collected at the surface had significant metal values. These contained 113 to 8,080 parts per billion (ppb) gold, 0.8 to 3.05 parts per million (ppm) silver, 9 to 430 ppm arsenic, 0.11 to 2,600 ppm bismuth, 13 to 26 ppm copper, and less than 2 to 12 ppm antimony. Five holes were drilled in 2000 by Hyder Gold and another 9 holes were drilled in 2004 by AngloGold Ashanti (USA); these totaled 3,054 meters. The drilling intersected 26 stockwork zones with significant gold values that varied in thickness from 0.2 to 1.5 meters; the best of these intervals contained by 437 to 7,896 ppb gold, 0.1 to 4.0 ppm silver, 13 to 4,430 ppm arsenic, 1 to 100 ppm bismuth, and 1 to 77 ppm antimony. The stockwork zones, many of them lacking sulfides, consists of quartz, albite, and calcite, and are associated with variable sericitic and chlorite alteration.

Alteration:

Stockwork zones in granitic rocks are associated with sericitic and chloritic alteration.

Age of mineralization:

Probably about 107 Ma based on similarities with the nearby Pogo Mine.

Generic deposit model:

Deposit model:

Quartz veins and stockwork zones related to nearby Cretaceous intrusions.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Extensive surface sampling and geochemistry and geophysical surveys beginning in 1999 and continuing through 2007. Five holes were drilled in 2000 by Hyder Gold and another 9 holes were drilled in 2004 by AngloGold Ashanti (USA); these totaled 3,054 meters.

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Boundary

Site type: Prospect

ARDF no.: BD062

Latitude: 64.418

Quadrangle: BD B-1

Longitude: 144.3769

Location description and accuracy:

The Boundary prospect is on a ridge about 2.6 miles west, northwest of the junction of Tibbs Creek and Last Chance Creek. The coordinates are at about the center of a group of drill sites on a large block of claims outlined by Baknes (2008). The prospect is about 0.6 mile southeast of the center of section 4, T6 S., R. 17 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Bi, Sb

Other: Cu, Pb

Ore minerals: Arsenopyrite, pyrite, bismuthinite

Gangue minerals: Quartz

Geologic description:

The rocks in the area are part of the Yukon-Tanana Terrane of the northern Cordillera; they consist largely of late Paleozoic to Devonian medium- to high-grade metamorphic rocks that have been intruded by Cretaceous and Tertiary granitic stocks and batholiths (Baknes, 2008; Wilson and others, 1998). The metamorphic rocks are structurally complex with an older, middle to early Paleozoic and/or late Proterozoic unit that consists of gneiss, schist, quartzite, and amphibolite and a younger, Mississippian and/or Devonian unit that consists largely of augen gneiss that locally forms domal structures. The metamorphic rocks are intruded by 55 Ma to 107 Ma, granitic plutons. The structure of the area is complex and difficult to determine because of poor exposure but several major thrust fault have been identified as well as a series of northeast-trending, northwest-dipping high-angle faults.

The dominant mineralization in the area and the target of most of the exploration are deposits related to Cretaceous intrusions, several classic examples being the Fort Knox Mine (FB115) near Fairbanks and the nearby Pogo Mine (BD033). These deposits are characterized by an association with moderately reduced, I- and S- type granitic intrusions and a lithophile, gold-bismuth-tungsten-arsenic-tellurium-molybdenum(-tin-copper-lead-antimony) suite of elements. The deposits vary from low-sulfide, sheeted or stockwork deposits in the intrusions to replacement deposits, veins, and stockworks in the country rock. The mineralization at the nearby Pogo deposit is the model used in exploring this and other prospect in the area. The mineralization at Pogo consists of thick gently-dipping quartz veins that grade laterally into pegmatite dikes related to 107 Ma syenite and monzonite intrusions. The quartz veins contain about 3 percent sulfides, mainly arsenopyrite, pyrite, pyrrhotite, loellingite, chalcopyrite, bismuthinite, native bismuth and native gold. The veins are associated with biotite alteration overprinted by sericite-dolomite-chlorite-quartz alteration, that extends into the country rock for several meters.

Soon after the recognition of nearby Pogo as a major and economically attractive deposit in 1998, Rimfire Minerals Corporation in conjunction with several joint-venture partners began work in the area and identified this deposit. In 2008, they entered into a joint venture with Rubicon Minerals Corporation and commissioned a thorough technical report on their properties in the Goodpaster District (Baknes, 2008), which is the source of most of the information on this prospect.

The rocks in the area of the Boundary deposit are iron-stained gneiss intruded by granitic dikes and sills

that are generally aplite but locally grade into pegmatite. The gneiss shows variable sericite-quartz-pyrite/pyrrhotite alteration. The rocks are poorly exposed and the only recognizable structures are lineaments that probably represent faults. Several shows of mineralization occur in an area about 2 kilometers in diameter that roughly coincides with an arsenic-bismuth-antimony-gold soil anomaly of about 1.5 x 2.5 km in size. The Boundary stockworks is a 100 by 300 meters talus zone with scattered, vuggy quartz veinlets that contain traces of arsenopyrite and bismuthinite. The Daydreamer showing is an area of about 25 meters by 75 meters in size with quartz boulders that contain finely disseminated blebs of arsenopyrite and rare pyrite and bismuthinite. The Topgun showing is an area about 10 meters in diameter with mineralization similar to the Daydreamer showing. The Pebble showing is 15 to 20 meters in size with weathered quartz pebbles and fine-grained quartz breccia. Eighteen samples collected at the surface from these showing contained significant metal values: 20 to 24,853 parts per billion (ppb) gold), 0.6 to 33.2 parts per million (ppm) silver, 2 ppm to more than 1 percent arsenic, 12 to 1,215 ppm bismuth, 8 to 168 ppm copper, and 6 to 1,055 ppm lead. Five holes that totaled 1,446 meters were drilled at the Boundary prospect in 2000 and 2001. Three of the holes intercepted mineralization 0.1 to 4.2 meters long; the metal values in these intercepts varied from 1,110 to 35,240 ppm gold, 1 ppm to more than 1 percent arsenic, and 14 to 1,250 ppm bismuth.

Alteration:

The gneiss host rocks show variable sericite-quartz-pyrite/pyrrhotite alteration.

Age of mineralization:

Probably about 107 Ma based on similarities with the nearby Pogo Mine.

Generic deposit model:

Deposit model:

Quartz veins and stockwork zones related to nearby Cretaceous intrusions.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Extensive surface sampling and geochemical and geophysical surveys beginning in 1999 and continuing through 2007. Five holes that totaled 1,446 meters were drilled in 2000 and 2001.

Production notes:

None.

Reserves:

None.

Gangue minerals: Quartz

Geologic description:

The rocks in the area are part of the Yukon-Tanana Terrane of the northern Cordillera; they consist largely of late Paleozoic to Devonian medium- to high-grade metamorphic rocks that have been intruded by Cretaceous and Tertiary granitic stocks and batholiths (Baknes, 2008; Wilson and others, 1998). The metamorphic rocks are structurally complex with an older, middle to early Paleozoic and/or late Proterozoic unit that consists of gneiss, schist, quartzite, and amphibolite and a younger, Mississippian and/or Devonian unit that consists largely of augen gneiss that locally forms domal structures. The metamorphic rocks are intruded by 55 Ma to 107 Ma, granitic plutons. The structure of the area is complex and difficult to determine because of poor exposure but several major thrust fault have been identified as well as a series of northeast-trending, northwest-dipping high-angle faults.

The dominant mineralization in the area and the target of most of the exploration are deposits related to Cretaceous intrusions, several classic examples being the Fort Knox Mine (FB115) near Fairbanks and the nearby Pogo Mine (BD033). These deposits are characterized by an association with moderately reduced, I- and S- type granitic intrusions and a lithophile, gold-bismuth-tungsten-arsenic-tellurium-molybdenum(-tin-copper-lead-antimony) suite of elements. The deposits vary from low-sulfide, sheeted or stockwork deposits in the intrusions to replacement deposits, veins, and stockworks in the country rock. The mineralization at the nearby Pogo deposit is the model used in exploring this and other prospect in the area. The mineralization at Pogo consists of thick gently-dipping quartz veins that grade laterally into pegmatite dikes related to 107 Ma syenite and monzonite intrusions. The quartz veins contain about 3 percent sulfides, mainly arsenopyrite, pyrite, pyrrhotite, loellingite, chalcopyrite, bismuthinite, native bismuth and native gold. The veins are associated with biotite alteration overprinted by sericite-dolomite-chlorite-quartz alteration, that extends into the country rock for several meters.

Soon after the recognition of nearby Pogo as a major and economically attractive deposit in 1998, Rimfire Minerals Corporation in conjunction with several joint-venture partners began work in the area and identified this deposit. In 2008, they entered into a joint venture with Rubicon Minerals Corporation and commissioned a thorough technical report on their properties in the Goodpaster District (Baknes, 2008), which is the source of most of the information on this prospect.

Most of the Beverly prospect is in augen gneiss intruded by granitic dikes. The area has been studied only

in reconnaissance and the only mineralization consists of quartz boulders in float; a sample contained 2,370 parts per billion (ppb) gold, 0.2 part per million (ppm) silver, 39 ppm bismuth, and 90 ppm copper. Rubicon Minerals Corp. drilled 6 holes in the Beverly area that totaled 1,505.6 meters. Two of the holes cut 4 significant intersections of mineralization 0.76 to 10.30 meters long; they contained 0.96 to 2.24 grams of gold per ton, 0.92 to 10.3 grams of silver per ton, and 436 to greater than 1 percent arsenic.

Alteration:

Not specified.

Age of mineralization:

Probably about 107 Ma based on similarities to the nearby Pogo Mine.

Generic deposit model:

Geologic description:

The rocks in the area are part of the Yukon-Tanana Terrane of the northern Cordillera; they consist largely of late Paleozoic to Devonian medium- to high-grade metamorphic rocks that have been intruded by Cretaceous and Tertiary granitic stocks and batholiths (Baknes, 2008; Wilson and others, 1998). The metamorphic rocks are structurally complex with an older, middle to early Paleozoic and/or late Proterozoic unit that consists of gneiss, schist, quartzite, and amphibolite, and a younger, Mississippian and/or Devonian unit that consists largely of augen gneiss that locally forms domal structures. The metamorphic rocks are intruded by 55 Ma to 107 Ma, granitic plutons. The structure of the area is complex and difficult to determine because of poor exposure but several major thrust fault have been identified as well as a series of northeast-trending, northwest-dipping high-angle faults.

The dominant mineralization in the area and the target of most of the exploration are deposits related to Cretaceous intrusions, several classic examples being the Fort Knox Mine (FB115) near Fairbanks and the nearby Pogo Mine (BD033). These deposits are characterized by an association with moderately reduced, I- and S- type granitic intrusions and a lithophile, gold-bismuth-tungsten-arsenic-tellurium-molybdenum(-tin-copper-lead-antimony) suite of elements. The deposits vary from low-sulfide, sheeted or stockwork deposits in the intrusions to replacement deposits, veins, and stockworks in the country rock. The mineralization at the nearby Pogo deposit is the model used in exploring this and other prospect in the area. The mineralization at Pogo consists of thick gently-dipping quartz veins that grade laterally into pegmatite dikes related to 107 Ma syenite and monzonite intrusions. The quartz veins contain about 3 percent sulfides, mainly arsenopyrite, pyrite, pyrrhotite, loellingite, chalcopyrite, bismuthinite, native bismuth and native gold. The veins are associated with biotite alteration overprinted by sericite-dolomite-chlorite(-quartz) alteration, that extends into the country rock for several meters.

Soon after the recognition of nearby Pogo as a major and economically attractive deposit in 1998, Rimfire Minerals Corporation in conjunction with several joint-venture partners began work in the area and identified this deposit. In 2008, they entered into a joint venture with Rubicon Minerals Corporation and commissioned a thorough technical report on their properties in the Goodpaster District (Baknes, 2008), which is the source of most of the information on this prospect.

The geochemical anomalies and mineralization at the Southeast Surf prospect are mainly in Devonian to

Mississippian augen gneiss near a granitic stock. Few lineaments can be identified but they appears to trend consistently north and northeast. Two areas of mineralization have been identified at the surface. The Spur showing covers an area about 200 by 250 meters where numerous samples of granitic float contain vuggy quartz stockworks. The mineralized granite is altered to quartz, sericite, and dolomite, and some samples are intensely silicified. The quartz stockworks contain pyrite, arsenopyrite and traces of stibnite. Four samples contained 1,020 parts per billion (ppb) gold, 0.2 to 3.2 parts per million (ppm) silver, 1,385 to 6,730 ppm arsenic, less than 2 to 2 ppm bismuth, 2 to 32 ppm copper, and 6 to 970 ppm lead. At the Ol' Timer showing, strongly sericitized augen gneiss with quartz stockworks can be traced for 50 meters in talus. The quartz contains arsenopyrite, pyrite, and traces of stibnite. A sample contained 1,020 ppb gold, less than 0.2 ppm silver, 1,950 ppm arsenic, less than 2 ppm bismuth, 8 ppm antimony, 98 ppm antimony, and 20 ppm lead. No holes have been drilled at the Southeast Surf prospect.

Alteration:

The granitic host rocks are altered to quartz, sericite, and dolomite near the mineralization; some of the granitic rocks are intensely silicified.

Age of mineralization:

Probably about 107 Ma based on similarities to the nearby Pogo Mine.

Generic deposit model:

Deposit model:

Quartz veins and stockworks related to nearby Cretaceous intrusions.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Extensive surface sampling and geochemistry and geophysical surveys beginning in 1999 and continuing through 2007.

Production notes:

None.

Reserves:

None.

Location description and accuracy:

The Uncle Sam prospects cover an area about 4 miles in diameter. The center of the area is about 2.5 miles southeast of the center of Koepke's Slough on the Salcha River; it is near the center of section 6, T. 5 S., R. 8 E., of the Fairbanks Meridian. The location is accurate within 500 feet.

Commodities:

Main: Au

Other: As, Bi, Sb

Ore minerals: Antimony, bismuth, gold

Gangue minerals: Quartz

Geologic description:

The area is blanketed by loess and surficial material and there is little outcrop. The rocks in the area consist of Paleozoic and/or Proterozoic migmatitic schist and gneiss intruded by felsic igneous rocks (Wilson and others, 1998). At least two intrusive bodies are known on the property, each of which is associated with mineralization.

Kennecott Exploration began exploration in the area in the late 1990s and they staked a block of more than 500 claims on 'exceptionally large' bismuth-arsenic-antimony stream-sediment anomalies (Millrock Resources Inc., 2010; Eden, 2010). Individual prospects within the Uncle Sam project area were identified in 2000. These include Lone Tree (ARDF number BD075) , Lone Wolf (ARDF number BD076), and Christmas Tree (ARDF number BD077), described individually in detail in separate records. Kennecott worked and drilled the property through 2003 and then passed it on to Geoinformatics Exploration Ltd., who did additional drilling under an agreement with Midas Resources Ltd. There have been 23 core holes totaling 4,198 meters on the property and 57 reverse-circulation holes totaling 2,844 meters, as well as considerable geochemical work, geophysical surveys, and sampling. It was optioned by Millrock Resources Inc. in 2009 and in 2011 the property was covered by 194 unpatented 40-acre Alaska state mining claims.

The drilling cut 19 intercepts, 3 to 12 meters wide, with more than 1.0 gram of gold per tonne (Millrock Resources Inc., 2010; Eden, 2010). Three main centers of mineralization have been identified: the Lone Wolf, Christmas, and Lone Tree zones (Millrock Resources Inc., 2010). The Lone Wolf zone is marked by a soil anomaly in gold that is over 2 kilometers long. The zone is also associated with a pronounced magnetic low. Two of the best drill intercepts are 4.0 meters with 3.03 grams of gold per tonne and 11.2 meters with 2.38 grams of gold per tonne. The Christmas zone features a soil anomaly in gold over 4 kilometers long. One drill intercept of 5.5 meters contained 4.94 grams of gold per tonne. The Lone Tree zone is magnetic high that may reflect a buried felsic intrusive. Of the several drill intercepts, the best was 6.1 meters with 10.6 grams of gold per tonne.

In 2011, Millrock with funding by Crescent Resources Inc., drilled five holes in the Lone Tree zone that totaled 1,329 meters (Millrock Resources, Inc., 2011; Crescent Resources Inc., 2011b). Some notable intercepts were 19.22 meters that averaged 2.03 grams of gold per tonne, 6.0 meters that averaged 1.79 grams of gold per tonne, and 14.0 meters that averaged 1.65 grams of gold per tonne.

Alteration:

Locally sericite, carbonate, silicification, and/or disseminated sulfides (Eden, 2010).

Age of mineralization:

Cretaceous based on the age of the associated plutons (Wilson and others, 1998)?

Generic deposit model:

Deposit model:

Possibly an intrusion related, Fort Knox type, gold porphyry.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Kennecott Exploration began exploration in the area in the late 1990s when they staked a block of more than 500 claims on 'exceptionally large' bismuth-arsenic-antimony stream-sediment anomalies (Millrock Resources Inc., 2010; Eden, 2010). Kennecott worked and drilled the property through 2003 but then passed it on to Geoinformatics Exploration Ltd., who did additional drilling under an agreement with Midas Resources Ltd. There have been 23 core holes totaling 4,198 meters on the property and 57 reverse-circulation holes totaling 2,844 meters, as well as considerable geochemical work, geophysical surveys, and sampling. It was optioned by Millrock Resources Inc. in 2009 and in 2010; the property was covered by 194 unpatented 40-acre Alaska state mining claims.

In 2011, Millrock with funding by Crescent Resources Inc., drilled five holes in the Lone Tree zone that totaled 1,329 meters (Millrock Resources, Inc., 2011; Crescent Resources Inc., 2011b).

In December 2011, Crescent announced amendment of terms of option to earn 100 percent interest in the Uncle Sam project (Crescent Resources, 2011a). As of September 2011, the property owner is Coventry Resources Inc., which is a 100 percent owned subsidiary of Crescent Resources Inc. (Coventry Resources Inc., 2012).

Great American Minerals Exploration Inc. (GAME) consolidated ownership of the 26,639-acre Uncle Sam property and made a deal with Stone Boy Inc. on their adjacent Monte Cristo property; the area encompassing these properties, now termed the Sam project, is located about 40 miles west of Pogo mine. In 2011, the Naosi zone, a gold-silver-antimony prospect within the larger Monte Cristo property, was drilled; results included 7.92 meters of 7.8 grams of gold per tonne, 19.7 grams of silver per tonne, and 0.1 percent antimony; and, 22.83 meters grading 4.2 grams of gold per tonne, 48 grams of silver per tonne, and 0.17 percent antimony. From 2008 through 2012, Stone Boy Inc. drilled 79 holes at Naosi, outlining the deposit for about 1,500 meters along strike and to a depth of about 500 meters (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Additional comments:

In 2014, individual ARDF records were made for Lone Wolf, Lone Tree, and Christmas Tree. As recently as the 2012 ARDF update, these prospects were included within part of the Uncle Sam prospects; however, each prospect has discrete geology characteristics.

In December 2011, Crescent announced amendment of terms of option to earn 100 percent interest in the

Uncle Sam project (Crescent Resources, 2011a). As of September, 2012, the property owner is Coventry Resources Inc., which is a 100 percent owned subsidiary of Crescent Resources Inc. (Coventry Resources Inc., 2012).

The Sam Project as of 2016 includes the Uncle Sam, Naosi, and Monte Cristo properties. More information about the Naosi and Monte Cristo properties will be forthcoming.

Last report date: 2017-08-26

Site name(s): Junction

Site type: Prospect

ARDF no.: BD068

Latitude: 64.3375

Quadrangle: BD B-6

Longitude: 146.5412

Location description and accuracy:

The Junction prospect is about 2.0 miles west-southwest of the mouth of Democrat Creek on Junction Creek. It is about 0.6 mile north-northeast of hill 1984 and about 0.2 mile west-northwest of the center of section 3, T. 7 S., R. 6 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, Au

Other: As, Bi, Pb, Sb, Zn

Ore minerals: Gold, pyrite

Gangue minerals: Quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

The Junction prospect was discovered in 1991 by searching for the source of anomalous stream sediment and panned concentrate samples collected during a regional geochemical study done by the Tri-Valley Corporation and TSNIGRI of the Russian Ministry of Geology (Vartanyan, 1992; Freeman, 2011). Half of the samples from streams draining the north side of the Junction prospect had visible gold. The concentrates also had high contents of pyrite, ilmenite, tourmaline, magnetite, and biotite.

The country rocks at the prospect consist of quartz-muscovite schist and quartz-feldspar-biotite schist cut by east-trending, steeply-dipping, quartz-feldspar porphyry dikes 100 to 250 meters thick, similar to those at the nearby Democrat Mine (BD014). The mineralization consists of closely-spaced quartz and quartz-pyrite veinlets in the dike. Talus boulders up to 0.3 meter in diameter consist of druzy to coarsely-crystalline quartz with fine-grained silver-lead-bismuth minerals. Weak to intense, greisen-like, quartz-muscovite-sericite alteration is notable in and at the margin of the quartz-feldspar-porphyry dike but does not extend far into the country rock. Twenty-eight samples contained from less than 5 to 307 parts per billion gold, from l 0.2 to 41.1 parts per million (ppm) silver, 14 to 710 ppm arsenic, less than 5 to 76 ppm bismuth, 9 to 4,500 ppm lead, less than 5 to 54 ppm antimony, and 3 to 171 ppm zinc.

Alteration:

Age of mineralization:

Probably about 90 Ma as is other mineralization in the district.

Generic deposit model:

Deposit model:

Intrusion-related gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Only surface sampling and mapping.

Production notes:

None.

Reserves:

None.

Site name(s): First Chance Creek

Site type: Prospect

ARDF no.: BD069

Latitude: 64.4269 **Quadrangle:** BD B-5

Longitude: 146.4809

Location description and accuracy:

This placer deposit is near the middle of a creek that is not named on the USGS topographic maps but has been known locally and in mining literature since at least 1905 as First Chance Creek. It is about 9.9 miles north-northwest of Richardson on the Richardson Highway. It is about 2.4 miles northeast of the junction of Redmond Creek and Shamrock Creek, and about 0.6 mile northwest of the center of section 1, T. 6 S., R. 6 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Cassiterite, cinnabar, gold, molybdenite, scheelite

Gangue minerals:

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

Olson and others (1985) report mining on First Chance Creek in 1905 but there is little hard evidence of mining in subsequent years. Based on an old newspaper article, Mitchell (1989) noted that prospecting on First Chance Creek at some uncertain time found auriferous gravel with 0.25 ounce of gold per pan at a depth of 80 feet. Mitchell located old dumps next to by shafts on First Chance Creek but they were too small to indicate significant production. A 1906 newspaper article reported as much as 5 ounces of gold per cubic yard from from gravel in shafts 40 to 90 feet deep on First Chance Creek; the gold was said to be accompanied by cassiterite, cinnabar, scheelite, and molybdenite. Freeman (2011) questions that location and there is no documentation of the amount of gold produced from First Chance Creek from 1905 to 2011.

In 2003, the Tri-Valley Corporation drilled 44 reverse-circulation holes on the placer in lower First Chance Creek. The holes averaged 18.6 meters deep and the deepest was 28.5 meters (Vardanyan and others, 2003; Freeman, 2011). The drilling indicated a 60-meter-wide zone of old drift mining on the lower part of First Chance Creek that verifies that there was some early mining. Samples collected in 1999 by Placer Dome (USA) and by TSNIGRI working with the Tri-Valley Corporation found visible gold 0.1 to 3.0 millimeters in size as well as cassiterite, scheelite, cinnabar, and molybdenite in the heavy sand fraction.

The 2003 drilling defined two pay streaks that extend for more than 3 kilometers along the creek. An

upper auriferous channel was covered by aeolian silt; the lower auriferous channel was on bedrock The gravel in the upper channel was about 2.8 meters thick beneath 4.6 meters of overburden; the gravel averaged 0.38 gram of gold per cubic meter. The gravel in the lower channel was about 2.6 meters thick under about 16.8 meters of overburden; the gravel averaged 0.86 gram of gold per cubic meter. Vartanyan and others (2003) estimated that lower First Chance Creek has a total resource of 37,871 ounces of gold in 1,661,000 cubic yards of gravel overlain by 7,100,000 yards of overburden.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

There are indications of mining in 1905 and perhaps for a few more years but little evidence of when and how much gold was produced. Placer drilling in 2003 identified a 60-meter-wide zone of old drift mining on the lower part of First Chance Creek that verifies that there was some early mining. In 2003, the Tri-Valley Corporation drilled 44 reverse-circulation holes on lower First Chance Creek that identified a measurable placer gold resource.

Production notes:

There is no documentation of placer production on First Chance Creek, but there was mining at least in 1905. Drilling in 2003 identified a 60-meter-wide zone of old drift mining of uncertain age but may date to before WWI.

Reserves:

As defined by 44 holes drilled in 2003, Vartanyan and others (2003) estimated that lower First Chance Creek has a total resource of 37,871 ounces of gold in two channels of auriferous gravel that total 1,661,000 cubic yards of material. The auriferous gravel is overlain by 7,100,000 yards of overburden.

Gangue minerals: Quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

Vartanyan and others (1991) indicate that the bedrock in the upper third of First Chance Creek is primarily pelitic schist. The schist in the lower two-thirds is deformed and contains numerous quartz veins and veinlets, and dacite (?) dikes 150 to 500 meters long.

The First Chance lode deposit was discovered in 1991 during the search for the source of high gold and arsenic in panned concentrate samples from the south flank of hill 1275 on the north side of lower First Chance Creek (Vartanyan and others, 1991; Freeman, 2011). Subsequent soil sampling to the north and south of First Chance Creek identified a northwest-trending area anomalous in gold and arsenic; the area is about 1,500 meters long and about 400 meters wide on the hill slopes between Last Chance Creek and hill 1275 (Vartanyan and others, 2003). Twenty-four chip samples of quartz were collected in the anomalous area that contained up to 3 grams of gold per tonne.

Last report date: 2012-04-01

Site name(s): Hilltop

Site type: Prospect

ARDF no.: BD071

Latitude: 64.4237 **Quadrangle:** BD B-6

Longitude: 146.6563

Location description and accuracy:

The Hilltop prospect is on hill 1920 about 13.9 miles northwest of Richardson on the Richardson Highway and about 6.0 miles east of the center of Harding Lake. It is about 0.4 mile east of the center of section 1, T. 6 S., R. 5 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, Au

Other: As, Au, Bi, Cu, Sb

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014). The poorly exposed rocks at the Hilltop prospect are predominantly quartz-feldspar-biotite+/-muscovite gneiss with some amphibolite.

The Hilltop prospect was first suspected when Vartanyan and others (1991) identified anomalous gold in stream sediment and panned concentrated samples from streams draining Hill 1920. No outcrop is exposed on Hill 1920 but in 2000, Vartanyan and others (1991) collected 63 rock-chip samples, 24 samples from trenches to bedrock, and 195 soil samples from 203 pits to bedrock. Rock samples contained 0.003 to 1.726 ounces of gold per ton, up to 289 parts per million (ppm) bismuth, up to 30 parts per million (ppm) copper, up to one percent or more arsenic, and up to 276 ppm antimony. Many of the soil samples were highly anomalous in gold and arsenic. Based on limited field work, the Hilltop deposit appears to trend north-northwest, and is estimated to be 200-900 feet wide and extends along strike for over 3,000 feet.

Alteration:

Not specifically noted.

Age of mineralization:

Uncertain but probably 90 Ma as are many of the intrusion-related gold deposits in the district.

Generic deposit model:

Deposit model:

Intrusion-related gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Covered by regional geochemical surveys with stream sediment and panned concentrate samples in 1991. No outcrop is exposed on Hill 1920 but in 2000, Vartanyan and others (1991) collected 63 rock-chip samples, 24 samples from channels to bedrock, and 195 soil samples from 203 pits to bedrock.

Production notes:

None.

Reserves:

None.

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

The Gold Run prospect is associated with a coarse-grained, porphyritic quartz monzonite stock, the Gold Run intrusive (Swainbank and others, 1984; Rogers, 1999). The stock extends over an area about 1.8 by 2.3 kilometers in size. Only the top of the stock is exposed and the southern margin is bounded by a fault. The stock is rimmed by fine- to medium-grained equigranular granite, locally mixed with gneiss. Pegmatite dikes composed mainly of quartz, feldspar, muscovite, and biotite are common beyond the stock. Biotite from the stock has been dated as 92 Ma by Ar/Ar methods (Graham, 2002).

Mineralization at the Gold Gun prospect was first suspected in 1991 from the presence of gold in rock and panned concentrate samples collected in a regional geochemical survey (Vartanyan and others, 1991). Placer Dome (USA) subsequently collected soil samples at the top of bedrock over the area on a 200-meter grid. That geochemical survey defined a bismuth anomaly about 0.5 kilometer wide by 1.2 kilometers long (Rogers and others, 1999). Rock samples contained from less than 5 to 40 parts per billion gold, and low arsenic and bismuth. Freeman (2011) suggests that the the prospect is an intrusion-related gold deposit.

Alteration:

Age of mineralization:

Probably related to the 92 Ma stock that hosts the deposit.

Generic deposit model:

Deposit model:

Intrusion-related gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Covered by geochemical surveys; the prospect has had only limited surface sampling and mapping.

Production notes:

None.

Reserves:

None.

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014). As seen in the core from three holes drilled in 2000 at or near the Bald Knob prospect, the rocks in the area consist of gneiss, migmatite, and felsic granitic dikes that vary from pegmatite to aplite (Noyes and others, 2006).

The Bald Knob prospect was discovered by the Tri-Valley Corporation during reconnaissance exploration in 1998 after 10 float samples of quartz were found that contained 0.35 to 1.54 ounces of gold per ton at the nearby Buckeye prospect (BD048); the samples also contained up to 846 parts per million (ppm) bismuth and up to 127 ppm tellurium (Vantanyan and others, 1998). In late 1998, the Tri-Valley Corporation and Placer Dome (USA) formed a joint venture that initially concentrated their work in the headwaters of Banner Creek over the Buckeye prospect but soon was extended to this prospect about a mile and a half to the north. In 1999, Placer Dome collected 1,037 soil samples on bedrock, collected 136 rock samples, and drilled three hole that totaled 516.5 meters (Rogers and others 1999). The soil samples defined a strong gold-bismuth-tellurium anomaly over the Buckeye and Bald Knob prospects. One drill hole was at the Buckeye prospect, the other two were at the Bald Knob prospect. Placer Dome did more soil and rock sampling in 2000 and drilled three more holes (Graham 2002; Noyes and others, 2006). Low-grade intercepts of more than 100 parts per billion gold were seen in the six holes drilled in 1999 and 2000. The high gold values in the core can be correlated with high bismuth and tellurium but there seems to be no correlation of gold with such pathfinder elements as silver, arsenic, antimony, copper, lead, or zinc, elements that are commonly associated with other gold deposits in the district. The higher gold values are

associated with narrow quartz veins that cut otherwise unaltered gneiss. Additional soil sampling was done in 2005 but added little to the extent of the previous anomalies. The source of the rich gold-bismuth-tellurium-quartz samples found at the surface near the Buckeye prospect in 1998 remains unknown. Freeman (2011) in his synthesis of the previous work on the gold mineralization of the Richardson district suggests that the mineralization at the Bald Knob prospect is a distal intrusion-related gold deposit.

Alteration:

Notable lack of alteration in the gneiss host rock.

Age of mineralization:

Probably 90 Ma as are most of the gold deposits in the district.

Generic deposit model:

Deposit model:

Distal intrusion-related gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Three generations of soil sampling on bedrock from 1998 to 2005. Numerous rock samples collected and analyzed. Nine holes were drilled in 1999 and 2000 at this and the nearby Buckeye prospect (BD048).

Production notes:

None.

Reserves:

None.

Longitude: 146.3465

Location description and accuracy:

The Banner prospect is on a hillside in the headwaters of Banner Creek and about 4.1 mile north of Richardson on the Richardson Highway. It is about 1.0 mile north of the mine symbol shown on the USGS 1:63-360-scale topographic map at the head of Banner Creek and about 0.3 mile west of the center of section 34, T. 6 S., R. 7 E., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au

Other: Cu, Pb, Sn, W

Ore minerals: Andorite, arsenopyrite, chalcopyrite, freibergite, jamesonite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Richardson District is characterized by gentle slopes and broad, alluvium-filled valleys (Prindle and Katz, 1913). The area is unglaciated and largely overlain by windblown silt, sand, and loess, locally up to 50 meters thick (Foster and others, 1979). The rocks consist of three structure-bounded units (Weber and others, 1978; Swainbank and others, 1984; Noyes and others, 2006; Freeman, 2011). There is a core that consists mainly of biotite-hornblende-feldspar-quartz gneiss and lesser amphibolite, quartzite, marble and calc-silicate hornfels. The core is bounded on the north and south by amphibolite-grade pelitic schist. The contacts between the units are probably low-angle faults; north-trending vertical faults occur widely. Weber and others (1978) assign the pre-metamorphic age of the rocks to the Precambrian or Paleozoic. They were metamorphosed in the Middle to Late Devonian and recrystallized in the Early Cretaceous (Dusel-Bacon and others, 2004; Freeman, 2011). The metamorphic rocks are intruded by 90 Ma, felsic to intermediate dikes and plugs, notable the mineralized quartz-feldspar porphyry dike at the nearby Democrat Mine (BD014).

The Banner prospect was discovered in 1992 in the search for the source of visible gold in stream sediment and panned-concentrate samples (Vartanyan and others, 1992; 1998). Work in 1992 and 1998 consisted of considerable sampling in several long trenches, along road cuts, and in 30 hand-dug pits.

The northern portion of the prospect is mostly biotite-quartz-feldspar paragneiss intruded by a series of north-northwest-trending quartz-feldspar-porphyry dikes similar to the dike at the nearby Democrat Mine (BD014). The southern portion is in paragneiss and orthogneiss cut by two zones of steeply dipping granodiorite dikes that trend southeast. The quartz-feldspar porphyry varies from unaltered to intensely altered to greisen-like rock with pyrite veinlets and clots of pyrite. The alteration is strongest along the dike margins. Early quartz-sericite alteration is cut by brecciation, quartz veins, and quartz-sulfide veins.

The mineralization consists of sulfide-pyrite-quartz- veins, often with open-space textures (Freeman, 2011). The veins have up to 30 percent ore minerals; arsenopyrite and jamesonite are common; andorite, freibergite, sphalerite, and chalcopyrite less so. The 128 rock samples that were analyzed contained up to 1,729 parts per billion gold, up to 171.9 parts per million (ppm) silver, up to 2,454 ppm arsenic, up to 242 ppm copper, up to 3,948 ppm lead, up to 2,000 ppm arsenic, up to 51 ppm tin, and up to 91 ppm tungsten. Bismuth and tellurium were below the detection limit.

Freeman (2011) interprets the prospect as a high-level, volatile-rich silver-tin-polymetallic hydrothermal system with strong affinities to intrusion-related gold deposits.

Alteration:

The quartz-feldspar porphyry that hosts the veins varies from unaltered to intensely altered to greisen-like rock with pyrite veinlets and clots of pyrite. The alteration is strongest along the dike margins. Early quartz-sericite alteration is cut by brecciation, quartz veins, and quartz-sulfide veins.

Age of mineralization:

Probably 90 Ma as is most of the gold mineralization in the Richardson district.

Generic deposit model:

Deposit model:

Gold-silver-tin-polymetallic hydrothermal system with strong affinities to intrusion-related gold deposits.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Banner prospect was discovered in 1992 in the search for the source of visible gold in stream sediment and panned-concentrate samples (Vartanyan and others, 1992; 1998). Work in 1992 and 1998 consisted of considerable sampling in several long trenches, along road cuts, and in 30 hand-dug pits.

Production notes:

None.

Reserves:

None.

Last report date: 2012-04-01

Site name(s): Lone Tree

Site type: Prospect

ARDF no.: BD075

Latitude: 64.5161 **Quadrangle:** BD C-5

Longitude: 146.2098

Location description and accuracy:

The prospect is part of the Uncle Sam property. The coordinates are located at the center of the claim. The prospect is about 0.4 mile southwest of the center of section 31, T. 4 S., R. 8 E., of the Fairbanks Meridian, 2.5 miles east-southeast of the junction of Koepke Slough, of the Salcha River, and Twentyfive Mile Creek. It is located 65 km southeast of Fairbanks, Alaska and 60 km west of the Pogo Gold Mine. The location is accurate to within about 500 feet of the center of the prospect.

Commodities:

Main: Au, Pb, Zn

Other: Bi, Sb

Ore minerals: Arsenopyrite, galena, gold, jamesonite, pyrite, sphalerite, stibnite

Gangue minerals: Biotite, calcite, chlorite, kaolinite, halloysite?, sericite (illite)

Geologic description:

Lone Tree is a prospect at the Uncle Sam property, within the Tintina Gold Belt. The area is blanketed by loess and surficial material and there is little outcrop. The rocks in the area consist of Paleozoic and/or Proterozoic migmatitic schist and gneiss intruded by felsic igneous rocks (Wilson and others, 1998). At least two intrusive bodies are known on the property, each of which is associated with mineralization (Eden, 2010).

Lone Tree is characterized as a gold soil anomaly with a pronounced magnetic low. It appears to be structurally controlled in a brittle-ductile shear zone that strikes roughly east-west with moderate to gentle northward dips.

In the Lone Tree area Au correlates strongly with As, Ag, Cd, and Sb and more erratically with Zn, Pb, and Bi (Eden, 2010).

The area surrounding Lone Tree was discovered by Kennecott Exploration Company in 1999 during regional grass-roots reconnaissance of the Big Delta Quadrangle. During 1999 and 2001, Kennecott Exploration Company collected a total of 2648 soil samples, identifying Lone Tree in 2000 through soil geochemistry. At this time, Kennecott also conducted geophysical surveys consisting of an airborne magnetic survey, a gravity survey and two IP/Resistivity surveys. Soil targets were drill tested, totaling seven holes at Lone Tree. Potential ore-grade intercepts from the 2000 and 2001 drilling programs conducted by Kennecott Exploration came from the Lone Tree area with intervals of 15.93 m (USC-001), 19.22 m (USC-011) and 14 m (USC-013) that averaged 1.1 g/t, 2.03 g/t and 1.65 g/t. In 2003 Kennecott optioned the claim block to Geoinformatics Exploration LTD., who then (2005) entered into an agreement in principle with Midas Resources Ltd. with respect to Geoinformatics' Uncle Sam gold project in Alaska (Eden, 2010).

In April 2006, Midas Resources Ltd. completed an RC drilling program. In the beginning of 2007, Midas Resources Ltd. withdrew from the Uncle Sam gold project an returned it to Geoinformatics Alaska Exploration Inc. In 2009, Millrock Resources Inc. executed an option agreement with Geoinformatics Alaska Exploration Inc. and Kiska Metals Corporation pertaining to the Uncle Sam property. In 2010, Millrock released a 43-101 compliant technical report (Eden, 2010).

Alteration:

Nearly all of the mineralization observed to date is associated with shears or fault zones. Alteration in shears consists of intense sericite (illite) alteration of primary feldspars and biotite, apparently overprinting an earlier chlorite + calcite + sericite alteration. Kaolinite and/or halloysite alteration of feldspars is common adjacent to Au zones and appears to be late. District wide, Au mineralization shows a strong relationship with illite alteration of primary feldspars and biotite. In addition, Au correlates strongly with As, Ag, Cd, and Sb and more erratically with Zn, Pb, and Bi (Eden, 2010).

Age of mineralization:

Cretaceous based on the age of the associated plutons (Wilson and others, 1998)?

Generic deposit model:

Deposit model:

Mineralization related to shear veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site type: Occurrence

ARDF no.: BD076

Latitude: 64.4966 **Quadrangle:** BD B-5

Longitude: 146.2948

Location description and accuracy:

The prospect is part of the Uncle Sam property. The coordinates are located at the center of the claim. The prospect is about 0.2 mile east of the center of section 14, T. 5 S., R. 7 E., of the Fairbanks Meridian, 2.5 miles south of the junction of Koepke Slough, of the Salcha River, and Twentyfive Mile Creek. It is located 65 km southeast of Fairbanks, Alaska and 60 km west of the Pogo Gold Mine. The location is accurate to within about 500 feet of the center of the prospect.

Commodities:

Main: Au, Cu

Other: Bi, Sb, Te, W

Ore minerals: Arsenopyrite, gold, pyrite, pyrrhotite, stibnite

Gangue minerals: Sericite, mica, quartz

Geologic description:

Lone Wolf is a prospect at the Uncle Sam property, within the Tintina Gold Belt. The area is blanketed by loess and surficial material and there is little outcrop. The rocks in the area consist of Paleozoic and/or Proterozoic migmatitic schist and gneiss intruded by felsic igneous rocks (Wilson and others, 1998). At least two intrusive bodies are known on the property, each of which is associated with mineralization. Lone Wolf has weak to moderate gold soil anomalies and strongly anomalous trace element values (bismuth, tellurium, tungsten, arsenic and copper) in addition to a geophysical magnetic high. Geophysical interpretation of magnetic data indicates the presence of at least three granitoid intrusive bodies at depth (Eden, 2010).

Drilling in 2006 by Midas Resources returned gold anomalous results from a zone of quartz stockwork, sericite altered quartz-mica schist accompanied by pyrite-arsenopyrite, stibnite, and pyrrhotite sulfide development. The mineralized alteration zone is coincident with a shallow (40 degree) southwest dipping structure. This structure and its associated alteration zone and shearing form a cohesive zone which has been drill intersected over a strike extent of 110 m and to a vertical depth of 100 m. Altered but only weakly gold anomalous granite dikes/sills were intersected by the drilling in 2006 and lend support to the geophysical interpretation of larger granite stocks at depth. The mineralized shear zone intersected by the 2006 drill program at Lone Wolf is coincident with one of several interpreted northwest trending structural lineaments as interpreted from magnetic imagery. The most significant mineralization was intersected in USRC-022 from 24.38 –30.48 m (6.1 m at 10.61 g/t Au) and in USR-055 from 51.8 - 64 m (12.2 m at 1.47 g/t Au) (Eden, 2010).

Alteration:

Quartz stockwork, sericite altered quartz-mica schist accompanied by pyrite arsenopyrite + stibnite, and pyrrhotite sulfide development (Eden, 2010).

Age of mineralization:

Cretaceous based on the age of the associated plutons (Wilson and others, 1998)?

Generic deposit model:

Deposit model:

Intrusion-related gold?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The mineralization surrounding Lone Wolf was discovered by Kennecott Exploration Company in 1999 during regional grass-roots reconnaissance of the Big Delta Quadrangle. During 1999 and 2001, Kennecott Exploration Company collected a total of 2648 soil samples, identifying Lone Wolf in by 2000 through soil geochemistry in a tight grid sampling of 100 by 100 m. At this time, Kennecott also conducted geophysical surveys consisting of an airborne magnetic survey, a gravity survey and two induced polarization (IP)/Resistivity surveys, and soil targets were drill tested. In 2003 Kennecott optioned the claim block to Geoinformatics Exploration LTD., who then (2005) entered into an agreement in principle with Midas Resources Ltd. with respect to Geoinformatics' Uncle Sam gold project in Alaska (Eden, 2010).

In April 2006, Midas Resources Ltd. completed a rotary chip (RC) drilling program, designed to test the Lone Wolf target area where previous drilling had intersected significant gold mineralization (Midas Resources, 2006). Results of this drilling program included 12.2 m grading at 1.47 g/t gold in drill hole USR-055 and 6.1 m grading at 1.15 g/t gold in drill hole USR-056 (Eden, 2010).

In the beginning of 2007, Midas Resources Ltd. withdrew from the Uncle Sam gold project and returned it to Geoinformatics Alaska Exploration Inc. In 2009, Millrock Resources Inc. executed an option agreement with Geoinformatics Alaska Exploration Inc. and Kiska Metals Corporation pertaining to the Uncle Sam property. In 2010, Millrock released a 43-101 compliant technical report (Eden, 2010).

Production notes:

Site name(s): Christmas Tree

Site type: Prospect

ARDF no.: BD077

Latitude: 64.4906 **Quadrangle:** BD C-5

Longitude: 146.2404

Location description and accuracy:

The prospect is part of the Uncle Sam property. The coordinates are located at the center of the claim. The prospect is about 0.2 mile south of the center of section 7, T. 5 S., R. 8 E., of the Fairbanks Meridian, 3.2 miles south-southeast of the junction of Koepke Slough, of the Salcha River, and Twentyfive Mile Creek. It is located 65 km southeast of Fairbanks, Alaska and 60 km west of the Pogo Gold Mine. The location is accurate to within about 500 feet of the center of the prospect.

Commodities:

Main: Au

Other: Bi, Sb

Ore minerals:

Gangue minerals: Carbonates, goethite, quartz, sericite, tourmaline

Geologic description:

Christmas Tree is a prospect at the Uncle Sam property, within the Tintina Gold Belt. The area is blanketed by loess and surficial material and there is little outcrop. The rocks in the area consist of Paleozoic and/or Proterozoic migmatitic schist and gneiss intruded by felsic igneous rocks (Wilson and others, 1998). Christmas Tree is characterized as a gold soil anomaly over with a magnetic high thought to be associated with a mafic schist package that has been domed in the middle of the Christmas Tree area. The Christmas Tree soil anomaly is over four kilometers long and parallels northwest trending structure interpreted from airborne magnetics (Eden, 2010).

This prospect displays narrow Au mineralization related to brittle-ductile shear zones hosted within schist and schistose gneiss that are thought to be shallow to moderately dipping. Sheared veins of quartz-tourmaline ± carbonate are common and have associated goethite after sulfides. Wallrock alteration consists chiefly of intense sericitization of primary feldspars and micas along with minor silicification. The highest-grade intercept came from drilling in 2006 by Midas Resources as USC-006 (161.3-163 m), where a 1.3 m thick quartz-tourmaline veined brittle-ductile shear zone assayed 6.7 g/t Au. The most significant mineralization was intersected in USRC-0007 from 24.5-30 m (5.5 m at 4.94 g/t Au) and in URC-021 from 18.9 – 29.8 m (11.9 m at 1.61 g/t Au) (Eden, 2010).

Alteration:

Sheared veins of quartz-tourmaline ± carbonate are common and have associated goethite after sulfides. Wallrock alteration consists chiefly of intense sericitization of primary feldspars and micas along with minor silicification (Eden, 2010).

Site name(s): Sugar Daddy

Site type: Mine

ARDF no.: BD078

Latitude: 64.9606 **Quadrangle:** BD D-4

Longitude: 145.8647

Location description and accuracy:

The Sugar Daddy gold deposit is located about 9 miles southeast of Chena Hot Springs resort; about 0.2 mile from the center of section 35, T. 1 N., R. 10 E., of the Fairbanks Meridian (Bohan, 2013). Accurate within about 1/4 mile.

Commodities:

Main: Au

Other:

Ore minerals: Gold, magnetite

Gangue minerals: Limonite, quartz

Geologic description:

The Sugar Daddy gold deposit is a placer deposit on Ottertail Creek containing gold bearing gravels, benches, plus immense rust oxidized zones of crumbly weathered bedrock. The placer gravels also overlie a shallow gold lode deposit (Bohan, 2013).

The placer gold is associated with sulfides composed of partially oxidized to limonite and magnetite. The lode gold is hosted in a garnet-bearing phyllite to phyllitic schist. The gold-bearing sulfides are layered in mineralized zones along quartz reef-like fissure veins and surrounding in foliated boudinaged veins. Refractory gold also exists within the fissure lode quartz. The placer is a combination of gravel concentrates plus the weathered lode rock that lies beneath the pay leads (Bohan, 2013).

The placer contains both coarse and fine gold. The larger, coarse nuggets come from stacked fissure veins within a zone of boudinaged quartz in a garnet schist. The finer equigranular gold nuggets come from a skarn deposit and a monzonite pluton located on the north claim blocks (Bohan, 2013).

Pegmatite with the gemstone schorl (black tourmaline) is also found in float cobbles. This sodium, iron rich tourmaline is notable in that its presence suggests that boron is introduced into the hornfels facies contact system (Bohan, 2013).

Alteration:

Iron oxidation (Bohan, 2013).

Age of mineralization:

Placer gold mineralization is Quaternary in age (Weber and others, 1978).

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au-PGE (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Sugar Daddy gold load/placer is at the greenfields stage of exploration and has had very little exploration completed. The 2010-2013 field season yielded gold reserves from 65 cubic yards of gravel washed per ounce of gold to 45 cubic yards of gravel moved (Bohan, 2013).

Production notes:

A six-inch suction dredge was used for sampling on the Sugar Daddy prospect on Ottertail Creek in 2002. Later in 2004, an industrial dredge replaced the six-inch and can run 2-4 yards per hour (Bohan, 2013).

Reserves:

None.

Additional comments:

Gold recovery will be estimated 45 cubic yards gravel washed per ounce of gold recovered on high grade pay leads. The lower grade end of gold leads should average 65 cubic yards of gravel washed per ounce of gold recovered (Bohan, 2013).

Site name(s): Tuluksak River

Site type: Mine

ARDF no.: BH014

Latitude: 60.9877 **Quadrangle:** BH D-3

Longitude: 159.9873

Location description and accuracy:

The Tuluksak River has been almost continuously mined by dredge and mechanized equipment for more than 8 miles downstream from the mouth of California Creek to about a mile upstream from the mouth of Granite Creek. The Tuluksak placer extend from the Russian Mission quadrangle into the Bethel quadrangle and the coordinates above represent the center of the placer in the Bethel quadrangle. The Tuluksak River site in the Russian Mission quadrangle is ARDF site RM028. The information is duplicated in the separate records in the two quadrangles. The location accuracy is unknown.

Commodities:

Main: Au

Other: Pt

Ore minerals: Gold

Gangue minerals:

Geologic description:

Gold was first discovered in the Nyac district on Bear Creek (RM032), a tributary of the Tuluksak River, near the mouth of Bonanza Creek in 1907 or 1908 and soon after gold was discovered on the Tuluksak River. Dredging began on the Tuluksak River in 1936 and for many years the mining in the district, which was mainly on the Tuluksak River, was carried out by the New York-Alaska Company and its successor the New York-Alaska Gold Dredging Company. The company built a company town, Nyac and an extensive physical plant and community facilities including a hydroelectric power station to power the dredges, the town, and other mining in the district. In 1965, the property was taken over by the Tuluksak Dredging Company and since 1990, the Nyac Mining Company has been actively mining in the area under an agreement with the Calista Native Corporation, which now owns most of the placer claims in the district.

Parts from a small wood-hulled dredge that had operated on Bear Creek between 1928 and 1935 were used to build a steel-hulled dredge on the Tuluksak River in 1936. In 1937, another steel-hulled dredge was built and began mining (Mining World, 1941). Dredging continued in the 1960s by the New York-Alaska Dredging Company. There has also been extensive mechanized mining using draglines, tractors, and non-floating washing plants over the years along the Tuluksak. As of 2006, the Tuluksak River is marked by dredge tailings a thousand feet or more wide that extend almost continuously from the mouth of California Creek to about five miles below Nyac. In recent years, there apparently has been little mining along the Tuluksak River itself. However in the early 1980s, Tuluksak Dredging and Northland Dredging rebuilt the steel-hulled dredge about 5 miles downstream from Nyac; they operated it for a year or more until they shut down as a result of a water-quality dispute. There apparently is no public record of it but the conventional wisdom in 2006 among those familiar with the district was that Northland Dredging had drilled out reserves that contained (still contain?) about 37,000 ounces of gold in the vicinity of their dredge above the mouth of Granite Creek (D.J. Grybeck, conversations with miners and knowledgeable individuals during field work, 2006).

There is no public record of the production specifically from the Tuluksak River. But the district produced a minimum of 600,000 ounces of gold (Calista Corp., 2008), all from placers, and a large part of that,

perhaps more than half, came from the Tuluksak River judging on the extent of the tailings.
Joesting (1942) reported that some platinum was produced with the gold and that asbestos and graphite were dredged from bedrock. There is no evidence that any significant amount of platinum was produced. Inquiries in 2006 about platinum (D.J. Grybeck, conversations with local miners) at best indicated a vague knowledge that someone may have found some platinum in the gold placers but it has not been a component of placer concentrates in recent years.
Most of the rocks in the drainage basin of the Tuluksak River are hornfelsed or metamorphosed Jurassic volcanic and sedimentary rocks cut by mid-Cretaceous granitic plutons and Jurassic gabbro (Box and others, 1993; Wenz, 2005).
Historic field work at Tuluksak River include rock and soil sampling (Calista Corp., 2000).
In 2012, the property was operated by Nyac Gold LLC. Work performed at Tuluksak River includes magnetic susceptibility readings on outcrops (Flanders and others, 2012).

Alteration:

Age of mineralization:
Quaternary (Wenz, 2005).

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer Au-PGE (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; medium

Site Status: Undetermined

Workings/exploration:
Gold was first discovered in the Nyac district on Bear Creek (RM032), a tributary of the Tuluksak River, near the mouth of Bonanza Creek in 1907 or 1908 and soon after gold was discovered on the Tuluksak River. But the district produced a minimum of 600,000 ounces of gold (Calista Corp, 2008), all from placers, and a large part of that, perhaps more than half, came from the Tuluksak River judging fromthe extent of the tailings.

Joesting (1942) reported that some platinum was produced with the gold and that asbestos and graphite were dredged from bedrock. There is no evidence that a any significant amount of platinum was produced. Inquiries in 2006 about platinum (D.J. Grybeck, conversations with local miners) at best indicated a vague knowledge that someone may have found some platinum in the gold placers but it has not been a component of placer concentrates in recent years.

Reserves:

There apparently is no public record of it but the conventional wisdom in 2006 among those familiar with the district was that Northland Dredging had drilled out reserves that contained (still contain?) about 37,000 ounces of gold in the vicinity of their dredge above the mouth of Granite Creek (D.J. Grybeck, conversations with miners and knowledgeable individuals during field work, 2006).

Site name(s): Tuluksak River (below Granite Creek)

Site type: Prospect

ARDF no.: BH016

Latitude: 60.969 **Quadrangle:** BH D-4

Longitude: 160.1994

Location description and accuracy:

Maddren (1915) located this placer prospect near the Tuluksak River about 5 miles downstream from the mouth of Granite Creek (BH015). The coordinates given here are at about this location, about 0.6 mile southwest of the center of section 12, T. 10 N., R. 62 W. However, there is no other reference to this prospect and its exact location is uncertain. This is locality 9 of Cobb (1972 [MF 455]) and of Hoare and Cobb (1977).

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Maddren (1915) reported that fine gold was found in a 50-foot prospect shaft through frozen ground near the Tuluksak River about 5 miles below the mouth of Granite Creek (BH015). The prospect is on the lower part of the river, where the gradient decreases as it enters onto the lowlands of the lower Kuskokwim River. The low elevation and proximity to the Kuskokwim River lowlands suggest that Quaternary sea level fluctuations could have influenced placer development on the lower Tuluksak River. There apparently has been no other work on the Tuluksak River below the mouth of Granite Creek.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

A 50-foot prospecting shaft was dug before 1915 through frozen ground.

Production notes:

None.

Reserves:

None.

Site name(s): Kapon Creek

Site type: Mine

ARDF no.: BH020

Latitude: 60.11 **Quadrangle:** BH

Longitude: 160.16

Location description and accuracy:

Kapon Creek is an east tributary to the Eek River. The mouth of Kapon Creek is 9.5 miles downstream of the mouth of Rainy Creek (BH002) on the Eek River. This placer mine was referred to under the name 'Kapon Ck.' by Hoare and Cobb (1977). The map site is in the SE1/4 of section 6, T. 1 S., R. 63 W., of the Seward Meridian. It is approximately located, perhaps within miles, as the headwaters of this creek are about 4 miles further upstream from the map site.

Commodities:

Main: Au, Hg

Other:

Ore minerals: Arsenopyrite, cinnabar, gold, magnetite

Gangue minerals:

Geologic description:

Placer gold mining along Kapon Creek is reported to have taken place in 1914 and 1915 (Hoare and Cobb, 1977, p. 18). The lower part of the creek is in a glaciated area of outwash deposits. The upper reaches do not appear to have been occupied by glaciers but some outwash deposits may be present. The extreme headwaters of Kapon Creek are across a narrow saddle from the headwaters of Rainy Creek (BH002), where lode cinnabar mineralization has been identified (BH001). Coarse gravels in Kapon Creek were ground-sluiced in 1914 and found to be of low grade (Maddren, 1915, p. 357). The gold was dark and flaky and accompanied by magnetite, arsenopyrite, and small cinnabar pebbles. Bedrock in the Kapon Creek drainage is clastic sedimentary rocks of the mid-Cretaceous Kuskokwim Group locally cut by felsic and mafic dikes (Hoare and Cobb, 1977; Box and others, 1993).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au-PGE (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Kapon Creek has been prospected and some small surface workings are probably present locally along the creek.

Production notes:

None.

Reserves:

None.

Site name(s): Golden Alder

Site type: Prospect

ARDF no.: BH023

Latitude: 60.2651 **Quadrangle:** BH B-2

Longitude: 159.4082

Location description and accuracy:

The Golden Alder prospect is about 1.1 mile north of (unnamed) lake 1541 which is about 3 miles northeast of Gold Lake. The prospect is about 0.5 mile east-northeast of the center of section 18, T. 2 N., R. 58 W., of the Seward Meridian.

Commodities:

Main: Ag, Au

Other: Pb, Sb, W

Ore minerals: Galena

Gangue minerals: Calcite, chlorite, quartz

Geologic description:

As originally described by the U.S. Geological Survey, the mineralization at the Golden Alder prospect consists of oxidized, pyrite-bearing rhyolite dikes and sulfide-bearing quartz veins that cut Jurassic volcaniclastic rocks (Box and others, 1993). Anomalous values of silver, arsenic, gold, copper, mercury, molybdenum, lead, antimony, and tungsten were found in samples of quartz veins, altered dikes, and hydrothermal breccia (Frost, 1990; Frost and others, 1993). The maximum gold value was 2 parts per million (ppm) and the maximum silver value was 7 ppm. The dikes are variably replaced by sericite, illite, and quartz. Galena is the only sulfide mineral Fort and others (1993) identified in the quartz veins.

The prospect was re-examined, mapped, and resampled by Gold Crest Mines Inc. in 2007 (Gold Crest, 2011 [summary]). They identified an area about 200 meters wide by 600 meters long showing diffuse carbonate-sulfide alteration (Gold Crest Mines Inc., 2011 [geology]. They collected 30 rock chip samples (Gold Crest Mines Inc., 2011 [rocks and soils]) that averaged 1.6 grams of gold per tonne; the highest contained 8.2 grams of gold per tonne.

Alteration:

Silicification, argillization, and oxidation.

Age of mineralization:

Jurassic or younger based on the age of the host rock. May be related to a buried pluton, many of which in the region are Late Cretaceous or Early Tertiary (?) (Box and others, 1993).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Inactive

Workings/exploration:

Reconnaissance surface sampling by the U.S. Geological Survey (Box and others 1993). Re-examined, mapped, and resampled by Gold Crest Mines Inc. in 2007 (Gold Crest, 2011 [summary]).

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-28

Site name(s): Kisa Breccia; Golden Dyke

Site type: Prospects

ARDF no.: BH028

Latitude: 60.3546 **Quadrangle:** BH B-1

Longitude: 159.3011

Location description and accuracy:

The Kisa Breccia prospect is about 0.3 mile north-northwest of peak 3690 and about 2.3 miles north of the narrow channel between the two basins of Kisaralik Lake. It is about 0.3 mile north of the center of section 14, T. 3 N., R. 58 W., of the Seward Meridian. This location is probably accurate. The exact location of the Golden Dyke prospect is uncertain but it is nearby.

Commodities:

Main: As, Au

Other: Ag, Bi, Cu, Mo, Te, W

Ore minerals: Pyrite

Gangue minerals: Carbonate, quartz

Geologic description:

Gold Crest Mines Inc. (2011 [Kiska summary]) has explored a poorly exposed, extensively carbonate-sulfide altered breccia body along a ridge crest and on steep, north-facing slopes by surface mapping and sampling, geophysical surveys, and drilling. The breccia is composed of altered sedimentary and igneous clasts, many of which show multiple generations of veining and brecciation. The breccia is exposed over an area about 500 meters by 300 meters, a vertical distance of about 250 meters. Rock chips collected systematically of the breccia averaged more than 1.25 grams of gold per tonne; some samples contained up to 7 grams of gold per ton (Gold Crest Mines Inc., 2011 [Kiska rock chip]). Several types of igneous rocks form clasts in the breccia and the breccia may represent the top of a mineralized stock. Gold Crest drilled 5 holes in the breccia totaling more than 940 meters (Gold Crest Mines Inc., 2011 [Kiska drill holes]). Some notable intercepts were: 206 meters with an average grade of 0.3 gram of gold per tonne; 115 meters with an average grade of 0.7 gram of gold per tonne; 44 meters with an average grade of 1.13 gram of gold per tonne, and several intercepts of more than 2 meters that averaged up to 0.25 ounce of gold per ton. The sulfides are not specified.

The U.S. Geological Survey visited the site earlier and collected several samples of pyrite-bearing rhyolite dikes and sulfide-bearing quartz veins (Frost, 1990; Box and others, 1993). Rock samples from a large, red-weathering area, which possibly is the Kisa prospect, contained up to 0.41 parts per million (ppm) gold, 1.5 ppm silver, 7,000 ppm arsenic and 100 ppm antimony.

The rocks in the area are Jurassic marine, volcaniclastic sandstone, conglomerate, and argillite; no nearby plutonic rocks are mapped by Box and others (1993).

The exact location of the Golden Dyke prospect is unknown but it is nearby (Gold Crest Mines Inc., 2011 [Golden Dyke summary]). As described by Gold Crest Mines Inc. (2011), the mineralization at this prospect consists of numerous, altered, silica-carbonate-sulfide rhyolite dikes and sills. More than 20 dikes and sills are known that vary from about 3 feet thick to over 30 feet thick; many pinch and swell and locally form small stock-like bodies. Rock chips were collected systematically from the dikes and altered sandstone, allowing for the steep and rugged terrain. The samples contained up to 0.18 ounce of gold per ton, major arsenic, up to 328 ppm antimony, 57 ppm bismuth, 45 ppm molybdenum, 6 ppm silver, 1 percent copper, 30 ppm tellurium, and 48 ppm tungsten (Gold Crest Mines Inc., 2011 [Golden Dyke rock chip]).

Alteration:

Extensive carbonate-sulfide alteration in mineralized breccia; rhyolite dikes nearby have silica-carbonate-sulfide alteration.

Age of mineralization:

Jurassic or younger based on the age of the host rock. May be related to a buried pluton, many of which in the region are Late Cretaceous or Early Tertiary (?) (Box and others, 1993).

Generic deposit model:

Deposit model:

Mineralized breccia and rhyolite dikes with gold values.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Considerable surface mapping and sampling; aerial geophysical surveys; and 5 holes drilled at the Kisa prospect.

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-28

Site name(s): Luna

Site type: Prospect

ARDF no.: BH030

Latitude: 60.4379 **Quadrangle:** BH B-2

Longitude: 159.4851

Location description and accuracy:

The Luna prospect is located along the North Fork of the Kisaralik River approximately 2 miles downstream of North Fork Lakes in the central-west area of section 14, T. 4 N., R. 59 W. of the Seward Meridian. The location is centered on an outcrop that returned a rock chip sample containing 64.7 grams per tonne gold (Southern Crown Resources Limited, 2014a). The previous recorded location incorrectly put the Luna prospect 3.6 miles northwest of the outlet of the Kisaralik River on Kisaralik Lake.

Commodities:

Main: Ag, Au, Cu

Other: As, Bi, Mo, Sb, Sn, Te

Ore minerals: Arsenopyrite, chalcopyrite, pyrite, sphalerite, stibnite

Gangue minerals: Carbonate, quartz

Geologic description:

Mineralization at the Luna prospect is in Cretaceous calcareous siltstone, shale, sandstone, argillite, conglomerate, tuff and tuffaceous chert that are intruded by Late Cretaceous to Early Tertiary quartz monzodiorite, granodiorite, and biotite granite stocks and aplite dikes (Box and others, 1993).

The Luna prospect is located along a northeast structural corridor with apparent strike slip movement and evidence of additional cross-cutting complexity. A shear zone over 700 meters wide has been mapped along the river beds underneath alluvial cover (Southern Crown Resources Limited, 2014a). Results from a ground geophysical survey completed in 2014 show a very clear northeast trending structure, the Luna Fault, with the Luna prospect located on a structural splay (Southern Crown Resources Limited, 2014b). Channel and auger drill samples show anomalous metal values following the northeast trend next to the Luna Fault with bismuth being the best pathfinder element (Southern Crown Resources Limited, 2014c).

Quartz-carbonate stockwork veins contain anomalous gold, silver, antimony, bismuth, arsenic, molybdenum, tellurium, and tin. The northeast end of the mineralized trend (Luna East) contains highly anomalous copper (Southern Crown Resources Limited, 2014a). Several zones of stratiform, replacement mineralization were found that contain up to 70 percent sulfides, primarily pyrite, arsenopyrite and stibnite, with lesser chalcopyrite and sphalerite. More than half of the 72 rock samples that were collected before 2014 contained anomalous gold. Several of the airborne geophysical anomalies correspond to the location of the semi-massive sulfides on the ground. The mineralization is accompanied widespread fracturing and clay alteration (Gold Crest Mines Inc., 2011).

Alteration:

Mineralization is accompanied by widespread clay alteration (Gold Crest Mines Inc., 2011).

Age of mineralization:

Late Cretaceous or younger based on the age of the host rocks and intrusions (Box and others, 1993).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

The Luna prospect was discovered in 2006 by Gold Crest Mines Inc. while field checking an airborne geophysical survey. Further field work that year included ground induced polarization and magnetic surveys and rock and stream-sediment sampling. The stream sediment sampling outlined an area of 10 square miles with anomalous values in gold, arsenic, and antimony. Rock samples contained up to 0.75 ounce per ton gold, 8,400 parts per million (ppm) arsenic, 158 ppm antimony, 36 ppm bismuth, 64 ppm molybdenum, 23 ppm silver, 0.44 percent copper, 12 percent lead, and 0.6 percent zinc. In 2007, 50 State of Alaska mining claims were staked that covered an area of about 8,000 acres.

In 2014 Southern Crown Resources Limited began exploration at Luna through an option with Afranex Gold Limited (Southern Crown Resources Limited, 2014a). Results from a ground geophysical survey completed in 2014 show a very clear northeast trending structure, the Luna Fault, with the Luna prospect located on a structural splay (Southern Crown Resources Limited, 2014b). Channel and auger drill samples show anomalous metal values following the 1.3 kilometer northeast trend next to the Luna Fault. Channel samples returned up to 1480 part per billion (ppb) gold with anomalous silver, antimony, bismuth and arsenic while auger drilling returned rock samples with up to 140 ppb gold and 1200 ppb silver. Vegetation samples were also collected over 3 kilometers of the Luna trend with 350 samples taken to look at biogeochemistry which generally correlated well with the rock sample geochemistry (Southern Crown Resources Limited, 2014c).

Production notes:

None.

Reserves:

None.

Site name(s): Gossan Ridge

Site type: Prospect

ARDF no.: BH031

Latitude: 60.2301 **Quadrangle:** BH A-2

Longitude: 159.3963

Location description and accuracy:

The Gossan Ridge prospect probably is on the north side of the ridge south of (unnamed) lake 1541 (which is about 3 miles northeast of Gold Lake. It is probably about 1.3 mile south of the northeast corner of lake 1541, about 0.3 mile south of the center of section 29, T. 2 N., R. 58 W., of the Seward Meridian. However, the location is uncertain and the prospect may be a mile or more distant.

Commodities:

Main: Ag, As, Au, Bi, Sb, Te, W

Other: Mo

Ore minerals: Arsenopyrite, stibnite

Gangue minerals: Quartz

Geologic description:

The Gossan Ridge prospect was first identified in the late 1980s by following up highly anomaly gold, arsenic, and antimony values in panned concentrates. The anomalous values covered an area at least 1,500 meters long and 330 meters wide that coincides with a conspicuous rusty-orange color anomaly (Gold Crest Mines Inc., 2011 [summary]). Samples collected by Gold Crest in an area about 450 meters long by 200 meters wide averaged over 0.1 gram of gold per ton and contained up to 0.2 ounce of gold per ton. The mineralization is related to a series of feldspar breccias, porphyry dikes and altered country rock. Numerous epithermal arsenopyrite-stibnite-quartz veins and replacement zones occur along faults and dike margins. The intrusive rocks show pervasive biotite and sericite alteration. The rocks outside the mineralized area are Upper Jurassic or Lower Cretaceous argillite and tuffaceous chert (Box and others, 2003).

The prospect was restaked and reexamined by Gold Crest in 2006 (Gold Crest Mines Inc., 2011 [summary]). They collected 39 rock samples; all had detectable gold. The highest value was 4.8 grams of gold per tonne and the samples contained up to 140 parts per million (ppm) bismuth, 25 ppm silver, 60 ppm molybdenum, 1,000 ppm antimony, 35 ppm tungsten, and 12 ppm tellurium (Gold Crest Mines Inc., 2011 [geochemistry]. Several detailed ground geophysical surveys in 2007 suggest that the prospect is the mineralized cap of a buried intrusion (Gold Crest, 2011 [aeromagnetic]).

Alteration:

The intrusive rocks associated with the mineralization show pervasive biotite and sericite alteration; the country rock is also altered.

Age of mineralization:

Jurassic or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Vein and disseminated mineralization in breccias, dikes, and altered country rock.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Sampled and mapped in the late 80s(?) and sampled and mapped in 2006 and 2007 by Gold Crest Mines Inc. Covered by extensive geochemical and ground and aerial geophysical surveys.

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-28

Site name(s): Ako; East Ako; West Ako; Ako Saddle

Site type: Prospects

ARDF no.: BH032

Latitude: 60.2802 **Quadrangle:** BH B-2

Longitude: 159.6964

Location description and accuracy:

The exact locations of these three prospects is uncertain but they are generally along the western margin of the Crooked Mountain pluton between the upper parts of Swift and Akoswift Creeks. The likely center of these prospects is about 2.3 miles northeast of the center of (unnamed) lake 2050 on Akoswift River, and about 0.5 mile east-northeast of the center of section 9, T. 2 N., R. 60 W., of the Seward Meridian. The location is accurate to within a mile.

Commodities:

Main: As, Au, Cu, Mo

Other: Bi, Sb, W

Ore minerals: Arsenopyrite, chalcopyrite, gold, molybdenite

Gangue minerals: Quartz

Geologic description:

The three prospects of this site are along the western margin of the Late Cretaceous, Crooked Mountain pluton, which has been dated at 69.8 Ma (Box and others, 1993). This composite pluton is about 10 kilometers in diameter. Its core of biotite granodiorite and granite is rimmed by a shell of gabbro and diorite. The pluton is bordered to the west by Late Cretaceous volcanic rocks and tuff that are hornfelsed near its contact.

The Ako prospects were found in the the late 1980s during a regional geochemical survey (Gold Crest Mines Inc., 2011 [summary]). They generally are associated with anomalous arsenic, antimony, bismuth and tungsten, and by iron-stained color anomalies.

The mineralization at the East Ako prospect consists of disseminated, fracture-controlled, and stockwork-veined zones in the Crooked Mountain pluton (Gold crest Mines Inc., 2011 [antimony]; Gold Crest Mines Inc., 2011 [gold]). Several zones of arsenopyrite-quartz veins with sparse molybdenite and chalcopyrite are well exposed. The veins are accompanied by argillic, propylitic, silic, and potassic alteration. The mineralization can be traced for about 150 meters and is up to 75 meters wide.

The mineralization at the West Ako prospect consists of intense biotite alteration, potassium-feldspar flooding, silicification, and quartz-sulfide stockworks along a resistant 'rib' in the pluton. The mineralized zone is 10 to 20 meters thick and can be traced for about 100 meters. Samples across 3 to 5 meters contained up to 0.4 gram of gold per tonne (Gold Crest Mines Inc., 2011 [rock samples]).

The Ako Saddle prospect coincides with a extensive rusty-orange color anomaly. Samples of pyritic, sericite-altered granodiorite had anomalous gold values.

Alteration:

The East Ako mineralization is accompanied by argillic, propylitic, silic, and potassic alteration. The West Ako mineralization is accompanied by intense biotite alteration, potassium-feldspar flooding, and silicification.

Age of mineralization:

Late Cretaceous or younger. The veins cut a 69.9 Ma granitic pluton and may be genetically related to it.

Generic deposit model:

Deposit model:

Polymetallic veining and stockworks in the periphery of a granitic pluton.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Several episodes of mapping and sampling from 1988 to 2007. Covered by regional geochemical and geophysical surveys.

Production notes:

None.

Reserves:

None.

Reporter(s): D.J. Grybeck (Contractor, USGS)

Last report date: 2011-02-28

Site name(s): Deadfall; Powdermilk

Site type: Prospect

ARDF no.: BM010

Latitude: 67.4616 **Quadrangle:** BM B-4

Longitude: 160.7957

Location description and accuracy:

The Deadfall prospect is just southeast of the confluence of the two major headwater forks of a major, unnamed, southeast flowing tributary of the Omar River. The coordinates are for the approximate center of the prospect which covers an area of 2 square kilometers in sections 24 and 25, T. 24 N., R. 10 W., of the Kateel River Meridian. The location is accurate.

Commodities:

Main: Ag, Pb, Zn

Other: Ba, Cd?

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Barite

Geologic description:

The Deadfall deposit consists of disseminations and clots under 2.5 centimeters in diameter of sphalerite, galena, and rare pyrite in Devonian light-gray dolostone (Schmidt and Allegro, 1988). The sphalerite is coarsely crystalline, locally zoned, and medium to dark brown and red. Barite forms veins in the dolostone. Soil samples from the western river bank exposure contain as much as 1,600 parts per million (ppm) lead, 420 ppm zinc and 7.2 ppm silver. Rock samples from the more oxidized, eastern exposure in the creek contain as much as 280 ppm lead, 230 ppm zinc, and 21 ppm silver. Rock samples contain as much as 20 percent sphalerite, 8 percent galena, and 5 percent pyrite.

The host dolostone strikes NE and dips nearly vertically; a synform structure is suggested (Schmidt and Folger, 1986). Some gray limestone occurs east of the prospect. The Deadfall deposit is similar to southeast Missouri lead-zinc deposits (Cox and Singer, 1986; model 32a) in host rock and mineralization. The sulfides are epigenetic with respect to the host dolostone. Mineralization may be structurally controlled by the synform.

In 2006, NovaGold Resources Inc. began working in the region and staked a large block of claims that covered this and other similar prospects nearby (TintinaGold Resources Inc., 2010). In 2007, NovaGold carried out extensive field work in the area, emphasizing geologic mapping and geochemical sampling. Their geochemical work indicates that the Deadfall prospect is part of a northwest-trending belt of mineralization up to 3 kilometers long and 0.5 kilometer wide. They sampled a 47-meter-long trench in recrystallized dolomite with disseminated coarse sphalerite and galena. Samples from a 12-meter section in the trench contained 10.1 percent zinc and 42.4 grams of silver per tonne; samples from the full 47 meters contained 6 percent zinc and 21.7 grams of silver per tonne.

Alteration:

Surficial weathering resulted in sparse iron oxide staining and local clay alteration.

Age of mineralization:

Devonian?

Generic deposit model:

Deposit model:
Southeast Missouri Pb-Zn (Cox and Singer, 1986; model 32a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
32a

Production Status: None

Site Status: Active

Workings/exploration:
The U.S. Geological Survey did reconnaissance mapping, took a line of 39 soil samples, and collected additional rock and pan concentrate samples (Zayatz and others, 1988). In 2006, NovaGold began working in the region and staked a large block of claims that covered this and other similar prospects nearby (TintinaGold Resources Inc., 2010). In 2007, they carried out extensive field work in the area emphasizing geologic mapping, geochemical sampling, and trench sampling.

Production notes:
None.

Reserves:
None.

Last report date: 2010-04-02

Site name(s): Frost

Site type: Prospect

ARDF no.: BM011

Latitude: 67.4804 **Quadrangle:** BM B-4

Longitude: 160.6727

Location description and accuracy:

The Frost prospect is along both sides of Frost Creek, an informally-named east-flowing branch of a northwest tributary of the Omar River. It is in sections 15, 16, and 22, T. 24 N., R. 9 W., of the Kateel River Meridian. The coordinates are at the approximate center of the prospect.

Commodities:

Main: Ba, Cu, Zn

Other: Ag, Pb

Ore minerals: Barite, chalcopyrite, galena, sphalerite

Gangue minerals: Calcite, fluorite, limonite, quartz

Geologic description:

The Frost prospect consists of discontinuous pods or lenses of barite in a zone 30 feet wide and 5,000 feet long. An iron-stained silicified zone surrounds the barite and is weakly mineralized. The silicified zone dips 25 to 45 degrees W and contains disseminated sphalerite and chalcopyrite, and sulfide-bearing quartz-calcite-barite veins. These veins trend N 70 E. Bedrock consists entirely of Devonian, light- to dark-gray limestone and medium- to coarse-grained, stratified dolomite and marble (Degenhart and others, 1978).

An 8-pound sample of barite assayed 96 percent $BaSO_4$ and 0.5 percent zinc. A sample from an 8-foot-wide, quartz-calcite-barite-sulfide vein assayed 0.49 percent copper, 13.2 percent zinc, and 20.7 percent barium. This vein could only be traced for about 10 feet along strike before disappearing under talus (Degenhart and others, 1978).

The analytical results from three rock samples (Schmidt and Allegro, 1988) follow: 1) sample T, a limestone boulder with disseminated sulfides contains 110 parts per million (ppm) arsenic, greater than 100 ppm cadmium, 230 ppm antimony, greater than 2,000 ppm zinc, 1 ppm silver, 1,000 ppm barium, 500 ppm copper, and 3000 ppm lead; 2) sample V, a boulder with quartz, fluorite, sphalerite, galena, and bornite contained 40 ppm arsenic, greater than 100 ppm cadmium, 130 ppm antimony, greater than 2,000 ppm zinc. 0.7 ppm silver, greater than 5,000 ppm barium, 500 ppm copper, 200 ppm lead and 5,00 ppm strontium; 3) sample X, a boulder with vein galena and fine-grained pyrite and sphalerite contained 80 ppm arsenic, 70 ppm cadmium, 170 ppm antimony, greater than 2,000 ppm zinc, 5 ppm silver, 1,000 ppm barium, 700 ppm copper, 5 ppm molybdenum, and 7,000 ppm lead.

In 2006, NovaGold began working in the region and staked a large block of claims that covered this and other similar prospects nearby (TintinaGold Resources Inc., 2010). In 2007, NovaGold carried out extensive field work in the area emphasizing geologic mapping and geochemical sampling. They describe the Frost prospect as a northwest-trending zone about 750 meters long and 200 meters wide of sparse outcrop and abundant rubble crop of barite-sulfide-fluorite mineralization. The sulfides are mainly sphalerite, galena, bornite, and chalcopyrite. Both stratabound and crosscutting mineralization is present. Selected rock samples contain up to 30.6 percent zinc, 20.2 percent copper, and 52.5 grams of silver per tonne.

Alteration:

Silicification.

Age of mineralization:

Devonian.

Generic deposit model:

Deposit model:

Kipushi Cu-Pb-Zn (Cox and Singer, 1986; model 32c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

32c

Production Status: None

Site Status: Active

Workings/exploration:

The Frost deposit was discovered in 1963 by Bear Creek Exploration during a regional stream and soil sampling program. Exposure in the area is poor. An IP survey was done in 1965 (Walters, 1969). During an investigation of the prospect by the U.S. Bureau of Mines in 1978, over 140 soil, silt and rock samples were collected and analyzed (Degenhart and others, 1978). Detailed mapping and sampling were done by the U.S. Geological Survey in the late 1980s (Schmidt and Allegro, 1988; Zayatz and others, 1988). In 2006, NovaGold began working in the region and staked a large block of claims that covered this and other similar prospects nearby (TintinaGold Resources Inc., 2010). In 2007, NovaGold carried out extensive field work in the area emphasizing geologic mapping and geochemical sampling.

Production notes:

None.

Reserves:

Walters (1969) suggested reserves of from 1 to 10 million tons of barite.

Site name(s): Omar

Site type: Prospect

ARDF no.: BM012

Latitude: 67.4898 **Quadrangle:** BM B-4

Longitude: 160.8834

Location description and accuracy:

The main occurrences at the Omar prospect are centered approximately 0.5 mile northwest of what is informally called Omar Mountain. They are mostly in the lower portions of sections 9 and 10, T. 24 N., R. 10 W., of the Kateel River Meridian. The location is accurate.

Commodities:

Main: Cu

Other: Ag, Co, Zn

Ore minerals: Bornite, chalcopyrite, covellite, malachite, pyrite, tetrahedrite

Gangue minerals: Calcite, dolomite, iron oxides, quartz

Geologic description:

The Omar deposit was discovered by Bear Creek Exploration in 1962 as a result of a regional geochemical reconnaissance program. Work done on the prospect into the 1980s includes geologic mapping, soil, silt and rock sampling, hand trenching, ATM and EM surveys, and 19 cored drill holes. The geophysical surveys produced indifferent results even though they were in areas of known mineralization (C.G. Bigelow, personal communication, 1975).

The Omar deposit consists of copper and iron sulfides in discordant veinlets, blebs and stringers in Devonian carbonates. Outcrops are rare at Omar and extensive frost-heaved rubble obscures most lithologic contacts. A 3-kilometer-long, complex fracture zone trends north-northwest across the prospect and hosts the deposit. Highly leached gossans are in the southern and central areas of the prospect. Three samples of gossan contained 1,070 parts per million (ppm) copper, greater than 20,000 ppm copper, and 13,400 ppm copper. Mineralized zones containing chalcopyrite, bornite, covellite and malachite in breccias and fracture fillings are 300 to 1,000 meters long and up to 30 meters wide. Bornite and chalcopyrite are the dominant copper sulfides. Typical samples of sulfide-bearing talus contain 9.6 percent copper. A sample from the southwest slope of hill 2455 contained 15.39 percent copper; other samples collected along the 3-kilometer trend varied from 0.1 to 9.6 percent copper (Degenhart and others, 1978). High values of cobalt accompany the copper sulfides, as well as minor zinc and silver. The best intercepts from two drill cores 300 feet apart were 25 to 30 feet of 9 percent copper. These holes intersected two parallel shear zones (C.G. Bigelow, personal communication, 1975).

Microscopic examination shows that the chalcopyrite forms coherent exsolution lamellae and noncoherent blebs and dots in bornite or tetrahedrite. Solution of the host dolostone created open spaces which were filled by dolomite, sulfides, and quartz. The mineralizing event occurred prior to metamorphism and deformation associated with the middle Jurassic to Cretaceous Brooks Range orogeny (Folger and Schmidt, 1986). The carbonate sequences at Omar have been folded into broad anticlines and synclines. Most rock units at Omar strike north-northeast to northwest. Dips vary from 6 degrees to vertical.

In 2006, NovaGold began working in the region, staked a large block of claims, and subsequently acquired the Omar property (TintinaGold, 2010). In 2007, NovaGold carried out extensive field work in the area, emphasizing geologic mapping and geochemical sampling. Their work indicates that the Omar prospects are part of a north-northwest-trending belt of mineralization three kilometers long and up to a half

kilometer wide. Rock samples contained up to 34.3 percent copper, 0.85 percent zinc, and 0.4 percent cobalt. NovaGold subsequently passed the property to TintinaGold who did considerable field work in the area in 2009. See also the similar Frost (BM011), Deadfall (BM010), and Peak (BM022) prospects nearby that were also studied by NovaGold and TintinaGold.

Alteration:

Hydrothermal dolomitization.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Kipushi Cu-Pb-Zn (Cox and Singer, 1986; model 32c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

32c

Production Status: None

Site Status: Active

Workings/exploration:

The Omar deposit was discovered by Bear Creek Exploration in 1962 as a result of a regional geochemical reconnaissance program. Work done on the prospect includes geologic mapping, soil, silt and rock sampling, hand trenching, ATM and EM surveys, and 19 core drill holes. The geophysical surveys produced indifferent results even though they were run in areas of known mineralization (C.G. Bigelow, personal communication, 1975).

In 2006, NovaGold began working in the region, staked a large block of claims, and subsequently acquired the Omar property (TintinaGold, 2010). In 2007, NovaGold carried out extensive field work in the area emphasizing geologic mapping and geochemical sampling. TintinaGold Resources Inc. continued the NovaGold work and did considerable field work in the area in 2009. See also the similar Frost (BM011), Deadfall (BM010) and Peak (BM022) prospects nearby that were also studied by NovaGold and TintinaGold.

Production notes:

None.

Reserves:

Based on results of two drill holes, Bear Creek Exploration calculated possible reserves of 200,000 tons of ore containing 9 percent copper.

Last report date: 2010-04-02

Site name(s): Peak

Site type: Prospect

ARDF no.: BM022

Latitude: 67.5638 **Quadrangle:** BM C-4

Longitude: 160.7914

Location description and accuracy:

The Peak prospect is at the head of an unnamed northwest tributary to the Omar River. The mineralization forms a belt that extends from the lower half of section 18 to the northwest portion of section 13, T. 24 N., R. 9 W. of the Kateel River Meridian. The coordinates are at about the center of the belt. The location is accurate.

Commodities:

Main: Ba, Cu, Pb, Zn

Other:

Ore minerals: Barite, galena, smithsonite, sphalerite

Gangue minerals: Carbonates, quartz

Geologic description:

In 2006, NovaGold Resources began working in the region and staked a large block of claims that covered this and other similar prospects nearby (TintinaGold Resources Inc., 2010). In 2007, NovaGold carried out extensive field work in the area, emphasizing geologic mapping and geochemical sampling, in the course of which they discovered this previously unrecognized mineralization.

The rocks in the area consist of folded and faulted, Paleozoic limestone and dolomite of the Paleozoic Baird Group. In 2009, TintinaGold worked extensively on the Peak prospect. They identified scattered narrow trains of mineralization that include gossan, silica veins, and barite-rich rock that extends for more than 1.5 kilometers. The mineralization consists of smithsonite encrustations, coarsely crystalline sphalerite and galena, and massive barite. A two-meter-wide sample of a silica-barite vein in carbonates contained 5.3 percent zinc. Samples of gossan contained up to 1 percent zinc, 0.5 percent lead, and 500 parts per million (ppm) copper. Selected samples contained up to 33.1 percent zinc and 4.1 percent lead. Most of the mineralization is strongly oxidized at the surface.

Alteration:

Silicification; sulfides are largely oxidized to gossan.

Age of mineralization:

Paleozoic or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Zinc-lead mineralization in Paleozoic carbonates. Insufficient data to determine whether epigenetic or (remobilized?) syngenetic.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 2006, NovaGold began working in the region and staked a large block of claims that covered this and other similar prospects nearby (TintinaGold Resources Inc., 2010). In 2007, NovaGold carried out extensive work in the area. The previously unknown mineralization at the Peak prospect was identified by additional surface mapping, sampling, and soil geochemistry.

Production notes:

None.

Reserves:

None.

Last report date: 2010-04-02

Site name(s): Harrys Creek

Site type: Prospect

ARDF no.: BN055

Latitude: 65.9263 **Quadrangle:** BN D-3

Longitude: 163.3466

Location description and accuracy:

Harrys Creek is a small unnamed headwater tributary to Cunningham Creek, which flows into Hannum Creek. The Harrys Creek prospect extends across Harrys Creek approximately 1,500 feet above its mouth. It is about 0.5 mile north of the center of section 17, T. 6 N., R. 22 W. The location is accurate.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals: Boulangerite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area consist of a Paleozoic, poorly exposed, interlayered sequence of pelitic schist and schistose dolomitic marble that strikes northwest and dips 15 to 65 degrees north (Till and others, 1986; Hawley, 2007; Stevens, 2008). Part of this metasedimentary sequence is siliceous and described as quartzite (Herreid, 1966). The frozen ground here and at the Hannum prospect area has handicapped efforts to expose bedrock (Mulligan, 1965; Herreid, 1966). Most of the area is covered by surficial material that obscures the structure of the rocks.

The galena-bearing lode was first noted by 1905 (Moffit, 1905). On both sides of Harrys Creek, over a distance of 1,400 feet, deeply weathered, gossanous exposures of bedrock and surficial debris are exposed in 6 trenches that in dozer trenches show alteration and mineralization in marble and siliceous schist (Hudson and others, 1977). The mineralization is near a contact between dolomitic marble and siliceous schist (Hudson and others, 1977). Herreid (1966) describes the silica-rich rock as quartzite and interprets it to be silicified marble. The silica-rich zones are coarse-grained, porous, and contain some quartz-crystal-lined cavities (Herreid, 1966). Mineralization includes pods, veinlets, and disseminations of galena in silica-rich rock, in places with disseminated pyrite and sphalerite. Pebbles and cobbles of massive galena are abundant in the stream bed of Harrys Creek at and below the dolomitized marble outcrops. Boulangerite is disseminated in galena from gossan float in a dozer trench on the south side of the creek (Herreid, 1966). Light brown, surficial material containing fragments of silica-rich rock and massive limonite gossan contained 0.05 percent copper, 4.0 percent lead, 0.62 percent zinc, 0.04 ounce of gold per ton, and 1 ounce of silver per ton. An 18-inch-wide gossan with a 2- to 3-inch core of galena assayed 0.05 percent copper, 10 percent lead, 2.2 percent zinc, 1.76 ounce of silver per ton, and no gold (Herreid, 1966). Samples of surficial materials from slopes and dozer trenches have more than 1,000 parts per million (ppm) lead over a length of 1,250 feet. Sampling by Mulligan (1965) also indicated traces of gold in the mineralized zones. The dozer trenches primarily expose deeply weathered material and not bedrock. Burand (1957) collected a series of 5-foot channel samples in two of the dozer trenches: 1) five samples of yellow, sandy soil with visible quartz and galena contained 2.3 to 5.8 percent lead, 0.37 to 10.11 ounces of silver per ton, and no gold; 2) eight samples over poorly exposed carbonate-bearing bedrock contained 1.7 to 6.2 percent lead, 0.23 to 7.52 ounces of silver per ton, and nil to 0.03 ounce of gold per ton; and 3) five samples over a yellow clay-rich zone contained 2.3 to 9.6 percent lead, 6.42 to 10.09 ounces of silver per ton, and 0.01 to

0.06 ounce of gold per ton. The mineralized zone is open to both the northwest and southeast. Similar mineralization occurs on strike on at the Inmuchuk prospect (BN056), 4,000 feet southeast.

From 2002 to 2005, Royal Pretoria Mines did considerable geochemical sampling in the area and defined a strong anomaly in zinc and lead that extends from the Harrys Creek prospect to the Inmachuk prospect (BN056) (Hawley, 2007).

Alteration:

Development of silica-rich rock is characteristic; it is variably developed but extensive. The deposit is deeply weathered and oxidized.

Age of mineralization:

The deposit may be epigenetic and younger than the lower Paleozoic host rocks. Epigenetic deposits on Seward Peninsula are primarily Cretaceous in age. If the deposit is stratiform, it may be similar in age to the Paleozoic host rocks (Till and others, 1986).

Generic deposit model:

Deposit model:

Pods, veinlets, and disseminations of galena and sphalerite in silicified marble.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Six dozer trenches totaling 1,250 feet were dug on the south side of Harrys Creek prior to 1966. Royal Pretoria Mines did considerable geochemical sampling in the area from 2002 to 2005.

Production notes:

None.

Reserves:

None.

Site name(s): Inmachuk; Hannum

Site type: Prospect

ARDF no.: BN056

Latitude: 65.9212 **Quadrangle:** BN D-3

Longitude: 163.3216

Location description and accuracy:

The Inmachuk prospect is on the west bank of Hannum Creek, about 1,000 feet upstream from the mouth of Cunningham Creek. Hannum Creek is a north tributary to Inmachuk River. The prospect is about 0.3 west of the center of section 16, T. 6 N., R. 22 W. The location is accurate.

Commodities:

Main: Pb, Zn

Other: As, Ba

Ore minerals: Arsenopyrite?, galena, pyrite, sphalerite

Gangue minerals: Barite?, calcite, limonite, quartz

Geologic description:

The rocks in the area consist of a Paleozoic, poorly exposed, interlayered sequence of pelitic schist and schistose dolomitic marble that strikes northwest and dips 15 to 65 degrees north (Till and others, 1986; Hawley, 2007; Stevens, 2008) . Part of this metasedimentary sequence is siliceous and described as quartzite (Herreid, 1966). Herreid considers the quartzite here and at Harrys Creek (BN055), 4,000 feet to the northwest, to be silicified marble. Hudson and others (1977) described outcrops of the silica-rich rock on Harrys Creek as siliceous schist. The frozen ground in the Hannum prospect area has handicapped efforts to expose bedrock (Mulligan, 1965; Herreid, 1966). Most of the area is covered by surficial material that obscures the structure of the rocks.

The prospect has been known since 1906 and there has been considerable activity since 1966 when Bunker Hill Mining Company dug about 1,500 feet of trenching in at least 6 trenches, drilled 15 core holes, and collected numerous soil samples that defined several zones of anomalous zinc and lead (Hawley, 2007; Stevens, 2008). The mineralization is only locally exposed in the trenches; a 30-foot-wide gossan zone within marble is exposed in one trench. Mineralization is apparently pods and stringers of sulfides, primarily galena, sphalerite, and pyrite, in silica-rich rock. An assay of a 6-foot -wide siliceous zone contained 0.05 percent copper, 0.38 percent zinc, 0.12 percent lead, and no silver and gold (Herreid, 1966). Soil samples collected upslope 125 to 375 feet to the west, contained lead and zinc values up to more than 1,000 parts per million. Soil samples near the prospect commonly contain more zinc than lead (Herreid, 1966). From 2002 to 2005, Royal Pretoria Mines in their own behalf and in 2006 for Full Metal Minerals did considerable work in the area and defined a large anomaly that covered the prospect and the Harrys Creek prospect (BN055) (Hawley, 2007; Stevens, 2008). Although it is likely that the mineralization at the Hannum prospect continues west to the Harrys Creek prospect (BN055), this has not been confirmed.

In September, 2007, Millrock Resources Inc. (Stevens, 2008) drilled 5 holes that totaled 644.1 meters to test the Inmachuk mineralization. The drilling was spread along a line about 1,300 meters long on the south side of Cunningham Creek, northwest of the mouth of Hannum Creek. The drilling was along a zone that is strongly anomalous in zinc (Hawley, 2007). Mineralization was intersected in three of the holes and consists of oxidized lead-zinc minerals. The best intercepts were: 3.05 meters with 12.34 percent zinc; 6.61 meters with 2.06 percent zinc; 0.61 meter with 5.55 percent zinc and 3.66 percent lead; and 0.91 meter with 4.56 percent zinc. The mineralization apparently occurs in flat-lying pods that replace marble. The pods are

generally narrow and low grade and the mineralization seems to thin down-dip. MIllrock relinquished the property to Full Metal Minerals in March, 2008.

Alteration:

Pervasive development of silica-rich rock in the marble. The deposit is deeply weathered and oxidized.

Age of mineralization:

The deposit may be epigenetic and younger than the host schist and marble; epigenetic deposits on the Seward Peninsula are primarily Cretaceous. If it is stratiform and syngenetic, it is Paleozoic.

Generic deposit model:

Deposit model:

Sphalerite-galena replacement pods in marble.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

At least six trenches were dug with a bulldozer in the mid-60s along the west bank of Hannum Creek. The trenches total about 1,500 feet but they only locally expose mineralization. Fifteen core holes were drilled in 1966. Five holes totaling 644.1 meters were drilled in 2007; three intersected mineralization.

Production notes:

None.

Reserves:

None.

Last report date: 2010-04-02

Site name(s): Unnamed (on Old Glory Creek)

Site type: Occurrence

ARDF no.: BN059

Latitude: 65.8468 **Quadrangle:** BN D-3

Longitude: 163.187

Location description and accuracy:

This occurrence is on both sides of Old Glory Creek at the mouth of Nelson Creek. It is about 0.4 mile west of the center of section 7, T. 5 N., R. 22 W. The location is accurate.

Commodities:

Main: As, Au, Sb, Zn

Other: Ag

Ore minerals: Arsenopyrite, pyrite, sphalerite, stibnite

Gangue minerals: Quartz

Geologic description:

Herreid (1966) described mineralized, quartz segregations and boudins in schist and marble in an old placer cut just above the mouth of Nelson Creek. A sample contains 0.02 ounce of gold per ton, 0.10 ounce of silver per ton, 0.05 percent copper, 0.05 percent lead, and 0.05 percent zinc (Herreid, 1966). The rocks in the area are Paleozoic schist and marble (Till and others, 1986); they are locally bleached and altered to clay at the occurrence.

In 2006, Royal Pretoria Mines working for Millrock Resources Inc. carried out geochemical surveys in the area; they defined a geochemical anomaly in gold, arsenic, and antimony over this occurrence (Hawley, 2007). Subsequently, they discovered mineralized float on both sides of Old Glory Creek. The float consisted of silicified carbonate rocks with quartz veinlets and a iron-stained quartz boulder with various combinations of stibnite, arsenopyrite, and pyrite. Five samples contained up to 0.92 parts per million (ppm) gold, more than 10,000 ppm antimony, 4,750 ppm zinc, and 3,130 ppm arsenic.

Alteration:

Schist is bleached locally and crosscut by a zone of clay alteration.

Age of mineralization:

Unclear, other than the mineralization is younger than the Paleozoic host rocks. Epigenetic mineralization in metamorphic rocks of Seward Peninsula is primarily of Cretaceous age.

Generic deposit model:

Deposit model:

Gold-stibnite-arsenopyrite-quartz veins in marble.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

Mineralized float occurs on both sides of Old Glory Creek; sampled by government and industry geologists.

Production notes:

None.

Reserves:

None.

Site name(s): Billiken; Kugruk

Site type: Prospect

ARDF no.: BN075

Latitude: 65.69 **Quadrangle:** BN C-1

Longitude: 162.4931

Location description and accuracy:

The Billiken prospect is about 1.4 miles northwest of the junction of Independence Creek and the Kugruk River. It is at an elevation of about 580 feet near the center of section 6, T. 3 N., R. 18 W. The location is accurate.

Commodities:

Main: Au, Cu, Fe

Other: Ag, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, magnetite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Actinolite, chlorite, clinohumite, diopside, dolomite, garnet, idocrase, olivine, phlogopite, pyrite, pyroxene, scapolite, serpentine

Geologic description:

This magnetite-rich skarn prospect was discovered and core drilled by Placid Oil and Minerals in the mid-1970s. Although tundra cover is extensive in this area, the deposit is well expressed in aeromagnetic data. A large, positive, north-south trending aeromagnetic anomaly over this prospect is about 0.4 mile wide and 2 miles long. The deposit contains massive to brecciated magnetite, with blebs to stringers of pyrite and chalcopyrite, in dolomite (Hudson and others, 1977). Newberry and others (1997) classify it as a magnesian-iron skarn developed in dolomite. It contains clinohumite, olivine, diopside, and idocrase. Serpentine minerals replace diopside, and olivine and phlogopite are present. A sample of the skarn contained 0.06 ounce of silver per ton, 0.0003 ounce of gold per ton, 0.2 percent copper, 0.02 percent zinc, 0.01 percent cobalt, and 45 percent iron (Newberry and others, 1997). This deposit is in the east contact zone of the Kugruk pluton, which has a K/Ar age of 94.9 +/- 2.9 Ma (Till and others, 1986, p. A-15).

In 2005, NovaGold began staking a large block of claims that eventually covered much of the basin of the Kugruk River and its tributaries (TintinaGold Resources Inc., 2010 [prospect]). In their extensive regional work, they collected about 2000 soil samples over the Kugruk pluton and the mineralized area of the Billiken prospect. TintinaGold Resources Inc. acquired the property in the spring of 2009. Their 2009 work included ground and aerial surveys, geochemical sampling, geologic mapping, and prospect evaluation. They particularly noted a north-trending belt, up to 2.1 miles wide and 7.5 miles long, of strong geophysical anomalies and copper anomalies in soil on the east side of the Kugruk pluton. The Billiken prospect is in this belt.

TintinaGold drilled three holes near the Billiken prospect in 2010 to test a large magnetic high, coincident with a resistivity low, gravity high, and IP chargeability high (Chutas and Robinson, 2010; TintinaGold, 2010 (drill results]). The first hole went through a zone more than 50 meters thick of massive magnetite with calc-silicate alteration and copper mineralization. The other holes intersected additional zones of copper mineralization associated with magnetite-rich calc-silicate alteration. Chalcopyrite is the primary copper mineral; in some magnetite-rich zones, it is accompanied by pyrite, pyrrhotite, and traces of sphalerite and galena. The alteration assemblages commonly contain pyroxene, garnet, magnetite, scapolite, and locally retrograde chlorite, actinolite, and epidote. Some notable intercepts in the 2010 drilling were: 22 meters with 0.44 percent copper and 49.0 percent iron, and 31.2 meters with 1.70 percent copper, 21.7

percent iron, 0.604 gram of gold per tonne, and 18.6 grams of silver per tonne.

Alteration:

Mg-bearing skarn developed adjacent to a Cretaceous pluton.

Age of mineralization:

Cretaceous; this deposit is probably related to the nearby 94.9 +/- 2.9 Ma pluton (Till and others, 1986, p. A-15).

Generic deposit model:

Deposit model:

Magnesian-iron skarn (Newberry and others, 1997; Cox and Singer, 1986; model 18d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18d

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was initially explored by Placid Oil by core drilling in the 1970s. Beginning in 2005, NovaGold began staking a large block of claims that eventually covered much of the basin of the Kugruk River and its tributaries (TintinaGold Resources Inc., 2010 [prospect]). In their extensive regional work, they collected about 2,000 soil samples over the Kugruk pluton and the mineralized area of the Billiken prospect. TintinaGold Resources Inc. acquired the property in the spring of 2009. Their 2009 work included both ground and aerial surveys, geochemical sampling, geologic mapping, and prospect evaluation. Tintina Gold drilled 3 holes in 2010.

Production notes:

None.

Reserves:

None.

Site name(s): Independence

Site type: Mine

ARDF no.: BN076

Latitude: 65.6717 **Quadrangle:** BN C-1

Longitude: 162.467

Location description and accuracy:

The Independence Mine is at the nose of a low ridge south of the junction between lower Independence Creek and Kugruk River. The deposit is also exposed in outcrop on the east side of Kugruk River, about 1,000 feet upstream of the mouth of Independence Creek and the mineralization can be followed for about a mile to the south along a low ridge. The location is accurate.

Commodities:

Main: Ag, Pb

Other: Zn

Ore minerals: Galena, pyrite, sphalerite, tetrahedrite

Gangue minerals: Actinolite?, calcite, limonite, manganese oxides?, quartz, siderite

Geologic description:

The Independence Mine is along a north-south trending marble-schist contact that is faulted and sheared. The contact dips steeply west and the marble is in the hanging wall. Mineralization has been traced laterally along this contact zone for 6,200 feet and vertically to a depth of 136 feet. On the 40-foot level of the mine, galena, sphalerite, tetrahedrite, and some pyrite are primarily in the footwall schist, although siderite-rich bodies reportedly replace marble locally, and ore minerals in turn replace siderite and marble (Levensaler, 1941). On the 140-foot level, at least part of the schist is described as calcareous (Levelsaler, 1941). The mode of ore mineral occurrence in the underground workings has not been described but boulders of limonitic galena and lead carbonates up to 2 feet in diameter are on surface dumps. The ore minerals may be in veins and stringers that pinch and swell, in disseminations, or as irregular replacements. Four ore zones were sampled on the 40-foot level and one on the 140-foot level. On the 40-foot level, the four ore zones include: 1) a 10-foot-wide by 75-foot-long zone that averaged 6.8 percent lead, and 10 ounces of silver per ton; 2) a 20-foot-wide by 38-foot-long zone averaging 7 percent lead and 10 ounces of silver per ton; 3) a 7-foot-wide by 75-foot-long zone that averaged 6 percent lead and 6.4 ounces of silver per ton; and 4) a 10-foot-wide by 25-foot-long zone that averaged 6 percent lead and 6.3 ounces of silver per ton. On the 140-foot level, the workings exposed an ore zone that was 5 feet wide and 35 feet long; it averaged 3.4 percent lead and 2.5 ounces of silver per ton. The fourth ore zone on the 40-foot level continued beyond the end of the drift. (Note, however, that the descriptions vary widely about the mineralogy, grade, and dimensions of the ore bodies.)

This deposit has historically been thought of as epigenetic; however, there is a possibility that it is stratabound. The faulted and deformed high grade mineralization is apparently discontinuous both laterally and vertically. Bedrock is extensively covered by tundra, but what is exposed in the area is part of a Lower Paleozoic metasedimentary assemblage (Till and others, 1986). Bedrock to the east of Independence Creek and northwest of Kiwalik Mountain may contain felsic metavolcanic rocks. Felsic metavolcanic rocks are associated with several massive sulfide prospects in the area, one near upper Minas Creek (BN119) and one at Big Bar (BN083) southeast of Kiwalik Mountain.

TintinaGold Resources Inc. (2009) explored the area in 2009. They noted that the Independence Mine was along a narrow belt of silver-lead-zinc-copper deposits that extends north-northeast for about 5 miles.

Alteration:

The deposit is oxidized and an early description (Levensaler, 1941) notes that siderite bodies replace limestone (marble).

Age of mineralization:

If the deposit is epigenetic, it is probably Cretaceous because epigenetic mineralization in metamorphic rocks of Seward Peninsula is primarily Cretaceous. If the deposit is stratabound, it may be the same age as the Ordovician to Devonian, sedimentary host rocks.

Generic deposit model:

Deposit model:

Massive to disseminated sulfide minerals along a deformed and faulted marble-schist contact. Polymetallic veins? (Cox and Singer, 1986; model 22c?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Exploration and production workings include dozer trenches, three shafts, and two levels with short drifts. The main shaft, 136 feet deep, was sunk on outcropping mineralization near the Kugruk River. Two drifts driven from this shaft included one 36 feet deep (referred to as the 40 foot level) that trended southerly for 260 feet and northerly for 15 feet along structure and another at a depth of 136 feet (referred to as the 140 foot level) that trended southerly for 205 feet and northerly for 45 feet along structure. A 30-foot-deep exploration shaft was dug (on the Galena Homestake claim) 5,000 feet south of the main shaft. Another exploration shaft (the Valley Galena claim) was dug 1,200 feet north of the main shaft on the west side of Kugruk River.

Production notes:

Two high-grade ore shipments are known (Levensaler, 1941). A shipment of thirty three tons was received at the Selby smelter on October 28, 1921 that contained 33.25 ounces of silver per ton, 29.9 percent lead, 4.8 percent zinc, 5.8 percent silica, 20.8 percent iron, and no arsenic or antimony. On December 10, 1922, 1.75 tons were received at the Bunker Hill smelter that contained 29.4 ounces of silver per ton, 33.5 percent lead, 6.3 percent zinc, and 12.3 percent iron.

Reserves:

None.

Site name(s): Boulder Creek; Death Valley

Site type: Prospect

ARDF no.: BN089

Latitude: 65.0507 **Quadrangle:** BN A-1

Longitude: 162.2467

Location description and accuracy:

The Boulder Creek or Death Valley (in the early literature) uranium deposit is in the headwaters of Boulder Creek, a north tributary to the middle Tubutulik River. It is 3.5 miles south of where the Tubutulik River leaves Death Valley, and about 0.3 mile southeast of the center of section 14, T. 3 S., R. 19 W. The deposit has been explored on the east side of Boulder Creek; the discovery pits are 1.0 mile southeast of Hill 990 and 1.0 mile east of Tubutulik River.

Commodities:

Main: U

Other:

Ore minerals: Coffinite, meta-autunite, pyrite, sphalerite

Gangue minerals:

Geologic description:

The Boulder Creek or Death Valley (in the early literature) sandstone-type uranium deposit (Dickinson and others, 1987) was discovered in 1977 and soon explored and drilled by Houston International Minerals Corporation.

The Death Valley deposit is in lower Eocene continental sedimentary rocks that unconformably overlie deeply weathered granitic rocks of the Darby pluton (Miller and Bunker, 1976; Johnson and others, 1979). The Eocene sediments were deposited in a graben between the uplifted Darby pluton to the west and lower Paleozoic metamorphic rocks to the east. This is probably an onshore, exposed equivalent of the deeper parts of the offshore Norton basin. Proximity to the slightly uraniferous Darby pluton seems to be an important control on the development of this deposit. The continental sedimentary rocks are conglomerate, arkosic sandstone, mudstone, and coal. The nonconformable contact between the coarse-grained, poorly sorted basal sedimentary strata and the granitic pluton is gradational and some strata in this part of the section are interpreted as mud flows in alluvial systems. The upper part of the sedimentary section contains mudstones deposited in a lacustrine environment. Eocene basalt is interbedded with and caps the sedimentary section in this area. This basalt may have created a dam that led to lacustrine sedimentation. The lacustrine mudstones contain laminated siderite but all the sediments compositionally reflect their probable source in the granitic rocks of the Darby pluton. Granitic clasts, quartz, and k-feldspar are common detrital components. Carbonized wood fragments are also common in the section which also contains bituminous coal beds up to 100 feet thick.

Uranium mineralization is both epigenetic and supergene. The epigenetic mineralization consists of coffinite, small amounts of pyrite, and trace amounts of sphalerite; it extends vertically over a stratigraphic interval of 300 feet, both above and below basalt layers. This primary mineralization, interpreted to be early Eocene in age, is formed by the reduction of oxidized groundwaters derived from areas of granitic bedrock by carbonized wood in conglomerate and arkosic sandstone. The principal mineralized zone defined by drilling covers an area of 395 by 9,850 feet and averages 10 feet thick. With an average grade of 0.27 percent U3O8, this deposit has a calculated resource of 1,000,000 pounds of U3O8 (Dickinson and others, 1987). The supergene mineralization, which is related to the present surface, consists of several varieties of

meta-autunite in soil and weathered bedrock intervals. The supergene mineralization is less than 20 feet thick. The mineralized surficial materials include three zones: (1) a one-foot thick zone of organic-rich mudstone and sandstone containing basalt cobbles that may be a debris flow; (2) a zone up to 10 feet thick of arkosic sandstone containing carbonized wood fragments; and (3) a zone of granitic grus or semi-consolidated arkosic sandstone and mudstone. Some arkosic sandstone fragments contain 11 percent U3O8 and some basalt fragments have uraniferous weathering rinds. Epigenetic mineralization is considered to be early Eocene in age, a time when the climate was temperate or subtropical (Dickinson and others, 1987). This is the age of the host rocks and the mineralization must have occurred before later Tertiary faulting disrupted groundwater flow eastward from the Darby pluton. The supergene mineralization is Recent in age and may be ongoing today. The Death Valley sandstone-type uranium deposit is the farthest north of its type in the world. At the time of its formation, it was probably at an even higher latitude than it is today, 64 degrees north.

The Boulder Creek deposit is currently (2008) a joint venture between Full Metals Minerals (2007) and Triex Minerals (2007), with Triex as the operator. Triex completed a four-week reconnaissance program in 2005 and identified several geochemical anomalies in the surrounding area. In 2006, they drilled 14 core holes totaling 1,237 meters. Twelve of the holes were on the Boulder Creek deposit; the drilling did not change the known dimensions of the deposit. They drilled two additional holes on geochemical anomalies about 6 kilometers north-northwest of the Boulder Creek deposit; they did not intersect significant mineralization but they did cut rocks favorable for uranium mineralization. Triex drilled another 8 holes in 2007 that totaled 890 meters to better define the deposit. Triex noted that 'No new and continuous zones of significant radioactivity were intersected' although the drilling through 2007 confirmed the grade and thickness of the deposit.

On the basis of airborne geophysical anomalies, Triex also staked a large block of claims in 2006 about 25 kilometers to the southwest in the southeast portion of McCarthy Marsh. They followed up these anomalies in 2006 by considerable soil sampling and biogeochemical surveys.

Alteration:

Various clays are developed in the sedimentary host rocks of the epigenetic deposit that may reflect alteration processes. The supergene enrichment accompanies alteration associated with weathering processes.

Age of mineralization:

The epigenetic mineralization is considered to be early Eocene in age, a time when the climate was temperate or subtropical (Dickinson and others, 1987). This is the age of the sedimentary host rocks and mineralization must have occurred before Tertiary faulting disrupted groundwater flowing eastward from the Darby pluton. Supergene processes are at least Recent in age and may be ongoing today.

Generic deposit model:

Deposit model:

Sandstone U (Cox and Singer, 1986; model 30c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

30c

Production Status: None

Site Status: Active

Workings/exploration:

The Death Valley sandstone-type uranium deposit (Dickinson and others, 1987) was discovered in 1977 and soon explored and drilled by the Houston International Minerals Corporation. Houston Oil and Minerals completed 3,300 meters of core drilling in 52 holes and about 60 m of near-surface split-tube sampling in 21 holes, focused on the Discovery Zone area. Surface grab samples reported by previous

operators returned up to 34 percent U3O8; intercepts of up to 3.3 meters, averaged 0.58 percent U3O8.
As of 2008, the Boulder Creek deposit was a joint venture between Full Metals Minerals and Triex Minerals, with Triex as the operator. Triex completed a four-week reconnaissance program in 2005 and identified several geochemical anomalies in the surrounding area. In 2006, they drilled 14 core holes totaling 1,237 meters. Twelve of the holes were on the Boulder Creek deposit. They drilled two additional holes on geochemical anomalies about 6 kilometers north-northwest of the Boulder Creek deposit; they did not intersect significant mineralization but they did cut rocks favorable for uranium mineralization. Triex drilled another 8 holes in 2007 that totaled 890 meters to better define the deposit.

On the basis of airborne geophysical anomalies, Triex also staked a large block of claims in 2006 about 25 kilometers to the southwest in the southeast portion of McCarthy Marsh. They followed up these anomalies in 2006 by considerable soil sampling and biogeochemical surveys.

Production notes:

None.

Reserves:

The principal mineralized zone that has been defined by drilling covers an area of 395 by 9,850 feet and averages 10 feet in thickness. This deposit has a calculated resource of 1,000,000 pounds of U3O8 at an average grade of 0.27 percent U3O8 (Dickinson and others, 1987). This is the largest presently known uranium deposit in Alaska. The work by Triex and Full Metal Minerals from 2005 to 2007 confirms the grade and thickness of the deposit but they emphasize that the historical reserve figures are not in conformity with modern standards.

Site type: Prospect

ARDF no.: BN143

Latitude: 65.8572 **Quadrangle:** BN D-3

Longitude: 163.2146

Location description and accuracy:

This prospect is on the ridge between the headwaters of the Inmachuk River and Old Glory Creek in the SW1/4 of section 1, T. 6 N., R. 22 W. It is at an elevation of about 1,000 feet and about 0.8 mile northwest of the Nelson Creek lode gold occurrence (BN059).

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz?

Geologic description:

In the Fall of 2004, Royal Pretoria Gold Ltd. staked 2 State of Alaska mining claims and did a soil survey on this prospect. Altar Resources developed the prospect concept, conducted the field work, and held the property in 2004. Soil samples were collected on a 2,200 by 2,400 meter soil grid; the samples were taken 100 meters apart on nine, east-west sample lines, 300 m apart. The samples defined a northwest-trending gold anomaly. The gold content of the soil was as high as 735 parts per billion; anomalous gold values were obtained on 7 of the 9 soil sample lines. Other anomalous elements include arsenic and antimony. On April 7, 2006, Full Metal Minerals (2006, ID=53) announced that it had entered an agreement to acquire 100 percent of this property.

The rocks in the area of this prospect are Paleozoic metasedimentary schist and marble (Till and others, 1986). A northwest-trending fault zone may localize gold mineralization in this area.

Alteration:

Silicification?

Age of mineralization:

Probably mid-Cretaceous.

Generic deposit model:

Deposit model:

Probably quartz veins and segregations in metasedimentary rocks (Cox and Singer, 1986, model 36a?)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a?

Production Status: None

Site Status: Active

Site name(s): Fireweed

Site type: Prospect

ARDF no.: BN144

Latitude: 65.2284 **Quadrangle:** BN A-1

Longitude: 162.4863

Location description and accuracy:

The Fireweed prospect is at the northwest end of Death Valley near the head of Granite Creek. it is about 1.2 miles east of hill 1284 and about 0.3 mile west of the center of section 13, T. 3 S., R. 19 W. The location is accurate.

Commodities:

Main: U

Other:

Ore minerals:

Gangue minerals: Hematite, quartz

Geologic description:

The Fireweed prospect was discovered in 2007 by a joint effort of Triex Minerals Corp. (2007) and Full Metal Minerals during a regional program of uranium exploration. The program was based on an airborne geophysical survey that identified several strong radiometric anomalies and an exploration model based on other uranium deposits in the area. The Fireweed area was covered by a grid of soil samples, ground geophysical surveys, sampling of rocks at the surface, and 5 short diamond-drill holes totaling 267 meters in 2007.

The prospect is on the eastern flank of a coarse-grained Cretaceous quartz syenite stock. But at the prospect itself, the rock is largely weathered outcrops of green feldspar porphyry and aplite. Twenty-one rock samples collected from three areas along nearly 2 kms of the prospect contained 0.14 to 0.82 percent U_3O_8. More than 300 pebbles of silica-hematite rock that were collected over an area about 1,800 meters long by 700 meters wide, had an average scintillometer reading of 4,500 counts per second and 34 had values above 15,000 counts per second. The five drill holes were mostly in quartz syenite; one cut hematite-silica zones similar in mineralogy to the pebbles collected at the surface.

Alteration:

The mineralization is associated with zones of hematite and quartz.

Age of mineralization:

Probably Cretaceous or Tertiary based on the age of the host rocks and similarities to other uranium deposits in the area.

Generic deposit model:

Deposit model:

Uraniferous, hematite-quartz zones in syenite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Last report date: 2011-02-28

Site name(s): Gold Bench

Site type: Mine

ARDF no.: BT003

Latitude: 66.981 **Quadrangle:** BT D-2

Longitude: 150.6367

Location description and accuracy:

Gold Bench is on a prominent bend in the South Fork Koyukuk River, about 1.2 miles upstream from the mouth of John R Creek. The mine is named on the current (1975) Bettles D-2 topographic map. The placer is about 1,000 feet wide, 2,000 feet long, and covers an area of about 60 to 100 acres. The location is accurate.

Commodities:

Main: Au

Other: Bi?, Cu, Hg, Pb, REE, Sn, Th, Ti, U, W

Ore minerals: Bismuthinite?, cassiterite, chalcopyrite, cinnabar, galena, gold, magnetite, monazite, pyrite, rutile, scheelite, uranothorianite

Gangue minerals: Garnet, hematite, magnetite, sphene

Geologic description:

Gold Bench was one of the richest of the bench gravels that have been mined along the South Fork of the Koyukuk River Kurtak and others, 2002). Gold was discovered in 1900 and there were several episodes of mining, notably from 1901 to 1910, and in 1945. The early mining was by ground sluicing and shoveling in and by 1937 about 100 acres had been mined. Hydraulic mining in the mid-1940s used a dragline. Production of 8,788 ounces of gold can be documented from incomplete records.

The gold-bearing gravel lies on top of a sloping bench inside a prominent bend in the South Fork of the Koyukuk River. The bench is about 1,000 feet wide and 4,000 feet long. Maddren (1913) reported that the gold was on false bedrock of reddish sand. The richest area was 150 to 200 feet wide and about 1,200 feet long. The gold is fine, flattened, and flaky. Reed (1938) reported that the gold was on false bedrock of blue clay developed from shale, overlain by 6 to 10 feet of gravel with many large boulders.

Samples of concentrates contained a variety of accessory minerals including magnetite, hematite, garnet, pyrite, chalcopyrite, cinnabar, rutile, cassiterite, scheelite, monazite, uranothorianite, galena, sphene, possibly bismuthinite and up to 0.18 percent equivalent uranium (Wedow and others, 1952; Nelson and others, 1954). The source of the gold is not known. Maddren (1913) speculated that it might have come from the Tramway Bar (WI006) area on the Middle Fork Koyukuk River or, more likely, from the hills to the south. Cobb (1973) thought that at least some of the gold was probably from reworked glacial deposits.

Kurtak and others (2002) sampled the placer for the Bureau of Land Management and estimated an 'inferred resource' of 160,000 cubic yards with an average grade of 0.005 ounce of gold per cubic yard. They also indicated that the bench gravel has mostly been mined out and the gravel in the modern channel of the river was subeconomic.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Probably inactive

Workings/exploration:

Site name(s): Ironside Bench; Ironside Bar

Site type: Mine

ARDF no.: BT004

Latitude: 66.987 **Quadrangle:** BT D-2

Longitude: 150.6103

Location description and accuracy:

The Ironside Bench is along the south side of the South Fork Koyukuk River about a mile upstream from Gold Bench (BT003). Both Ironside Bench and Gold Bench are named on the current (1975) Bettles D-2 topographic map. The mine is near the center of the south boundary of section 5, T. 25 N., R. 14 W., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Placer gold was discovered on the Ironside Bench of the South Fork of the Koyukuk river in 1900 (Maddren, 1913; Kurtak and others, 2002). Placer mining by hand methods and with heavy equipment continued at erratic intervals until 1941, but only 243 ounces of gold production can be documented. These were mined by ground sluicing and shoveling in 1937 and about 40 acres were said to have been mined by that time (Reed, 1938). Mining took place on a channel about 30 feet higher than the modern channel of the South Fork of the Koyukuk River. The gold was in gravel on a false bedrock (?) surface of decomposed shale. The gravel is coarse with few boulders and there was 6 to 30 feet of gravel, muck and ice over the false bedrock. The gold was distributed through gravel that assayed 0.007 to 0.016 ounce of gold per cubic yard. There was prospecting as recently as 1999 and numerous test pits, tailings piles, and mining equipment from past mining were on the property in 2000. In a 7-foot-deep test pit, Kurtak and others (2002) collected a sample of unmined gravel that contained 0.107 ounce of gold per cubic yard. Kurtak and others (2002) estimated an 'inferred resource' of 50,000 cubic yards with a grade of 0.107 ounce of gold per cubic yard.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

Placer gold was discovered on the Ironside Bench of the South Fork of the Koyukuk river in 1900 (Maddren, 1913; Kurtak and others, 2002). Placer mining by hand methods and with heavy equipment continued at erratic intervals until 1941, but only 243 ounces of gold production can be documented. These were mined by ground sluicing and shoveling in 1937 and about 40 acres were said to have been mined by that time (Reed, 1938). There was prospecting as recently as 1999 and numerous test pits, tailings piles, and mining equipment from past mining were on the property in 2000. Sampling by the U.S. Bureau of Land Management in the early 2000s.

Production notes:

Kurtak and others (2002) document production of 243 ounces of gold but the data are incomplete.

Reserves:

Kurtak and others (2002) estimate an 'inferred resource' of 50,000 cubic yards with a grade of 0.107 ounce of gold per cubic yard.

Site name(s): Davis Creek

Site type: Mine

ARDF no.: BT006

Latitude: 66.994 **Quadrangle:** BT D-1

Longitude: 150.4687

Location description and accuracy:

Davis Creek is a tributary to the South Fork, Koyukuk River; the lower half mile of the creek has been extensively mined. The mouth of Davis Creek is about 3.6 miles northwest of the center of Grayling Lake. The center of the mining is about 0.3 mile west of the center of section 17, T. 25 N., R. 13 W., of the Fairbanks Meridian.

Commodities:

Main: Au

Other: Bi, Cu, W, Zn

Ore minerals: Bismuth?, gold, pyrrhotite, scheelite

Gangue minerals: Quartz

Geologic description:

The lower one-quarter to one-half mile of Davis Creek has been extensively placer mined by hand and mechanized methods (Kurtak and others, 2002). Gold was discovered on Davis Creek prior to 1908 but there apparently was little mining between World War I and World War II (Maddren, 1913; Reed, 1938). Kurtak and others (2002) report small-scale mining from 1995 to 2001.

Placer gold was recovered on bedrock along the modern channel of Davis Creek and on benches on the north side of the creek. For about a quarter mile above its mouth, Davis Creek cuts through gravel up to 50 feet thick that was probably deposited by the ancestral South Fork of the Koyukuk River. The modern stream and bench placers may be the result of reworking this ancestral gravel. Samples of the placer concentrates are anomalous in bismuth, tungsten, zinc, and copper. One placer concentrate assayed 1,591 part per million (ppm) bismuth and a soft metallic grain in the concentrates may have been native bismuth.

The total production is unknown but 242 ounces of gold were produced from 1900 to 1909 (Maddren, 1913). Kurtak and others (2002) estimate a resource of 23,000 cubic yards of gravel with an average grade of 0.016 ounce of gold per cubic yard.

Bedrock near the mouth of the creek is Paleozoic chlorite schist with lenses of metamorphic quartz up to 1.0 foot thick (Kurtak and other, 2002). Select samples of quartz with pyrrhotite contained up to 150 parts per billion gold and 444 ppm copper. The schist is overlain by Jurassic, mafic volcanic and intrusive rocks, Jurassic ultramafic rocks, and Cretaceous quartz-pebble conglomerate.

Site name(s): Prospect Creek

Site type: Mine

ARDF no.: BT008

Latitude: 66.793 **Quadrangle:** BT D-2

Longitude: 150.5119

Location description and accuracy:

The mouth of Prospect Creek on the Jim River is near the Prospect Creek camp on the Dalton Highway. There has been considerable mining and exploration along the lower 6.5 miles of Prospect Creek. The coordinates are about 6 miles upstream on the creek where there was a substantial mining operation in 2001, near the center of section 14, T. 23 N., R. 13 W., of the Fairbanks Meridian.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Although gold was discovered on Prospect Creek in 1909 (Maddren, 1913) and there are numerous test pits and tailings along the lower 6 or 7 miles of the creek that may predate World War II, there were few descriptions of the placers until the 1970s (Kurtak and others, 2002). In the 1970s and 1980s there was much claim staking and and prospecting by several parties. The creek was placer mined in 1993 and 1997 and in 2001 there was a substantial placer mine using mechanized equipment and a washing plant about 6.5 miles above the mouth of the creek. There is no public record of production which may have been substantial from 1993 to 2001.

The placers worked from the late 1990s to 2001 were in elevated bedrock benches; the gold was in blue clay, covered by 3 to 20 feet of gravel on greenstone bedrock. The pay zones assayed 0.004 to 0.007 ounce of gold per cubic yard. Nuggets weighted up to 0.7 ounce.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Site name(s): Bonanza, Beef

Site type: Prospect

ARDF no.: BT009

Latitude: 66.6301 **Quadrangle:** BT C-1

Longitude: 150.0261

Location description and accuracy:

The Bonanza prospect is near the center of a small hill informally called Windy Knob, which is about 14.8 miles at an azimuth of 302 degrees from the high peak of Dall Mountain. it is about 0.3 mile south-southwest of the center of section 19, T. 21 N., R. 12 W., of the Fairbanks Meridian. Other similar, lower grade deposits are scattered over an area about 1.5 miles wide and 5.5 miles long, which extends east into the adjacent Beaver 1:250,000-scale quadrangle. The coordinates are the center of the Bonanza claim block, which is the locus of the principal mineral showings in the area. The location is accurate.

Commodities:

Main: Mo, Pb, W, Zn

Other: Ag, Cu

Ore minerals: Chalcopyrite, molybdenite, pyrrhotite, scheelite, sphalerite

Gangue minerals: Calc-silicate minerals, garnet, pyroxene, quartz

Geologic description:

The Bonanza prospect was found by BP Exploration in 1976 by following up a stream-sediment anomaly (Kurtak and others, 2002). From 1978 to 1982, the prospect was mapped and sampled by WGM Inc., Union Carbide, and Patino Inc. Six trenches were cut.

The Bonanza prospect is the most significant of several deposits along a 5-mile long, east-striking belt of intermittent skarn mineralization along the north side of the Cretaceous Kanuti Pluton which intrudes Proterozoic and lower Paleozoic sedimentary rocks (Clautice, 1983, 1984, 1987; Kurtak and others, 2002; Patton and others, 2009). At the Bonanza prospect, small masses of limestone are altered to calc-silcate rocks that vary from fine-grained, siliceous pyroxene-garnet skarn to dark green, pyroxene skarn. The skarn contains up to 10 percent pyrrhotite, coarse-grained scheelite, sphalerite, and minor chalcopyrite, molybdenite, and galena. The scheelite commonly occurs as disseminated grains in relatively sulfide-free pyroxene-garnet skarn. Scheelite also occurs on fracture surfaces in calc-silicate schist and less commonly in quartz veins. Molybdenite typically occurs as rosettes and small flakes in quartz veins in biotite-quartz monzonite and less commonly in aplite, pegmatite, and calc-silicate rock. The skarn zones are discontinuous, irregularly shaped, and are up to 16 feet wide and 50 feet long. Kurtak and others (2002) collected several samples that contained up to 1.44 percent tungsten, 1,438 parts per million (ppm) zinc, and 936 ppm lead. Clautice (1983) collected a sample that contained 0.89 percent tungsten, 300 grams of silver per tonne, and 0.65 percent copper.

Kurtak and others (2002) briefly examined similar, lower grade skarn mineralization at the Beef claims, about 1.6 mile east of the Bonanza prospect. Trace molybdenite was identified along fractures in the skarn; a sample contained 521 ppm tungsten and 80 ppm molybdenum.

Alteration:

Calc-silicate skarn.

Age of mineralization:

Cretaceous skarn deposit at the periphery of a felsic pluton.

Generic deposit model:

Deposit model:
W skarn deposit (Cox and Singer, 1986; model 14a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
14a

Production Status: None

Site Status: Probably inactive

Workings/exploration:
The Bonanza prospect was found by BP Exploration in 1976 by following up a stream sediment anomaly (Kurtak and others, 2002). From 1978 to 1982, the prospect was mapped and sampled by WGM Inc., Union Carbide, and Patino Inc. Six trenches were cut.

Production notes:
None.

Reserves:
None.

Additional comments:
The skarn mineralization extends east into the Beaver, 1:250,000-scale, quadrangle.

Site name(s): Unnamed (southeast of Sithylemenkat Lake)

Site type: Occurrences

ARDF no.: BT018

Latitude: 66.0265 **Quadrangle:** BT A-3

Longitude: 151.1472

Location description and accuracy:

This record describes several lode occurrences approximately 9 to 10 miles southeast of the center of Sithylemenkat Lake. The occurrences are centered at an elevation of about 2,350 feet, about 0.3 mile east-northeast of the center of section 21, T. 14 N., R.17 W., of the Fairbanks Meridian. Similar lode deposits are about 1 mile south and about 1.5 mile northeast. The location is accurate. (See also the nearby tin placer at the head of Kanuti Kilolitna River (BT020) whose source is probably these lode deposits.)

Commodities:

Main: Sn

Other: As, Bi, Cs, Cu, Nb, Pb, Rb, REE, Ta, W

Ore minerals: Arsenopyrite, cassiterite, galena, hematite, ilmenite, magnetite, molybdenite, monazite?, pyrite, wolframite

Gangue minerals: Chlorite, garnet, quartz, sericite, tourmaline

Geologic description:

The tin lodes and placers in this area were first identified by Asarco in 1975 after a review of geochemical data collected by the U.S. Geological Survey in 1968 and 1969 (Patton and Miller, 1973; Kurtak and others, 2002). From 1975 to 1983 a succession of companies and organizations including the U.S. Bureau of Mines, WGM Inc., British Petroleum, Patino Inc., and Doyon Ltd. mapped and studied the lodes and placers (Bright, 1989; WGM Inc., 1978, 1979a, 1979b, 1980a, 1980b; Patino Ltd., 1981, 1982; Barker and Foley, 1986).

The lode tin prospects are associated with the Early Cretaceous Sithylemenkat granitic batholith (Barker and Foley, 1986; Kurtak and others, 2002). Cassiterite has been identified in chlorite-rich and locally magnetite-bearing greisen zones in the granitic rocks. Mineralized samples exhibit variable effects of greisenization, with tourmaline and magnetite sometimes present. Sericite-quartz veins and altered dikes contain abundant secondary chlorite and may contain up to several percent sulfides. The sulfide minerals include pyrite, arsenopyrite, galena, and molybdenite. The greisen range in color from light to dark green; the highest tin values are in the darker varieties. The extent of the greisen is difficult to determine owing to poor exposures. Some zones have been traced for as much as 1,200 feet, and one greisen zone is up to 10 feet thick (Barker and Foley, 1986).

Thin sections of the greisen show relict porphyritic texture; feldspar phenocrysts are replaced by intergrown quartz and sericite, which in the more altered samples are replaced by chlorite and clay minerals.

Greisen samples contained 25 to 2,300 parts per million (ppm) tin (Barker and Foley, 1986). The analyses also showed up to 5,126 ppm arsenic, 326 ppm, bismuth, 253 ppm cesium, 1,808 ppm copper, 3.4 percent lead, 1,156 ppm rubidium, 135 ppm tungsten, and 4,044 ppm zinc. Other samples contained anomalous tin, zinc, copper, and lead, as well as up to 25.9 ppm silver, 75.6 ppm uranium, and 101 ppm thorium (Kurtak and others, 2002).

Alteration:

Greisenization.

Age of mineralization:

The Sithylemenkat pluton, which is probably the source of the deposits, is Early Cretaceous based on a K/Ar date of 106 +/- 3 my for biotite (Patton and Miller, 1973).

Generic deposit model:

Deposit model:

Sn greisen deposits (Cox and Singer, 1986; model 15c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

15c

Production Status: None

Site Status: Undetermined

Workings/exploration:

Considerable mapping and sampling of the lode tin deposits by several government and private organizations from 1975 to 1983.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (near Prospect Creek)

Site type: Prospect

ARDF no.: BT019

Latitude: 66.7756 **Quadrangle:** BT D-2

Longitude: 150.591

Location description and accuracy:

This prospect is in the canyon of Prospect Creek, about 4.0 mile east-southeast of the Prospect Creek camp on the Dalton Highway. It is about 0.3 mile east of the center of section 33, T. 23 N., R. 14 W., of the Fairbanks Meridian.

Commodities:

Main: Au,Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals: Quartz

Geologic description:

An east-trending, vertica l(?), felsic dike or sill, 50 or more feet thick, is exposed in a series of knobs for about 0.8 mile in the canyon of Prospect Creek (Kurtak and others, 2002). The dike locally contains a stockwork of quartz veinlets with minor chalcopyrite, galena, and sphalerite. The rocks on the south side of Prospect Creek are interlayered slate, siltstone, phyllite, and andesite. The rocks on the north side of the creek are Triassic to Jurassic basalt, diabase, and gabbro. Samples of the quartz veinlets contained up to 1,522 parts per million (ppm) zinc, 835 ppm lead, 130 ppm copper, and 24 parts per billion gold. Avalon Development Corporation explored in the area in 1999.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Mineralized felsic dike with chalcopyrite, galena, and sphalerite.

Geologic description:

Tin lodes and placers in this area were first identified by Asarco in 1975 after a review of geochemical data collected by the U.S. Geological Survey in 1968 and 1969 (Patton and Miller, 1973; Kurtak and others, 2002). From 1975 to 1983 a succession of companies and organizations including the U.S. Bureau of Mines, WGM Inc., British Petroleum, Patino Ltd., and Doyon Ltd. mapped and studied the lodes and placers (Bright, 1989; WGM Inc., 1978, 1979a, 1979b, 1980a, 1980b; Patino Ltd., 1981, 1982; Barker and Foley, 1986). The lode tin deposits and the tin placers are associated with the Early Cretaceous Sithylemenkat granitic batholith (Barker and Foley, 1986; Kurtak and others, 2002).

A 1.4-mile section of the upper Kanuti Kilolitna River was drilled and bulk sampled by Patino Ltd. in 1980 and 1981 (Patino Inc., 1981, 1982). Placer samples taken in gravel that averaged about 20 feet thick contained up to 0.4 pound of tin per cubic yard, with lesser tantalum, columbium, tungsten, and rare earth minerals. In addition to cassiterite, the placer concentrates also contained wolframite, pyrite, ilmenite, hematite, garnet, and monazite (?). Patino estimated an 'indicated resource' of 3.5 million cubic yards that contained an average of 0.67 pound of tin per cubic yard. But they concluded the placer was uneconomic because of its small size and low grade.

Site name(s): No Name Creek

Site type: Prospect

ARDF no.: BT021

Latitude: 66.1191 **Quadrangle:** BT A-1

Longitude: 150.0608

Location description and accuracy:

The prospect is about 8 to12 miles up the No Name Creek valley from its confluence with the Ray River. Site for this record is the confluence of the south fork of No Name Creek and a small, unnamed tributary from the north. Accuracy of the location is less than 1,000 feet. The prospect area extends into the Beaver Quadrangle. The prospect area is accessible from the Dalton Highway, which crosses the creek about three miles downstream of the site. This placer prospect is on, and potentially includes much of the lower No Name Creek valley, although the creek is infilled with loess and vegetation and drilling would be required. Mineralized exposures at the site are limited to hand trenches that expose a series of bench channels to both the north and south of the present drainage (Barker, 1991a,b), located in the NW¼, NE ¼ Section 22 and the SW ¼ of the SE ¼ Section 15, T. 15 N., R. 12 W., of the Fairbanks Meridian.

Commodities:

Main: Au, Sn

Other: Nb, REE, Ta, Ti, W, Zr

Ore minerals: Cassiterite, gold, ilmenite, monazite, wolframite, xenotime, zircon

Gangue minerals:

Geologic description:

The No Name Creek drainage, including its southern fork with headwaters in the Ft. Hamlin Hills pluton, flows southwesterly approximately 20 miles, ultimately joining the Ray River at the point where the Ray bends south to join the Yukon River. Much of the No Name Creek drainage downstream of the Dalton Highway is incised into, or has cut through, Miocene-age basalt flows (Albanese, 1987; Barker, 1991a, b) that overlay Tertiary (?) white gravel (Barker, 1991b). At least low grade placer tin, rare earth elements (REE), and gold occur in all heavy mineral samples collected from poorly exposed cutbanks downstream of the Dalton Highway (Barker, 1983, 1991a). At the site, however, remnant channel exposures on several low bench features contain up to six pounds of tin per cubic yard (3,580g/m3) plus significant REE mineral concentrate. Gold is noted in all samples from lower No Name but is absent in the bench channels upstream at the site (Barker, 1991a).

The Fort Hamlin Hills pluton is considered part of the broad northeast-trending peraluminous Ruby Batholith of central Alaska (Chapman and others, 1982; Patton and Miller,1970, 1973; Barker and Foley; 1986; Herreid, 1969). Generally the granitic rocks are coarse-grained, equigranular to porphyritic, orthoclase-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been recognized locally. The granitic rocks cut Paleozoic schist, phyllite, quartzite, and lesser greenstone and limestone. The granitic plutons feature alteration zones including chloritic and hematic greisen veins/bodies that are the apparent source of at least some of the detrital cassiterite and REE minerals. Mineralogical examination of heavy mineral concentrates from the remnant bench channels confirmed abundant cassiterite and an anomalously high percentage of xenotime relative to monazite (Mariano, A., mineralogist, 2012, personal communication).

The heavy mineral concentration is enhanced by multiple stages of fluvial downcutting of the No Name

Creek drainage which has repeatedly re-concentrated earlier sediments. The result of this channel down-cutting/reworking/re-deposition at continually lower elevations is a highly concentrated heavy mineral fraction. Remnants of former alluvial terrace deposits occur high on the west and north slopes of the Fort Hamlin Hills and are found to mantle the basalt flows on lower No Name (Albanese, 1987, Barker, 1991b). Each repeated downcutting event removes and transports more of the lighter aggregate downstream, thus potentially upgrading the residual heavy mineral concentrations. Upgrading of the heavy mineral fraction in the alluvial deposits is well exemplified by the series of bench channels on east fork of No Name Creek where the highest grades are in the lowest elevation bench channels.

Remnant (late Tertiary?) terraces as high as 100 meters (320 feet) along the left limit of No Name near the Dalton Highway are evidence of ancient alluvial gravel deposition and though mineralized they contain less REE and tin in heavy mineral fractions than the present creek bed. These high-level channels of ancient No Name Creek have been developed for construction aggregate used along the Trans Alaska Pipeline (Barker, 1991a).

Alteration:

Thermal alteration from the batholith is widespread and silicification extends well into the Paleozoic host rocks. Locally extensive, tourmalization, potassic, carbonate, and argillic styles of advanced alteration can be mapped and generally are associated with regional-scale faulting. Such zones of altered and weakened rock give rise to locally intense large-scale disintegration of the bedrock granite, which has released the contained heavy minerals. Source of the placer tin- and REE- minerals appears to be widespread argillic alteration and greisen vein-like occurrences locally overprinted with chloritic and/or hematic alteration (Herreid, 1969; Barker and Foley, 1986). Greisen samples will generally contain 100 ppm to as much as 2500 ppm Sn and elevated REE. Cassiterite has also been found associated with quartz veins at a few locations in the batholith. The older fluvial deposits as represented by the remnant channels on No Name Creek also exhibit a degree of residual (in-place) concentration that are characterized by feldspar grains altered variably to white and brown clayey quartz-rich sediments that are locally seen to grade upward into unaltered cross-bedded fluvial gravel.

Age of mineralization:

The Ruby batholith region is within the glacial ice-free Quaternary province of Beringia, defined as the non-glaciated intermontane region extending from eastern Siberia and eastward across a then-dry Bering Sea floor, thence transecting interior Alaska, and extending into northwestern Canada. Across the Beringia region, the fluvial processes have generally continued since the Tertiary and consequently the region is historically known for the Pleistocene mammals that survived there, as well as a multitude of placer gold camps and districts such as the Klondike. In the Ruby batholith region, the on-going erosional and mineral concentration processes that concentrated valuable heavy minerals have apparently remained uninterrupted since the late Tertiary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer tin (Cox and Singer, 1986; model 39e).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39e

Production Status: None

Site Status: Active

Workings/exploration:

The No Name Creek prospect has been explored by the U.S. Bureau of Mines as part of the Critical and Strategic Minerals Program in the 1970s-1980s (Barker, 1983, 1991a,b; Barker and Foley, 1986). Gravel samples have been collected and processed from numerous locations along the creek and from the remnant

bench channels at the site. All samples were processed by gravity methods for the analysis of the heavy mineral content (Barker, 1991a). Ucore Rare Metals, Inc. acquired the No Name Creek claim block in 2011 and in 2012 announced additional sample results for heavy mineral concentrates from the bench channels (see data table http://ucore.com/projects/ray-mountains-alaska and (Ucore.com, Ucore Confirms Widespread Rare Earth Mineralogy in Central Alaska, January 16, 2012).

Production notes:

None.

Reserves:

A 'very preliminary' estimate of the tin resource potential for the combined Ray River and No Name Creek drainages was made by the U.S. Bureau of Mines 'for the purpose of land-use management and planning purposes.' A total of 62 to as much as 172 million pounds-tin in 300 million cubic yards of gravel was estimated to be present (Barker, 1991a). Grade is estimated between 0.2 and 0.5 pounds-tin per cubic yard; highest grade values are mostly from upper No Name Creek. No estimate was made for the REE, gold, or other possible placer minerals.

Additional comments:

No Name Creek flows through lands on which the State of Alaska has filed 'Priority Selection' under the land entitlement provision of the 1959 Statehood Act. Various temporary land withdrawals remain to be lifted by the Bureau of Land Management (BLM) before these selections can be processed. The BLM will not issue any permits for surface disturbance activities including exploration under these withdrawals or State Selection status.

Reporter(s): J.C. Barker

Last report date: 2016-03-15

Site name(s): Gravel Pit Prospect No. 2

Site type: Occurrence

ARDF no.: BT022

Latitude: 66.0286 **Quadrangle:** BT

Longitude: 150.1823

Location description and accuracy:

The site is located about 6.5 miles southeast of the No Name Creek bridge and uphill (easterly) from the Dalton Highway. The site is southeast of the pipeline crossing over Fort Hamlin Hills Creek. The site for this record is a gravel pit adjacent to the Trans-Alaska Pipeline. The occurrence is accessible from the Dalton Highway with permission of the Pipeline security personnel. Accuracy of the location is less than 1000 feet. The site is located in the NE¼, NE ¼ Section 20, T. 14 N., R. 12 W., of the Fairbanks Meridian.

Commodities:

Main: REE, Sn

Other: Nb, Ti, W, Zr

Ore minerals: Cassiterite, monazite, wolframite, xenotime, zircon

Gangue minerals:

Geologic description:

At the site, a bulk channel sample from a well-developed remnant channel exposed in the wall of a gravel pit contained 0.24 pounds of tin per cubic yard (Barker, 1991a). The channel is incised into granite bedrock of the Fort Hamlin Hills pluton. The channel is composed granitic and metasedimentary gravel and semi-rounded granitic boulders, and likely represents an ancient channel of the Fort Hamlin Hills Creek. The Fort Hamlin Hills pluton is considered part of the broad northeast-trending peraluminous Ruby Batholith of central Alaska (Chapman and others, 1982; Patton and Miller, 1973; Barker, 2012; Barker and Foley, 1986; Herreid, 1969). Generally the granitic rocks are coarse-grained equigranular to porphyritic orthoclase-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been recognized locally. The granitic rocks cut Paleozoic schist, phyllite, and quartzite within a half-mile downhill to the west.

Alteration:

Thermal alteration from the batholith is widespread and silicification extends well into the Paleozoic host rocks. The source of the placer tin and rare earth element minerals appears to be unexposed greisen zones in the granite in the Fort Hamlin Hills Creek valley. Greisen samples from the Ruby Batholith region will generally contain 100 ppm to as much as 2500 ppm tin and elevated rare earth elements. Cassiterite has also been found associated with quartz veins at a few locations elsewhere.

Age of mineralization:

Quaternary; the occurrence represents ongoing erosional and mineral concentration processes that have concentrated valuable heavy minerals, a process that has apparently continued since the late Tertiary.

Multiple stages of fluvial activity and downcutting of the Ray River drainage and its tributaries has resulted in these streams further incised into local bedrock. The Prospect Pit #2 occurrence represents an ancient channel abandoned as the creek cut new channels to its present level several hundred feet lower than the site (Barker, 1991a,b). Sampling of the present channel of Fort Hamlin Hills Creek was not possible due to infilling of frozen silt and vegetation.

These remnant terraces and channels, as high as 300ft (100 m) above present drainages along the west of the Fort Hamlin Hills pluton, are evidence of ancient (late Tertiary(?)) alluvial gravel deposition and are now perched above present-day channels of the No Name Creek and the Ray River valleys (Barker, 1991a, b, 2012).

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Sn (Cox and Singer, 1986; model 39e).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39e

Production Status: None

Site Status: Inactive

Workings/exploration:

The Gravel Pit Prospect No. 2 occurrence has been mapped and sampled by the U.S. Bureau of Mines as part of the Critical and Strategic Minerals Program in the 1970s-1980s (Barker, 1983, 1991a, 1991b). The occurrence serves as evidence of the evolving development of the accumulated placer minerals in the present active channel of Fort Hamlin Creek, which is infilled with silt and vegetation. All samples were processed by gravity methods for the analysis of the heavy mineral content (Barker, 1991a).

Production notes:

None.

Reserves:

None.

Additional comments:

The site is gated due to the close proximity to the Trans Alaska Pipeline.

Site name(s): Gravel Pit Prospect No. 1

Site type: Occurrence

ARDF no.: BT023

Latitude: 66.1212 **Quadrangle:** BT A-1

Longitude: 150.132

Location description and accuracy:

The site is located adjacent to the Trans-Alaska Pipeline about 0.5 miles southeast of its crossing of No Name Creek and east from the Dalton Highway. Site for this record is along the north side of the gravel pit and accurate to within 500 feet. The occurrence is accessible from the Dalton Highway with permission of the pipeline security personnel. Two mineralized ancient channel exposures were mapped and sampled in the pit wall (Barker, 1991a,b). The site is located in the W1/2 SE1/4 Section 17, T. 14 N., R. 12 W., of the Fairbanks Meridian.

Commodities:

Main: REE, Sn

Other: Nb, Ti, W, Zr

Ore minerals: Cassiterite, ilmenite, monazite, wolframite, xenotime, zircon

Gangue minerals:

Geologic description:

At the site, two well-developed remnant channels are exposed in the wall and floor of a gravel pit perched on a prominent basalt bluff facing north toward the present No Name Creek. Channels are oriented to the southwest as is the modern No Name channel. These perched channels are ancestral No Name Creek, which is now located about 2000 feet north and about 150 feet lower. Samples contain trace to 0.12 pounds of tin per cubic yard (Barker, 1991a, b). The channels are filled with coarse gravel including cobbles of mostly granitic rock of the Fort Hamlin Hills pluton, schist, and quartz. Exposures were sampled where the channels are incised into basalt bedrock. The Fort Hamlin Hills pluton is considered part of the broad northeast-trending peraluminous Ruby Batholith of central Alaska (Chapman and others, 1982; Patton and Miller, 1970, 1973; Barker and Foley, 1986; Herreid, 1969). Generally the granitic rocks are coarse-grained equigranular to porphyritic orthoclase-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been recognized locally in the nearby granite pluton.

Alteration:

Thermal alteration from the batholith is widespread, and silicification extends well into the Paleozoic host rocks. Source of the placer tin and rare earth element minerals appears to be unexposed greisen zones in the granite in the Fort Hamlin Hills pluton. Greisen samples will generally contain 100 ppm to as much as 2500 ppm tin and elevated levels of rare earth elements. Cassiterite has also been found associated with silicification and quartz veins at a few locations elsewhere.

Age of mineralization:

Quaternary; the occurrence represents ongoing erosional and mineral concentration processes that have concentrated valuable heavy minerals, a process that has apparently continued locally since the late Tertiary. An age-date from a nearby basalt flow indicates an age of 30.59 m.y. +/- 0.92 (Albanese, 1987). Multiple stages of fluvial activity and downcutting of the No Name Creek drainage has obviously occurred near this

site.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer tin (Cox and Singer, 1986; model 39e).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39e

Production Status: None

Site Status: Inactive

Workings/exploration:

The Gravel Pit Prospect No. 1 occurrence has been mapped and sampled by the U.S. Bureau of Mines as part of the Critical and Strategic Minerals Program in the 1970s-1980s (Barker, 1983, 1991a,b, 2012). The occurrence serves as evidence of the evolving development of the accumulated placer minerals in the present active channels of No Name Creek.

All samples were processed by gravity methods for the analysis of the heavy mineral content and the channel samples contain trace to 0.12 pounds of tin per cubic yard (Barker, 1991a). Values for contained REE were not estimated.

Reworking the fluvial sediment from these elevated channels due to downcutting of the modern stream generally will generally increase the grade of the heavy mineral content. By comparison, gravel from a small bar in the modern channel due north of Gravel Pit Prospect #1 contained 0.17 pounds tin per cubic yard. Discontinuous exposures of the ancient channels in Gravel Pit Prospect No. 1 would be expected to be present at similar elevations to the northeast and southwest.

Production notes:

None.

Reserves:

None.

Additional comments:

The site is gated due to the close proximity to the Trans Alaska Pipeline.

Site name(s): Unnamed (east fork of Kilolitna River)

Site type: Prospect

ARDF no.: BT024

Latitude: 66.0395 **Quadrangle:** BT A-3

Longitude: 151.0673

Location description and accuracy:

The prospect is a series of tin, tungsten, and rare earth element placer prospects along the entire 10-mile length of the unnamed creek upstream of its confluence with the Kilolitna River. The site for this record is the confluence of the two principal upper tributaries. Accuracy of the location is less than 1,000 feet. The site is located in the SW¼, NW¼ Section 13, T. 14 N., R. 17 W., of the Fairbanks Meridian, but the prospect includes Sections 2, 7, 9, 10, 11, 13, 14, 15, 16, 17, 18, 23, and 24 of T. 14 N., R. 17 W., continuing west into T. 14 N., R. 18 W. Sections 12, 13, and 14. The prospect area is best accessible by helicopter from the Dalton Highway.

Commodities:

Main: Sn, W

Other: Nb, REE, Ta, Ti, Zr

Ore minerals: Cassiterite, ilmenite, monazite, scheelite, wolframite (ferberite end-member), xenotime, zircon

Gangue minerals:

Geologic description:

The 10-mile long, unnamed creek, referred to by Ucore Rare Metals, Incorporated as the Caribou Heights prospect, drains about one-third of the known extent of the Sithylemenkat pluton (Ucore, 2012, 2014). Geological investigations recognized regional tin potential as early as 1969 (Herreid, 1969; Patton and Miller, 1970, 1973; Barker, 1983; and in early 1980s tin was specifically recognized in the valley of this record (Barker and Foley, 1986; Barker, 2012). Additional regional geochemical sampling by the Alaska Division of Geological and Geophysical Survey was reported in Bachmann, and others (2013).

The Sithylemenkat pluton is considered part of the broad northeast-trending peraluminous Ruby Batholith of central Alaska (Patton and Miller, 1970, 1973; Barker and Foley, 1986; Herreid, 1969). Generally, the granitic rocks are coarse-grained, equigranular to porphyritic, orthoclase-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been recognized locally. The granitic rocks cut Paleozoic schist, phyllite, quartzite, and lesser greenstone and limestone. Mineralogical examination of heavy mineral concentrates from the bench channels and streambed samples confirmed abundant cassiterite and rare-earth minerals of monazite and xenotime (Barker and Foley, 1986).

Alteration:

The granitic pluton features alteration zones, including a large central area of argillic alteration enveloping chloritic and hematic greisen veins/bodies that are the apparent source of at least some of the detrital cassiterite, wolframite, and REE minerals. A three-mile long north-northeast trend of these intermittent and cross-cutting greisen veins/zones occurs along the ridges in sections 11, 14, 21, and 22, T. 14 N., R. 17 W., immediately south of this creek (see Figures 6 and 7 in Barker and Foley, 1986).

Thermal alteration from the batholith is widespread and silicification extends well into the Paleozoic host rocks. Locally extensive, tourmalization, potassic, carbonate, and argillic styles of advanced alteration can be mapped and generally are associated with regional-scale faulting. Such zones of altered and weakened

rock give rise to locally intense large-scale disintegration of the bedrock granite, which has released the interstitial or disseminated heavy minerals. The source of the placer tin and rare earth minerals appears to be widespread argillic alteration and greisen vein-like occurrences as described above, locally overprinted with chloritic and/or hematitic alteration (Herreid, 1969; Barker and Foley, 1986). Greisen samples will generally contain 100 ppm to as much as 2500 ppm tin and elevated rare earth elements.Cassiterite has also been found associated with quartz veins at a few locations in the batholith.

Age of mineralization:

The prospect is Quaternary age. The Ruby batholith region is within the glacial ice-free Quaternary province of Beringia, defined as the non-glaciated intermontane region extending from eastern Siberia eastward across a then-dry Bering Sea floor, thence transecting interior Alaska, and extending into northwestern Canada. Across the Beringia region, the fluvial processes have generally continued since the Tertiary and the ongoing erosional and mineral concentration processes continue to concentrate valuable heavy minerals. A few small cirques are evident to the south in the higher elevations of the Ray Mountains, but evidence of glacial disruption of accumulating placer gravel deposits at this site was not seen.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer tin (Cox and Singer, 1986; model 39e).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39e

Production Status: None

Site Status: Active

Workings/exploration:

The prospect valley of the east fork of the Kilolitna River has been explored by the U.S. Bureau of Mines as part of the Critical and Strategic Minerals Program in the 1970s-1980s. In 1970s tin and tungsten potential of the areas adjacent to the Trans-Alaska pipeline were investigated and included 17 sample sites within this prospect area (Barker, 1983) and nearly all were anomalous; Barker and Foley, in 1986, sampled the creek for its placer potential, described the apparent placer prospect, and reported results for 30 concentrated samples. In 2011 Ucore Rare Metals, Incorporated, through their subsidiary Landmark Alaska, LLP, filed a claim block and reported more detailed sample results for 27 heavy mineral concentrates from several specific bench and active channel areas (see data table, Ucore, 2012, 2014). Bucket-size channel samples of an exposed bench deposit along the uppermost right limit of the southern tributary reported as much 9,700 g of rare earth elements plus tin per cubic meter of gravel. Generally anomalous results occur along the length of the creek though frozen ground makes sampling difficult. An additional well-defined mineralized terrace was located along the left limit of the creek in Section 13, T. 14 N., R. 18 W. (Ucore, 2012).

Production notes:

None.

Reserves:

None.

Additional comments:

The creek flows through lands on which the State of Alaska has filed ‘Priority Selection’ under the land entitlement provision of the 1959 Statehood Act. Various temporary land withdrawals remain to be lifted by the Bureau of Land Management (BLM) before these selections can be processed. The BLM will not issue any permits for surface disturbance activities including exploration under these withdrawals or State

Selection status. Mining claims staked in the vicinity of this prospect are located according to the State of Alaska regulations for mineral locations on State Selected land.

Site name(s): Fort Hamlin Hills Metalliferous Coal

Site type: Occurrence

ARDF no.: BT025

Latitude: 66.0 **Quadrangle:** BT A-1

Longitude: 150.3386

Location description and accuracy:

The site location is the Ray River drainage where the river enters the Bettles quadrangle. The occurrences are found in a series of about six small topographic basins through which the Ray River meanders. Samples of mineralized occurrences begin on the west at 66.0240N, 150.2932W, and mineralized occurrences extend downstream for about twelve miles to at least 65.9331N, 150.0180W, where the occurrence area is covered by Quaternary gravel. It is possible that occurrences extend downstream to within a mile of the confluence with the Yukon River. Accuracy of the site and sample locations presented here is about 1,000 feet. The site location is in the SE¼, NE ¼ Section 32, T.14 N., R. 13 W., of the Fairbanks Meridian. An additional, geologically related occurrence location is reported approximately 10 miles farther upstream of the site report area and is described in the Tanana Quadrangle records (Sample No. 1, located at 65.9852, 150.5560).

Commodities:

Main: Ge, Pb, W

Other: Ag, Au, Cu, Ga, Mo, REE, Sb, U, Zr

Ore minerals:

Gangue minerals: Coal, coal ash

Geologic description:

Metalliferous coal beds occur in small, semi-closed basins along the lower Ray River immediately west of the Fort Hamlin Hills pluton and east of the Ray River pluton (Barker, 2006). Both plutons are considered part of the broad, northeast-trending, peraluminous Ruby Batholith of central Alaska (Patton and Miller, 1973; Barker and Foley, 1986). Generally the granitic rocks are coarse-grained, equigranular to porphyritic, orthoclase-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been locally recognized. The granitic rocks cut Paleozoic schist, phyllite, quartzite, and lesser greenstone and limestone. The Ray River coal-bearing basins are part of a regional series of Tertiary basins that occur intermittently along the southeast margin of the batholith.

Along the lower Ray River the small, semi-closed basins, are mapped as graben features and range from several square miles in area to as little as 200 acres (Barker, 1991b, 2006). Metals are found highly concentrated in the calcium-rich coal ash derived from the coal. When prepared according to American Society for Testing Materials (ASTM, 1979) standards, ash samples will contain 0.01 to in excess of 1.0 percent each of germanium, lead, and tungsten. Ash samples also contain up to 0.5 percent total rare earth elements, and up to 0.1 percent antimony, copper, gallium, molybdenum, uranium, and zirconium. Gold and silver values are also present. All samples are variably mineralized within these limits (Barker, 2006). Tungsten in particular is consistently present with over half of the 21 samples analyzed found to contain in excess of 0.25 percent W.

The coal beds are poorly exposed and only several small rubble crops were located. However, during high water events the Ray River will rip coal fragments from the coal beds within the mudstone and conglomerate section that comprises the shallow bedrock under the river alluvium in this region. Most of the

samples comprise random chip collections of fresh material found on gravel bars following spring breakup and the accompanying seasonal high water.

Alteration:

Metal values in coal appear related to a northeast-trending series of geothermal springs that altered and mineralized the organic material during and/or after the coal-forming period, a process that was perhaps accentuated by overlying fissure basalt flows. Phosphoric alteration at the underlying contact of the basalt flows was mapped at an outcrop on the Ray River (Barker, 2006). Known geothermal springs extend about 65 miles N 60 E from Ishtalitna Creek on the southwest to the Dall River on the northeast and are assumed to correlate to a splay of the Porcupine-Kaltag fault.

Age of mineralization:

A sample of tephra from the Coal Creek-Dall River section was dated at 38.6 +/- 1.6 Ma (Barker, 1981). Albanese, 1987, reported an age of 30.59 m.y. +/- 0.92 Ma for the basalt flows at a location nearer the Dalton Highway and immediately east of the Ray River. Coal from the Ft. Hamlin Hills area is estimated to be Eocene in age.

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The site was explored by the U.S. Bureau of Mines as part of the Critical and Strategic Minerals Program in the 1970s-1980s (Barker, 1981, 1991b, 2006; Barker and Foley, 1986). All coal rank analyses and preparation of 21 coal ash samples were done by the University of Alaska, Mineral Industry Research Laboratory. Metal values were determined by certified commercial laboratories.

Coal in the Fort Hamlin Hills area, when fresh, will break with a conchoidal fracture and will have an apparent rank of high-volatile, lignite A to subbituminous B, generally with a 6-10 weight percent ash yield. Maceral composition is dominated by vitrinite. Higher metal values of the Fort Hamlin area coal beds occur in higher sulfur (greater than 1.4 percent) coals underlying the Ray River valley as compared to nonmineralized low-sulfur coal in the Dall River valley to the northeast and elsewhere in interior Alaska, although mudstone beds stratigraphically above the Dall River coal beds are enriched in these same metals (ARDF number BV005).

Microprobe studies suggest the finely disseminated mineralization found in coal of the Ray River valley mostly occurred in peat bogs prior to, or concurrent with, diagenesis and coal formation (Barker, 2006). Mineralization is likely related to geothermal activity associated with rifting in a granitic terrane and volcanism. Water samples from six of the seven known nearby hot springs/warm springs were tested and determined to contain anomalous levels of tungsten. Mineralization processes affecting the original peat accumulations, or within the coal beds, were likely accentuated due to Oligocene fissure basalts that entrapped the geothermal waters in the coal-forming section. To the northeast mudstones in the Dall River-Coal Creek area contain elevated tungsten likely concentrated during formation of lacustrine deposits in shallow lakes fed by geothermal water and intermittently covered by ash falls; however, associated coal beds were not mineralized (Barker,1981, 2006).

Production notes:

None.

Reserves:

None.

Additional comments:

The Fort Hamlin Hills coal occurrences are on lands on which the State of Alaska has filed 'Priority Selection' under the land entitlement provision of the 1959 Statehood Act. Most of this occurrence lies within the 'inner corridor' of the Trans-Alaska Pipeline as defined by the Bureau of Land Management (BLM). Various temporary land withdrawals remain to be lifted by the BLM before these selections can be processed. The BLM will not issue any permits for surface disturbance activities including exploration.

Location description and accuracy:

The Coal Creek uranium-tungsten occurrence outcrops in the south bank of Coal Creek approximately one-half mile above its confluence with the Dall River. The occurrence is in the NE¼NE¼ sec. 11, T. 17 N., R. 11 W., of the Fairbanks Meridian. The site is accurate within 1,000 feet. The Coal Creek occurrence is located about 12 miles east of the Trans Alaska Pipeline.

Geologic description:

A coal-bearing semi-closed Miocene basin, about four miles across and elongate in a NE-SW orientation, occurs along the Dall River and centers about 66.3384, 149.8300. The crude NE orientation of the basin appears to follow a regional suture feature. At the site interbedded, water-lain, white to green tuff and manganese-coated gray mudstone are exposed in a series of low cutbanks along the south side Coal Creek (Barker, 1981, 2006). A 12-foot vertical section of bedrock was exposed by trenching, then mapped, and sampled. Disseminated grains of carbonized organic matter and increased radioactivity were noted in the mudstone beds. The mudstone layers reported about 400 to 450 cps cf. to background of 70 to 90 cps on a handheld scintillation counter. Associated coal seams were also drilled and reported (Barker, 1981, 2006).

Channel samples that were cut through individual mudstone beds contain 20 to 50 parts per million (ppm) uranium and up to 190 ppm tungsten (Barker, 1981, 2006). Values for arsenic, barium, cerium, cesium, copper, phosphorous, and thorium were elevated as well. Samples cut across the interbedded tuff beds were only slightly elevated with uranium and tungsten. The presence of elevated tungsten is unexplained but may be related to a similar origin as the highly elevated tungsten values in coal ash from coal beds under the Ray River about 20 miles to the southwest (Barker, 2006). A sample tested for phosphorous oxide reported 1.6 percent. Phosphorous as vivianite and hydroxylapatite were identified in the Coal Creek area.

The sedimentary section appears to form the tundra-covered south bank of the creek for at least 1,000 feet to the west before being lost under permafrost silt and thicker tundra. A coal-bearing sequence observed about 800 feet to the west of the site tentatively appears to underlie the mudstone and tuff section. Several auger holes were drilled into the coal and cut 18 feet of subbituminous coal (Barker, 1981).

Rubble exposures of quartz arenite were noted about one-half mile to the northeast where it was exposed in the trace of the old winter trail (Hickel Highway). Slightly radioactive, hematitic sandstone with plant trash (3-5 percent) in a porous groundmass occurs about 2,000 feet to the north of the site and is also exposed as scant rubble along the trace of the old winter trail. Beyond the west margins of the Dall River basin, the sedimentary basin is covered by basalt flows. To the east, the basin appears to daylight and overlie basement Paleozoic phyllite and limestone that is locally intruded by granitic rocks of the Coal Creek pluton. There was no outcrop or rubble to the southeast along the Dall River but a small tributary stream about 4 miles downstream of the site reported 185 ppm uranium in the sediment.

Workings/exploration:

In 1978 and 1979, the U.S. Bureau of Mines (USBM) examined the Dall River area as part of the statewide mineral resource studies of areas proposed for inclusion in federal parks and wildlife refuges. The work was in conjunction with the investigation of tin and REE mineralization including the Coal Creek and Fort Hamlin Hills plutons (Barker and Foley, 1986). The USBM collected rock samples for geochemical analysis, conducted a heavy mineral survey, and mapped mineral occurrences. Sample analyses were provided by the National Uranium Resource Evaluation program and samples were processed in Los Alamos (Averett and Barker, 1981). In the Dall River area the USBM drilled several coal seams and examined the area for sandstone-hosted uranium (Barker, 1981, 2006).

Production notes:

None.

Site type:

Mine

ARDF no.: CA002

Latitude: 65.2082 **Quadrangle:** CA A-5

Longitude: 161.1639

Location description and accuracy:

The Dime Creek gold placer is just east of the village of Haycock, which is about 19 miles north of the village of Koyuk on Norton Sound. The gold placer flows through the east half of sections 20 and 29 and the west half of section 21 and 28 of T. 3 S., R. 12 W.

Commodities:

Main: Au

Other: Pt

Ore minerals: Gold, PGE minerals

Gangue minerals:

Geologic description:

There is little rock exposed in the Dime Creek area but the creek appears to generally parallel a fault (?) contact between Paleozoic metamorphosed limestone and Jurassic-Cretaceous andesite flows (Patton, 1967). The flows are intruded by small, mafic and ultramafic plutons.

Bundtzen (2009) tabulated the gold production by year as best the data allows but production records are lacking for many years. He estimates that at least 3,391 ounces of gold was produced by dredging from 1918 to 1941 and at least 36,000 ounces of gold were produced by drift mining and other hand methods from 1915 to 1955, the last year of mining. However, other estimates put the total as high as 60,000 ounces of gold.

The gold occurs both along the modern stream channel and along benches Bundtzen, 2009). The benches are thought to be caused by wave action. The gold in the placers is mainly on metamorphosed andesite bedrock but some is in the overlying 2 to 3 feet of gravel. Harrington (1919) reported gold values as high as $2 per square foot of bedrock. On both creek and bench claims the overburden varies from 10 to 30 feet thick; all of the ground was frozen. Heavy minerals in the concentrate include iron-oxides, abundant chrome spinel, olivine, pyroxene, rare garnet, and rutile (Harrington, 1919).

The placers also contained platinum in about the ratio of one ounce of platinum to 200 ounces of gold (Bundtzen, 2009). Analysis of platinum-group minerals in the placer concentrates showed them to consist of 88.8 percent platinum, 14.7 percent iridium, 4.3 percent osmium and iridium, 1.1 percent rhenium, and 1.1 percent palladium (Mertie, 1969). The placer deposits in the upper portion of the creek produced almost twice as much platinum as the lower claims.

Linux Gold Corp. located 12 mining claims on Dime Creek in March 2005, and initiated surface geology studies and sampling in August 2005. Bundtzen (2009) on behalf of Linus estimated that there remains about 1,125,000 cubic yards of unmined auriferous gravel, but the data is not sufficient to estimate its grade.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Placer Au-PGE (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Dime Creek placers were mined intermittently from 1915 until 1955. The placers were worked mostly by drift and open-cut mining. A small dredge operated from 1918 to 1941. Linux Gold Corp. located 12 mining claims on Dime Creek in March 2005, and initiated surface geology studies and sampling in August 2005.

Production notes:

Bundtzen (2009) tabulated the gold production by year as best the data allows, but production records are lacking for many years. He estimates that at least 3,391 ounces of gold was produced by dredging from 1918 to 1941 and at least 36,000 ounces of gold were produced by drift mining and other hand methods from 1915 to 1955, the last year of mining. However, other estimates put the total as high as 60,000 ounces of gold. If 1 ounce of platinum was recovered for every 200 ounces of gold, Dime Creek produced about 200 to 300 ounces of platinum-group metals.

Reserves:

Bundtzen, (2009) estimated that there remains about 1,125,000 cubic yards of unmined auriferous gravel, but the data is not sufficient to estimate its grade.

Site name(s): Gossan

Site type: Prospect

ARDF no.: CA011

Latitude: 65.4201 **Quadrangle:** CA B-5

Longitude: 161.353

Location description and accuracy:

The Gossan prospect is at an elevation of about 780 feet on the south end of Gossan Ridge. It is about 3.7 miles west-southwest of the top of Granite Mountain and about 0.5 mile north-northwest of the center of section 9, T. 1 S., R. 13 W., of the Kateel River Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Bi, Cu, Mo, Pb, Sb, Th, U, W, Zn

Other:

Ore minerals: Arsenopyrite, bismuthinite, chalcopyrite, galena, molybdenite, pyrargyrite, pyrite, pyrrhotite, scheelite, sphalerite, stibnite, uranothorianite

Gangue minerals: Carbonates, fluorite, quartz

Geologic description:

As initially described by Miller and Elliott (1969) this prospect is near the border of the mid-Cretaceous Quartz Creek pluton, a hook-shaped, quartz monzonite body at least 16 miles long and up to a mile wide. The pluton is surrounded by an alteration zone 2 to 5 miles wide that is marked by numerous mineral occurrences along the entire length of the pluton. The alteration zone is in Jurassic-Cretaceous andesitic volcanic and sedimentary rocks. Fine-grained dikes of varying composition cut the andesite near the pluton.

In 2005, the Linus Gold Corp. began work in the area and by 2006 had staked 176 Alaska (state) claims that covered this prospect and others along the 'Kiwalik trend' of mineralization that roughly coincides with the Quartz Creek pluton and its alteration zone. Exposures are poor in the area and their initial work relied heavily on soil geochemistry and surface sampling. As described by Adams (2007), there are several types of mineralization, many occurring together, along the Kiwalik trend: 1) sulfide-tourmaline-quartz veins with galena, sphalerite, and pyrite and locally minor arsenopyrite, pyrrhotite, chalcopyrite, and molybdenite; 2) disseminated pyrite and arsenopyrite in hairline veinlets that also locally contain sparse galena, stibnite, and bismuthinite; 3) sulfide-rich veins and veinlets with various assemblages of pyrite, pyrrhotite, chalcopyrite, arsenopyrite, sphalerite, galena, stibnite, molybdenite, and pyrargyrite, 4) pyrite-chlorite-calcite-quartz veins, 5) sulfide-quartz veins and stockworks with pyrite, pyrrhotite, arsenopyrite, galena, stibnite, sphalerite, chalcopyrite, and scheelite, and 6) fluorite-molybdenite-galena-pyrite-uranothorianite veinlets and disseminations. There are several distinct types of alteration: 1) phyllic, 2) silicification, 3) carbonate, 4) argillic, 5) propylitic, 6) tourmalinization, 7) alunitic, and 8) potassic. Gossans with remnant galena and sphalerite are found locally.

In 2006, Linus drilled 2 holes at the Gossan prospect where the surface is mostly rubble crop of andesite, basalt, dacite, epiclastic rocks, and gossan. The rocks at the surface and in the drill holes are characterized by pervasive propylitic alteration of the mafic volcanic rocks, quartz-sericite+/-carbonate alteration of the dacite, and irregular zones of silicification, carbonate alteration, and sericitization of the massive syenite that was intersected at a depth of 880 feet in one hole. The drill holes intersected several types of mineralization: 1) multiple 2- to 20-meter-thick zones of disseminated sulfides and veinlets in interlayered dacite, andesite tuff, and siltstone; 2) ubiquitous disseminated pyrite and pyrite-chlorite -actinolite-calcite-quartz veinlets; 3) sulfide-tourmaline-quartz veins, veined breccias, and massive tourmaline replacement in

zones less than one meter thick; and 4) sulfide-rich veins and breccias in several zones. The sulfides include variable amounts of arsenopyrite, pyrite, galena, and stibnite. The best intercept in the two drill holes was 5 feet that contained 204 parts per billion gold; many intercepts contained significant values in silver, bismuth, molybdenum, copper, thorium, uranium, lead, and antimony.

Alteration:

The rocks in the drill holes at the Gossan prospect are characterized by pervasive propylitic alteration of the mafic volcanic rocks, quartz-sericite+/-carbonate alteration of the dacite, and irregular zones of silicification, carbonate alteration, and sericitization of syenite.

Age of mineralization:

Cretaceous of younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Disseminated and veined, Ag-As-Au-Bi-Cu-Mo-Pb-Sb-Th-U mineralization in several styles that occurs widely for 16 miles along the altered border zone of a Cretaceous quartz monzonite pluton.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was discovered by the U.S. Geological Survey in the late 1960s (Miller and Elliott, 1969). It was subsequently examined by several companies. In 2005, the Linus Gold Corp. began work in the area and by 2006 had staked 176 Alaska (state) claims that covered this project and others along the 'Kiwalik trend' that roughly coincides with the Quartz Creek pluton and its alteration zone. Exposures are poor in the area and their initial work relied heavily on soil geochemistry and surface sampling. In 2006, Linus drilled two holes on the Gossan prospect.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (upper Peace River)

Site type: Prospect

ARDF no.: CA013

Latitude: 65.4544 **Quadrangle:** CA B-5

Longitude: 161.0809

Location description and accuracy:

This prospect is on the north side of the headwaters of the Peace River, about 4.8 miles east-northeast of the top of Granite Mountain. It is about 0.6 mile southwest of the center of section 25,T. 1 N., R. 12 W., of the Kateel River Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Mo, Pb, W

Other: Bi, Cr, Th, U, Zn

Ore minerals: Bornite, galena, chalcopyrite, chromite, ferrimolybdite, gold, gummite, molybdenite, pyrite, pyrrhotite, scheelite, sphalerite, tetradymite, uranothorianite

Gangue minerals: Fluorite, hematite, magnetite, quartz

Geologic description:

The upper Peace River area is underlain by a small satellitic stock of the Late Cretaceous Granite Mountain pluton. The stock is composed of several varieties of syenite. Locally, the syenite is cut by quartz veins and contains abundant disseminated pyrite cubes, some fine-grained molybdenite, and abundant magnetite and purple fluorite. A canary-yellow alteration product found both in the veins and in the syenites was identified as ferrimolybdite. The syenite is bleached, oxidized, and contains disseminated pyrite, and where it is cut by quartz-pyrite veins, sporadic molybdenite. The syenite and associated quartz veins locally contain anomalous amounts of molybdenum, bismuth, silver, copper and lead. Numerous rock and soil samples were collected from this area by Miller and Elliott (1969). One rock sample contained: 150 parts per million (ppm) silver, 30 ppm molybdenum, 3,000 ppm lead, 700 ppm copper, and 0.04 ppm gold. Another rock sample contained: 1.5 ppm silver, greater than 2,000 ppm molybdenum, 500 ppm copper, and 300 ppm lead. Both were grab samples of oxidized syenite.

Gault and others (1953) collected pan-concentrate stream-sediment samples from this area in their search for uranium. Their samples contained anomalously high concentrations of uranothorianite and other metallic minerals, including galena, chalcopyrite, bornite, tetradymite, sphalerite, pyrite, and pyrrhotite. Intergrowths of galena, sphalerite, chalcopyrite, pyrite, and gummite were observed in some mineral grains. The mineral associations suggested to them that the uranium minerals are derived from a sulfide-bearing lode (or vein), rather than occurring as accessory minerals in in granitic rocks.

Linux Gold Corp. (2007) located 16 mining claims on this prospect in March 2005 and began mapping the geology at the surface and sampling in August, 2005 (Linux Gold Corporation 2007). As described by Adams (2007), the deposit is associated with a small stock of pinkish, fine- to medium-grained Cretaceous hornblende-biotite nepheline syenite that intrudes undifferentiated volcanic rocks. The exposure in the area is poor but the stock is at least a half mile across. Garnet-bearing syenite crops on the ridge to the northeast.

The mineralization is largely hosted in the syenite but locally occurs in pyroxenite or altered andesite near the contact of the stock. Gossans occur locally. The syenite has undergone weak to strong phyllic alteration and is locally intensely silicified. Five types of mineralization are recognized: 1) weakly altered syenite with sparse disseminated sulfides, 2) altered syenite with well-developed sulfides, 3) altered syenite with quartz-sulfide veinlets, 4) highly altered syenite with sulfide veinlets, and 5) highly silicified syenite

breccia with disseminated sulfides. The sulfides are ubiquitous fine-grained pyrite and locally fine-grained molybdenite, often accompanied by fluorite. Surface oxidation has formed hematitic surface coatings and hematite along fracture fillings; locally, bright-yellow ferromolybdite from the oxidation of molybdenite is abundant. Samples of the syenite contain highly anomalous silver, lead, bismuth, copper, tungsten, antimony, uranium, and thorium. Four samples contained up to 306 parts per billion gold, 83.3 parts per million (ppm) silver, 900 ppm arsenic, 139 ppm bismuth, 6,290 ppm copper, 1,135 ppm molybdenum, 144 ppm lead, 1,001 ppm antimony, 10.9 ppm tin, 137.5 ppm thorium, 46.20 ppm uranium, 190.50 ppm tungsten, and 1,155 ppm zinc.

Adams (2007) considers the mineralization to be a highly fractionated, alkaline porphyry-Mo deposit, prospective for uranium and rare-earth elements.

Alteration:

The syenite that hosts the mineralization has undergone weak to strong phyllic alteration and is locally intensely silicified.

Age of mineralization:

Probably Late Cretaceous.

Generic deposit model:

Deposit model:

Highly-fractionated alkaline porphry-molybdenum deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The area was mapped by the U.S. Geological Survey and examined by various exploration companies beginning in the 1950s. Linux Gold Corp. located 16 mining claims on this prospect in March 2005 and initiated surface geology studies and sampling in August, 2005. Surface and geochemical work continued in 2006.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (at head of Quartz Creek); Saddle

Site type: Prospects

ARDF no.: CA016

Latitude: 65.4723 **Quadrangle:** CA B-5

Longitude: 161.3395

Location description and accuracy:
These prospects are at an elevation of about 1,250 feet on a ridge between the headwaters of Kiwalik River and Quartz Creek. The site is in section 22, T. 1 N., R. 13 W., of the Kateel River Meridian. It is location 32, figure 2 of Miller and Elliot (1969).

Commodities:

Main: Ag, Au, Pb, Zn

Other: As, B, Cd, Co, Cu, Mn, W

Ore minerals: Argentiferous galena, arsenopyrite, chalcopyrite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, quartz, tourmaline

Geologic description:
This area is on the eastern Seward Peninsula where base metal, silver, and some gold-bearing mineralization occurs in a 4 x 16 kilometer belt of hydrothermally altered, hornfelsed andesite and intrusive rocks. The Cretaceous andesitic volcanic rocks are locally intruded by andesitic dikes and elongate stocks of monzonite, syenite, and quartz monzonite. A swarm of subparallel aplite and monzonite dikes and a small rhyolite stock locally intrude the mineralized belt. Mineralization and alteration are localized in structurally down-dropped blocks adjacent to coarse-grained intrusions that include the large, composite Granite Mountain pluton about 3 kilometers to the southeast.

The mineralization was originally discovered by the U.S. Geological Survey in the 1960s (Miller and Elliott, 1969). Greatland Exploration Ltd. explored this prospect in the 1970s and still holds mining claims in the area (Ron Sheardown, oral communication, 2005). This exploration included geologic mapping, stream-sediment surveys, grab sampling of rocks and soils, two local soil geochemical surveys, and four short diamond drill holes. The four drill holes are in one area, total 449 meters in length, and reached vertical depths of 50 to 126 meters. Attempts to obtain geophysical data were inconclusive.

Argentiferous galena, sphalerite, pyrite, arsenopyrite, and minor chalcopyrite occur in veins and disseminations both in volcanic hornfels and intrusive rocks (Miller and Elliott, 1969). The sulfide minerals commonly are in quartz-tourmaline veins and replacements. Massive pyrrhotite with some chalcopyrite locally replaces volcanic hornfels. Sphalerite-, galena-, and chalcopyrite-bearing calcite veins are widely scattered through the mineralized belt. Sulfide mineralization commonly is structurally controlled along fractures, faults, and shear zones that cut all bedrock units. Placer gold was recovered from Quartz Creek for many years.

Highly anomalous lead, zinc, silver, copper and boron are common in stream sediments of upper Quartz Creek and its tributaries. Rock and soil samples from the area contain up to 300 parts per million (ppm) silver, 1 ppm gold, more than 10,000 ppm arsenic, more that 10,000 ppm boron, more than 500 ppm cadmium, 2,000 ppm cobalt, 2,000 ppm copper, more than 5,000 ppm manganese, more than 19 percent lead, 100 ppm scandium, and more than 5 percent zinc. One sample contained more than 10,000 ppm tungsten. Soil surveys identified several highly anomalous zones including one 1.3 x 1.4 kilometer area, open on one side, where lead values exceed 200 ppm and zinc values exceed 300 ppm; many lead and zinc values exceed 1,000 ppm in this area. Gold was commonly not determined in the early geochemical

investigations.

In 2005, Linus Gold Corporation (2007, Anomalies) began work in the area by staking about 30 square miles of claims, followed by a geologic reconnaissance, rock sampling and a geochemical soil survey that defined several anomalous areas in base and precious metals. Linus carried out considerable work in the area in the summer of 2006, including 4 diamond drill holes that totaled 2,970 feet. All the drill holes intersected altered, mineralized volcanic rocks that were cut by dikes or sills of syenite and granodiorite that were in turn cut by thin rhyolite to dacite dikes. A new gold prospect in intensely altered plutonic rocks was found at the surface near Quartz Creek; grab samples contained 114 to 325 parts per billion (ppb) gold, 10.6 to 35.4 ppm silver, up to 872 ppm copper, and 2.1 percent combined lead and zinc. Surface samples at the Saddle prospect contained up to 2.58 grams of gold per ton, 250 grams of silver per ton, and 3.0 percent lead and zinc.

Alteration:

Volcanic hornfels and intrusive rocks are variably altered and are cut by sulfide, calcite, and quartz-tourmaline veins. Volcanic hornfels and intrusive rocks are locally intensely replaced by sericite, pyrite, quartz, and tourmaline. Late carbonate veins and replacements cut intrusive rocks and scapolite is a common alteration mineral in volcanic rocks. Oxidation is extensive and gossan zones characterize the 4 kilometer by 16 kilometer mineralized belt.

Age of mineralization:

Late Cretaceous.

Generic deposit model:

Deposit model:

Sulfides with gold values in altered andesite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Last report date: 2007-04-08

Site name(s): Nortz

Site type: Prospect

ARDF no.: CA025

Latitude: 65.5318 **Quadrangle:** CA C-5

Longitude: 161.4002

Location description and accuracy:

This records includes several prospects exposed in outcrops for about a mile and a half along the west side of the south fork of upper Quartz Creek. The center of these occurrences is about 0.5 mile east of the center of section 32, T. 2 N., R. 13 W., of the Kateel River Meridian. The location is accurate.

Commodities:

Main: Ag, Pb, Zn

Other: Au, Cu

Ore minerals: Arsenopyrite, bismuthinite, chalcopyrite, galena, molybdenite, pyrargyrite, pyrite, pyrrhotite, scheelite, sphalerite, stibnite, uranothorianite

Gangue minerals: Carbonates, fluorite, quartz

Geologic description:

Many of the outcrops for about a mile and a half along the west side of the south fork of upper Quartz Creek are mineralized. This mineralization was first recognized by Miller and Elliott (1969) who sampled many of the outcrops. Some of their higher grade samples contained: 1) 7 parts per million (ppm) silver, 1 percent arsenic, 500 ppm copper, 1 percent lead, and 200 ppm zinc; 2) 7 ppm silver, greater than 1 percent arsenic, 150 ppm copper, 0.7 percent lead, and 700 ppm zinc; 3) 50 ppm silver, 2,000 ppm copper, greater than 2 percent lead, and greater than 1 percent lead; 4) up to 200 ppm silver, up to 1,000 ppm copper, greater than 2 percent lead, and greater than 1 percent zinc; 5) 150 ppm silver, 700 ppm copper, 15 ppm molybdenum, greater than 2 percent lead, and greater than 1 percent zinc.

The Nortz prospect is near the border of the mid-Cretaceous Quartz Creek pluton, a hook-shaped, quartz monzonite body at least 16 miles long and up to a mile wide. The pluton is surrounded by an alteration zone 2 to 5 miles wide that is marked by numerous mineral occurrences along the entire length of the pluton. The alteration zone is in Jurassic-Cretaceous andesitic volcanic and sedimentary rocks. Fine-grained dikes of varying composition cut the andesite and sedimentary rocks near the pluton.

The mineralization along Quartz Creek was examined by numerous geologists after its discovery and in 2005 the Linus Gold Corp. began work in the area. By 2006 they had staked 176 Alaska (state) claims that covered this prospect and others along the 'Kiwalik trend' of mineralization that roughly coincides with the Quartz Creek pluton and its alteration zone (Adams, 2007). They drilled several of the prospects along the belt to the south (see CA011, CA051, and CA052) and briefly examined the Nortz prospect at the north end of their claims and collected one sample. They describe the rocks as hornfelsed, highly sheared, highly mineralized, mafic volcanic rocks that are characterized by phyllitic alteration and tourmalinization. The rocks contain zones with abundant veins and stockworks that contain pyrite, calcite, quartz, arsenopyrite, stibnite, and galena. The sample contained 325 parts per billion gold, 34.5 ppm silver, 16,450 ppm lead, 449 ppm antimony, 872 ppm copper, and 4,345 ppm zinc.

Although Linus only briefly described this prospect, it is undoubtedly similar to the others to the south along the Kiwalik trend. Adams (2007) defines several types of mineralization along the belt, many occurring together: 1) sulfide-tourmaline-quartz veins with galena, sphalerite, and pyrite and locally minor

arsenopyrite, pyrrhotite, chalcopyrite, and molybdenite; 2) disseminated pyrite and arsenopyrite in hairline veinlets that also locally contain sparse galena, stibnite, and bismuthinite; 3) sulfide-rich veins and veinlets with various assemblages of pyrite, pyrrhotite, chalcopyrite, arsenopyrite, sphalerite, galena, stibnite, molybdenite, and pyrargyrite, 4) pyrite-chlorite-calcite-quartz veins, 5) sulfide-quartz veins and stockworks with pyrite, pyrrhotite, arsenopyrite, galena, stibnite, sphalerite, chalcopyrite, and scheelite, and 6) fluorite-molybdenite-galena-pyrite-uranothorianite veinlets and disseminations. There are several distinct types of alteration associated with the mineralization: 1) phyllitic, 2) silicification, 3) carbonate, 4) argillic, 5) propylitic, 6) tourmalinization, 7) alunitic, and 8) potassic. Gossans with remnant galena and sphalerite are found locally.

Alteration:

Phyllitic alteration and tourmalinization of the mafic volcanic host rocks.

Age of mineralization:

In the alteration zone of a Late Cretaceous quartz monzonite pluton.

Generic deposit model:

Deposit model:

Disseminated and veined, Ag-As-Au-Bi-Cu-Mo-Pb-Sb-Th-U mineralization in several styles that occurs widely for 16 miles along the altered border zone of a Cretaceous quartz monzonite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was discovered by the U.S. Geological Survey in 1969 and examined by numerous private geologists in succeeding years. In 2005, Linus Gold Corp. began work in the area and by 2006 had staked 176 Alaska claims that covered this prospect and others along the 'Kiwalik trend' that roughly coincides with the Quartz Creek pluton and its alteration zone. They drilled several of the prospects to the south along the Kiwalik trend and visited and sampled this prospect.

Production notes:

None.

Reserves:

None.

Site name(s): Gusty

Site type: Prospect

ARDF no.: CA051

Latitude: 65.4434 **Quadrangle:** CA B-5

Longitude: 161.3749

Location description and accuracy:

The Gusty prospect is about 0.4 mile east of hill 1431 and about 4.6 miles west-northwest of the top of Granite Mountain. It is about 0.3 mile south-southwest of the center of section 33, T. 1 N., R. 13 W, The location is accurate.

Commodities:

Main: Ag, As, Au, Bi, Cu, Mo, Pb, Sb, Th, U, W, Zn

Other:

Ore minerals: Arsenopyrite, bismuthinite, chalcopyrite, galena, molybdenite, pyrargyrite, pyrite, pyrrhotite, scheelite, sphalerite, stibnite, uranothorianite

Gangue minerals: Carbonates, fluorite, quartz

Geologic description:

The Gutsy prospect is near the border of the mid-Cretaceous Quartz Creek pluton, a hook-shaped, quartz monzonite body at least 16 miles long and up to a mile wide. The pluton is surrounded by an alteration zone 2 to 5 miles wide that is marked by numerous mineral occurrences along the entire length of the pluton. The alteration zone extends into Jurassic-Cretaceous andesitic volcanic and sedimentary rocks around the pluton. Fine-grained dikes of varying composition cut the andesite near the pluton.

In 2005, the Linus Gold Corp. began work in the area and by 2006 had staked 176 Alaska claims that covered this prospect and others along the 'Kiwalik trend' of mineralization that roughly coincides with the Quartz Creek pluton and its alteration zone. Exposures are poor in the area and their initial work relied heavily on soil geochemistry and surface sampling. The Gutsy prospect is similar to most of the rest of the deposits along the Kiwalik trend. As described by Adams (2007), there are several types of mineralization, many occurring together: 1) sulfide-tourmaline-quartz veins with galena, sphalerite, and pyrite and locally minor arsenopyrite, pyrrhotite, chalcopyrite, and molybdenite; 2) disseminated pyrite and arsenopyrite in hairline veinlets that also locally contain sparse galena, stibnite, and bismuthinite; 3) sulfide-rich veins and veinlets with various assemblages of pyrite, pyrrhotite, chalcopyrite, arsenopyrite, sphalerite, galena, stibnite, molybdenite, and pyrargyrite, 4) pyrite-chlorite-calcite-quartz veins, 5) sulfide-quartz veins and stockworks with pyrite, pyrrhotite, arsenopyrite, galena, stibnite, sphalerite, chalcopyrite, and scheelite, and 6) fluorite-molybdenite-galena-pyrite-uranothorianite veinlets and disseminations. There are several distinct types of alteration: 1) phyllitic, 2) silicification, 3) carbonate, 4) argillic, 5) propylitic, 6) tourmalinization, 7) alunitic, and 8) potassic. Gossans with remnant galena and sphalerite are found locally.

The Gutsy prospect was discovered by Linus in 2005 (Adams, 2007). The rocks are poorly exposed at the surface, mainly as rubble, but include quartz monzonite cut by syenite and granodiorite dikes and hornfelsed mafic rocks along the contact of the quartz monzonite. A small bedrock exposure nearby in the creek consists of massive hornfelsed basalt with numerous sulfide-calcite-quartz veins. Linus drilled one hole in 2006 to a depth of 767 feet. The mineralization at the surface and in the drill hole consists of localized zones of sulfide-tourmaline-quartz veinlets, sulfide disseminations, and semi-massive sulfide veins. The top of the hole was in altered syenite, the lower portion in granodiorite dikes and hornfels. The rocks are characterized by pervasive silicification and phyllitic alteration in the syenite at the top and by propylitic

alteration and silicification in the volcanic rocks at the bottom. The syenite-hosted mineralization consists of pyrite-arsenopyrite-stibnite disseminations and stockwork veinlets that form a halo around a narrow interval of pyrrhotite-tourmaline-quartz veins. Semi-massive sulfide veins and veined breccia occur in andesite and hornfels below the syenite. The massive sulfides consist of a complex intergrowth of pyrrhotite, chalcopyrite, arsenopyrite, sphalerite, argentiferous galena, and possibly pyrargyrite and stibnite. Two samples collected at the surface contained 10 and 177 parts per billion (ppb) gold, 0.2 and 24.30 parts per million (ppm) silver, 17 and more than 1,000 ppm arsenic, 1.1 and 113.50 ppm bismuth, 264.4 and 1,405 ppm copper, 26.9 and 1,800 ppm lead, 6.1 and 107 ppm antimony, 7 and 7.9 ppm tin, 4 and 2.80 ppm thorium, 1.7 and 1.00 ppm uranium, 1 and 3.50 ppm tungsten, and 115 and 2,010 ppm zinc. The best intercept in the drill hole was 40 feet that contained 84.75 ppb gold, 2.63 ppm silver, 105 ppm copper, 730 ppm lead, 190 ppm antimony, 786 ppm thorium, 3.1 ppm uranium, and 4,461 ppm zinc.

Alteration:

The rocks in the drill hole at the Gutsy prospect are characterized by pervasive silicification and phyllitic alteration in the syenite in the upper part of the hole and by zones of propylitic alteration and silicification in the volcanic rocks in the bottom part.

Age of mineralization:

Cretaceous or younger based on the age of the host rocks; possibly genetically related to nearby Cretaceous plutons.

Generic deposit model:

Deposit model:

Disseminated and veined, Ag-As-Au-Bi-Cu-Mo-Pb-Sb-Th-U mineralization in several styles that occurs widely for 16 miles along the altered border zone of a Cretaceous quartz monzonite pluton.

Site name(s): Saddle

Site type: Prospect

ARDF no.: CA052

Latitude: 65.4648 **Quadrangle:** CA B-5

Longitude: 161.3861

Location description and accuracy:

The prospect is just east of Weather Ridge in the saddle at the divide between the head of the Kiwalik River and the western headwater tributary to Quartz Creek. It at an elevation of about 1,210 feet, about 0.5 mile north-northwest of the center of section 28, T. 1 N., R. 13 W.

Commodities:

Main: Ag, As, Au, Bi, Cu, Mo, Pb, Sb, Th, U, W, Zn

Other:

Ore minerals:

Gangue minerals: Carbonates, fluorite, quartz

Geologic description:

The Saddle prospect is near the border of the mid-Cretaceous Quartz Creek pluton, a hook-shaped, quartz monzonite body at least 16 miles long and up to a mile wide. The pluton is surrounded by an alteration zone 2 to 5 miles wide that is marked by numerous mineral occurrences along the entire length of the pluton. The alteration zone is in Jurassic-Cretaceous andesitic volcanic and sedimentary rocks. Fine-grained dikes of varying composition cut the andesite near the pluton.

In 2005, the Linus Gold Corp. began work in the area and by 2006 had staked 176 Alaska (state) claims that covered this prospect and others along the 'Kiwalik trend' of mineralization that roughly coincides with the Quartz Creek pluton and its alteration zone. Exposures are poor in the area and Linus's initial work relied heavily on soil geochemistry and surface sampling. The Saddle prospect is similar to most of the rest of the deposits along the Kiwalik trend. As described by Adams (2007), there are several types of mineralization, many occurring together: 1) sulfide-tourmaline-quartz veins with galena, sphalerite, and pyrite and locally minor arsenopyrite, pyrrhotite, chalcopyrite, and molybdenite; 2) disseminated pyrite and arsenopyrite in hairline veinlets that also locally contain sparse galena, stibnite, and bismuthinite; 3) sulfide-rich veins and veinlets with various assemblages of pyrite, pyrrhotite, chalcopyrite, arsenopyrite, sphalerite, galena, stibnite, molybdenite, and pyrargyrite, 4) pyrite-chlorite-calcite-quartz veins, 5) sulfide-quartz veins and stockworks with pyrite, pyrrhotite, arsenopyrite, galena, stibnite, sphalerite, chalcopyrite, and scheelite, and 6) fluorite-molybdenite-galena-pyrite-uranothorianite veinlets and disseminations. There are several distinct types of alteration: 1) phyllic, 2) silicification, 3) carbonate, 4) argillic, 5) propylitic, 6) tourmalinization, 7) alunitic, and 8) potassic. Gossans with remnant galena and sphalerite are found locally.

The Saddle prospect was discovered by Linus in 2005 (Adams, 2007). It is in the east contact zone of the quartz monzonite pluton; the rocks at the surface are a volcanic assemblage of andesitic and dacitic rock and interbedded epiclastic rocks. The rocks are widely chloritized and locally tourmalinated, silicified, and carbonatized. Seven samples collected at the surface contained less than 10 to 2,580 parts per billion (ppb) gold, 0.45 to 250 parts per million (ppm) silver, 5.6 to 12,300 ppm arsenic, 0.6 to 30.3 ppm bismuth, 44.9 to 194 ppm copper, 2.4 to 19.6 ppm molybdenum, 66.40 to 13,700 ppm lead, 19 to 418.1 ppm antimony, 13.7 to 105.3 ppm tin, 0.3 to 12 ppm thorium, 0.2 to 3.2 ppm uranium, 1.2 to 42.6 ppm tungsten, and 354 to 17,100 ppm zinc. In 2006, Linus drilled one hole to a depth of 499 feet. The upper portion of the hole was was in dacitic tuff and siltstone, followed by andesitic tuff that is altered to biotite-tourmaline hornfels at

depth. The middle portion is largely in altered granodiorite. The bottom portion is mostly in biotite-tourmaline hornfels but the bottom of the hole is in granodiorite. Hornfelsing and tourmalination increased dramatically with depth. The drill hole intersected two zones of sulfide-tourmaline-quartz veins with various assemblages of sulfides, mainly pyrrhotite, galena, sphalerite, and arsenopyrite. Some of the better intercepts were 50 feet with 3.9 ppm silver, 1, 722 ppm lead, 15.43 ppm tungsten, and 6,652 ppm zinc; 10 feet with 60 ppb gold, 0.7 ppm silver, 13.2 ppm thorium, and 6.85 ppm uranium; and 10 feet with 46.5 ppm gold, 2.1 ppm silver, 960 ppm lead, 14.5 ppm thorium, 8 ppm uranium, and 8,093 ppm zinc.

Alteration:

The rocks are widely chloritized and locally tourmalinized, silicified, and carbonitized. In one drill hole, hornfelsing and tourmalization increased dramatically with depth.

Age of mineralization:

Cretaceous or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Disseminated and veined, Ag-As-Au-Bi-Cu-Mo-Pb-Sb-Th-U mineralization in several styles that occurs widely for 16 miles along the altered border zone of a Cretaceous quartz monzonite.

Site name(s): Mallard Duck Bay; Calcite; Marshinlak

Site type: Occurrences

ARDF no.: CG002

Latitude: 56.231 **Quadrangle:** CG A-2

Longitude: 158.511

Location description and accuracy:

This site represents an area southeast of Chignik Lagoon at the head of Mallard Duck Bay (Berg and Cobb, 1967, locality 2; Cobb, 1972: MF-374, locality 2; MacKevett and Holloway, 1977, locality 2; Cox and others, 1981, locality 8; Nokleberg and others, 1987, locality AP 11). The map site is plotted at an elevation of about 1000 feet, about 0.2 miles southeast of the head of Mallard Duck Bay. The location is accurate to within 1/4 mile.

Commodities:

Main: Ag, Au, Cu, Mo, Pb, Zn

Other: As

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Calcite, quartz, siderite

Geologic description:

This site represents a large propylitically altered zone covering an area 6 miles by 2 1/2 miles at the head of Mallard Duck Bay (Wilson and Cox, 1983). Elevation of the zone varies from sea level to 600 meters. The altered zone is associated with widespread introduction of pyrite and with low-order drainage anomalies (60 ppm copper, 15 ppm molybdenum, 0.3 ppm silver).

Rock types include diorite stocks up to 2000 feet in diameter and a system of northeast-trending quartz-diorite dikes which are up to 1/2 mile in length and up to several hundred feet in thickness. A system of andesite dikes trends N 30 to 40 W and dips vertically across a 4000-foot wide zone. All of these intrusives cut Eocene-Oligocene volcanics of the Meshik Formation which consists of andesite and basalt flows, volcaniclastic breccias, volcaniclastic sediments, and tuffaceous units.

Within the large area of propylitized rock is a zone of intense argillic alteration which covers an area of approximately 2 miles by 1/2 mile. This is referred to as the central argillic zone (Anderson and others 1979). The argillic alteration appears to be related to the northwest-trending andesite dikes because it forms envelopes up to 100 feet wide on either side of the dikes. The altered areas exhibit some silicification and introduction of disseminated pyrite. They also contain coarse stockworks of fractures, some of which contain quartz, pyrite, and rarely molybdenite.

Molybdenum mineralization occurs primarily in a stockwork that lies between two parallel andesite dikes outside of the central argillic zone. The mineralized rock is limonitic and exihibits silicification and minor argillization. As the dikes are approached the alteration increases and the molybdenum mineralization decreases (Anderson and others, 1979). The molybdenum zone has been traced for 100 feet but the total length is unknown. Fields (1977) notes molybdenum values ranging from 2 to 99 ppm in rock samples.

Systems of northwest-trending polymetallic veins are present in the propylitized volcanics. The Calcite and Mallard Duck vein systems occur in an area 1/2 to 1 mile southwest of the central argillic zone. Individual veins are up to 800 feet long and 10 feet wide. Other veins are known to extend along this trend for over 4 miles northwest to the beach exposures at Mallard Duck Bay. The Marshinlak vein system is located approximately 2 miles north of the central argillic zone and has been traced intermittently for over 6500 feet in a northwest direction. These veins are up to 15 feet in thickness. Minor strike trends include

northeast, north-south, and east-west. The veins vary in composition from quartz to quartz-calcite to quartz-siderite and may carry up to 5 percent sulfides, including arsenopyrite, chalcopyrite, galena, pyrite, and sphalerite. Some veins exhibit cockscomb features and some show evidence of repetitive pulsing of quartz and sulfides.

Metal values in the Calcite and Mallard Duck systems range as follows: 3360 ppm to 4.2 percent copper, less than 0.02 ppm to 3.3 ppm gold, 1100 ppm to 4.45 percent lead, 20 ppm to 21 ounces silver ounces per ton, 1100 ppm to 22.7 percent zinc (Butherus and others, 1981). Trace amounts of antimony and mercury were also detected. Copper, lead, and zinc values obtained in the Marshinlak system were all less than 100 ppm. Gold values ranged from 0.48 ppm to 0.163 ounce per ton and silver values from 3.4 ppm to 0.54 ounce per ton.

As recently as 2013 at least, Millrock Resources Inc has made an agreement with Bristol Bay Native Corporation, the mineral land owner, to explore for minerals. By 2013, a regional aeromagnetic survey was completed. There appears to be good correlation between magnetic highs and known porphyry occurrences. Historic work includes reconnaissance surface sampling, regional scale mapping by Full Metal Minerals, an IP survey of one line, and a ground magnetic survey of one line (Beischer, 2013).

Alteration:

Propylitically altered volcanics cover an area of approximately 6 by 2 1/2 miles. Within this altered zone argillic alteration forms envelopes up to 100 feet wide peripheral to northwest-trending andesite dikes, resulting in a central argillic zone which covers an area of approximately 2 by 1/2 miles.

Age of mineralization:

The probable age of mineralization is estimated at 21-27 million years (Cox and others, 1981).

Generic deposit model:

Deposit model:

Porphyry copper; porphyry copper-molybdenum; polymetallic veins (Cox and Singer, 1986; models 17, 21a, 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17, 21a, 22c

Production Status: None

Site Status: Active?

Workings/exploration:

Gold claims were staked in the early part of the century. Bear Creek Mining Company mapped and sampled this zone in 1975 and 1976. Resource Associates of Alaska did detailed mapping and sampling in 1979, 1981, and 1982.

As recently as 2013 at least, Millrock Resources Inc. has made an agreement with Bristol Bay Native Corporation, the mineral land owner, to explore for minerals. By 2013, a regional aeromagnetic survey was completed. There appears to be good correlation between magnetic highs and known porphyry occurrences. Historic work includes reconnaissance surface sampling, regional scale mapping by Full Metal Minerals, an IP survey of one line, and a ground magnetic survey of one line (Beischer, 2013). In 2014, Millrock completed a geophysical survey or high-resolution airborne magnetic and radiometric data (Millrock Resources Inc., 2014).

Production notes:

None.

Reserves:

None.

Additional comments:

This site is on land patented by or interim conveyed to the Bristol Bay Native Corporation.

Site name(s): Port Heiden

Site type: Occurrence

ARDF no.: CG003

Latitude: 56.7918 **Quadrangle:** CG D-4

Longitude: 159.0709

Location description and accuracy:

This occurrence site consists of 20 miles of beach placers on the northwest coast of the Alaska Peninsula between the Seal Islands and Port Heiden. The coordinates are at about the center of this section of beach near the center of section 24, T. 35 S., R. 62 W., of the Seward Meridian. The location is accurate.

Commodities:

Main: Fe, Ti

Other: Au

Ore minerals: Gold, ilmenite, magnetite

Gangue minerals:

Geologic description:

This occurrence consists of beach placer deposits of ilmenite and titaniferous magnetite in narrow spits and bars along the outer shores of low-lying mud flats. The beaches are sandy gravel, often loosely packed.

Berryhill (1963) collected twenty-four auger samples along 20 miles of beach. They were screened, tabled, and run through a magnetic separator. In the magnetic fraction, the iron content varied from 2.2 to 103.6 pounds per cubic yard, and the titanium oxide content varied from 0.6 to 21.9 pounds. In the non-magnetic fraction, the titanium oxide content varied from 0 to 1.2 pounds per cubic yard. A trace of flour gold was present in 5 samples.

Through at least 2006 and 2007, 7th Sea Holding Company LLC was actively exploring the property (7th Sea Holding Company, 2012) and they had acquired 34 miles of claims and private properties in the area. They identified a 'resource' of 8 billion tonnes of magnetite sands and 3 billion tonnes of explored probable reserves'. The project that they planned to develop in 2007 'has an average raw iron ore grade of 58 percent'. In 2010, Advanced Exploration Inc. (2010) optioned the property from 7th Sea and in May 2011, they announced that they had begun an aerial survey (Advanced Exploration, 2011 [Airborne]). In December, 2011, they terminated the agreement (Advanced Exploration Inc., 2011 [Corporate update].

Site name(s): Bee Creek; Dry Creek

Site type: Prospect

ARDF no.: CG007

Latitude: 56.5117 **Quadrangle:** CG C-2

Longitude: 158.3846

Location description and accuracy:

This prospect is in T. 42 S., R. 58 W., of the Seward Meridian, located in a northeast facing valley near the headwaters of an unnamed creek entering Dry Creek approximately 1 mile north of Chignik Bay. The location is accurate to 1 mile.

Commodities:

Main: Ag, Au, Cu, Mo

Other: Pb, Zn

Ore minerals: Chalcopyrite, chrysocolla, galena, gold, magnetite, malachite, molybdenite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Gypsum, quartz

Geologic description:

At this prospect sandstone, siltstone, argillite, and conglomerate of the Jurassic Naknek Formation have been intruded by a small dacite stock, which is surrounded by a sulfide system and alteration halo covering approximately 2 square miles (Fields, 1977). The intrusive is mainly dacite, but quartz diorite, andesite, and quartz porphyry have also been reported. The intrusive is part of a nearly east-west trending linear belt extending from Weasel Mountain (CG008) on the east to Cathedral Creek (CG001) on the west. The Bee Creek prospect was explored by Bear Creek Mining Company in 1975 and 1976 and by Resource Associates of Alaska in 1979 and 1981.

The prospect is marked by geochemical and color anomalies. Clusters of arsenic, copper, gold, lead, silver, and zinc anomalies surround the deposit. The main mineralized area is in a steep cirque basin that varies from 500 to 1,500 feet in elevation. Work by Resource Associates of Alaska (Anderson and others, 1979) suggests that mineralization may extend southwest into the McKinsey Valley.

The mineralization is mainly at the border of the dacite stock in arkose, conglomerate, and quartzite. Resource Associates of Alaska (Anderson and others, 1979) state that the hornfelsed sediments near the contact contain the best mineralization and that the mineralization decreases towards the core of the intrusive. The age of the mineralization is between 3.2 and 3.8 million years (Wilson, 1980; Wilson and Cox, 1983).

Chalcopyrite and pyrite occur in a stockwork of hairline fractures containing quartz-sulfide veinlets throughout an area about 2,000 feet in diameter. Disseminated chalcopyrite and pyrite occur in biotitized hornfels and these sulfides replace mafic minerals in the dacite. Molybdenite is finely disseminated in quartz veinlets, in gypsum veinlets, and in clots of chalcopyrite. Pyrite forms a halo on the periphery of the system. Some magnetite veins have been reported; they appear to be early in the mineralization sequence and contain no sulfides. Veins containing lead and zinc values are peripheral to the copper zone. Within the copper zone, richer surface samples contained 500 to 2,000 parts per million (ppm) copper, 0.04 to 0.18 ppm gold, 20 to 220 ppm molybdenum, and 0.4 to 0.18 ppm silver (Fields, 1977).

Secondary biotite is widely distributed both within and beyond the chalcopyrite zone. It replaces mafic minerals and forms fine-grained aggregates both in the pluton and in the surrounding sediments. The biotite zone centers on the stock and extends irregularly southward over an area of 1,500 by 3,400 feet.

Discontinuous zones of sericitic alteration are peripheral to the biotite zone and are locally superimposed on the potassic and propylitic alteration. Propylitic alteration of chlorite and epidote forms an outer alteration zone. A strong zone of argillic alteration located between the phyllic and propylitic zones also has been reported (Butherus and others, 1981).

After drilling at Bee Creek in 2006, Full Metal Minerals and Metallica Resources interpreted the deposit as a multiphase dioritic intrusion within a coincident copper-gold-molybdenum anomaly centered on a magnetic high about 2 kilometers in diameter (Full Metal Minerals, 2008; Metallica Resources, 2008).

Alteration:

The alteration at this prospect appears to be the classic porphyry type with a potassic core grading outward through phyllic, argillic, and propylitic alteration zones although these may not all be developed fully. The best copper mineralization is in the potassic zone (Fields, 1977).

Age of mineralization:

Pliocene (Fields, 1977), between 3.2 and 3.8 Ma (Wilson, 1980).

Generic deposit model:

Deposit model:

Porphyry copper; porphyry copper-molybdenum (Cox and Singer, 1986; models 17, 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17, 21a

Production Status: None

Site Status: Active

Workings/exploration:

Bear Creek Mining Company drilled 5 holes in the copper zone in 1975 and 1976. Four holes averaged 500-1200 ppm copper and 5-28 ppm molybdenum. The best hole averaged 0.25 percent copper, 0.01 percent molybdenum, and 0.06 ppm gold over 500 feet. In 1979 Resource Associates of Alaska discovered two areas of polymetallic quartz veins. Samples of this material contained up to 5700 ppm copper, 4.4 ppm gold, 1.18 percent lead, 530 ppm molybdenum, 4.2 ounces silver per ton, and 1.62 percent zinc (Anderson and others, 1979). A resource of 4.5 to 9 million tonnes grading 0.25 percent copper and 0.01 percent molybdenum has been estimated (Young and others, 1997).

Along with geological mapping, geochemical sampling, and ground-based geophysics, Full Metal Minerals (FMM) and Metallica Resources (Metallica) drilled 2 holes on the Bee Creek porphyry in 2006. Notable intercepts in the two holes were: 1) 34 meters that contained 0.26 percent copper and 0.085 gram of gold per ton, 2) 118 meters that contained 0.31 percent copper and 0.126 gram of gold per ton, including 40 meters that contained 0.51 percent copper and 0.212 gram of gold per ton. The holes were mostly in sedimentary rocks cut by numerous intermediate to felsic dikes (Full Metal Minerals, 2008; Metallica Resources, 2008).

FMM and Metallica conducted field work in 2008, which included vein sampling and an orientation drainage survey employing bulk leach extractable gold (BLEG) analysis and drilled two holes. One grab sample of a quartz-sphalerite-galena vein float in one of the eastern secondary drainages (314322) contained 5.180 parts per million (ppm) gold, 251 ppm silver, 1050 ppm copper, 3.8 percent lead, and 5.9 percent zinc. Results from BLEG analysis were up to 0.232 ppm gold (Lipske and Rotert, 2008).

In 2013, a regional aeromagnetic survey was completed. There appears to be good correlation between magnetic highs and known porphyry occurrences (Gregory Beischer, Millrock Resources, Inc., oral communication, 2013). In 2014, Millrock Resources Inc. completed a high-resolution airborne magnetic survey, which indicated that known mineralization may continue to the southwest below a ridge in that area (Millrock Resources Inc., 2014).

Mineralization, alteration and anomalous copper values in soils and rocks extend over a broad area at the

Dry Creek prospect indicating the potential for a significant porphyry Cu-Mo-Au deposit near surface and potentially at depth. Although several holes have been drilled at the property, few of the geochemical or geophysical anomalies have been tested (Millrock Resources, Inc., 2015).

Production notes:

None.

Reserves:

The prospect contains an estimated resource of 4.5 to 9 million tonnes grading 0.25 percent copper, 0.01 percent molybdenum, and trace gold (Young and others, 1997).

Additional comments:

This prospect is located on land conveyed to or patented by the Bristol Bay Native Corporation. In August 2005, Metallica Resources entered into a joint venture agreement with Full Metal Minerals to explore on BBNC lands.

In 2013, Millrock Resources Inc. made an agreement with the BBNC to explore for minerals (Millrock Resources Inc., 2014).

Site name(s): Marshinlak; Marshinlak Creek

Site type: Prospect

ARDF no.: CG023

Latitude: 56.2647 **Quadrangle:** CG B-2

Longitude: 158.5109

Location description and accuracy:

The Marshinlak prospect is located near the peak of a north-northwest trending ridge about 1.8 miles from where Marshinlak Creek enters Mallard Duck Bay; 0.3 mile southwest from the center of section 21, T. 45 S., R. 59 W., of the Seward Meridian. This location is accurate to within 1/4 mile of the center of the prospect.

Commodities:

Main: Ag, Au, Cu

Other: As, Sb

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite

Gangue minerals: Calcite, quartz

Geologic description:

The Marshinlak Creek precious metal vein prospect is located on Chignik Lagoon Native Corp. (CLNC) lands approximately 4 kilometers north of the porphyry center at the Mallard Duck Bay prospect (CG002). The area was visited briefly by Resource Associates of Alaska (RAA) in 1982. Their efforts were focused on a subparallel set of poorly-exposed silver-gold bearing quartz veins located south of Marshinlak Creek. They collected a total of 25 vein samples, 23 of which contained gold with an average of 0.5 gram per tonne (parts per million (ppm)). The area is prospective for epithermal-style vein mineralization and/or a deep-seated porphyry target (Lipske and Rotert, 2008).

Rock types include diorite stocks up to 2000 feet in diameter and a system of northeast-trending quartz-diorite dikes, which are up to a half mile in length and up to several hundred feet in thickness. A system of andesite dikes trends N 30 to 40 W and dips vertically across a 4000-foot wide zone. All of these intrusives cut Eocene-Oligocene volcanics of the Meshik Formation, which consists of andesite and basalt flows, volcaniclastic breccias, volcaniclastic sediments, and tuffaceous units (Anderson and others, 1979).

South of Marshinlak Creek, a swarm of discontinuous and poorly-exposed quartz ± calcite ± pyrite ± arsenopyrite veins are exposed in subcrops and frost boils. The host andesites bear weak propylitic alteration but are strongly hydrolytized along veins. It is inferred that two or three west-northwest-trending veins are exposed over a zone measuring one kilometer in width by approximately 1.5 kilometers along strike, and at least 300 meters vertically. Subcrops were typically no wider than two meters, though RAA reported vein widths of up to five meters (15 feet). Vein mineralogy consists of white sugary to clear drusy quartz plus accessory calcite, pyrite, and local arsenopyrite. Uppermost vein exposures were dominated by calcite. A 3 kilometer by 1 kilometer area of bleached and oxidized andesite is located immediately north of Marshinlak Creek and comprises variable quartz-sericite-pyrite alteration with a widespread argillic overprint. Minor amounts of high-level advanced argillic alteration characterized by vuggy residual quartz and coarse white mica with local jarosite was recognized via handlens at uppermost levels. The sericitic-argillic alteration zone is haloed by weakly propylitized andesite (Lipske and Rotert, 2008).

A suite of 35 hand samples were submitted for supplemental portable infrared mineral analyzer (PIMA) testing. Through PIMA analyses from 2008 work, mineral species including smectite, illite, kaolinite, dickite, chlorite, and epidote were positively identified. Possible accessory carbonate, silica, and amphibole

were reported in several samples. Based on these results, the hydrothermal alteration at Marshinlak Creek consists of propylitic, argillic, and advanced argillic assemblages (Lipske and Rotert, 2008).

The rock chip and vein sampling completed at Marshinlak Creek in 2008 confirms the high grade results reported from previous workers. A total of 25 vein samples were collected and returned results of up to 84.7 ppm gold, 745 ppm silver, 853 ppm copper, 1490 ppm arsenic, and 155 ppm antimony. The upper range of each is defined by the results of sample 314182, a quartz vein in float that contained 1 to 2 volume percent visible chalcopyrite, arsenopyrite, and an unidentified black sooty sulfide or sulfosalt. The float was observed downslope from a sample location that RAA reported as a 15-foot wide quartz vein. Excluding sample 314182, vein samples averaged 0.511 ppm gold, 0.4 ppm silver, 78.6 ppm copper, and 261 ppm arsenic, which are consistent with the results reported by RAA in Moller et al., 1982 (Lipske and Rotert, 2008).

Alteration:

Propylitic, argillic, sericitic, and silica alteration (Lipske and Rotert, 2008).

Age of mineralization:

The probable age of mineralization is estimated at 21 to 27 million years (Wilson, 1980).

Generic deposit model:

Deposit model:

Porphyry copper; porphyry copper-molybdenum; polymetallic veins (Cox and Singer, 1986; models 17, 21a, 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17, 21a, 22c

Production Status: None

Site Status: Active?

Workings/exploration:

A field program was performed in by Metallica Resource Inc. with a joint venture agreement with Full Metal Minerals (USA) Inc., on behalf of Bristol Bay Native Corporation (BBNC). This 2008 program entailed preliminary reconnaissance mapping and sampling at Marshinlak (Lipkse and Rotert, 2008).

A total of 31 vein samples and two lines of ground magnetics were collected south of Marshinlak Creek. North of Marshinlak Creek, approximately forty samples were collected on 50 meter centers and four lines of ground magnetics were completed. A suite of 35 hand samples were submitted for supplemental portable infrared mineral analyzer (PIMA) testing (Lipkse and Rotert, 2008).

Production notes:

None.

Reserves:

None.

Additional comments:

This record was created in 2014 to separate Marshinlak from Mallard Duck Bay (CG002), in which this site was previously combined with. The geology, location, and reports all separated these prospects.

Site name(s): Unnamed (near Siwash Creek)

Site type: Occurrence

ARDF no.: CH002

Latitude: 67.1198 **Quadrangle:** CH A-5

Longitude: 149.4035

Location description and accuracy:

The occurrence is about 4.1 miles east of the junction of Siwash Creek and Mosquito Fork, at an elevation of about 2,300 feet. It is about 0.3 mile southwest of the center of section 3, T. 27 N., R. 8 W.. The location is accurate to within 1 mile.

Commodities:

Main: Cu

Other:

Ore minerals: Azurite, copper sulfides, malachite

Gangue minerals:

Geologic description:

This occurrence was originally described as copper sulfides and copper stains in a small body of chert in Devonian(?) volcanic rocks (Brosgé and Reiser, 1964; DeYoung, 1978). Kurtak and others (2002) describe a bluff about 30 feet high and 100 feet wide of highly silicified pyroxene diorite. The diorite is cut by several quartz veins 1 to 2 inches thick. Analyses of two samples of pyrite-bearing quartz and a sample of the mafic rock did not show any significant base or precious metals.

Location description and accuracy:

This occurrence is at an elevation of about 3,000 feet, about 2.4 mile west of the junction of Siwash Creek and Mosquito Fork. It is about 0.2 mile southeast of the center of section 25, T. 27 N., R. 10 W.

Commodities:

Main: Cr, Cu, Ni

Other: Ni

Ore minerals: Azurite, copper sulfides, magnetite, malachite

Gangue minerals:

Geologic description:

This occurrence was originally described as copper sulfides and copper staining at the contact between Devonian(?) black phyllite and slate and Devonian(?) pyroxene diorite and andesite flows (Brosgé and Reiser, 1964). Kurtak and others (2002) indicated that the diorite and andesite flows may be part of a 1,000-foot-wide band of mafic-ultramafic rocks bounded on both sides by chlorite-quartz schist. The mafic-ultramafic rock contains magnetite, is serpentinized at the margins of the band, and may be dunite. Samples of the serpentinized rock averaged 977 parts per million (ppm) nickel and 1,078 ppm chromite.

Site name(s): Slate Creek

Site type: Mine

ARDF no.: CH007

Latitude: 67.2269 **Quadrangle:** CH A-6

Longitude: 149.8969

Location description and accuracy:

Slate Creek is a west-flowing tributary to the Middle Fork Koyukuk River; its mouth is at the old mining town of Coldfoot on the Dalton Highway, the road that parallels the Trans-Alaska Pipeline. The creek was placer mined at various locations for more than 10 miles but the most productive ground was centered in upper Slate Creek at a camp about 5 miles above the mouth of Myrtle Creek. That ground extended for about a mile above and a mile below the camp. Most of the mining was in sections 24 and 26, T. 28 N., R. 11 W.

The most productive ground on Slate Creek is in the upper portion of the creek in the Chandalar A-6 quadrangle; the lower part of the creek that was also placer mined is in the Wiseman A-1 quadrangle.

Commodities:

Main: Ag, Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Slate Creek has been mined for more than 10 miles at various times since 1898 but the most productive ground was centered in upper Slate Creek about 5 miles above the mouth of Myrtle Creek; this ground extended for about a mile below and a mile above this point.

Gold was discovered at the junction of Myrtle Creek and Slate Creek in 1899 (Schrader, 1900) and by 1904 the workings extended for 5 or 6 miles up Mrytle Creek and farther along Slate Creek (Schrader, 1904). Mining continued intermittently along Slate Creek to at least 2000 by a succession of operators using hand methods, heavy equipment, and by drift mining (Kurtak and others, 2002). The gold production from Slate Creek is not well documented; U.S. Bureau of Mines records indicate that Slate Creek may have produced as much as 1,394 ounces of gold and 121 ounces of silver to 1963 (Kurtak and others, 2002).

Most of the mining on upper Slate Creek was along the modern channel. There was also some mining on a low bench on the south side of the creek; the bedrock at the bottom of the bench is only a few feet above the bedrock at the bottom of the modern channel. No deep channels have been found on upper Slate Creek. Mosier and Lewis (1986) analyzed several samples of gold from upper Slate Creek; they varied from 880 to 952 fine.

On lower Slate Creek, gold has been mined in the modern channel in gravel 10 to 40 feet thick. Reed (1938) indicates that it was possible for the early miners to recover $3 to $4 per day of flour gold (approx. 0.15 - 0.20 ounce of gold) by rocker. At least three high channels were identified from the mouth of Slate Creek to the mouth of Myrtle Creek but they did not contain enough gold to justify mining (Reed, 1938).

Site name(s): Myrtle Creek

Site type: Mine

ARDF no.: CH008

Latitude: 67.2573 **Quadrangle:** CH B-6

Longitude: 149.9805

Location description and accuracy:

The mouth of Myrtle Creek on Slate Creek (CH007) is about 4.6 miles east-southeast of Coldfoot. Myrtle Creek has been placer mined at various locations for more than 6 miles above its mouth but the most productive part extended from 2.5 miles to 5 miles above its mouth. The coordinates are at about the middle of this area, near the center of section 3, T. 28 N., R. 11 W.

The most productive ground on Myrtle Creek is in the upper portion of the creek in the Chandalar A-6 and B-6 quadrangles; the lower part of the creek that was also placer mined is in the Wiseman A-1 quadrangle.

Commodities:

Main: Ag, Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Gold was first discovered on Myrtle Creek in 1899 and by 1904 the workings extended 5 or 6 miles up the creek (Schrader, 1900, 1904; Maddren, 1913; Reed, 1938; Kurtak and others, 2002). By 1906, 80 men were hand mining along Myrtle Creek and hydraulic mining began in 1909. There was mining in open cuts and drift mining most years from 1914 to 1939. The first heavy equipment, a dragline and dozer, started mining in 1940. Mining resumed after World War II and continued at intervals until at least 2000, when a small suction dredge was being used to mine potholes in the creek. Myrtle Creek has produced consistently since 1900. Gold was produced in 27 of the years between 1900 and 1941, every year from 1948 to 1955, and during periods from 1979 to 2000. The records are incomplete, but Mrytle Creek produced 16,952 ounces of gold from 1900 to 1955. The most productive years were 1902 when 2,417 ounces of gold were produced and 1950 when 3,141 ounces of gold were produced (Kurtak and others, 2002). An uncertain amount of gold was also produced after 1955.

The most productive part of Mrytle Creek extended from about 2.5 miles above its mouth to about 5 miles above its mouth (Reed, 1938, Kurtak and others, 2002). Most of the gold came from the modern channel of Myrtle Creek in thawed ground that was 30 to 300 feet wide. The gravel was 2 to 7 feet thick and the gold was generally on bedrock or in crevices that held gold down to a depth of about 3 feet in the schist bedrock. The gold seemed to be evenly distributed across the channel. The gold was coarse, clean, and somewhat flattened; occasional nuggets up to an ounce were found and Smith (1942) reported a 23-ounce nugget. By 1937, the modern channel had largely been mined out.

There are several high bench channels on both sides of lower Mrytle Creek that extend for about 3 miles above its mouth (Reed, 1938; Kurtak and others, 2002). In 1937, they had not been mined to any extent but there were attempts to mine them after World War II. One notable bench along the lower two miles of Myrtle Creek has a channel perched 10 to 15 feet above the modern channel, and is covered by 10 to 30 feet of gravel. The ground on the bench was said to run about 0.01 to 0.023 ounce of gold per square foot of bedrock.

Production Status: Yes

Site Status: Undetermined

Workings/exploration:

Gold was first discovered on Myrtle Creek in 1899 and by 1904 the workings extended 5 or 6 miles up the creek (Schrader, 1900, 1904; Maddren, 1913; Reed, 1938; Kurtak and others, 2002). By 1906, 80 men were hand mining along Myrtle Creek and hydraulic mining began in 1909. There was mining in open cuts and drift mining most years from 1914 to 1939. The first heavy equipment, a dragline and dozer, started mining in 1940. Mining resumed after World War II and continued at intervals until at least 2000, when a small suction dredge was being used to mine potholes in the creek.

Production notes:

Myrtle Creek has been one of the largest placer gold producers in the Koyukuk district and it produced consistently from 1900 to 1955. The records are incomplete but Mrytle Creek produced 16,952 ounces of gold from 1900 to 1955; the most productive years were 1902 when 2,417 ounces of gold were produced and 1950 when 3,141 ounces of gold were produced (Kurtak and others, 2002). An uncertain amount of gold was produced after 1955.

Reserves:

Probably none of any significant size although pockets of auriferous gravel may remain in potholes along the creek, adjacent to previously mined sections, of the creek, and in the benches along lower Mrytle Creek.

Primary Reference: Reed, 1938; Kurtak and others, 2002

Reporter(s): J.M. Britton (Anchorage, Alaska); D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-18

Site name(s): Unnamed (near Horse Creek)

Site type: Occurrence

ARDF no.: CH018

Latitude: 67.3985 **Quadrangle:** CH B-4

Longitude: 148.97

Location description and accuracy:

This occurrence is at elevation of about 4,000 feet, a mile south of peak 4792, and about 10 miles southwest of the south end of Chandalar Lake. It is about 0.3 mile north of the center of section 30, T. 30 N., R. 6 W.

Commodities:

Main: Cu, Sb

Other:

Ore minerals: Azurite, copper sulfides, malachite

Gangue minerals:

Geologic description:

Brosgé and Reiser (1972) described this occurrence as copper sulfides and copper staining in small pods and veinlets in Devonian quartz-mica schist intercalated with greenschist and greenstone. Kurtak and others (2002) examined the area but could not find any copper minerals. They did locate a 30-foot-long area of limonite-stained quartz-mica schist that contained 0.84 percent antimony. A rubblecrop sample of a metamorphosed quartz vein that crosscut that schist contained 549 parts per million antimony. No antimony mineral was identified.

Alteration:

Age of mineralization:

Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Data too sparse to determine.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling by the U.S. Geological Survey and Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Site name(s): Dennys Gulch; O'Keefe

Site type: Mine

ARDF no.: CH019

Latitude: 67.3955 **Quadrangle:** CH B-5

Longitude: 149.1413

Location description and accuracy:

This placer mine is at an elevation of about 2,400 feet in Dennys Gulch, which is about 6 miles south of the south end of Twin Lakes. It is at the mine symbol on the 1:63,360-scale topographic map, about 0.4 mile east of the center of section 29, T. 30 N., R. 7 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

This record describes the placer mine in Dennys Gulch. Both this placer and the lode prospect at the head of the gulch (CH123) are associated with Denny O'Keefe, who had claims and explored the area from 1948 to 1957; much of the work on the placer and the lode probably coincided (Kurtak and others, 2002). A magnetometer survey was run over Dennys Gulch and Sawlog Creek in 1951 (Williams, 1952); there was uranium exploration by the U.S. Geological Survey in 1956 (Freeman, 1963); 6 lode claims were staked in 1955 (Heiner and Wolff, 1968); and WGM Inc. explored in the area from 1975 to 1976, and in 1983 (Dashevsky, 1986).

O'Keefe sank several shafts along the gulch, presumably at the mine shown on the 1:63,360-scale topographic map. One shaft hit bedrock at 40 feet and another at 75 feet. Only a little gold was found in these shafts, where it was concentrated in a layer of red gravel (Kurtak and others, 2002). Heiner and Wolff (1968) reported that placer gold has been mined and that coarse nuggets valued as much as $100 were recovered, but that no pay streak was found. (Kurtak and others (2002), however, imply that the coarse nuggets came from the upper part of Dennys Gulch, perhaps at or near the lode prospect there (CH123)).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Undetermined

Workings/exploration:

Both this placer and the lode prospect at the head of the gulch (CH123) are associated with Denny O'Keefe, who had claims and explored the area from 1948 to 1957; much of the work on the placer and the lode probably coincided (Kurtak and others, 2002). A magnetometer survey was run over Dennys Gulch and Sawlog Creek in 1951 (Williams, 1952); there was uranium exploration by the U.S. Geological Survey in 1956 (Freeman, 1963); 6 lode claims were staked in 1955 (Heiner and Wolff, 1968); and WGM Inc. explored in the area from 1975 to 1976, and in 1983 (Dashevsky, 1986).

O'Keefe sank several shafts along the gulch, presumably at the mine shown on the 1:63,360-scale topographic map. One shaft hit bedrock at 40 feet and another at 75 feet. Only a little gold was found in these shafts where it was concentrated in a layer of red gravel (Kurtak and others, 2002). Heiner and Wolff (1968) reported that placer gold has been mined and that coarse nuggets valued as much as $100 were recovered, but that no pay streak was found. Kurtak and others (2002), however, imply that the coarse nuggets came from the upper part of Dennys Gulch, perhaps at or near the lode prospect there (CH123).

Production notes:

Some unknown but probably small amount of gold was produced from 1948 to 1957.

Reserves:

None.

Site name(s): Sawlog Creek

Site type: Mine

ARDF no.: CH020

Latitude: 67.404 **Quadrangle:** CH B-5

Longitude: 149.1656

Location description and accuracy:

Sawlog Creek is a small headwater tributary to the South Fork Koyukuk River; its mouth is about 5 miles south-southwest of the south end of Twin Lakes. The small placer mine on Sawlog Creek is sometimes confused with the nearby one on Dennys Gulch (CH019) because there was placer activity on both in which Denny O'Keefe was involved. For this record, the site is arbitrarily located on upper Sawlog Creek at an elevation of about 2,300 feet. It is about 0.6 mile north-northwest of the center of section 29, T. 30 N., R. 7 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Brosgé and Reiser (1964) reported placer activity about 1 mile upstream from where Sawlog Creek enters the valley of the South Fork Flats. However, this activity my refer to the better known placer and lode work in Dennys Gulch (CH019), just over the low divide at the head of Sawlog Creek. Kurtak and others (2002) note that claims were staked on Sawlog Creek in 1949 and that a magnetic survey was run in 1951 that covered Dennys Gulch and Sawlog Creek. Williams (1952) reported that the results of the magnetometer survey were generally inconclusive. The survey was performed at the request of the property owners, however, which suggests some activity at that time. A placer claim was staked on Sawlog Creek in 1960 (Heiner and Wolff, 1968) and DeYoung (1978) reported placer mining in 1964. Kurtak and others (2002) (briefly?) visited Sawlog Creek in their comprehensive study of the mineral resources of the Koyukuk mining district but found no evidence or past or current mining.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Undetermined

Workings/exploration:

Site name(s): Shamrock Creek; Butte Creek

Site type: Prospect

ARDF no.: CH022

Latitude: 67.4828 **Quadrangle:** CH B-5

Longitude: 149.3745

Location description and accuracy:

Shamrock Creek (Butte Creek in older reports) is a short creek that flows into the south side of Bob Johnson Lake (formerly Big Lake) about a mile and a half west of its east end. There is an old report of mining at some unspecified location. For this record, the site is arbitrarily located about a half mile above the mouth of the creek near the center of section 29, T. 31 N., R. 8 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Reed (1938) reported that 'pay' had been found on Shamrock Creek in 1920 but there is no further indication of mining. A placer claim was staked in 1978. Kurtak and others (2002) visited Shamrock Creek in their study of the mineral resources of the Koyukuk mining district. They found no sign of mining and their samples did not show any visible or analytical gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Inactive

Workings/exploration:

Reed (1938) reported that 'pay' had been found on Shamrock Creek in 1920 but there is no further

indication of mining. A placer claim was staked in 1978. Kurtak and others (2002) visited Shamrock Creek in their study of the mineral resources of the Koyukuk mining district. They found no sign of mining and their samples did not show any visible or analytical gold.

Production notes:

Some gold may have been recovered during prospecting in 1920.

Reserves:

None.

Site name(s): California Creek

Site type: Mine

ARDF no.: CH023

Latitude: 67.4719 **Quadrangle:** CH B-5

Longitude: 149.4918

Location description and accuracy:

There was mining on California Creek near the mouth of Jim Pup, about 3.8 miles south-southwest of the north end of Bob Johnson Lake (formerly Big Lake). The mining was in the north half of section 35, T. 31 N., R. 9 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Maddren (1913) reported shovel-and-sluice mining from 1901 to 1909 on California Creek near the mouth of Jim Pup. From 1915 to 1931, a miner sank 18, 18-foot shafts, drove two inclines on a deep channel, and produced a small amount of gold. The records are incomplete but 102 ounces of gold were produced from California Creek from 1901 to 1919. Claims were held during the 1940s and 1950s, and from 1980 to 1986. There was mining in 1985 (Dillon (1987); in 1990 (Swainbank and others, 1991); and from 1999 to at least 2000, when the ground was being worked with a suction dredge and a backhoe (Kurtak and others, 2002). High benches are present but apparently were not mined. (Also see the placers on nearby Jim Pup (CH024) and Wakeup Creek (CH025) which are geologically similar and may be contiguous.)

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

Maddren (1913) reported shovel-and-sluice mining from 1901 to 1909 on California Creek near the mouth of Jim Pup. From 1915 to 1931, a miner sank 18, 18-foot shafts, drove two inclines on a deep channel, and produced a small amount of gold. The records are incomplete but 102 ounces of gold were produced from California Creek from 1901 to 1919. Claims were held during the 1940s and 1950s, and from 1980 to 1986. Site name(s): Jim Pup; Jim Pup Creek; Jim Gulch; Jim Creek

Site type: Mine

ARDF no.: CH024

Latitude: 67.4726 **Quadrangle:** CH B-5

Longitude: 149.4759

Location description and accuracy:

The lower mile of Jim Pup Creek has been placer mined. The creek is a tributary to California Creek, about 6.7 miles south of the north end of Bob Johnson Lake (formerly Big Lake). Most of the mined area is near the northeast corner of section 35, T. 31 N., R. 9 W. (The creek is labeled 'Jim Pup' on the 1971, 1:63,360-scale topographic map, but was called Jim Gulch, Jim Pup Creek, or Jim Creek in old reports.)

Commodities:

Gangue minerals:

Geologic description:

Gold was discovered on Jim Pup in 1901. There was intermittent mining well into the 1920s and again in 1941; 735 ounces of gold were produced from 1901 to 1941 from the lower mile and a half of the creek. Claims were held during the 1940s and 1950s. There was mining in 1985 (Dillon, 1987); in 1990 (Swainbank and others, 1991); and in 1998 when a suction dredge was being used above the old tailings (Kurtak and others, 2002). There is no record of the amount of gold that was produced after 1941 but some was probably recovered.

The early mining was by hand methods along the modern channel of Jim Pup and tailings are stacked on both sides of the lower mile of the creek. The gold was said to be coarse; a $50 nugget was recovered in the early days (Reed, 1938). The pay streak was about 10 feet wide, and overlain by 3 to 5 feet of gravel over bedrock. Several shafts, one 104 feet deep, were sunk on one or more deep channels on the north side of the creek but they were apparently not mined. (Also see the placers on nearby California Creek (CH023) and Wakeup Creek (CH025), which are geologically similar and may be contiguous.)

Geologic description:

Although gold was discovered near Wakeup Creek on California Creek (CH023) and Jim Pup (CH024) by 1901, the first reported gold production on Wakeup Creek was in 1926 (Kurtak and others, 2002). Drift mining continued most years until 1941 and a total of 1,795 ounces of gold was produced from 1926 to 1941. Shafts were sunk in 1948 and 1949 and there were active claims at various times until at least 1997.

There are three types of placers on Wakeup Creek: 1) in the modern channel, 2) in a deep channel, and 3) in a high channel. The modern channel rests on older gravel, i.e., it does not go down to bedrock. The early mining was along the modern channel but most of the original shallow gravel has been covered by tailings from later mining. The deep channel, which was the most productive, was drift mined for about 1,500 feet upstream from the mouth of Wakeup Creek. It is probably the continuation of the deep channel on Jim Pup (CH024). Bedrock is about 55 feet deep at the mouth of the creek and deepens to 112 feet upstream. The deep channel is incised into hard, smooth, schist bedrock with five or six gutters, 2 to 4 feet deep, along its bottom The channel is about 25 feet wide at its lower end and narrows upstream to 15 to 20 feet. The gold is generally on the high points of the bedrock between the gutters, but in places is also distributed throughout the gravel. The gold is fine but rough with only a few larger pieces. The ground ran from $3.50 to $4.00 in gold per square foot of bedrock (at $35 per ounce of gold). The high channel appears to be a continuation of a channel on Jim Pup Creek (CH024) that drained into Bob Johnson Lake. The gravel in the high channel was about 20 feet deep when it was explored in 1937. There is no record of gold being produced from the high channel but it was said to run about $0.50 in gold (at $35 per ounce of gold) per square foot of bedrock (Reed, 1938). Kurtak and others (2002) suggest that most of the deep channel has been mined out and that the high channel has low gold values. (Also see the placer on nearby California Creek (CH023) which is geological similar and may be contiguous.)

Site name(s): Lake Creek

Site type: Mine

ARDF no.: CH026

Latitude: 67.4956 **Quadrangle:** CH B-5

Longitude: 149.4524

Location description and accuracy:

Lake Creek flows into the south side of Bob Johnson Lake (formerly Big Lake) about a mile and a half south of its north end. Lake Creek has been mined from about 300 feet to 3,200 feet upstream from its mouth. The coordinates are at the mine symbol on the the 1:63,360-scale topographic map, near the center of section 24, T. 31 N., R. 9 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Gold was discovered on Lake Creek in 1915, followed by hand and drift mining near the mouth of the creek in 1916 (Reed, 1938; Kurtak and others, 2002). In the 1930s, shafts were sunk in upper Lake Creek near the divide with Wakeup Creek (CH025) and there was hydraulic and drift mining nearly every year to 1941 at various places along the creek. From 1949 to 1959 mining continued by hydraulic and sluicing methods on claims that extended the length of Lake Creek. Dillon (1987) reported mining from 1980 to 1986. Lake Creek produced gold in 23 of the years between 1921 and 1955, although never more than 99 ounces of gold a year; the total production during that period was 807 ounces of gold.

Gold was mined from placers along the modern channel of Lake Creek, from benches, and from a deep channel in the upper part of the creek. (Reed, 1938; Kurtak and others, 2002). When Reed visited the creek in 1937, the modern channel had been worked from about 300 feet to about 1,500 feet above its mouth. The channel was 10 to 20 feet wide and the gravel was 9 to 12 feet deep. The stream fill consisted of coarse-grained schist 'slide' rock mixed with fine sand and coarse waterworn gravel (Reed, 1938). The gold was coarse and the ground ran about $0.50 in gold per square foot of bedrock (with gold at $35 per ounce). Several benches were mined along Lake Creek. One bench deposit, exposed in a cut about 0.5 mile from the mouth of the creek, was 75 to 100 feet higher than the modern channel of Lake Creek. The gold was concentrated in a channel about a foot wide on bedrock. Beginning in 1930, shafts were sunk through 30-40 feet of overburden on a deep channel in upper Lake Creek near the divide to Wakeup Creek (CH025). The deep channel may be an extension of the high channel on Wakeup Creek on the other side of the divide. The overburden consisted of thick blue-gray mud and gravel. The gold was in the the bottom foot of the gravel and the ground had about 0.01 ounce of gold per square foot of bedrock.

Site name(s): Bore Creek; Boer Gulch; Boer Creek; Boar Creek

Site type: Prospect

ARDF no.: CH027

Latitude: 67.4631

Quadrangle: CH B-6

Longitude: 149.5717

Location description and accuracy:

Bore Creek is one of the headwater tributaries to California Creek. The site is plotted at an elevation of about 2,200 feet near old tailings. It is about 1.0 mile upstream from the mouth of the creek and about 0.4 mile south of the center of section 33, T. 30 N., R. 9 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Maddren (1913) reported small-scale mining in about 1901 at some uncertain location on Bore Creek. The gold recovery was said to be poor, earning only enough to cover wages. Reed (1938) found no evidence of mining, and local miners reported that prospecting had never located ground worth mining. An individual prospected on Bore Creek in 1959 but was unsuccessful. Eight claims were staked in 1977-1978, and in 2001, another group was prospecting their claims (Kurtak and others, 2002).

During their study of the mineral resources of the Koyukuk mining district, Kurtak and others (2002) found an old cabin, various mining equipment, and an area of hand-stacked tailings about 100 feet long, a mile to a mile and a half above the mouth of the creek. They collected several quartz samples in the surrounding area. The samples contained up to 1 percent pyrite, 714 parts per million (ppm) arsenic, 2,000 ppm strontium, 785 ppm copper, and 338 ppm zinc. The best was a sample from a loose quartz boulder that contained 97 parts per billion gold, 1.17 percent lead, and 1.01 percent antimony. However, the sample was found near a cabin and may have been brought in from elsewhere.

Site name(s): Little Gold Creek

Site type:

ARDF no.: CH028

Latitude: **Quadrangle:**

Longitude:

Location description and accuracy:

This was a vague site to begin with that only describes an old shaft on a minor unnamed tributary to a well known creek. However, there was mechanical mining in this area as recently as 2001 and what we're really looking at is mining at the far end of Gold Creek that has been mined relatively continuously for more than six miles. Little Gold Creek is referenced in the Gold Creek (CH080) record but events have long overtaken this site.

Site name(s): Sheep Creek; Sheep Gulch

Site type: Mine

ARDF no.: CH029

Latitude: 67.4965 **Quadrangle:** CH B-6

Longitude: 149.8061

Location description and accuracy:

Sheep Creek is a west-flowing tributary to the Middle Fork Koyukuk River. The mine is shown by symbol and label on the 1:63,360-scale topographic map. It is about 0.5 mile west of the center of section 21, T. 31 N., R. 10 W. Placer mining extends for about 0.5 mile downstream and 1 mile upstream from the mine symbol on the map.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

There are several generations of mining on Sheep Creek and much old mining equipment remains on the property (Kurtak and others, 2002). Tailings piles up to 30 feet high are along the creek from 1,500 feet to 2,100 feet elevation. The first production was in 1907, and by 1914, 113 ounces of gold had been produced Maddren, 1913). The creek was mined most years between 1933 and 1942, both by drift mining and by booming and shoveling, along the modern stream channel; 543 ounces of gold was produced. There was mining in 1948 and 1949, and in 2000, Bureau of Land Management geologists found evidence of recent mining.

Reed (1938) reported that the Sheep Creek placers are in both the modern channel and a deep channel. In 1910, the deep channel was discovered along the north side of the creek and mined for about 7,000 feet upstream, beginning where the valley of Sheep Creek opens into the valley of the Middle Fork Koyukuk River. Above this, the deep channel grades into the modern stream stream channel. At the lower end of the deep channel, the gravel was about 90 feet thick and was drift mined. There are few large boulders in the tailings from the deep channel. The gravel from the deep channel ran about $1 per square foot of bedrock in 1937, but some small areas had much more gold. The deep channel could extend west into the relatively flat valley of the Middle Fork Koyukuk River, but it may have been cut off as was the deep channel of Gold Creek (CH080) about a mile to the north.

Reed (1938) implied that mining had then just begun in the modern channel of Sheep Creek, about 1,000 feet upstream from where Sheep Creek valley enters the valley of the Middle Fork. The gravel over the schist bedrock was about 6 feet thick and very coarse with many large schist boulders. The gold was coarse and water worn. The preliminary estimates in 1937 were that the ground had about $0.50 in gold (0.014 ounces) per square foot of bedrock.

Kurtak and others (2002) panned samples along the creek and many contained visible gold. However, they indicated that there is probably little unmined gravel left along the creek.

Workings/exploration:

There are several generations of mining on Sheep Creek and much old mining equipment remains on the property (Kurtak and others, 2002). Tailings piles up to 30 feet high are along the creek from 1,500 feet to 2,100 feet elevation. The first production was in 1907, and by 1914, 113 ounces of gold had bee produced (Maddren, 1913). The creek was mined most years between 1933 and 1942, both by drift mining and by booming and shoveling along the modern stream channel. There was mining in 1948 and 1949, and in 2000, Bureau of Land Management geologists found evidence of recent mining.

Production notes:

Kurtak and others (2002) document that 780 ounces of gold was produced from 1907 to 1948 but the records are incomplete. Most of the gold was produced from 1907 to 1914 and from 1933 to 1942. There may have been mining as recently as 2000.

Reserves:

Kurtak and others (2002) indicated that there was probably little unmined gravel left along the creek.

Site name(s): Nugget Creek

Site type: Mine

ARDF no.: CH030

Latitude: 67.4784 **Quadrangle:** CH B-6

Longitude: 149.846

Location description and accuracy:

Nugget Creek flows into the Middle Fork Koyukuk River, about 9 miles northeast of Wiseman. There is little information about mining along Nugget Creek but there was some prospecting and mining below the mouth of Victor Gulch. This site is somewhat arbitrarily located at about the midpoint of the creek between the Middle Fork and the mouth of Victor Gulch, near the southwest corner of section 29, T. 31 N., R. 10 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Kurtak and others (2002) found considerable evidence of mining along Nugget Creek below the mouth of Victor Gulch, including a trench, tailings, sluice boxes, suction dredging equipment, and several cabins. There is little information on the mining, however. Reed (1938) reported that fair prospects had been found although little mining had been done. Claims were staked in the early 1980s. Several placer claims were being worked from 1994 to at least the early 2000s, (Kurtak and others, 2002). Kurtak and others (2002) sampled and panned along the creek; several of the pans contained visible or analytical gold. The ground is shallow along most of the creek; less than 3 feet of gravel covers bedrock.

Site name(s): Unnamed (near Howard Creek)

Site type: Occurrence

ARDF no.: CH034

Latitude: 67.3779 **Quadrangle:** CH B-6

Longitude: 149.9188

Location description and accuracy:

This occurrence is at an elevation of about 4,900 feet on the ridge east of the head of Howard Creek. It is about 5.4 miles east-southeast of Wiseman and about 0.6 mile southwest of the center of section 36, T. 30 N., R. 11 W.

Commodities:

Main: Cu, Pb, Zn

Other: Ni

Ore minerals: Chalcopyrite, galena, pyrrhotite

Gangue minerals: Quartz

Geologic description:

This occurrence was originally noted by Brosgé and Reiser (1964) as an occurrence of metallic minerals that contained copper and nickel. Mulligan (1974) described it as widely but very sparsely distributed, cherry-sized pods of quartz and pyrrhotite with traces of galena and chalcopyrite in chloritic schist. Goethite stains accompanies these pods. Pyrite veinlets along joints and fractures in the schist contain trace amounts of copper. The rocks in the area are lower Paleozoic to Proterozoic, interlayered quartzite and graphitic albite-chlorite-muscovite-quartz schist near a contact with Lower Paleozoic to Proterozoic calcareous schist and marble (Dillon and Reifenstuhl, 1995). At or near this occurrence, Kurtak and others (2002) investigated about 1.5 miles of the contact of interbedded quartzite and graphitic schist with calcareous schist and marble. They collected 11 samples of marble, schist, and quartz veins. They found no mineralization and the only anomalous metal value was in a sample of pyritic quartz-chlorite schist that contained 455 parts per million zinc.

Alteration:

Oxidized Fe sulfides.

Age of mineralization:

Paleozoic or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Insufficient information to assign.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling by the U.S. Geological Survey and Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Site name(s): Little Squaw Creek

Site type: Mine

ARDF no.: CH039

Latitude: 67.5702 **Quadrangle:** CH C-3

Longitude: 148.1602

Location description and accuracy:

The main workings of the Little Squaw Creek placer mine are about 2 miles southeast of the southeast end of Squaw Lake. Gold can be found along much of the upper part of the creek but most of the mining to 2004 took place on a lower portion of the creek called the Mello Bench in the southwest quarter of section 26, T. 32 N., R. 3 W., of the Fairbanks Meridian. The coordinates are at about the center of the Mello Bench. The location is accurate.

Commodities:

Main: Au

Other: As, Pb, W

Ore minerals: Arsenopyrite, galena, gold, monazite, scheelite

Gangue minerals:

Geologic description:

The first gold in the Chandalar district was discovered on Little Squaw Creek in 1905 and it has produced about half of the placer gold that has come from the district (Barker and Bundtzen, 2004; Barker, 2007). By 1916, most of the shallow placers in the upper valley of the creek were exhausted by hand mining and most of the mining to 2004 took place on the Mello Bench in the lower part of the creek, just above where the creek flows out on the floor of the Squaw Lake valley. Mining through the 1930s on Mello Bench was was almost entirely by drifting through thick, frozen gravel and until recently there has been little mining with heavy equipment on the creek. The placer concentrates contain pyrite, hematite, arsenopyrite, scheelite, galena, and monazite, in addition to gold. The early drift mining worked ground that contained nearly an ounce of gold per cubic yard and there were cleanups at the Mello camp that contained up to 4.85 ounces of gold per cubic yard. Barker and Bundtzen (2004) estimate that to 2004, Little Squaw Creek produced 29,237 ounces of gold from 30,466 cubic yards of material with an average grade of 0.960 ounce per cubic yard. Almost all of that was produced by Manual Mello and his sons from drift mining on the Mello Bench.

The gold in the lower portions of Little Squaw Creek frequently occurs at several horizons in the gravel; the auriferous horizons are separated by barren glaciofluvial material with clay layers that often serve as false bedrock. Some of the gold is on bedrock in alluvial gravel covered by glacial deposits. The several gold-bearing horizons are the result of the interplay of gold being transported by streams from the lode deposits at the head of Big Squaw Creek, several episodes of Pleistocene glaciation with the the deposition of glacial outwash and drift, and downcutting and readjustment of the drainages in response to several glacial advances.

Placer gold in uncertain amounts was long known to extend in the gravel below the Mello Bench in a broad alluvial fan and in benches where lower grade material extended out from the old drift mines. There were several episodes of drilling below the Mello Bench from the 20s through the late 90s (Barker and Bundtzen, 2004). In 2003, Little Squaw Gold Mining Company estimated that Little Squaw Creek has proven resources of 39,875 cubic yards of material with an average grade of 0.016 ounce of gold per cubic yard, a probable resource of 50,000 cubic yards with an average grade of 0.028 ounce of gold per cubic yard, and a possible resource of 12,030 cubic yards with an average grade of 0.013 ounce of gold per cubic

yard (Barker and Bundtzen, 2004).
In 2007, Little Squaw Gold Mining Company, now Goldrich Mining Company, drilled 110 holes on the lower portion of Little Squaw Creek along drill lines spaced 500 feet apart. As of February 9, 2009, Goldrich (Barker and others, 2009) calculated the measured and indicates resources of lower Little Squaw Creek as 9,101,600 cubic yards of material with an average grade of 0.0243 ounce of gold per cubic yard and an inferred resource of 1,401,666 cubic yards of material with an average grade of 0.0265 ounce of gold per cubic yard. These figures were encouraging enough that Goldrich test mined a portion of the ground with earth-moving equipment in the summer of 2009 (Goldrich Mining Company, 2009). In a period of 27 days, they produced 593.5 ounces of gold from 13,825 cubic yards of material. Goldrich mined in 2010 and produced 1,522 ounces of gold and 259 ounces of silver (Goldrich Mining Company, 2010 [production]).

Alteration:

Age of mineralization:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:
The first gold in the Chandalar district was discovered on Little Squaw Creek in 1905 and it has produced about half of the placer gold that has come from the district (Barker and Bundtzen, 2004; Barker, 2007). By 1916, most of the shallow placers in the upper valley of the creek were exhausted by hand mining and most of the mining to 2004 took place on the Mello Bench in the lower part of the creek, just above where the creek flows out on the floor of the Squaw Lake valley. Mining through the 1930s on Mello Bench was was almost entirely by drifting through thick, frozen gravel and until recently there has been little mining with heavy equipment on the creek.
In 2007, Little Squaw Gold Mining Company, now Goldrich Mining Company, drilled 110 holes on the lower portion of Little Squaw Creek along drill lines spaced 500 feet apart. These figures were encouraging enough that Goldrich test mined a portion of the ground with earth-moving equipment in the summer of 2009 (Goldrich Mining Company, 2009).

Production notes:
Barker and Bundtzen (2004) estimate that to 2004, Little Squad Creek produced 29,237 ounces of gold, almost all by drift mining, from 30,466 cubic yards of material with an average grade of 0.960 ounce per cubic yard. Goldrich Mining Company test mined a portion of the ground with earth-moving equipment in the summer of 2009 and produced 593.5 ounces of gold from 13,825 cubic yards of material (Goldrich Mining Company, 2009). Goldrich mined in 2010 and produced 1,522 ounces of gold and 259 ounces of silver.

Reserves:
Various estimates have been made of the gold resources of Little Squaw Creek. The latest (Barker and others, 2009) is based 110 holes drilled by Goldrich Mining Company in 2007. Lower Little Squaw Creek has a measured and indicated resource of 9,101,600 cubic yards of material with an average grade of

0.0243 ounce of gold per cubic yard and an inferred resource of 1,401,666 cubic yards of material with an average grade of 0.0265 ounce of gold per cubic yard. (Subsequently Goldrich produced 2,115 ounces of gold in 2009 and 2010).

Site name(s): Little Squaw Creek

Site type: Mine

ARDF no.: CH039

Latitude: 67.5702 **Quadrangle:** CH C-3

Longitude: 148.1602

Location description and accuracy:

The main workings of the Little Squaw Creek placer mine are about 2 miles southeast of the southeast end of Squaw Lake. Gold can be found along much of the upper part of the creek but most of the mining to 2004 took place on a lower portion of the creek called the Mello Bench in the southwest quarter of section 26, T. 32 N., R. 3 W., of the Fairbanks Meridian. The coordinates are at about the center of the Mello Bench. The location is accurate.

Commodities:

Main: Au

Other: As, Pb, W

Ore minerals:

Gangue minerals:

Geologic description:

The first gold in the Chandalar district was discovered on Little Squaw Creek in 1905 and it has produced about half of the placer gold that has come from the district (Barker and Bundtzen, 2004; Barker, 2007). By 1916, most of the shallow placers in the upper valley of the creek were exhausted by hand mining and most of the mining to 2004 took place on the Mello Bench in the lower part of the creek, just above where the creek flows out on the floor of the Squaw Lake valley. Mining through the 1930s on Mello Bench was was almost entirely by drifting through thick, frozen gravel and until recently there has been little mining with heavy equipment on the creek. The placer concentrates contain pyrite, hematite, arsenopyrite, scheelite, galena, and monazite, in addition to gold. The early drift mining worked ground that contained nearly an ounce of gold per cubic yard and there were cleanups at the Mello camp that contained up to 4.85 ounces of gold per cubic yard. Barker and Bundtzen (2004) estimate that to 2004, Little Squaw Creek produced 29,237 ounces of gold from 30,466 cubic yards of material with an average grade of 0.960 ounce per cubic yard. Almost all of that was produced by Manual Mello and his sons from drift mining on the Mello Bench.

The gold in the lower portions of Little Squaw Creek frequently occurs at several horizons in the gravel; the auriferous horizons are separated by barren glaciofluvial material with clay layers that often serve as false bedrock. Some of the gold is on bedrock in alluvial gravel covered by glacial deposits. The several gold-bearing horizons are the result of the interplay of gold being transported by streams from the lode deposits at the head of Big Squaw Creek, several episodes of Pleistocene glaciation with the the deposition of glacial outwash and drift, and downcutting and readjustment of the drainages in response to several glacial advances.

Placer gold in uncertain amounts was long known to extend in the gravel below the Mello Bench in a broad alluvial fan and in benches where lower grade material extended out from the old drift mines. There were several episodes of drilling below the Mello Bench from the 20s through the late 90s (Barker and Bundtzen, 2004). In 2003, Little Squaw Gold Mining Company estimated that Little Squaw Creek has proven resources of 39,875 cubic yards of material with an average grade of 0.016 ounce of gold per cubic yard, a probable resource of 50,000 cubic yards with an average grade of 0.028 ounce of gold per cubic yard, and a possible resource of 12,030 cubic yards with an average grade of 0.013 ounce of gold per cubic

yard (Barker and Bundtzen, 2004).

In 2007, Little Squaw Gold Mining Company, now Goldrich Mining Company, drilled 110 holes on the lower portion of Little Squaw Creek along drill lines spaced 500 feet apart. As of February 9, 2009, Goldrich (Barker and others, 2009) calculated the measured and indicates resources of lower Little Squaw Creek as 9,101,600 cubic yards of material with an average grade of 0.0243 ounce of gold per cubic yard and an inferred resource of 1,401,666 cubic yards of material with an average grade of 0.0265 ounce of gold per cubic yard. These figures were encouraging enough that Goldrich test mined a portion of the ground with earth-moving equipment in the summer of 2009 (Goldrich Mining Company, 2009). In a period of 27 days, they produced 593.5 ounces of gold from 13,825 cubic yards of material. Goldrich mined in 2010 and produced 1,522 ounces of gold and 259 ounces of silver (Goldrich Mining Company, 2010 [production]).

In 2016, Goldrich Mining Company formed a joint-venture partnership with project manager NyacAU, to form Goldrich NyacAU Placer, LLC. In 2016, Goldrich NyacAU surveyed the area on Little Squaw Creek beyond Line 11 and received a permit to conduct placer mining on Lines 11 to 18 in addition to permits already received to mine Lines 1 to 11. Production in 2016 totaled 10,209 ounces of alluvial gold (8,227 ounces of fine gold), at an estimated cost of approximately $960 per ounce (Athey and Werdon, 2017).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The first gold in the Chandalar district was discovered on Little Squaw Creek in 1905 and it has produced about half of the placer gold that has come from the district (Barker and Bundtzen, 2004; Barker, 2007). By 1916, most of the shallow placers in the upper valley of the creek were exhausted by hand mining and most of the mining to 2004 took place on the Mello Bench in the lower part of the creek, just above where the creek flows out on the floor of the Squaw Lake valley. Mining through the 1930s on Mello Bench was was almost entirely by drifting through thick, frozen gravel and until recently there has been little mining with heavy equipment on the creek.

In 2007, Little Squaw Gold Mining Company, now Goldrich Mining Company, drilled 110 holes on the lower portion of Little Squaw Creek along drill lines spaced 500 feet apart. These figures were encouraging enough that Goldrich test mined a portion of the ground with earth-moving equipment in the summer of 2009 (Goldrich Mining Company, 2009).

Production notes:

Barker and Bundtzen (2004) estimate that to 2004, Little Squad Creek produced 29,237 ounces of gold, almost all by drift mining, from 30,466 cubic yards of material with an average grade of 0.960 ounce per cubic yard. Goldrich Mining Company test mined a portion of the ground with earth-moving equipment in the summer of 2009 and produced 593.5 ounces of gold from 13,825 cubic yards of material (Goldrich Mining Company, 2009). Goldrich mined in 2010 and produced 1,522 ounces of gold and 259 ounces of silver.

Production in 2016 totaled 10,209 ounces of alluvial gold (8,227 ounces of fine gold), at an estimated cost of approximately $960 per ounce. The plant operated approximately 15 hours per day at a processing rate of 183 bank-cubic yards per hour (Athey and Werdon, 2017).

Reserves:

Various estimates have been made of the gold resources of Little Squaw Creek. The latest (Barker and others, 2009) is based 110 holes drilled by Goldrich Mining Company in 2007. Lower Little Squaw Creek has a measured and indicated resource of 9,101,600 cubic yards of material with an average grade of 0.0243 ounce of gold per cubic yard and an inferred resource of 1,401,666 cubic yards of material with an average grade of 0.0265 ounce of gold per cubic yard. (Subsequently Goldrich produced 2,115 ounces of gold in 2009 and 2010).

Site type: Mine

ARDF no.: CH040

Latitude: 67.5556 **Quadrangle:** CH C-3

Longitude: 148.1909

Location description and accuracy:

The Little Squaw Mine is about 0.7 mile north-northeast of Little Squaw Peak near the center of section 34, T. 32 N., R. 3 W., of the Fairbanks Meridian). The mine is shown by symbol on the USGS 1:63,360-scale topographic map. The location is accurate.

Commodities:

Main: Au

Other: Ag, Pb, Zn

Ore minerals: Arsenopyrite, galena, gold, pyrite, scorodite, sphalerite

Gangue minerals: Quartz

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Little Squaw vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite,

metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. The Little Squaw Mine is in the Upper Plate unit and although it is adjacent to the Little Squaw fault, one of the regional north-northwest faults, it is one of the deposits in the district that is associated with splays off the main fault.

The Little Squaw Mine was discovered by 1909 and by 1911 it had been explored by surface trenches, shafts, and a 64-foot adit. A road from the Little Squaw was built in 1909-10 to a small mill on lower Little Squaw Creek. Twenty-seven tons of ore were processed that recovered about 1.1 ounces of gold. In 1912, a 3-stamp mill was brought to Big Creek to test the Little Squaw ore and used until 1915. In 1933, the vein was described as having a proven length of 200 feet, a depth of 130 feet, and an average grade of 1.86 ounces of gold per ton across a width of 4 feet (Mertie, 1925; Boadway, 1933). Work continued erratically and by 1982, the workings consisted of adits at the 100-foot and 200-foot levels connected by several winzes and raises. An ore reserve of 10,000 tons of material with an average grade of 1.70 ounces of gold was established and a brief period of mining by the Chandalar Development Corporation took place in 1982 Barker and Bundtzen, 2005, Barker, 2006, Barker and others, 2009). In early 2010, this was one of the sites being studied by Goldrich Mining Company in their intensive exploration of the Chandalar area (Goldrich Mining Company, 2010).

The several veins at the Little Squaw Mine splay off the north-northwest-trending Little Squaw Fault are in a sequence of quartz-muscovite-chlorite phyllite, carbonaceous phyllite, quartzite, calcareous rocks, and a buff to red, siderite-bearing exhalative unit (Mertie, 1925; Boadway, 1933; Chipp, 1970; Dillon, 1982; Barker and Bundtzen, 2005, Barker, 2006, Barker and others, 2009). The footwall of the main vein as seen in the underground workings is gray muscovite-chlorite schist and phyllite; the hanging wall is muscovite schist. The gold values in the vein are concentrated in a one-foot band of ribbon quartz along the footwall; the quartz contains disseminated pyrite and arsenopyrite and minor galena and sphalerite. There are several generations of quartz. Massive, coarse-grained quartz is generally early and contains little or no gold; later fine-grained ribbon-banded quartz contains most of the ore minerals. The veins are generally oxidized to a depth of about 75 feet; the principal oxidation products are scorodite and limonite. The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004) by comparison with similar deposits elsewhere and in consideration of fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1983; Rose and others, 1988; Gacetta and Church, 1989).

On the surface, the mineralization vein can be traced in trenches for about 1,800 feet as discontinuous en echelon segments, with displacements of a few tens of feet. The principal vein is 2 to 8 feet thick, averages about 4 feet, and pinches and swells.

From 1975 to 1980, Callahan Mining Company and the Chandalar Development Corporation drilled 7 holes (Barker and others, 2009). None of the holes cut high-grade mineralization but did intersect several low-grade zones. The drilling showed the sheeted and discontinuous nature of the quartz veining and fault system. Little Squaw Gold Mining Company drilled 10 reverse-circulation holes in 2006; the best intercept was 20 feet that contained 4.21 parts per million (ppm) gold. They also did considerable trench sampling; one 1.9-foot channel sample assayed 129.5 ppm gold.

Alteration:

The veins are generally oxidized to a depth of about 75 feet; the principal oxidation products are scorodite and limonite.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:
Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:
The Little Squaw Mine was discovered by 1909 and by 1911 it had been explored by surface trenches, shafts, and a 64-foot adit. A road from the Little Squaw was built in 1909-10 to a small near lower Little Squaw Creek and 27 tons of ore were milled. In 1912, a 3-stamp mill was brought to Big Creek to test the Little Squaw ore and used until 1915. Work continued erratically and by 1982, the workings consisted of adits at the 100-foot and 200-foot levels connected by several winzes and raises. The Chandalar Development Corporation did some mining in 1982 (Barker and Bundtzen, 2005, Barker, 2006, Barker and others, 2009). From 1975 to 1980, Callahan Mining Company and the Chandalar Development Corporation drilled 7 holes (Barker and others, 2009). Little Squaw Gold Mining Company drilled 10 reverse-circulation holes in 2006. In early 2010, this was one of the sites being studied by Goldrich Mining Company in their intensive exploration of the Chandalar area (Goldrich Mining Company, 2010).

Production notes:
Limited mining from 1911 to perhaps 1915 and in 1982 by the Chandalar Development Corporation.

Reserves:
Probably none.

Additional comments:
See also the Mikado Mine (CH045). There is some confusion in the media between the Little Squaw Mine and others in the district, the Mikado Mine in particular. From 1959 to 2008, much of the Chandalar district, including the Little Squaw Mine, was owned by the Little Squaw Gold Mining Company (the Goldrich Mining Company since 2008). Much of the activity of the Little Squaw Gold Mining Company and the activity of their lessees was concentrated on the Mikado Mine and several other properties. There was relatively little work on the Little Squaw Mine itself. But especially in the news and trade press, the stories centered on the Little Squaw company, rather than on the work at the Mikado and the several placers on ground that the Little Squaw Company had leased. The distinction between the company and the Little Squaw Mine was often not clear.

Site name(s): Summit

Site type: Mine

ARDF no.: CH041

Latitude: 67.5387 **Quadrangle:** CH C-3

Longitude: 148.1853

Location description and accuracy:

The Summit Mine is on the ridge at the head of Big Squaw Creek about 0.6 mile south of Little Squaw Peak. It is at an elevation of about 4,600 feet about 0.5 mile west of the center of section 3, T. 31 N., R. 3 W. The location is accurate.

Commodities:

Main: Ag, Au

Other: As, Cu, Pb, Sb, Sn

Ore minerals: Arsenopyrite, galena, gold, scorodite, sphalerite, stibnite

Gangue minerals: Quartz

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Mikado vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Summit Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and as of early 2012, that effort continued (Goldrich Mining Company, 2012).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2007 [map]; 2007 [83 p.]. These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite.

Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. The rocks in the vicinity of the Summit Mine are mainly coarse- to fine-grained, rhythmically layered schist and phyllite of the Upper Plate.

By 1913, a 54-foot-deep shaft had been sunk on the Summit vein and a short adit driven on a 1.5- to 2.5-foot-thick gold-quartz vein (Maddren, 1913). The vein was exposed for 950 feet in a series of trenches. Numerous samples have been taken over the years by numerous companies of the Summit mineralization. Samples containing more than 1 ounce of gold are common, samples over 10 ounces per ton are not uncommon, and samples with visible gold can be found relatively easily. Heiner and Wolff (1968) report that there was some development work in the 1950s and a small mill was built by Ed Toussaint in 1957 and 1958 at the head of Big Creek to process ore from the Summit vein (Buzzell, 2007). It may not have milled any Summit ore although Barker and others (2008) note that it milled some ore from the Indicate vein (CH042) near the mill. Little Squaw Gold Mining Company drilled the Summit property in 2006 (Barker and others, 2009). Three of the holes intersected quartz veins; the best 5-foot intervals contained 5.71, 16.15, 5.52, and 3.24 parts per million gold. Goldrich Mining Corp. (2011) drilled 3 holes in 2011 that totaled 441 meters. Of the four intercepts 2.1 to 10.7 meters long that contained more than 0.50 grams of gold per tonne, the best was 2.1 meters that contained 1.23 ounces of gold per tonne.

The gold mineralization is localized along the Summit fault which strikes about N70-80W, dips 75-80 degrees north, and is marked by 1 to 6 inches of gray to black gouge (Chip 1970, Barker and Bundtzen, 2004, Barker, 2007; Barker and others, 2009). The rocks in the area are black to gray carbonaceous phyllite and schist of the Mikado Phyllite unit of Bundtzen and Laird (2007a, 2007b) overlain by lighter gray, muscovite, chlorite-quartz schist. Ashworth (1983) described two generations of quartz at the Summit lode. The older generation is coarsely crystalline, massive, white quartz. It is in the hanging wall and is as much as 4 feet wide. It contains less than 5 percent sulfides and little gold. The younger generation pinches and swells; it adjoins the older veins, but typically is in the footwall. It is generally finer grained and contains bands accentuated by smeared graphite and arsenopyrite. Scorodite is common, and free gold occurs as blebs and occasional wires. The veins are offset by near-vertical faults. In contrast to some of the other deposits in the area, e.g., the Little Squaw Mine (CH040), the Summit veins are usually moderately to strongly brecciated. The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004; Barker, 2006; Barker, 2007; Barker and others, 2009) by comparison with similar deposits elsewhere and in consideration of fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1983; Rose and others, 1988; Gacetta and Church, 1989).

The Chandalar Development Corporation mined the Summit vein from 1980 to 1983 (Barker and Bundtzen, 2004; Barker and others, 2009). They produced 1,347 ounces of gold from 1,401 tons of ore that averaged 1.29 ounces of gold per ton. The gold recovery was poor, apparently because the mill was not designed for the large amount of gouge in the ore.

In 2003, Little Squaw Gold Mining Company estimated that the 'probable resource' of the Summit Mine was 1,375 tons with a grade of 3.52 ounces of gold per ton and a 'possible resource' of 3,165 tons with an average grade of 2.13 ounces per ton (Barker and Bundtzen, 2004). However, the extensive trench and drill data collected during the work begun by Little Squaw Gold Mining Company in 2004 and continued by its successor Goldrich Mining Company indicate that the Summit vein is bordered by a wide aureole of lower grade, sheeting veins and disseminated gold. The high-grade veins that have traditionally been the exploration target may have overlooked the substantial potential in the low grade but large body of mineralization peripheral to the high grade veins (Barker and others, 2009).

Alteration:

Oxidation of vein material produced scorodite and limonite.

Age of mineralization:

Possibly mid-Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Undetermined

Site Status: Active

Workings/exploration:

By 1913, a 54-foot-deep shaft had been sunk on the Summit vein and a short adit driven on a 1.5- to 2.5-foot-thick gold-quartz vein (Maddren, 1913). The vein was exposed for 950 feet in a series of trenches. Numerous samples have been taken over the years by numerous companies of the Summit mineralization. Heiner and Wolff (1968) report that there was some development work in the 1950s and a small mill was built by Ed Toussaint in 1957 and 1958 at the head of Big Creek to process ore from the Summit vein (Buzzell, 2007). It may not have milled any Summit ore although Barker and others (2008) note that it milled some ore from the Indicate vein (CH042) near the mill. In addition to much surface sampling, trenching, and mapping, Little Squaw Gold Mining Company drilled the Summit property in 2006 (Barker and others, 2009). Goldrich Mining Corp. (2011) drilled 3 holes that totaled 441 meters in 2011.

Production notes:

The Chandalar Development Corporation mined the Summit vein from 1980 to 1983 (Barker and Bundtzen, 2004; Barker and others, 2009). They produced 1,347 ounces of gold from 1,401 tons of ore that averaged 1.29 ounces of gold per ton. The gold recovery was poor, apparently because the mill was not designed for the large amount of gouge in the mine-run ore.

Reserves:

In 2003, Little Squaw Gold Mining Company estimated that the 'probable resource' of the Summit Mine was 1,375 tons of material with a grade of 3.52 ounces of gold per ton and a 'possible resource' of 3,165 tons of material with an average grade of 2.13 ounces per ton (Barker and Bundtzen, 2004). However, the extensive trench and drill data collected during the work begun by Little Squaw Gold Mining Company in 2004 and its successor Goldrich Mining Company indicate that the Summit vein is bordered by a wide aureole of lower grade, sheeting veins and disseminated gold. The high-grade veins that have traditionally been the exploration target may have overlooked the substantial potential in the low grade but large body of mineralization peripheral to the high grade veins (Barker and others, 2009).

Gangue minerals: Quartz

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Indicate vein and several others in the vicinity, had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate,

chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults The rocks around the Indicate Mine are part of the Upper Plate and consist mainly of black carbonaceous phyllite and schist of the Mikado Phyllite.

There are several early reports of lode mineralization that became the Indicate Mine or are near it (Barker and Bundtzen, 2004, Barker, 2006; Barker, 2007). Reed (1930) noted that a 40-foot shaft of a drift mine on Big Creek exposed a wide quartz vein in bedrock. A two-stamp mill was set up in 1909 to process the quartz but there is no record of its production except that the recovery was poor and the ore grade was low. Anderson (1944) and Strandberg (1990) note an old report of a 20-foot-wide quartz vein that contained arsenopyrite, pyrite, and free gold. McKee (1939) reported a 15-foot-deep shaft near Big Creek that exposed a quartz vein with free gold; a dump sample contained 0.32 ounce of gold per ton. There was considerable trenching in the area and at least some production, probably until the late 1950s, when a small mill was set up by Ed Toussaint at the head of Big Creek (Buzzell, 2007). Barker (2007) indicates that it processed ore that contained about a third of an ounce per ton, probably from the Indicate vein (although Buzzell associated it with work at the Summit Mine (CH041)). Most of the area is covered by tundra and scree that has obscured many of the old trenches. But several on the Indicate vein were reopened in 1982; samples contained 1.7 and 6.0 ounces of gold per ton. The work in the early 1900s was able to follow the vein for about 350 feet.

The nearby Star Group prospects exposed an 8-to 10-foot wide vein in the early 1900s. Some of the trenches were reopened in 1982; samples contained up to 0.74 ounce of gold per ton. A prospect pit on the Star property exposed a 6-foot-wide, partly vuggy quartz vein containing visible arsenopyrite and scorodite (Chipp, 1970). The vein trends approximately N70W and dips 70 to 90 degrees northeast. A grab sample assayed 11 parts per million gold. Another pit exposed vuggy, brown-stained quartz containing phyllite inclusions and minor arsenopyrite. On the Tonopah claim (west of the airstrip on upper Big Creek) trenching has exposed a 50-foot-wide fracture zone containing numerous east-west-trending, vuggy, iron-stained, quartz-filled fractures two inches or less in width. Chipp (1970) suggests that this zone is probably the continuation of the Star vein system.

The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004) by comparison with similar deposits elsewhere and consideration of the fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1984; Rose and others, 1988; Gacetta and Church, 1989).

Alteration:

Oxidation of sulfides in the quartz veins.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Considerable trenching in the early 1900s and investigations of quartz veins found on bedrock in the placer workings. A period of activity sometime between WWII and 1962 may have resulted in some gold production. There was some exploration in the early 1980s; in early 2010, this was one of the areas being studied by Goldrich Mining Company in their intensive exploration of the Chandalar area (Goldrich Mining Company, 2010).

Production notes:

No records of production but some gold probably was recovered about 1909 and some between the end of WWII and 1962.

Reserves:

None.

Site name(s): Big Creek

Site type: Mine

ARDF no.: CH043

Latitude: 67.5201 **Quadrangle:** CH C-3

Longitude: 148.2076

Location description and accuracy:

About a mile and a half of Big Creek has been placer mined. The coordinates are at the mine symbol on the USGS 1:63,3600-scale topographic map. The mining took place in sections 10, 15, and 16, T. 31 N., R. 3 W., of the Fairbanks Meridian.

Commodities:

Main: Au

Other: Ag, As, Cu, Mo, Pb, REE, Sb, Th, Ti, U, W

Ore minerals: Gold

Gangue minerals:

Geologic description:

Big Creek is one of the major placer gold producers in the Chandalar district. The placers along the creek were worked only by small-scale methods and drift mining from about 1907 until WWII (Adney, 1945). From 1953 or 1954 and for a few years afterward, lower Big Creek was mining with heavy equipment. There was another period of placer mining with heavy equipment from 1993 to 1999.

As described by Reed (1930a, 1930b), the gravel in Big Creek mined in the 1920s was relatively shallow, averaging about 12 feet deep on the uppermost portion of the creek and deepening to about 20 to 22 feet on the lower portion of the creek. The gold occurred in the lower 3 to 5 feet of the gravel and there was very little gold on bedrock. The gravel was fairly coarse with numerous greenstone boulders as much as 3 feet in diameter. There is only one generation of placers in the drainage. The gold is reported to be bright yellow, generally irregular, and shot-like to flattened, but some occurs as crystals. The gold averages 1 millimeter with many 2- to 3-millimeter nuggets. A few nuggets include quartz, limonite, and goethite. It is also reported that the concentrates contain a large suite of heavy minerals in addition to the gold (Mertie, 1925; White, 1952). These heavy minerals include monazite, magnetite, hematite, rutile, pyrite, arsenopyrite, chalcopyrite, galena, stibnite, molybdenite, scheelite, and uranothorianite. A panned-concentrate sample had eU of 0.05 percent (White, 1952).

Barker and Bundtzen (2004) reported that the production from Big Creek was by: 1) hand mining before 1954 that produced 7,257 ounces of gold from gravel with an average grade of 0.209 ounce of gold per cubic yard, 2) drift mining before 1954 that produced 7,588 ounces of gold, 3) mechanical mining from 1954 to about 1960 that produced 7,954 ounces of gold from gravel that averaged 0.026 ounce per cubic yard, and 4) mechanical mining from 1993 to 1999 that produced 2,541 ounces of gold. This totaled 25,340 ounces of gold. (These figures include the production from St. Mary's Gulch (CH044)).

Strandberg (1990) estimated that the resource of Big Creek was 2.4 million cubic yards of gravel with an average grade of 0.0154 ounce of gold per cubic yard, or 35,505 ounces of gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; medium

Site Status: Active

Workings/exploration:
Big Creek was mined by hand mining and by drifting for many if not most years from 1907 to the beginning of World War II. Mining with heavy equipment began in 1953 or 1954, continued until about 1960, and then resumed from 1993 to 1999.

Production notes:
Barker and Bundtzen (2004) reported that the production from Big Creek was by: 1) hand mining before 1954 that produced 7,257 ounces of gold from gravel with an average grade of 0.209 ounce of gold per cubic yard; 2) drift mining before 1954 that produced 7,588 ounces of gold; 3) mechanical mining from 1954 to about 1960 that produced 7,954 ounces of gold from gravel that averaged 0.026 ounce per cubic yard; and 4) mechanical mining from 1993 to 1999 that produced 2,541 ounces of gold. This totaled 25,340 ounces of gold. These figures include the production from St. Mary's Gulch (CH044).

Reserves:
Strandberg (1990) estimated that the resource of Big Creek was 2.4 million cubic yards of gravel with an average grade of 0.0154 ounce of gold per cubic yard, or 35,505 ounces of gold. (But note that 2,541 ounces of gold was subsequently produced from Big Creek from 1993 to 1999).

Additional comments:
The first recorded occurrence of monazite in Alaska was from Big Creek (Mertie, 1925).

Location description and accuracy:

St Marys Creek is an informal name for the mile-long creek that flows southeast into upper Big Creek; the mouth of St Marys Creek is about 1.2 miles east of McLellan Mountain. Much of the creek in the southeast quarter of section 9, T. 32 N., R. 3 W., was mined. The location is accurate.

Commodities:

Main: Au

Other: As, Cu, Mo, Pb, REE, Sb, Th, Ti, U, W

Ore minerals:

Gangue minerals:

Geologic description:

Maddren (1913) noted that most of the gold produced in the Chandalar district had come from upper Big Creek and St Marys Gulch. Despite its early production, there is little information describing St Marys Creek in particular; most of the mining was done during the same time and/or in conjunction with the much more extensive mining on Big Creek and the production records for Big Creek probably include the production from St Marys Creek (Adney, 1945). Anderson (1956) noted that St Marys Creek was very rich. Some of the open cuts and drift mine worked ground that ran up to $8 in gold per square foot of bedrock (at $20.67 per ounce of gold). On the claim where St Marys Creek enters the valley of Big Creek, drift mining was working ground that ran about $2 in gold per square foot of bedrock in gravel that was 15 to 20 feet deep and 25 feet wide. Mining on St Marys Creek is mentioned only in passing after 1956. However, Bundtzen and Barker (2004) noted that several quartz veins (that became the St Marys lode prospect (CH113) were uncovered during placer mining on St Marys Creek in 1993.

Chipp (1970) noted that pan samples from Big Creek and St. Marys Gulch show the gold to be bright yellow and shot-like to flattened; a few crystals occur. The average grain size of the gold is said to be about 1 mm, and there are many 2- to 3-mm nuggets. Some nuggets include quartz crystals and iron oxides. In addition to the gold the concentrates contain a large suite of heavy minerals including monazite, magnetite, hematite, rutile, pyrite, arsenopyrite, chalcopyrite, galena, stibnite, molybdenite, scheelite, and uranothorianite.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; medium

Site Status: Active

Workings/exploration:
Gold was being mined on St Marys Creek from open cuts and by drift mining by 1913 and it may have continued to WWII as part of the much more extensive efforts on Big Creek (CH043). However, there is little production data on St Marys Creek specifically. Barker and Bundtzen (2004) mentioned in passing that several quartz veins were uncovered during placer mining on St Marys Creek in 1993.

Production notes:
Some production from the earliest mining in the district; mechanical mining with heavy equipment in 1993 and perhaps a few years more. But there is no data is available on St Marys Creek specifically; the production is probably included with that from Big Creek (CH043).

Reserves:
Probably none.

Site type:

Mine

ARDF no.: CH045

Latitude: 67.5335

Quadrangle: CH C-3

Longitude: 148.2528

Location description and accuracy:

The portal of the Mikado Mine is on the north side of the upper end of the east branch of Tobin Creek. It is at an elevation of about 4,600 feet, approximately 1.6 miles southwest of Little Squaw Peak and about 0.6 mile south-southeast of the center of section 5, T. 31 N., R. 3 W., of the Fairbanks Meridian. The location of the mine is well known and accurately located. The Mikado vein extends up to a mile to the southeast where it is known as the St. Mary's vein (CH113).

Commodities:

Main: Au

Other: Ag, As, Pb, Sb, Zn

Ore minerals: Arsenopyrite, galena, gold, pyrite, sphalerite, stibnite

Gangue minerals: Dolomite, quartz, siderite

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Mikado vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area. As of early 2012 that effort continued (Goldrich Mining Company, 2012).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2007 [map], 2007 [technical report]). These faults separate the rocks into two principal units: a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper

Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist, quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults.

The Mikado Mine is the most productive lode deposit in the Chandalar area and has been a center of attention from the earliest days of the Chandalar district (Barker and Bundtzen, 2004; Barker and others, 2009). The Mikado vein was discovered in 1909. Soon after, Maddren (1913) reported open cuts that exposed auriferous quartz in six places over a strike length of 3,000 feet. Underground workings, including a 100-foot shaft and 160-foot adit, were completed by 1913. In the following decades, the Mikado was frequently visited by industry and government. The underground workings were reopened in 1960, and over the next 24 years, there was considerable underground exploration, surface exploration and trenching, exploration and mining. Chandalar Gold Mining and Milling Company operated the Mikado Mine from 1967 to 1971 and produced 685 ounces of gold from ore that averaged 1.64 ounces of gold per ton (Barker and others, 2009); Callahan Mining mined in 1975 and recovered 185 ounces of gold from ore that averaged 0.85 ounce of gold per ton. Chandalar Development produced 6,822 ounces of gold from 1980 to 1983 from ore that averaged 0.93 ounce of gold per ton, although the mill recovery was poor. Since 2004, Little Squaw Gold Mining Company and its successor Goldrich Minerals have continued to explore the property (Barker and others, 2009; Goldrich Mining Company, 2011).

In 2011, Goldrich drilled 11 holes totaling 2,127 meters on the Mikado vein near the main portal of the old mine and about a half mile to the southeast on the vein's extension that is often called the St. Mary's vein (Goldrich Mining Company, 2011). The best intercepts were 0.9 meters with 4.58 grams of gold per tonne, 0.9 meters with 4.64 grams of gold per tonne, 0.9 meters with 10.25 grams of gold per tonne, 0.9 meters with 9.44 grams of gold per tonne, and 0.9 meters with 14.7 grams of gold per tonne.

As described by early workers, the Mikado vein is along a shear zone about 50 feet wide that contains sub-parallel, highly faulted and brecciated, steeply dipping gold-quartz veins and lenses up to 6 feet thick which have been exposed for over 3,000 feet along the Mikado fault (Maddren, 1913). Although the Mikado vein is said to average 6 feet in thickness over a 500-foot strike length, most of the ore shoots are discontinuous and generally are a few tens or hundreds of feet long. According to Boadway (1933), the Mikado vein in the underground workings consists of lenses of auriferous quartz, mostly on the hanging wall of the gouge-filled Mikado fault. The vein there appeared to be approximately 35 inches or less in width in the upper levels and narrowed to 16 inches at a depth of 99 feet. Ore shoots in the vein reportedly assayed from $37 per ton to as high as $439 per ton (at $20.67 per ounce of gold), and one ore shoot averaged $49.50 per ton over a 35-inch width (Chipp, 1970). Chipp indicated that white, crystalline to microcrystalline quartz is the dominant gangue mineral and that crystals of quartz are commonly found in small vugs. Banding in the quartz veins is produced by shearing and by elongate cavities in the veins parallel to the walls. Siderite occurs in minor amounts. Ashworth (1983) described three generations of quartz in the Mikado deposit: 1) lenses and pods of quartz plus or minus pyrite plus or minus dolomite, these are possibly pre-faulting metamorphic segregations; 2) massive, white, coarsely crystalline quartz with less than 5 percent sulfides and trace gold; and 3) 'main stage' quartz, which is fine grained, white, and in places vuggy. The sulfide assemblage in main stage quartz consists in decreasing order of abundance: arsenopyrite, galena, sphalerite, stibnite, and pyrite. Native gold, as flakes or wires, is common in the Mikado; the gold typically occurs along the borders of sulfide grains or in quartz near sulfides. Sulfides generally form less than 5 percent of the main-stage veins. The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004; Barker, 2006; Barker 2007; Barker and others, 2009) by comparison with similar deposits elsewhere and from fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1983; Rose and others, 1988; Gacetta and Church, 1989).

The Mikado Mine is in a distinctive band of gray, carbonaceous phyllite, a major part of the Mikado Phyllite unit. Barker and Bundtzen (2004) note that the Mikado deposit is distinct in the district in that the

structure in which the vein occurs, which may be tens of feet thick, is unusually thick and intensely sheared with abundant gouge. They also emphasize several generations of quartz veining, accompanied by faulting during, prior to, and after the mineralization event(s). Barker and others (2009) suggests that while rich pockets of ore were mined at the Mikado, they might better be considered as rich lenses along a 4,000-foot zone of mineralization that extends to the St. Marys deposit (CH113) and is open at both ends. The potential of this zone may be the extensive lower grade and probably more continuous mineralization that surrounds and extends beyond the smaller rich segments of the belt such as those that were mined in the Mikado.

Alteration:

Oxidation of vein material produces scorodite and limonite.

Age of mineralization:

Possibly mid-Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there are no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

The Mikado is the most productive lode deposit in the Chandalar area and has been a center of attention from the early history of the area. Maddren (1913) reported open cuts that exposed auriferous quartz in six places over a strike length of 3,000 feet. Underground workings, including a 100-foot shaft and 160-foot adit, reportedly were completed by 1913. The underground workings were reopened in 1960, and over the next 24 years, there was considerable underground exploration, surface exploration, trenching, and mining. Chandalar Gold Mining and Milling Company operated the Mikado Mine from 1967 to 1971 (Barker and others, 2009); Callahan Mining mined in 1975; and Chandalar Development mined from 1980 to 1983. In 2004, Little Squaw Gold Mining Company and its successor Goldrich Minerals began an aggressive exploration program in the district that included work at the Mikado (Barker and others, 2009; Goldrich Minerals, 2011). In 2011, Goldrich drilled 11 holes totaling 2127 meters on the Mikado vein in the vicinity of the main portal of the old mine and about a half mile to the southeast on the vein's extension that is often called the St. Mary's vein (Goldrich Mining Company, 2011).

Production notes:

The amount of gold produced from the Mikado vein prior to 1960 is unknown. There may have been some early production as a small stamp mill was constructed on Spring Creek by 1913 to process ore from the Mikado and Little Squaw Mines. The Mikado is the most productive lode deposit in the Chandalar area. Chandalar Gold Mining and Milling Company operated the Mikado Mine from 1967 to 1971 and produced 685 ounces of gold from ore that averaged 1.64 ounces of gold per ton (Barker and others, 2009); Callahan Mining mined in 1975 and recovered 185 ounces of gold from ore that averaged 0.85 ounce of gold per ton. Chandalar Development produced 6,822 ounces of gold that averaged 0.93 ounce of gold per ton, although the mill recovery was poor. As of the end of 2011, there had been no additional production (Barker and others, 2009).

Reserves:

Over the years, various geologists and engineers people have cited different reserve or resource figures for the Mikado Mine or the Chandalar district where the Mikado was the best known and largest deposit. For examples see Nokleberg and others (1987), Baggs and others (1), and Swainbank and others(1998). However the most recent estimate in 2005 after several periods of mining from 1967 to 1983 was by the Little Squaw Gold Mining Company (now Goldrich Mining Company) was that the Mikado Mine had 110 tons of proven resources with an average grade of 1.10 ounce of gold per ton and 5,200 tons of probable resources with an average grade of 1.05 ounce of gold per ton (Barker and Bundtzen, 2004; Barker and others, 2009).

Site name(s): Eneveloe; Bonanza; Jupiter; Woodchuck; Chandalar; Big Squaw

Site type:

Prospect

ARDF no.: CH046

Latitude: 67.5457 **Quadrangle:** CH C-3

Longitude: 148.203

Location description and accuracy:

The Eneveloe prospect is at an elevation of about 4,700 feet, approximately 1/4 mile south of Little Squaw Peak and about 0.7 mile northwest of the center of section 3, T. 31 N., R. 3 W., of the Fairbanks Meridian. The location is accurate. This site includes several other smaller veins and prospects nearby south of Little Squaw Peak including the Bonanza, Jupiter, Woodchuck, Chandalar, and Big Squaw.

Commodities:

Main: As, Au

Other: Ag, Cu, Pb, Sb, Zn

Ore minerals: Arsenopyrite, galena, gold, pyrite, scorodite, sphalerite

Gangue minerals: Quartz

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Mikado vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2012 that effort continued (Goldrich Mining Company, 2012).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2007 [map]; 2007 [83 p.]). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of

Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. The Eneveloe Mine and several nearby prospects are in the Upper Plate rocks.

An 165-foot adit was driven on the Eneveloe vein before 1913 (Maddren, 1913). Another adit was opened on the nearby Woodchuck claim, but there is no description of its extent. The property has also been explored for 1,000 feet along strike by open cuts and other shallow workings.

The Eneveloe lode consists of at least two discontinuous quartz veins up to 4 to 6 feet or more thick. The Eneveloe deposit is along a fault zone that trends N 65-80 W and dips steeply north (Chip, 1970; Barker and Bundtzen, 2005; Barker, 2006, Barker and others, 2009). According to Maddren (1913), a sample from a surface outcrop on the Last Chance claim assayed $198 (approximately 9.6 ounces of gold per ton). Prospect pits nearby on the Jupiter claim exposed quartz containing minor arsenopyrite and scorodite. At the Bonanza claim, prospect pits expose small and discontinuous quartz veins containing minor galena and scorodite.

The high-grade portion of the Eneveloe vein is similar to most of the quartz veins in the district. They are discontinuous along the regional fault on which they occur and usually pinch out within within a few hundred feet or less. Widths vary from a few inches to several feet but are generally less than 10 feet. The quartz veins exhibit evidence of shearing, which indicates that the veins were emplaced before or during fault movement. Sulfide content of the veins is typically less than 5 percent; the sulfides, in order of abundance are arsenopyrite, galena, sphalerite, and pyrite. Much of the gold occurs as native gold. Weathering near the surface has oxidized and leached the sulfides to produce scorodite and limonite. The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004) by comparison with similar deposits elsewhere and consideration of fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1983; Rose and others, 1988; Gacetta and Church, 1989).

In 1982, the Chandalar Development Company drove short adits at the 100-foot and 200-foot levels on the Eneveloe mineralization (Barker and Bundtzen, 2005; Barker 2006; Barker and others, 2009). The lower adit intersected the west end of the Eneveloe vein and then drifted on it for 500 feet. A high grade quartz lens 70 feet long was found that assayed 0.5 to 10.0 ounces of gold per ton. The upper adit was driven toward a massive quartz outcrop. The workings hit finely ground-up quartz on the north side of the massive quartz that assayed more than 2 ounces of gold per ton. (Both adits were caved in 2005.) Chandalar Development Company also diamond drilled 6 drill holes that totaled 1,113 feet. The core recovery was so poor that few assays were possible, but the drilling suggested parallel veins. Little Squaw Gold Mining Company trenched west of the 100-level adit but were unsuccessful in locating the vein.

There are several prospects nearby that are often considered part of the Eneveloe property (Barker, 2007). The Jupiter vein was trenched in 1981; samples from a 3-foot quartz vein contained up to 0.36 ounce of gold per ton. In 2006, three holes were drilled; two of the holes were unsuccessful in hitting the vein and the best intercept in the third was 10 feet that averaged 2.31 parts per million (ppm) gold. Samples from the Chandalar vein assayed up to 49.98 ounces of gold per ton. Old working were reopened in 2004; an 18-inch section of a 3-foot wide vein contained 33.6 ppm gold. At the Bonanza prospect, a composite 9-foot-wide band of mineralization that extends for 500 feet consists of crushed quartz, scorodite-stained clay and quartz, graphitic clay gouge, and massive quartz. Channel samples across the band contained an average of 2.71 ppm gold. At the Woodchuck prospect, a 3- to 6-foot vein can be traced for about 100 feet. Samples cited in the old reports contained 0.04 and 0.06 ounce of gold per ton. At the Big Squaw prospect west of the Eneveloe, a vein 7- to 12-feet wide was trenched and a short adit was driven on it. A sample taken in 2004 contained 0.30 ppm gold. In 2011, Goldrich Mining Corp. (2011) drilled 2 holes totaling 203 meters on the Bonanza vein about 0.4 mile south-southeast of Little Squaw Peak. Two intervals were cut that contained more than 0.50 ounce of gold per tonne; the best was 0.9 meter that contained 4.74 grams of gold per tonne.

Alteration:

Not specifically noted. However, many of the veins in the area such as Eneveloe are aligned along major faults that are marked by much clay and gouge.

Age of mineralization:

Possibly mid-Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Undetermined

Site Status: Active

Workings/exploration:

An 165-foot adit was driven on the Eneveloe vein before 1913 (Maddren, 1913). Another adit was opened on the nearby Woodchuck claim, but there is no description of its extent. The property has also been explored for 1,000 feet along strike by open cuts and other shallow workings. In 1982, The Chandalar Development Company drove short adits at the 100-foot and 200-foot levels and diamond drilled 6 holes that totaled 1,113 feet (Barker and Bundtzen, 2005; Barker 2006; Barker and others, 2009). The core recovery was so poor that few assays were possible. Little Squaw Gold Mining Company trenched west of the 100-level adit but were unsuccessful in locating the vein. In early 2010, this was one of the sites being studied by Goldrich Mining Company in their intensive exploration of the Chandalar area (Goldrich Mining Company, 2010).

Production notes:

None.

Reserves:

None.

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Mikado vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2010, that effort continued (Goldrich Mining Company, 2010).

In spite of the proximity of Big Squaw Creek to many of the gold-bearing veins in the Chandalar district, the placer mining on this creek appears to be limited to near the head of the creek, just below the Jupiter claim on the Eneveloe prospect (CH046) (Chipp, 1970). The mining was from small-scale surface workings by hand methods. Mining in 1923 was in gravel 3 to 4 feet deep. Mining was reported as late as 1928, but there is no information on any later activity. On the lower creek early efforts at mining the deeper gravels were thwarted because the gravels were thawed and drift mining through shafts was not possible because of water inflow and lack of support.

Strandberg (1994) postulated a possible ancestral auriferous channel of Big Squaw Creek near the airstrip on lower Big Creek. He estimated a possible 1,500,000 cubic yards of gravel with an average grade of 0.06 ounce per cubic yard in a bench near the airstrip. The data to justify Strandberg's estimate is unavailable

(Barker and Bundtzen, 2004). In 1997, Daglow Exploration drilled three holes to a depth of 96 feet on lower Big Squaw Creek near the airstrip (Fitch, 1997). Only traces of gold were recovered, but the holes did not reach bedrock. Testing the possibility that there might be a placer in lower Big Squaw Creek similar to the one in the pre-glacial fan in Lower Little Squaw Creek (CH039), Little Squaw Gold Mining Company drilled two test holes near the Squaw Lake airstrip (Barker and others, 2009). The gold particles that were recovered and the accompanying heavy mineral assemblage were to those in the Little Squaw Creek fan. The gold was scattered through the fluvial gravel but seemed to be more abundant at depth.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The only mining on Little Squaw Creek was from small-scale surface workings by hand methods. Mining in 1923 was in gravel 3 to 4 feet deep. Mining was reported as late as 1928, but there is no information on any later activity. There have been several generations of drilling on lower Big Squaw Creek near the airport, the latest in 2008, to test the possibility of gold bearing gravel in the valley of Squaw Lake similar to that in the lower part of Little Squaw Creek. Trace to some gold was found in the few holes.

Production notes:

Some small production that cannot be documented.

Reserves:

Strandberg (1994) estimated a possible resource of 1,500,000 cubic yards of gravel with an average grade of 0.06 ounce per cubic yard in a bench near the airstrip. The data to justify Strandberg's numbers are unavailable.

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941. Those properties were taken over in 1946 to what became the Little Squaw Mining Company in 1959 and the Little Squaw Gold Mining Company in 1968. In 2008, the Little Squaw Gold Mining Company became the Goldrich Mining Company, the operator as of early 2010 (Goldrich Mining Company, 2010). From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and as of early 2010, that effort continued (Goldrich Mining Company, 2010).

A total of about a mile and a half of the headwaters of Tobin Creek and two of its headwater tributaries, Woodchuck Creek and the tributary that leads to the Mikado Mine (CH045) have been mined (Barker and Bundtzen, 2004; Bundtzen and Laird, 2009a, 2009b; Barker, 2007; Barker and others, 2009). Prospecting on Tobin Creek began in 1930 with encouraging results and a rich pay streak was found in 1934. About 1,000 ounces of gold was produced from 1932 to 1966 from shafts and by open-cut mining. From 1966 to 1970, the Chandalar Gold Mining and Milling Company and Canalaska began mechanical mining with heavy equipment and produced 7,500 ounces of gold from material that ran about 0.535 ounce of gold per cubic yard. From 1979 to 1993, another 12,599 ounces of gold was produced by Gold Dust Mines from gravel that averaged about 0.021 ounce per cubic yard . In addition to gold, concentrates contain hematite, monazite, scheelite, pyrite, magnetite, rutile, and galena (White, 1952).

Strandberg (1990) estimated that Tobin Creek contained 2.5 million cubic yards with an average grade of 0.0283 ounce of gold per cubic yard. Barker and Bundtzen (2009) suggested that most of the high-grade has been mined and estimated the 'possible' resource as 91,333 ounces of gold in 2,352,000 cubic yards of gravel with an average grade of 0.060 ounce per cubic yard.

Site Status: Active

Workings/exploration:

A total of about a mile of the headwaters of Tobin Creek and two of its headwater tributaries, Woodchuck Creek and the tributary that leads to the Mikado Mine (CH045) have been placer mined (Barker and Bundtzen, 2004; Bundtzen and Laird, 2009a, 2009b; Barker and others, 2009). Prospecting on Tobin Creek began in 1930 with encouraging results and a rich pay streak was found in 1934. About 1,000 ounces of gold was produced from 1932 to 1966 from shafts and by open-cut mining. From 1966 to 1970, the Chandalar Gold Mining and Milling Company and Canalaska began mechanical mining with heavy equipment and produced 7,500 ounces of gold. From 1979 to 1993, another 12,599 ounces of gold was produced, mainly by Gold Dust Mines.

Production notes:

About 1,000 ounces of gold was produced from 1932 to 1966 from shafts and by open-cut mining. From 1966 to 1970, the Chandalar Gold Mining and Milling Company and Canalaska began mechanical mining with heavy equipment and produced 7,500 ounces of gold. From 1979 to 1993, another 12,599 ounces of gold was produced, mainly by Gold Dust Mines.

Reserves:

Strandberg (1990) estimated that Tobin Creek contained 2.5 million cubic yards of gravel with an average grade of 0.0283 ounce of gold per cubic yard. Barker and Bundtzen (2004) suggested that most of the rich gravel has been mined and estimated the possible resource as 91,333 ounces of gold in 2,352,000 cubic yards of gravel with an average grade of 0.060 ounce per cubic yard.

Site name(s): Kelty

Site type: Prospect

ARDF no.: CH049

Latitude: 67.5551 **Quadrangle:** CH C-3

Longitude: 148.2756

Location description and accuracy:

The Kelty prospect is in the pass at the head of the east fork of the McNett Fork and about 2.2 miles southwest of the junction of McNett Fork and Big Squaw Creek (which is called Squaw Creek on the USGS topographic maps). It is about 0.4 mile west of the center of section 32, T. 32 N., R. 3 W. The location is accurate.

Commodities:

Main: Au

Other: As

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Mikado vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and as of early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist- facies metamorphic rocks, mainly metamorphosed volcanic agglomerate,

chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults.

There is little information about the Kelty prospect. Maddren (1913) described it as an extension of the Eneveloe property (CH046). Dillon (1982) described it as steeply dipping (65SE) gold-quartz veins in schistose rock. In their extensive work on the Chandalar district beginning in 2004, Little Squaw Gold Mining Company and its successor Goldrich Mining Company visited the property. The Kelty deposit consists of a series of altered fault zones with thin quartz veins; samples contained minor gold values and anomalous arsenic. Soil from a mineral seep on the slope below contained 0.595 part per million (ppm) gold. Several small prospect pits that they identify as the Mercury, Caribou Gulch, and Caribou Gulch South are scattered for about a mile to the east along what is locally called Caribou Gulch. No vein material were identified at any of the pits although the fines from one pit contained 1.54 ppm gold. These scattered small deposits at the outer edge of the Chandalar mineralized area are probably similar in origin to the other gold-quartz veins in the Chandalar district. (e.g., the Mikado Mine (CH045). The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004; Barker, 2006; Barker 2007; Barker and others, 2009) by comparison with similar deposits elsewhere and in consideration of fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1984; Rose and others, 1988; Gacetta and Church, 1989).

Alteration:

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

None other than few scattered prospect pits. Visited by several industry and government geologists over the years but apparently no work beyond limited sampling.

Production notes:

None.

Reserves:

None.

Site name(s): Boulder Creek

Site type: Mine

ARDF no.: CH050

Latitude: 67.5599 **Quadrangle:** CH C-3

Longitude: 148.4085

Location description and accuracy:

This placer mine is on Boulder Creek which flows west into the North Fork Chandalar River; the mouth is is about a half mile north of Chandalar Lake. The mine is about 0.5 mile north of the center of section 34, T. 32 N., R. 4 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Kurtak and others (2002) noted a trommel, loader, and a backhoe at a large area of tailings about a mile and a half from the mouth of Boulder Creek There was also a camp and airstrip nearby and they noted 'current mining operations'. Placer claims were active on Boulder Creek in 1969 and during the 1990s. Apparently the first mining on Boulder Creek was in 1989 (Bundtzen and others, 1990).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Undetermined

Workings/exploration:

Kurtak and others (2002) noted a trommel, loader, and a backhoe at a large area of tailings about a mile and a half from the mouth of Boulder Creek There was also a camp and airstrip nearby and they noted

'current mining operations'. Placer claims were active on Boulder Creek in 1969 and during the 1990s. Apparently the first mining on Boulder Creek was in 1989 (Bundtzen and others, 1990).

Production notes:

The first placer mining on Boulder Creek apparently was in 1989. There was probably mining in the late 1990s and possibly in the 2000s. The amount of gold that was produced is unknown.

Reserves:

None?

Site name(s): Arsine

Site type: Prospect

ARDF no.: CH052

Latitude: 67.6593 **Quadrangle:** CH C-4

Longitude: 148.6657

Location description and accuracy:

The Arsine prospect is at an elevation of about 5,100 feet near the head of Anderson Creek, a south-flowing tributary of Baby Creek. It is about 0.6 miles west-northwest of the center of section 27, T. 33 N., R. 5 W. The location is accurate within one mile.

Commodities:

Main: Cu, Mo

Other: As, Sb

Ore minerals: Unspecified copper and molybdenum sulfides and an unspecified arsenic mineral; magnetite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

The Arsine prospect is near a thrust fault in lower Paleozoic metamorphic rocks between two masses of the Devonian(?) Baby Creek granitic batholith (Brosgé and Reiser, 1964) The prospect was staked in 1964 by the Oil Development Company of Texas based on soil samples with anomalous copper, arsenic, and antimony (Kurtak and others, 2002). Little is known about the exploration of the property other than that there is an indication that the target was gold and arsenic mineralization (DeYoung, 1978).

Kurtak and others (2002) found conspicuous, iron-oxide-stained gneiss with about 2 percent disseminated pyrite, pyrrhotite, and magnetite, that extends for about 2 miles along a contact of the granitic rocks with quartz-mica schist. A sample of siliceous, metamorphosed intrusive rock collected nearby contained 138 ppm copper and 135 ppm molybdenum. Kurtak and others (2002) suggest that the prospect may be a metamorphosed copper-molybdenum porphyry deposit.

Alteration:

Iron-staining of gneiss from oxidization of disseminated pyrite, pyrrhotite, and magnetite.

Age of mineralization:

Data too sparse to determine.

Generic deposit model:

Deposit model:

Data to sparse to classify.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

No indication of industry work beyond claim staking in 1964. Sampled by Bureau of Land Management (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (at head of Geroe Creek); MAS

Site type: Prospect

ARDF no.: CH053

Latitude: 67.6804 **Quadrangle:** CH C-4

Longitude: 148.814

Location description and accuracy:

This deposit is best exposed in cliffs at the head of the west, headwater tributary of Geroe Creek, in the southwest quarter of section 13, T. 33 N., R. 6 W. A block of 239 claims was staked over this deposit in the mid-1970s.

Commodities:

Main: Au, Cu, Mo

Other: Pb

Ore minerals: Chalcopyrite, molybdenite, pyrite

Gangue minerals: Chlorite, quartz, sericite

Geologic description:

Placid Oil Company staked a block of 239 claims over this prospect in 1975-1976. There apparently has been little industry work since then although the the area was examined by the Bureau of Land Management in their study of the Koyukuk mining district (Kurtak and others, 2002).

This prospect is one of several quartz stockworks and altered zones in the northeast-trending belt of Devonian peraluminous biotite-muscovite granite of the Baby Creek batholith and Devonian, metaluminous biotite-hornblende granite and granodiorite of the Horace Mountain pluton (Brosgé and Reiser, 1964; Newberry and others, 1986). Porphyritic phases occur locally in these plutons, and DeYoung and others (1997) report that the mineralizing intrusives are porphyritic meta-granodiorite and biotite meta-granite. The country rocks are mainly Paleozoic schist and marble, and peraluminous meta-granodiorite. DeYoung and others (1997) note the absence of skarn in the calcareous rocks adjacent to these plutons. The veinlets in the stockworks at this prospect contain disseminated molybdenite, chalcopyrite, and pyrite, accompanied by intense quartz-sericite-chlorite-(+/- epidote) alteration. Eakins and others (1983) report grades of up to 0.1 percent molybdenum, Nokleberg and others (1987) report that zones as much as several meters thick in the plutons contain 0.6 percent copper, 0.02 percent molybdenum, and 0.1 gram of gold per tonne. Kurtak and others (2002) identified a limonite-stained, altered area about 2,000 feet wide at the head of Geroe Creek that has disseminated pyrite and a gray mineral that is probably molybdenite. A sample contained 5,212 parts per million (ppm) molybdenum and 106 ppm lead. Minor chalcopyrite and copper staining are found occasionally and a float sample contained 1,457 ppm copper and 37 parts per billion gold.

Alteration:

Sericitization and propylitization of porphyritic host rocks; veinlets in stockworks are accompanied by intense quartz-sericite-chlorite-(+/- epidote) alteration.

Age of mineralization:

Devonian or younger based on Early Devonian Pb/Pb zircon ages from the Baby Creek batholith and Horace Mountain plutons that are similar to the igneous rocks that hosts this deposit (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Porphyry Cu-Mo (Cox and Singer, 1986; model 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

21a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Placid Oil Company staked a block of 239 claims over this prospect in 1975-1976. There has apparently been little industry work since then although the area was examined and sampled by the Bureau of Land Management in their study of the Koyukuk mining district (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Primary Reference: Newberry and others, 1986; Kurtak and others, 2002

Reporter(s): J.M. Britton (Anchorage, Alaska); D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-18

Site name(s): Unnamed (near Willow Creek)

Site type: Occurrence

ARDF no.: CH055

Latitude: 67.6436 **Quadrangle:** CH C-4

Longitude: 148.8936

Location description and accuracy:

This occurrence is at an elevation of about 4,000 feet on a hillside about 1.6 mile east-southeast of the junction of Willow Creek and Little Spruce Creek. It is about 0.5 mile west of the center of section 34, T. 33 N., R. 6 W.

Commodities:

Main: Au, Sb, Zn

Other:

Ore minerals: Gold, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

Brosgé and Reiser (1972) collected samples with anomalous zinc in Devonian(?) albite-chlorite-mica schist near the contact with calcareous schist and marble (Brosgé and Reiser, 1964). Two of the rock samples contained 0.8 to 5.6 parts per million gold. There or nearby, Kurtak and others (2002) found knobs of resistant marble and hornfels in rubble crop of chlorite-muscovite schist. The hornfels contains a small amount of disseminated sphalerite, pyrite, and pyrrhotite. Six samples of hornfels contained 36 ppm to 3.09 percent zinc. A sample of hornfels in float contained 1.56 percent antimony and 153 parts per billion gold.

Alteration:

Masses of hornfels developed in chlorite-muscovite schist.

Age of mineralization:

Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Hornfels with zinc, antimony, and gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only limited sampling by government agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2010-04-18

Site name(s): Big Jim Creek; Suklak Creek

Site type: Mine

ARDF no.: CH056

Latitude: 67.5349 **Quadrangle:** CH C-5

Longitude: 149.0484

Location description and accuracy:

Big Jim Creek flows into the north end of the southern of the Twin Lakes. Most of Big Jim Creek flows across the southern halves of section 1 and 2, T.31 N., R. 7 W. There is an early reference to placer mining along the creek at some unstated location. For this record, the site is arbitrarily plotted at an elevation of about 2,360 feet along the creek.

Commodities:

Main: Au

Other: Cu

Ore minerals: Copper, gold

Gangue minerals:

Geologic description:

Reed (1938) noted that this small placer mine produced native copper nuggets as well as gold. The amount of production was unknown, but probably was quite small. Kurtak and others (2002) visited the creek and panned samples. Their samples did not contain any gold nor did they find any sign of mining along the creek other than a cabin. Dillon (1987) reported a mining claim on the creek.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Probably inactive

Workings/exploration:

Worked by rocker and panning sometime before 1938; Kurtak and others (2002) found no sign of recent

mining.

Production notes:

A small amount of placer gold and copper nuggets were produced prior to 1938.

Reserves:

None.

Additional comments:

Suklak Creek is the old name for this stream and it was worked by 'Big Jim' Edwards. Much of the information in Reed (1938) is hearsay.

Last report date: 2010-04-18

Site name(s): Robert Creek; Sheep Creek

Site type: Prospects

ARDF no.: CH058

Latitude: 67.6359 **Quadrangle:** CH C-5

Longitude: 149.1891

Location description and accuracy:

Robert Creek is one of the principal tributaries to the Bettles River, and Sheep Creek is a major south-flowing tributary to Robert Creek. The creeks are many miles long. There is reference to early prospecting on Robert Creek, Sheep Creek, and their tributaries but no indication where. This site is arbitrarily plotted at the junction of Robert Creek and Sheep Creek near the southwest corner of section 32, T. 33 N., R. 7 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Maddren (1913) reported that placer gold prospects had been found on Sheep Creek and 'especially those tributary to Robert Creek', as well as on a number of other creeks in the headwaters of the Bettles River. Maddren also noted that the gold was found on the lower parts of the tributaries to Roberts Creek. Maddren (1913) did not visit this area; his reports are based on Schrader (1900) and information from local prospectors. The only other placer gold occurrence in tributaries to Robert Creek is Willow Creek (CH109). (Reed (1938) pointed out that Maddren (1913) incorrectly identified Sheep Creek as Spruce Creek and Willow Creek as Sheep Creek.)

Kurtak and others (2002) sampled and panned along several miles of Sheep Creek. They found no indication of past or recent mining and there was no visible gold in their pans. However, analyses of some of their panned concentrates found a small amount of gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

Maddren (1913) reported that gold prospects had been found on Sheep Creek and 'especially those tributary to Robert Creek', as well as in a number of other creeks in the headwaters of the Bettles River. Maddren also noted that the gold was found on the lower parts of the tributaries to Roberts Creek. Kurtak and others (2002) sampled and panned along several miles of Sheep Creek. They found no indication of recent mining and there was no visible gold in their pans.

Production notes:

Possibly a small amount of gold was produced during prospecting before 1913.

Reserves:

None.

Site name(s): Evelyn Lee

Site type: Prospect

ARDF no.: CH059

Latitude: 67.6587 **Quadrangle:** CH C-5

Longitude: 149.2571

Location description and accuracy:

The Evelyn Lee prospect is about 2.4 miles northwest of the mouth of Sheep Creek on Robert Creek. It is about 0.2 mile northwest of the center of section 25, T. 33 N., R. 8 W. Kurtak and others (2002) include a detailed map of the prospect and a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Bornite, chalcopyrite, gold?, pyrite

Gangue minerals:

Geologic description:

The Evelyn Lee prospect was discovered by Bear Creek Mining Company in 1967 along what would would become known as the Chandalar Copper Belt (Kurtak and others, 2002). Bear Creek and several other companies (Midwest Oil Company, WGM Inc., Arctic Resources Inc., and Ventures Resource Corp.) explored the property into the 1990s. The work consisted mainly of mapping. geochemical and geophysical surveys, and sampling. Bear Creek diamond drilled two holes, 512 and 183 feet deep, and drilled two core holes, 18 and 23 feet deep, with a packsack drill.

The Evelyn Lee prospect is one of a number of copper skarn deposits in the Chandalar area which have been described by Newberry and others (1986). They are located northwest of Devonian(?) Horace Mountain belt of metamorphosed granitic rocks, which are probably genetically related to the deposits. Many of the copper skarns exhibit both prograde garnet/pyroxene and retrograde epidote and actinolite mineral assemblages. Newberry and others (1986) concluded that the deposit's mineralogy, mineralization, and alteration suggested continental-margin, porphyry-related copper skarns.

Dillon and others (1996) mapped the area as Devonian, Horace Mountain granite gneiss and Devonian felsic schists with proximal tactite and calcareous hornfels. They interpreted the Devonian felsic schists as hypabyssal to plutonic in origin. The Evelyn Lee deposit consists of chalcopyrite, bornite, and pyrite in isolated skarn bodies intercalated with marble of the Skajit Limestone, argillite, and quartz-mica schist, near or at the contact with weakly mineralized Devonian hornblende-granodiorite porphyry that covers an area about 1,000 feet wide and 4,000 feet long (Kurtak and others, 2002). The skarn bodies reportedly are up to 300 feet long and 30 feet wide. Outcrop samples contain as much as 10 percent copper. The meta-granodiorite is altered and pyritized near the skarns. One of the drill holes cut 18 feet of skarn with 2.0 percent copper; another cut 23.5 feet of skarn with 3.5 percent copper. A notable 7-foot-thick zone of sulfides in skarn contained 9.9 percent copper and 8.17 ounces of silver per tonne, and a 5-foot-long surface sample contained 5.6 percent copper and 0.04 ounce of gold per ton. Kurtak and others (2002) sampled 700 feet of outcrop with prominent copper staining on the south-southwest side of the prospect; eight select samples averaged 4.06 percent copper and 11.9 ppm silver.

DeYoung (1978) estimated that the Evelyn Lee deposit has a resource of about 1 million metric tons with an average grade of 5 percent copper. Ventures Resource Corp. (1999) estimated the resource as 'tens of

million of tons that graded 2 percent to 5 percent copper with gold and silver credits'.

Alteration:

Propylitic alteration of the meta-granodiorite, with local areas of sericitic to potassic alteration. Hornfels and skarn developed in adjacent calcareous rocks.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Porphyry copper and related copper-skarn deposits (Cox and Singer, 1986; models 17 and 18a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17 and 18a

Production Status: None

Site Status: Undetermined

Workings/exploration:

The Evelyn Lee prospect was discovered by Bear Creek Mining Company in 1967 along what would would become known as the Chandalar Copper Belt (Kurtak and others, 2002). Site name(s): Ginger

Site type: Prospect

ARDF no.: CH060

Latitude: 67.7085 **Quadrangle:** CH C-5

Longitude: 149.2818

Location description and accuracy:

The Ginger prospect is along the ridge between Big Spruce Creek and Sheep Creek, about 3.7 miles northwest of the west peak of Horace Mountain. It is about 1.0 mile south of peak 5147 and about 0.5 mile north-northeast of the center of section 11, T. 33 N. R. 8 W. The location is accurate. Kurtak and others (2002) include a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Azurite, chalcopyrite, magnetite, malachite, pyrite

Gangue minerals:

Geologic description:

The Ginger prospect was discovered by Bear Creek Mining Company in 1967 in what would would become known as the Chandalar Copper Belt (Kurtak and others, 2002). Bear Creek explored the property until 1970 and from then to the 1980s WGM studied the deposit in conjunction with their work along the Copper Belt. Apparently, the work at the Ginger prospect consisted only of mapping and sampling, and geochemical and geophysical surveys. (Kurtak and others, 2002).

The Ginger prospect is a skarn deposit in Devonian Skajit Limestone that structurally overlies Ordovician phyllite, marble, and calcareous schist (Kurtak and others, 2002). Discontinuous masses of skarn crop out for 2.5 miles from peak 4109 to peak 5147. The Ginger prospect is in skarn that covers an area about 1,000 feet by 3,000 feet, about a mile south of peak 5147. The skarn contains zones of rubblecrop up to 50 by 100 feet in area with chalcopyrite, pyrite, and copper staining. Eight samples contained an average of 1.8 percent copper and 12.2 parts per million (ppm) silver. Three of the samples contained 548 to 1,201 parts per billion gold. Three samples of quartz-sericite schist next to the skarn contained 5,467 ppm copper and 3.3 ppm silver. Newberry and others (1986) concluded that the mineralogy, mineralization, and alteration of the skarns in the Chandalar Copper Belt suggest that they are continental-margin, porphyry-related copper skarns. The deposits along the belt are generally considered to be Devonian and genetically related to several meta-granodiorite plutons along the belt, notably the Horace Mountain pluton to the southeast (Dillon and others, 1996).

Alteration:

Copper skarn developed in limestone and calcareous rocks.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:
Cu skarn deposits (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
18b

Production Status: None

Site Status: Undetermined

Site name(s): Deimos

Site type: Prospect

ARDF no.: CH061

Latitude: 67.7263 **Quadrangle:** CH C-5

Longitude: 149.2323

Location description and accuracy:

The Deimos prospect is above the head of Sheep Creek about 0.7 mile east of peak 6031 and about 4.4 miles at an azimuth of 347 degrees from the west peak of Horace Mountain. It is about 0.5 mile west of the center of section 31, T. 34 N., R. 7 W. Kurtak and others (2002) include a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Cu

Other: Ag?

Ore minerals: Chalcopyrite, magnetite, pyrite

Gangue minerals: Epidote, garnet, quartz

Geologic description:

The Deimos prospect was discovered by Bear Creek Mining Company in 1967 in what would would become known as the Chandalar Copper Belt. Bear Creek explored the property until 1970 and from then to the 1980s WGM studied the deposit in conjunction with their work along the Copper Belt. The exploration at the Deimos prospect included geologic mapping, geophysical and geophysical surveys, and sampling (Kurtak and others, 2002).

The Deimos prospect is one of a number of skarn deposits in the Chandalar area which have been described by Newberry and others (1986). These skarns are all northwest of a belt of Devonian(?) granitic rocks informally named the Horace Mountain plutons that are probably genetically related to the skarns. Many of the skarns exhibit both prograde and retrograde mineral assemblages. Newberry and others (1986) stated that the mineralogy, mineralization, and alteration of the deposits indicate they are continental-margin, porphyry-related copper skarns.

The rocks at the Deimos prospect are Devonian Skajit Limestone that structurally overlies Ordovician phyllite, marble, and calcareous schist (Dillon and others, 1996). Nicol (1983) describes garnet-epidote skarn with pyrite, chalcopyrite, and minor magnetite that crops out over an area about 50 feet by 100 in size. The skarn is iron and copper stained and cut by quartz veins. A sample of skarn with 10 percent pyrite and chalcopyrite contained 1 part per million (ppm) gold, 46 ppm silver, and 2.64 percent copper. However, most of the samples contained 0.5 to 0.9 percent copper. Geochemical and geophysical surveys suggest that the skarn is no larger than what is exposed in outcrop. Kurtak and others (2002) re-examined the area but did not find any additional mineralization. They resampled what they though was Nicol's skarn; a select sample contained 3,871 ppm copper, 5 ppm silver, and 56 parts per billion gold.

Alteration:

Masses of skarn developed in limestone and calcareous rocks.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Cu skarn deposit (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Undetermined

Workings/exploration:

The Deimos prospect was discovered by Bear Creek Mining Company in 1967 in what would would become known as the Chandalar Copper Belt. Bear Creek explored the property until 1970 and from then to the 1980s WGM studied the deposit in conjunction with their work along the Copper Belt. The exploration at the Deimos prospect included geologic mapping, geophysical and geophysical surveys, and sampling (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site name(s): Hurricane-Diane

Site type: Prospect

ARDF no.: CH062

Latitude: 67.7223 **Quadrangle:** CH C-5

Longitude: 149.1827

Location description and accuracy:

The Hurricane-Diane prospect is on the ridge east of the head of Sheep Creek, about 0.3 mile north-northwest of peak 4452. It is about 0.5 mile south-southwest of the center of section 32, T. 34 N., R. 7 W. Kurtak and others (2002) include a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Cu

Other: Ag, Au

Ore minerals: Chalcopyrite, magnetite, pyrite, pyrrhotite

Gangue minerals: Actinolite, epidote, garnet

Geologic description:

The Hurricane-Diane prospect was discovered by Bear Creek Mining Company in 1967 in what would would become known as the Chandalar Copper Belt. Bear Creek explored the property until 1970 and WGM Inc. continued the exploration to the 1980s in conjunction with their other work along the Copper Belt. The exploration at the Hurricane-Diane prospect included geologic mapping, geophysical and geochemical surveys, and sampling. (Kurtak and others, 2002).

The Hurricane-Diane prospect consists of a northeast-trending line of resistant knobs of garnet-epidote skarn, about 40 feet wide and 1.5 miles long (Kurtak and others, 2002). Most of the prospect is tundra covered but the rocks in the vicinity are Ordovician phyllite, marble, and calcareous schist (Dillon and others, 1996). A geochemical survey suggests that the skarn and the mineralization is probably continuous below the tundra (WGM, Inc. 1979). Several samples of epidote-calc-silicate skarn with pyrite, pyrrhotite, and chalcopyrite collected by Nicol (1983) contained up to 930 parts per billion gold (ppb), 8.3 parts per million (ppm) silver, 3.76 percent copper, and 200 ppm arsenic. Six skarn samples with pyrite, chalcopyrite, pyrrhotite, and magnetite collected by Kurtak and others (2002) averaged 2.54 percent copper and 20.15 ppm silver; two chip samples averaged 1,286 ppb gold.

The Hurricane-Diane prospect is one of a number of skarn deposits in the Chandalar area which have been described by Newberry and others (1986). These skarns are northwest of a belt of Devonian(?) granitic rocks informally named the Horace Mountain plutons that are probably genetically related to the skarns. Many of the skarns exhibit both prograde and retrograde mineral assemblages. Newberry and others (1986) stated that their mineralogy, mineralization, and alteration indicate that most of these skarn deposits are continental-margin, porphyry-related copper skarns. However, the association of epidote, garnet, and actinolite in the Hurricane-Diane skarn is a retrograde assemblage and the deposit is probably distal mineralization in the Chandalar Copper Belt. An analysis of a sample they collected contained 1.5 percent copper, 105 ppm silver, 0.2 percent zinc, and 0.07 lead. Because the zinc and lead values are low, they classified it as a calcic copper skarn.

Alteration:

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Cu skarn deposit (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Inactive

Site name(s): Eva

Site type: Prospect

ARDF no.: CH063

Latitude: 67.6603 **Quadrangle:** CH C-5

Longitude: 149.4244

Location description and accuracy:

The Eva prospect is at an elevation of about 3,300 feet on the east side of the ridge between Big Spruce Creek and Mathews River. It is about 1.1 mile north-northwest of peak 4737 and about 0.6 mile west-northwest of the center of section 29, T. 33 N., R. 8 W. A map showing the geology of the area and the location this and the other deposits of the Chandalar Copper Belt is Figure C-1 of Kurtak and others (2002).

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, magnetite?, pyrite

Gangue minerals:

Geologic description:

The Eva prospect was discovered by Bear Creek Mining Company in 1967 along what would would become known as the Chandalar Copper Belt (Kurtak and others, 2002). Bear Creek and several other companies (Midwest Oil Company, WGM Inc., Arctic Resources Inc., and Venture Resources Corp.) explored the property into the 1990s. Their work included geological mapping, sampling, and geochemical and geophysical surveys.

The Eva prospect is one of several Cu deposits in the Chandalar area which have been described by Newberry and others (1986) as mostly copper skarn deposits. They are all northwest of a belt of Devonian(?) metamorphosed granodioritic rocks informally named the Horace Mountain plutons that are probably genetically related to these deposits. Many of these copper skarns exhibit both prograde garnet and pyroxene and retrograde epidote and actinolite mineral assemblages. Newberry and others (1986) stated that the mineralogy, mineralization, and alteration of these skarns tend to place them in the category of continental-margin, porphyry-related copper skarns.

Some of the descriptions of the Eva prospect include it with the nearby Victor (CH064) and Venus prospects (CH065) (DeYoung, 1978; Cobb and Cruz, 1983). The Venus prospect in particular is characterized as a porphyry deposit. Cobb and Cruz (1983) classify the Eva deposit as either a porphyry or skarn, whereas Newberry and others, (1086) classify it as a copper skarn, and the Eva prospect thus has been characterized as a porphyry copper and (or) copper skarn deposit (Cobb and Cruz, 1983). Newberry and others (1986), however, classified it as a Cu skarn.

Kurtak and others (2002) de-emphasize the skarn interpretation and describe the Eva prospect as restricted to a belt about a half mile long of conspicuous red-stained muscovite schist, associated with quartz-sericite schist, calcareous schists, calc-silicate schist, and some small metamorphosed igneous bodies. The mineralization is concentrated in the muscovite schist and consists of erratically-distributed, malachite-and-azurite-stained pods and lenses with disseminated chalcopyrite. A select sample contained 68 parts per billion (ppb) gold, 2.1 parts per million (ppm) silver, 2,835 ppm copper, 306 ppm lead, and 93 ppm zinc. The mineralization in the quartz-sericite schist, calcareous schist, and calc-silicate schist is relatively weak and spotty. However, a sample of calcareous schist with pyrite stringers contained 9.7 ppm silver, 3,395 ppm lead, 3,933 ppm zinc, and 23 ppb gold. A sample of calc-silicate schist contained an average of 64 ppb

gold, 2.45 ppm silver, and 4,740 ppm copper. The metamorphosed igneous rocks contain only a trace of sulfide minerals.

Nicholson (1990) estimated that the Eva and nearby Victor(CH064) prospects have a resource of 50,000 tons with an average grade of 2 percent copper. However, Kurtak and others (2002) note that the mineralization at the Eva prospect appears to be 'limited to small, discontinuous outcrops'.

Alteration:

Propylitic and sericitic alteration of the meta-granodiorite and retrograde epidote/actinolite alteration of the skarns.

Age of mineralization:

Probably related to a belt of Devonian(?) intrusive rocks.

Generic deposit model:

Deposit model:

Pods and lenses of copper mineralization in muscovite schist and copper skarn.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Site name(s): Victor

Site type: Prospect

ARDF no.: CH064

Latitude: 67.6305 **Quadrangle:** CH C-5

Longitude: 149.3837

Location description and accuracy:

The Victor prospect is at an elevation of about 4,200 feet on the ridge between Big Spruce Creek and Mathews River. It is about 4.2 miles north of the mouth of Limestone Creek on the Bettles River, and about 0.2 mile north of the center of section 5, T. 32 N., R. 8 W. A map showing the geology of the area and the location of this and the other deposits of the Chandalar Copper Belt is Figure C-1 of Kurtak and others (2002).

Commodities:

Main: Cu

Other: Au?

Ore minerals: Bornite?, chalcocite, chalcopyrite, digenite, magnetite, molybdenite

Gangue minerals: Quartz

Geologic description:

The Victor prospect was discovered by Bear Creek Mining Company in 1967 along what would would become known as the Chandalar Copper Belt (Kurtak and others, 2002). Bear Creek and several other companies (Midwest Oil Company, WGM Inc., Arctic Resources Inc., and Venture Resources Corp.) explored the property into the 1990s. The work apparently consisted mainly of mapping, sampling, and geochemical and geophysical surveys but there is an reference to some drilling.

The Victor prospect is one of several Cu deposits in the Chandalar area which have been described by Newberry and others (1986) as mostly skarn deposits. They are all northwest of a belt of Devonian(?) granitic rocks informally named the Horace Mountain plutons that are probably genetically related to these deposits (Dillon and others, 1996). Many of these Cu skarns exhibit both prograde garnet and pyroxene and retrograde epidote and actinolite mineral assemblages. Newberry and others (1986) stated that the mineralogy, mineralization, and alteration of these skarns tend to place them in the category of continental-margin, porphyry-related copper skarns.

The deposits at the Victor prospect are copper skarns that are exposed at several places near the contact of metamorphosed, Early Devonian hornblende granodiorite that has intruded Ordovician calcareous schist and limestone (Dillon and others, 1996; Kurtak and others, 2002). The skarns contain chalcopyrite, pyrite, pyrrhotite, magnetite, and minor bornite, in disseminations, stringers, and pods. The meta-granodiorite contains only a trace of copper but shows propylitic and sericitic alteration. The skarn is retrograded and consists mainly of garnet, clinopyroxene, actinolite, epidote, calcite, quartz, and chlorite (Nicholson, 1990).

A hand specimen from the Victor prospect, described in Newberry and others (1986), contained 1.1 percent copper, 5.5 parts per million (ppm) silver, less than 0.14 ppm gold, and negligible lead and zinc. Young and others (1997) reported that hundreds of meters of samples assayed 0.1 to 0.6 percent copper, with some values as high as 5.5 percent copper, 150 ppm molybdenum, and 0.41 ppm gold. Kurtak and others (2002) sampled several areas of skarn with chalcopyrite, pyrite, and pyrrhotite; the best two samples averaged 6.22 percent copper, 18.5 ppm silver, and 354 parts per billion gold. Nicholson (1990) estimated that skarn pods at the Victor and Eva (CH063) prospects have a resource of 50,000 tons with an average grade of 2 percent copper.

Alteration:

The Devonian meta-granodiorite shows propylitic and sericitic alteration; the skarns near the intrusive show retrograde alteration.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Copper skarn (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Undetermined

Workings/exploration:

Location description and accuracy:

The Venus prospect is exposed on the west bank of Spruce Creek about 3.1 miles north of its mouth on the Bettles River. It is in the northwest part of section 3 and the northeast part of section 4, T. 32 N., R. 8 W. The location is accurate. Kurtak and others (2002) include a detailed map of the prospect and a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Ag, Au, Cu

Other: Mo

Ore minerals: Bornite?, chalcopyrite, magnetite, molybdenite, pyrite

Gangue minerals: Amphibole, calcite, chlorite, diopside, epidote, garnet, quartz

Geologic description:

The Venus prospect was discovered by Bear Creek Mining Company in 1967 along what would would become known as the Chandalar Copper Belt (Kurtak and others, 2002). Bear Creek and several other companies (Midwest Oil Company, WGM Inc., Arctic Resources Inc., and Ventures Resource Corp.) explored the property into the 1990s. The work consisted mainly of mapping, geochemical and geophysical surveys, and sampling; 5 holes were drilled in 1973 and 1974 by WGM Inc. that totaled 2,466 feet.

The Venus prospect is a porphyry copper deposit associated with copper-gold-silver skarn (Kurtak and others, 2002). The Venus prospect and others along the Chandalar Copper Belt were described by Newberry and others (1986) as continental-margin, porphyry-related copper skarns; many exhibit both prograde and retrograde mineral assemblages. Ventures Resource Corporation (1998) and Dillon and others (1996) described the geology of the Venus prospect as an elongated, altered and foliated, Devonian granodiorite pluton bounded on the east by overthrust Silurian or Devonian, Skajit Limestone and on the west by Skajit Limestone and gray phyllite, felsic calc-schist, and chloritic schist.

The porphyry mineralization at Venus prospect consists of disseminations and fracture fillings of pyrite, chalcopyrite, and minor molybdenite in schistose Devonian meta-granodiorite porphyry (Kurtak and others, 2002). The meta-granodiorite porphyry is extensively propylitized and pyritized, with local zones of sericitic to potassic alteration. The intrusion-hosted mineralization contains about 0.1 to 0.2 percent copper Cu, and generally less than 0.01 ounce of gold per ton (Ventures Resource Corporation, 1999). A hand specimen described by Newberry and others (1986) as porphyry contains quartz, sericite, pyrite, chalcopyrite, chlorite, and molybdenite; the specimen contained 0.38 percent copper, 1 part per million (ppm) silver, less than 0.1 ppm gold, 0.002 percent zinc, and 0.001 percent lead. Three drill holes averaged 0.15 to 0.2 percent copper, but one averaged only 0.08 percent copper (WGM Inc., 1973; Nicholson, 1990).

The skarns form irregular masses in Skajit Limestone and calc-schist adjacent to, and as xenoliths in the meta-granodiorite. The skarns are principally garnet-magnetite-diopside bodies that show retrograde vein and replacement, epidote, amphibole, chlorite, calcite, and quartz. The mineralization consists of irregular masses of pyrite and chalcopyrite. The grade of the skarn deposits is variable but generally is about 1.5 percent to 6 percent copper, less than 0.01 ounce of gold per ton, and up to 1 ounce of silver per ton

(Newberry and others, 1986; Nicholson, 1990; Ventures Resource Corporation, 1999; Kurtak and others, 2002).

Based on limited data, Nicholson (1990) estimated that the deposit has a resource of 300,000 tons with an average grade of 0.3 percent copper. Ventures Resource (1990) estimated a resource of 495 million pounds of copper.

Alteration:

Extensive propylitic alteration of the meta-granodiorite, with local areas of sericitic to potassic alteration. Hornfels and skarn developed in adjacent calcareous rocks.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Porphyry copper and copper-skarn-related deposits (Cox and Singer, 1986; models 17 and 18a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17 and 18a

Production Status: None

Site Status: Active

Workings/exploration:

The Venus prospect was discovered by Bear Creek Mining Company in 1967 along what would become known as the Chandalar Copper Belt (Kurtak and others, 2002). Bear Creek and several other companies (Midwest Oil Company, WGM Inc., Arctic Resources Inc., and Ventures Resource Corp.) explored the property into the 1990s. The work consisted mainly of mapping, geochemical and geophysical surveys, and sampling; 5 holes were drilled in 1973 and 1974 that totaled 2,466 feet.

Production notes:

None.

Reserves:

Based on limited data, Nicholson (1990) estimated that the porphyry deposit has a resource of 300,000 tons with an average grade of 0.3 percent copper. Ventures Resource Corp. (1999) estimated a resource of 495 million pounds of copper.

Additional comments:

This prospect is on Doyon Ltd. selected lands; for more information, contact Doyon Ltd., Fairbanks, Alaska.

Reporter(s): J.M. Britton (Anchorage, Alaska); D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-18

Site name(s): Unnamed (at head of Limestone Creek)

Site type: Occurrence

ARDF no.: CH066

Latitude: 67.6043 **Quadrangle:** CH C-5

Longitude: 149.3897

Location description and accuracy:

This occurrence is at the head of Limestone Creek, a tributary of the Bettles River. It is about 0.8 mile southeast of peak 4570, about 0.6 mile northwest of the center of section 17, T. 32 N., R. 8 W. The location is accurate to a quarter of a mile.

Commodities:

Main: Ag, As, Au, Cu, Ni, Pd, Sb

Other:

Ore minerals: Chalcopyrite

Gangue minerals:

Geologic description:

Nickel, palladium, and silver were reported in an X-ray analysis of rock from a thrust sheet in Devonian or Silurian, Skajit Limestone (Brosgé and Reiser, 1964). The occurrence is in a section of Skajit Limestone that has overridden Devonian(?) quartz muscovite schist along a major northeast-trending thrust fault. A later examination of the occurrence by Foley and others (1989) found no evidence of anomalous nickel, palladium, and silver in their sample, nor did Kurtak and others (2002).

However, in their search for mineralization in the area, Kurtak and others (2002) found marble in outcrop nearby with 1 to 2 percent sulfides; a sample contained 1.3 parts per million (ppm) silver and 142 ppm arsenic. A float sample of marble with chalcopyrite was found about 1.5 miles upstream from the mouth of Limestone Creek; a sample contained 77 parts per billion gold, 3.3 ppm silver, 1.41 percent copper, and 109 ppm antimony.

Alteration:

Not specified.

Age of mineralization:

Silurian or younger based on the age of the marble host rock.

Generic deposit model:

Deposit model:

Chalcopyrite in marble with low silver, gold, arsenic, and antimony values.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling by government agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Mule Creek

Site type: Mine

ARDF no.: CH067

Latitude: 67.6005 **Quadrangle:** CH C-5

Longitude: 149.3532

Location description and accuracy:

Mule Creek is a small south-flowing tributary to the Bettles River. Its mouth is approximately 4 1/2 miles northeast of the north end of Bob Johnson Lake (formerly Big Lake). There was some mining in the late 1930s at an unknown location, and prior to 1910 there was mining 1 1/2 to 2 1/2 miles upstream from the mouth of the creek. The coordinates reflect this early mining in the west half of section 16, T. 32 N., R. 8 W.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Copper, gold, silver

Gangue minerals:

Geologic description:

Mule Creek was mined intermittently from 1901 to 1909 and produced at least 15 ounces of gold as well as copper and silver nuggets up to 7 pounds (Maddren, 1913). This early mining took place on a bench about 2 1/2 miles upstream from the mouth in 8 feet of gravel, and about 1 1/2 mile upstream in 2 feet of gravel. In the 1930s, two or three shafts were sunk in the alluvial fan near the mouth of the creek, and another about 1,000 feet upstream (Reed, 1938). Several of these shafts were 75 to 80 feet deep but flooded before reaching bedrock. Reed (1938) reported that the gravel was coarse and waterworn, with many large boulders, and that depth to bedrock was 3 to 8 feet (in the mining before 1910?). In 1937 and 1938, 35 ounces of gold was produced by hand mining. Dillon (1987) reported active claims in 1985. Kurtak and others (2002) examined Mule Creek as part of their study of the mineral resources of the Koyukuk mining district. They panned samples along the creek; a few pans showed visible gold but most did not. They located several of the shafts sunk in the 1930s but found no evidence of any recent mining.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Probably inactive

Workings/exploration:

Mule Creek was mined intermittently from 1901 to 1909 (Maddren, 1913). In the 1930s, two or three shafts were sunk in the alluvial fan near the mouth of the creek and another about 1,000 feet upstream (Reed, 1938). Several of these shafts were 75 to 80 feet deep but flooded before reaching bedrock. In 1937 and 1938, 35 ounces of gold was produced by hand mining. Dillon (1987) reported active claims in 1985. Kurtak and others (2002) examined Mule Creek as part of their study of the mineral resources of the Koyukuk mining district.

Production notes:

From incomplete records, Kurtak and others (2002) documented production of 50 ounces of gold from Mule Creek: 15 ounces in 1906, 10 ounces in 1937, and 25 ounces in 1938.

Reserves:

None.

Additional comments:

This prospect is on Doyon Ltd. selected lands; for more information, contact Doyon Ltd., Fairbanks, Alaska.

Reed (1938) pointed out that Maddren (1913) incorrectly identified Big Spruce Creek (the next tributary to the east of the Bettles River) as Mule Creek and that Mule Creek was unnamed.

Site name(s): Big Spruce Creek; Spruce Creek

Site type: Occurrence

ARDF no.: CH068

Latitude: 67.5905

Quadrangle: CH C-5

Longitude: 149.3008

Location description and accuracy:

Big Spruce Creek (Spruce Creek on older maps) is a major south-flowing tributary, more than 12 miles long, to the Bettles River. There is an old report that two prospect shafts were sunk near the mouth of Spruce Creek and there was prospecting upstream. The site is plotted near the mouth of Spruce Creek about 0.5 mile north of the center of section 22, T. 32 N., R. 8 W. The location of the prospecting above the mouth of Big Spruce Creek is vague.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Maddren (1910, 1913) reported limited prospecting in the 1900s on Big Spruce Creek. Reed (1938) reported that little or no gold was found in the 1930s in two shafts about 45 feet deep sunk along the west side of Big Spruce Creek near its mouth. Reed (1938) pointed out that Maddren (1913) incorrectly identified Spruce Creek as Mule Creek, which is the first south-flowing tributary to the Bettles River west of Spruce Creek, and that Mule Creek was unnamed.

Kurtak and others (2002) sampled along Spruce Creek and its tributaries as part of their study of the mineral resources of the Koyukuk mining district. None of their panned samples showed visible gold although analyses of their panned concentrates found minor amounts of gold. They found no signs of old or recent mining. Dillon (1987) reported an inactive claim about a mile upstream from the mouth of the creek.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

Maddren (1910, 1913) reported limited prospecting in the 1900s on Big Spruce Creek. Site name(s): Eightmile Creek

Site type: Mine

ARDF no.: CH070

Latitude: 67.5655 **Quadrangle:** CH C-5

Longitude: 149.3742

Location description and accuracy:

The lower half of Eightmile Creek has been mined and the site is plotted at about the middle of this area. Eightmile Creek is a tributary to the Bettles River; the creek is about 5 miles north of the center of Bob Johnson Lake (formerly known as Big Lake). The mined area flows northwest through the southeast quarter of section 29, T. 32 N., R. 8 W.

Commodities:

Main: Au

Other: Hg

Ore minerals: Cinnabar, gold

Gangue minerals:

Geologic description:

Eightmile Creek has been mined for at least a mile above its mouth (Kurtak and others, 2002). Prospecting began in 1900 but there was no substantial mining until 1938, and the creek produced 44 ounces of gold from 1939 to 1941. The creek was again mined from 1948 to 1953; it produced 24 ounces of gold in 1948. Two claims were staked in 1967 (Heiner and Wolff, 1968), and Dillon (1987) reported active claims in 1985. Placer cinnabar was reported (Joesting, 1943). Kurtak and others (2002) suggested that little gold remained in view of the extensive mining in the past.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Undetermined

Workings/exploration:

Eightmile Creek has been mined for at least a mile above its mouth (Kurtak and others, 2002). Prospecting began in 1900 but there was no substantial mining until the creek was mined from 1938 to 1941. The creek was again mined from 1948 to 1953. Two claims were staked in 1967 (Heiner and Wolff, 1968) and Dillon (1987) reported active claims in 1985.

Production notes:

Eightmile Creek has been mined for at least a mile above its mouth (Kurtak and others, 2002). Prospecting began in 1900 but there was no substantial mining until 1938, and the creek produced 44 ounces of gold from 1939 to 1941. The creek was again mined from 1948 to 1953; it produced 24 ounces of gold in 1948.

Reserves:

Kurtak and others (2002) suggested that little gold remained in view of the extensive mining in the past.

Last report date: 2010-04-18

Site name(s): Garnet Creek

Site type: Mine

ARDF no.: CH071

Latitude: 67.5602 **Quadrangle:** CH C-5

Longitude: 149.4034

Location description and accuracy:

The lower half mile of Garnet Creek has been mined and the site is plotted at about the middle of this area. Garnet Creek is a tributary to the Bettles River; the mouth of the creek is about 2.8 miles north-northeast of the north end of Bob Johnson Lake (formerly Big Lake). The part of the creek that was mined flows through the northeast quarter of section 31, T. 32 N., R. 8 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Most of the mining on Garnet Creek extended for about a half mile upstream from its mouth (Kurtak and others, 2002). Maddren (1913) reported the ground was producing about $7 to $9 dollars a man per day (at $20.67 per ounce of gold). Forty-eight ounces of gold was produced from 1900 to 1909. Claims were staked after World War I but the next significant mining was from 1937 to 1940 when 70 ounces of gold was produced. Reed (1938) reported that the mining was along the modern channel of the creek; the gold was on bedrock and the lower few feet of the overlying gravel. The gravel is coarse and waterworn, with many large boulders. It was about 8 feet thick near the mouth of the creek and thins to 1 to 3 feet thick a half mile upstream. The ground that was mined in 1937 was said to run about 0.022 ounce of gold per square foot of bedrock. The gold was fairly fine, with a few nuggets. Reed (1938) reported a high channel, but it had not been prospected to any extent at that time. In 1950, ground sluicing gave poor returns. Claims were staked in 1959 (Heiner and Wolff, 1968) and from 1980 to 1986 (Kurtak and others, 2002).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Undetermined

Workings/exploration:

Surface mining reported in 1937. Claims were staked in 1959 and from 1980 to 1986.

Production notes:

Production from 1900 to 1909 was reported to yield $7 to $9 per man-day and totaled $1,000, or about 48 ounces (Maddren, 1913).

Reserves:

None.

Site name(s): Bettles River

Site type: Mine

ARDF no.: CH072

Latitude: 67.559 **Quadrangle:** CH C-5

Longitude: 149.427

Location description and accuracy:

Placer mining took place along the Bettles River from the mouth of Mule Creek to at least a half mile below the mouth of Garnet Creek. The site is plotted about a half mile below the mouth of Garnet Creek where most of the mining apparently took place. It is about 0.6 mile northwest of the center of section 31, T. 32 N., R. 8 W.

Commodities:

Main: Au

Other: Cu

Ore minerals:

Gangue minerals:

Geologic description:

Many of the tributaries of the Bettles River north of Bob Johnson Lake (formerly Big Lake) have been placer mined. The Bettles River itself has been mined, especially below the mouth of Garnet Creek (CH071). In 1919, three holes were sunk to bedrock on the Discovery claim about a half mile below the mouth of Garnet Creek. There was considerable drift mining and prospecting in this area by several individuals from 1927 to 1939 (Kurtak and others, 2002). Both the modern channel of the river and benches were mined. Reed (1938) reported that the gravel was 7 to 18 feet deep; the productive gravel was 4.5 feet thick; and the ground was said to have run about $0.50 per square foot of bedrock (at $35 per ounce of gold.) A 2 ounce copper nugget was found in the pay gravel. Kurtak and others (2002) panned the gravel near the mouth of Limestone and Mule Creeks; the gold they recovered was very fine. Dillon (1987) reported active placer claims. There is no record of the amount of gold that was produced along the Bettles River but there was some production from 1919 to 1938, almost all from the mouth of Mule Creek to at least a half mile below the mouth of Garnet Creek.

Alteration:

Age of mineralization:

Site name(s): Last Chance Creek; Crab Creek

Site type: Occurrence

ARDF no.: CH073

Latitude: 67.516 **Quadrangle:** CH C-5

Longitude: 149.494

Location description and accuracy:

Last Chance Creek drains into the northwest end of Bob Johnson Lake (formerly Big Lake). For this record, this site is plotted at about the middle of the creek, about 0.3 mile north of the center of section 14, T. 31 N., R. 9 W. The creek was called Crab Creek by Reed (1938), but it is labeled Last Chance Creek on the modern topographic maps.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Last Chance Creek was prospected by at least three shafts to bedrock and an open cut (Reed, 1938). A 30-foot shaft was sunk in 1922, and 15-foot and 35-foot shafts were sunk in 1932. The 15-foot shaft reportedly was near the mouth of the creek and the 35-foot shaft was farther upstream 'at the forks'. Only a few grains of gold were found in the shafts and the open cut. Eleven claims were staked in 1969. There is no record of any significant mining on Last Chance Creek (Kurtak and others, 2002).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Last Chance Creek was prospected by at least three shafts to bedrock and an open cut (Reed, 1938). A 30-foot shaft was sunk in 1922 and 15-foot and 35-foot shafts were sunk in 1932. The 15-foot shaft reportedly was near the mouth of the creek and the 35-foot shaft was farther upstream 'at the forks'. Only a few grains of gold were found in the shafts and the open cut. Eleven claims were staked in 1969. There is no record of any significant mining on Last Chance Creek (Kurtak and others, 2002).

Production notes:

Apparently none beyond a few grains that were found during prospecting.

Reserves:

None.

Site name(s): Unnamed (near Wiehl Mountain)

Site type: Occurrence

ARDF no.: CH074

Latitude: 67.6576 **Quadrangle:** CH C-6

Longitude: 149.5105

Location description and accuracy:

This occurrence is at elevation of about 3,600 feet, about 3.9 miles north-northeast of Wiehl Mountain (peak 5765). It is about 0.2 mile northeast of the center of section 26, T. 33 N., R. 9 W. The location is accurate to within a half mile.

Commodities:

Main: Ag, As, Au, Cu, Pb, Zn

Other:

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, sphalerite

Gangue minerals: Quartz

Geologic description:

This occurrence was originally described as galena in Devonian(?) greenstone and greenschist near a contact with Devonian siltstone and grit (Brosgé and Reiser, 1964). Mulligan (1974) and Kurtak and others (2002) found a 3-foot-wide quartz vein exposed for 100 feet along strike. No sulfides were seen in place in the quartz vein but there is abundant quartz float in talus below the vein with 2 to 3 percent disseminated pyrite, arsenopyrite, chalcopyrite, galena, and sphalerite. Three samples averaged 72 parts per billion gold, 2.1 parts per million (ppm) silver, 258 ppm copper, 1,260 ppm lead, 303 ppm zinc, and 3,454 ppm arsenic.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Polymetallic quartz vein (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only limited sampling by government agencies.

Production notes:

None.

Reserves:

None.

Last report date: 2010-04-18

Site name(s): Unnamed (on Sukakpak Mountain)

Site type: Prospect

ARDF no.: CH076

Latitude: 67.5957 **Quadrangle:** CH C-6

Longitude: 149.7334

Location description and accuracy:

The main vein at this prospect extends for almost 600 feet; the center is at an elevation of about 3,500 feet, about 0.6 mile south-southeast of the summit of Sukakpak Mountain. It is about 0.6 mile east-southeast of the center of section 15, T. 32 N., R. 10 W. The location is accurate. Kurtak and others (2002, figure C-6)) include a detailed map of the prospect.

Commodities:

Main: Ag, Au, Sb

Other: Hg, Mo

Ore minerals: Cinnabar?, gold, molybdenite?, stibnite, tetrahedrite

Gangue minerals: Calcite, quartz

Geologic description:

Mineralization is exposed in two places at this prospect: the main 'upper vein' (at the coordinates), and a 'lower vein' about a half mile to the southwest. The veins do not appear to be continuous but they have the same general trend (Kurtak and others, 2002). Lode claims were staked in 1977 but they were invalid because the prospect is in the Trans-Alaska Pipeline corridor which is closed to mineral entry. There is a small prospect pit on the upper vein and some trenching on the lower vein.

This prospect is near the contact of marble of the Devonian Skajit Limestone and Cambrian muscovite-albite-quartz schist (Huber 1988; Dillon and Reifenstuhl, 1990; Kurtak and others, 2002). The mineralization is mainly in the marble but the trend of the veins parallels and is very close to the contact.

The upper vein is exposed for 120 feet, varies from 1 to 6 feet wide, and averages about two feet thick (Huber 1988; Kurtak and others, 2002). It strikes N55E, dips steeply to vertical, and can be traced for 570 feet in float and discontinuous exposures. The upper vein is entirely in marble about 50 feet from the contact with the schist. There are two generations of quartz; an early, nearly barren generation with traces of tetrahedrite, and a later generation with stibnite and gold. The stibnite often makes up 50 percent of the vein. There is minor arsenopyrite and the stibnite weathers to stibiconite and kermesite. (The red kermesite has been misidentified as cinnabar.) The stibnite contains native gold which is difficult to detect. The gold occurs as small cubes and as wire and flakes in fractures in the veins, with stibnite, quartz, and graphite. There is no evidence of alteration adjacent to the vein. The vein is banded with evidence of repeated movement during and after mineralization. The vein show open-space filling with crystalline stibnite and cockscomb quartz crystals. Huber (1988) collected 11 samples along the vein; they averaged 15.52 parts per million (ppm) gold and 20.8 percent antimony. Kurtak and others (2002) collected 9 continuous chip samples and 3 float samples from the upper vein. The samples average 39.59 ppm gold and 22.74 percent antimony, but the values were erratic along strike. Dillon (1982) reported mercury and molybdenum in samples from the vein. However, in the samples collected by Kurtak and others (2002), the highest mercury value was 2.9 ppm and the highest molybdenum value was 8 ppm.

The lower quartz vein at an elevation of about 2,500 feet is mineralized for about 50 feet and quartz-vein material can be traced in float and rubble for about 350 feet (Huber 1988; Kurtak and others, 2002. The mineralization is similar to the upper vein. Stibnite occurs sporadically in quartz-carbonate gangue. The vein

strikes N70E to N70W with a variable dip. The vein is in marble near the schist contact. Kurtak and others (2002) collected a spaced-chip sample; it contained 25.23 ppm gold and 21.22 percent antimony.
Dillon (1982) suggests that the mineralization is Albian (middle Cretaceous). Huber (1988) concluded that the mineralization is no older than the end of the Neocomian (Early Cretaceous), Brooks Range Orogeny.
Kurtak and others (2002) estimated an 'inferred resource' of 31,000 tons with 'weighted average grades' of 1.22 ounces of gold per ton and 18.44 percent antimony.

Alteration:

There is little gossan or other weathering associated with the veins and almost no wallrock alteration. The stibnite weathers to yellow stibiconite (Sb3O6(OH)) and red kermesite (Sb2S2O).

Age of mineralization:

Dillon (1982) suggests that the mineralization is Albian (Middle Cretaceous). Huber (1988) concludes that the mineralization is no older than the end of the Neocomian (Early Cretaceous) Brooks Range Orogeny.

Generic deposit model:

Deposit model:

Gold-stibnite-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

A small prospect pit and some trenching by industry. Mapped and sampled by government agencies. The occurrence was first reported in print in the early 1980s, although there are older workings on outcrops of the veins and evidence of drift mining nearby on Discovery Creek (CH077). Lode claims were staked in 1977 but they were invalid because the prospect is in the Trans-Alaska Pipeline corridor, which is closed to mineral entry.

Production notes:

None.

Reserves:

Kurtak and others (2002) estimated an 'inferred resource' of 31,000 tons with 'weighted average grades' of 1.22 ounces of gold per ton and 18.44 percent antimony.

Additional comments:

This prospect is in the Alaska pipeline inner corridor which is not open to mineral entry. It probably is the source of placer Au in Discovery Creek (CH077).

Site name(s): Discovery Creek

Site type: Prospect

ARDF no.: CH077

Latitude: 67.5825 **Quadrangle:** CH C-6

Longitude: 149.7705

Location description and accuracy:

Discovery Creek, which is not named on the 1:63,360-scale topographic map, drains the south flank of Sukakpak Mountain. It is about 1 1/2 miles long and much of it is below a gold-stibnite-quartz vein (CH076). The site is somewhat arbitrarily plotted about 1.2 miles upstream from the mouth of the creek below the vein. The site is about 0.5 mile west-southwest of the center of section 22, T. 32 N., R. 10 W.

Commodities:

Main: Au

Other: Sb?

Ore minerals: Gold, stibnite

Gangue minerals:

Geologic description:

Discovery Creek is downslope from the gold-stibnite-quartz veins on Sukakpak Mountain (CH076). Little is known about this prospect but clasts of stibnite-quartz-vein material have been found in the creek gravels and there is some evidence of past placer mining or prospecting (Dillon, 1982; Kurtak and others, 2002). Suction dredging was reported in 1982.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Inactive

Workings/exploration:

Suction dredging in 1982 and some evidence of drift mining in the early 1900s (Dillon, 1982; Huber,

1988; Kurtak and others, 2002).

Production notes:

Doubtful.

Reserves:

None.

Additional comments:

See also the nearby unnamed prospect on Sukapak Mountain (CH076) which is the probable source of any gold in this creek. This prospect is in the Alaska pipeline corridor which is not open to mineral entry.

Site name(s): Emery Creek; Emory Creek

Site type: Mine

ARDF no.: CH078

Latitude: 67.5499 **Quadrangle:** CH C-6

Longitude: 149.621

Location description and accuracy:

Emery Creek, a north-flowing tributary of the Bettles River, is about 2 miles northwest of Glacier Lake The creek is labeled Emery Creek on modern topographic maps but is called Emory Creek in the old reports. The site is on Emery Creek about a mile southwest of the Bettles River where there was mining in 1937. The site is near the southeast corner of section 31, T. 32 N., R. 9 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

According to Maddren (1913), Emory Creek produced about $10,000 in gold (484 ounces) from 1900 to 1909. The gold occurred on bedrock amidst boulders which had to be moved to recover the gold. Reed (1938) saw no evidence of the mining that Maddren reported, but did note prospecting and mining near the junction of Emory Creek and an east-flowing tributary about a mile south of the Bettles River. There was placer mining on the creek from 1993 to 1998 that produced 40 ounces of gold (Kurtak and others, 2002).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Probably inactive

Workings/exploration:

Placer mining from 1900 to 1909, in 1936, and from 1993 to 1998.

Production notes:

Emery Creek produced about $10,000 in gold (about 484 ounces) from 1900 to 1909; perhaps a small amount in the mid-1930s; and 40 ounces from 1993 to 1998.

Reserves:

None.

Site name(s): Magnet Creek

Site type: Mine

ARDF no.: CH079

Latitude: 67.514 **Quadrangle:** CH C-6

Longitude: 149.7274

Location description and accuracy:

Magnet Creek is a north-flowing tributary to Gold Creek that was mined near its mouth. It is about 5 miles north of the north (6180) peak of Poss Mountain and flows through the west half of section 14, T. 31 N., R. 10 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Gold was discovered on Magnet Creek in 1900. Reed (1938) reported that the modern channel of Magnet Creek was mined from an open cut near its mouth. A high bench near the mouth of Magnet Creek on Gold Creek (CG080) was also mined for about 500 or 600 feet. Claims were staked and there was activity on the creek during several periods between 1973 and 1999. Kurtak and others (2002) sampled and panned at several locations along Magnet Creek. Several of their samples and panned concentrates contained visible gold but most of the gold they found seemed to come from open crevices in the bedrock below the overlying gravel rather than from the gravel itself.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Inactive

Workings/exploration:

The modern channel of Magnet Creek near its mouth and a bench there were mined sometime prior to 1938. There was activity on the creek during several periods in the 1970s and 1990s but there is no record of production. Sampled by Bureau of Land Management in their study of the mineral resources of the Koyukuk mining district (Kurtak and others, 2002).

Production notes:

An uncertain amount of gold was produced before 1938 from near the mouth of the creek, and there was mining in the 1970s and 1990s.

Reserves:

None.

Site type: Mine

ARDF no.: CH080

Latitude: 67.5156 **Quadrangle:** CH C-6

Longitude: 149.7329

Location description and accuracy:

Gold Creek is a west-flowing tributary to the Middle Fork Koyukuk River, about 6 miles south of Sukakpak Mountain. Gold Creek has been placer mined almost continuously for more than 6 miles, beginning about 2 miles upstream from its mouth, to its head. For this record, the site is located below the mouth of Magnet Creek in about the middle of the productive area where there was active mining as recently as 2001. This location is about 0.4 mile east-northeast of the center of section 15, T. 31 N., R. 10 W.

Commodities:

Main: Au

Other: Sb

Ore minerals: Gold, stibnite

Gangue minerals:

Geologic description:

Gold Creek was one of the first creeks to be mined in the Koyukuk area and it has been placer mined almost continuously for more than 6 miles, beginning about 2 miles above its mouth, to its head. No gold has been found in the lower two miles. The drainage there has been rearranged by glacial advances and the ancestral lower channel of Gold Creek probably was to the north of the modern channel, toward the lower part of Linda Creek (CH081). That ancestral channel probably was the source of the placer gold that has been mined below the sharp bend in Linda Creek just to the north.

Placer gold was discovered on Gold Creek in 1900 and Schrader (1900) reported that the ground was 'all staked'. He noted that one claim produced $12,000 in gold (about 580 ounces) in ten days. From 1900 to 1905, Gold Creek produced 10,687 ounces of gold. Production fell off rapidly after 1905 but In 1914 five mines were operating in the winter and four in the summer (Brooks, 1915). Mining continued steadily, although production was somewhat erratic, until the mid-1940, and another 3,662 ounces of gold was produced. From 1997 to 2001, there was mining below Magnet Creek and at the head of Gold Creek (near a tributary called 'Little Gold Creek' (in some old reports). The records are incomplete but Gold Creek has produced more than 14 thousand ounces of gold, perhaps considerably more.

Placer gold has been mined in Gold Creek from the modern stream channel in gravel 2 to 7 feet deep; from a deeply buried channel; and from a high channel on benches about 8 feet above the modern channel (Reed, 1938; Kurtak and others, 2002). The gravel in the modern channel is coarse and waterworn, with many boulders. The high channels seem to be confined to the north side of the lower creek and the east side of the upper several miles of the creek. The high channel about 1.5 miles upstream from the mouth of Magnet Creek is about 8 feet above the modern channel; bedrock is 3 to 50 feet deep; and the ground averaged 0.01 ounce of gold per square foot of bedrock. Below Magnet Creek, benches on the north side of Gold Creek contained 0.04 to 0.07 ounce of gold per cubic yard, with 5 feet of overburden. The deep channels vary from side to side of the Gold Creek valley. About a mile below the mouth of Magnet Creek, the deep channel is 50 to 100 feet deep; the pay zone is 12 to 15 feet wide; and the ground runs about 0.04 ounce of gold per square foot of bedrock. The richest placers were between constrictions in the valley

formed by resistant schist and diorite. The richest claim was at the mouth of Magnet Creek, just downstream from a diorite dike. Most of the gold forms smooth, shot-like pieces and small nuggets, but some pieces from high on the creek are angular and may not have been transported far. Angular fragments of stibnite in quartz have been found in the gravels.

Kurtak and others (2002) collected numerous samples and panned along Gold Creek as part of the mineral resource study of the Koyukuk mining district. Some of the samples or panned concentrates contained visible or analytical gold, and some of the panned concentrates had elevated arsenic, antimony, tungsten. They concluded that 'Except for a few sites, Gold Creek appears to be mostly worked out.'

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Geologic description:

Linda Creek was a consistent gold producer from 1901 to at least 2002 (Kurtak and others, 2002). Gold was discovered in 1901 and by 1903, 871 ounces of gold had been produced, mainly from the discovery claim near the sharp bend in the creek about 0.8 mile upstream from its mouth. Placer mining continued intermittently by simple hydraulic and hand methods until 1938. Mining took place in 1962 and 1975 using heavy equipment. Drift mining by drilling and blasting and diesel haulage began in 1978 and continued until at least 2002. The total production from 1902 to 1999 was 2,069 ounces of gold.

The early placer mining was along the modern stream channel for about 0.25 mile downstream from the sharp bend in Linda Creek at the airfield. There is little information about the early mining except that nearly all the gold was mined from the Discovery claim about 1/2 mile above the mouth. But only the upper half of this claim was productive. Reed (1938) described a 'shoveling in' surface-mining operation. Eight feet of gravel overlay bedrock; the gold was in the lower 3 feet of gravel and the upper two feet of bedrock. About a quarter of a mile downstream from the bend, the bedrock changes to phyllite and slopes down steeply to the west; no gold has been found downstream. Maddren (1913) and most miners since have thought that the source of the gold at the bend was not in the upper portion of Linda Creek but that the gold came from an ancestral channel of Gold Creek (CH080) that drained toward the mouth of modern Linda Creek.

East of the bend, early drift mining located a high channel that was probably the ancestral course of Gold Creek (Kurtak and others, 2002). From 1982 to at least 2002, the deep gravel east of the bend in Linda Creek was mined with drills and explosives to free the frozen gravel and diesel haulage to bring the gravel to the surface. The auriferous gravel is about 100 feet wide; the gold is in the lower 2.5 to 3.0 feet of the gravel and the upper 1.5 feet of the phyllite bedrock. The gold apparently is not confined to a single channel but is distributed across a series of braided channels. Most of the gold occurs as flattened to rounded nuggets. The largest nugget was 0.99 ounce and the pay zones have as much as 1.0 ounce of gold per cubic yard. Figure C-7 of Kurtak and others (2002) is a map of the drift mine.

Kurtak and others (2002) suggested the possibility of a large gold resource in the deep buried channel of Linda Creek, east of the bend. They estimated an 'inferred resource' of 2.4 million cubic yards of gravel of uncertain grade.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Linda Creek was a consistent gold producer from 1901 to at least 2002 (Kurtak and others, 2002). Gold was discovered in 1901 and by 1903, 871 ounces of gold had been produced, mainly from the discovery claim near the sharp bend in the creek about 0.8 mile upstream from its mouth. Placer mining continued intermittently by simple hydraulic and hand methods until 1938. Mining took place in 1962 and 1975 using heavy equipment. Drift mining by drilling and blasting and diesel haulage began in 1978 and continued until at least 2000.

Production notes:

The total production from 1902 to 1999 was 2,069 ounces of gold.

Reserves:

Kurtak and others (2002) suggested the possibility of a large gold resource in the deep buried channel of Linda Creek, east of the bend. They estimated an 'inferred resource' of 2.4 million cubic yards of gravel of uncertain grade.

Reporter(s): J.M. Britton (Anchorage, Alaska); D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-18

Site name(s): Unnamed (south of the Hammond River)

Site type: Occurrence

ARDF no.: CH082

Latitude: 67.6246 **Quadrangle:** CH C-6

Longitude: 149.9863

Location description and accuracy:

This occurrence is at an elevation of about 4,300 feet, on a ridge south of the Hammond River, approximately 6.5 miles west-northwest of Sukakpak Mountain and 5.5 miles north of Jennie Creek Lake. It is about 0.3 mile southwest of the center of section 3, T. 32 N., R. 11 W. The location is accurate within one mile.

Commodities:

Main: As, Cu, Sb, Zn

Other:

Ore minerals: Azurite, chalcopyrite, galena, malachite

Gangue minerals: Quartz

Geologic description:

This occurrence was originally described as copper sulfides and malachite-azurite staining in Middle to Upper Devonian(?) conglomerate interbedded in black slate, phyllite, and chloritic siltstone of the Beaucoup Formation (Dillon and Reifenstuhl, 1995). Kurtak and other (2002) describe a quartz vein 1 to 4 inches thick, with trace chalcopyrite and galena, that crosscuts quartz-muscovite schist. Two samples contained up to 356 parts per million (ppm) antimony, 140 ppm arsenic, and 580 ppm zinc, but they were not analyzed for copper and lead.

Alteration:

Not noted.

Age of mineralization:

Late Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Quartz vein with chalcopyrite and galena.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited sampling by government agencies.

Production notes:

None.

Reserves:

None.

Additional comments:

This occurrence is in the Gates of the Arctic National Park which is closed to prospecting and mining.

Last report date: 2010-04-18

Site name(s): Cindy

Site type: Prospect

ARDF no.: CH098

Latitude: 67.7697 **Quadrangle:** CH D-4

Longitude: 148.9938

Location description and accuracy:

The Cindy prospect is about 7.3 miles at an azimuth of 24 degrees from the central (5425) peak of Horace Mountain and about 1.2 miles north-northeast of peak 5150. It is near the center of section 18, T. 34 N., R. 6 W. Kurtak and others (2002) include a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Ag, As, Au, Cu, Pb, Zn

Other:

Ore minerals: Arsenopyrite?, chalcopyrite, galena, hematite, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The Cindy prospect was staked by Placid Oil Company in 1972 and explored by them until 1977 (Kurtak and others, 2002). It was also one of the prospects listed in a report by Ventures Resources Corp. (1999) about their exploration of the Chandalar Copper Belt.

The Cindy prospect is at the northeast end of the Chandalar Copper Belt which is characterized by copper skarn deposits (Newberry and others, 1986). The rocks in the vicinity of the prospect are mainly lower Paleozoic greenschist, calcareous schist, and marble in thrust contact with Devonian Hunt Fork Shale and Silurian and Devonian Skajit Limestone (Brosgé and Reiser, 1964). Massive pyrite, galena, and chalcopyrite occur in veins and pods in silicified marble (Kurtak and others, 2002) Two samples from outcrop averaged 955.5 parts per billion (ppb) gold, 48.5 parts per million (ppm) silver, 225 ppm copper, 809.5 ppm lead, and 14,514 ppm arsenic. A float sample of massive hematite with 5 percent galena contained 144 ppb gold, 15 ppm silver, 1,591 ppm copper, 4.24 percent lead, 21.01 percent zinc, and 1,038 ppm arsenic. The mineralization appears to be limited to an area of about 500 square feet.

Alteration:

Silicification of marble.

Age of mineralization:

Probably a distal deposit of the Chandalar Copper Belt and thus Devonian(?) based on Early Devonian Pb/Pb zircon ages from the Baby Creek batholith and Horace Mountain plutons which are thought to be genetically tied to the mineralization of the belt (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Silicified marble with lead, silver, and copper.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

The Cindy prospect was staked by Placid Oil Company in 1972 and explored by them until 1977 (Kurtak and others, 2002). Sampled by Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Site name(s): Pilgrim

Site type: Prospect

ARDF no.: CH099

Latitude: 67.7544 **Quadrangle:** CH D-5

Longitude: 149.0175

Location description and accuracy:

The Pilgrim prospect is about 5.8 miles at an azimuth of 20 degrees from the central (5425) peak of Horace Mountain and about 0.4 mile south-southwest of peak 5150. It about 0.5 mile south-southwest of the center of section 24, T. 34 N, R, 7 W. Kurtak and others (2002) include a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Ag, Au?, Cu

Other: Zn

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals: Actinolite, epidote, garnet

Geologic description:

The Pilgrim prospect was staked by Placid Oil Company in 1972 and explored by them until 1977 (Kurtak and others, 2002). It was also one of the prospects listed in a report by Ventures Resources Corp. (1999) about their exploration of the Chandalar Copper Belt.

The Pilgrim prospect is at the northeast end of the Chandalar Copper Belt. The rocks in the vicinity are mainly lower Paleozoic greenschist, calcareous schist, and marble, in thrust contact with Devonian Hunt Fork Shale and Silurian and Devonian, Skajit Limestone (Brosgé and Reiser, 1964). A sample with garnet, epidote, actinolite, pyrite, sphalerite, and chalcopyrite contained 12.4 percent copper, 0.24 percent zinc, and 71 parts per million silver (Newberry and others, 1986). WGM Inc. (1980) identified coarse-grained pyrite and chalcopyrite in quartz-sericite schist and chlorite schist; grab samples contained up to 3.8 percent copper. Kurtak and others (2002) found similar mineralization in sericite-quartz schist and as well small amounts of disseminated chalcopyrite, and pyrite in calc-silicate rocks. Newberry and others (1986) classified the Pilgrim prospect as a copper(-zinc-silver) skarn, and Newberry and others (1997) classified it as a calcic copper skarn.

Alteration:

Local development of masses of skarn in calcareous rocks.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Cu skarn deposit (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
18b

Production Status: None

Site Status: Undetermined

Workings/exploration:
The Pilgrim prospect was staked by Placid Oil Company in 1972 and explored by them until 1977 (Kurtak and others, 2002). It was also one of the prospects listed in a report by Ventures Resources Corp. (1999) about their exploration of the Chandalar Copper Belt.

Site name(s): Mike

Site type: Prospect

ARDF no.: CH100

Latitude: 67.7707 **Quadrangle:** CH D-5

Longitude: 149.0532

Location description and accuracy:

The Mike prospect is on the hillside just east of the last bend at the head of Robert Creek and about 1.3 miles northwest of peak 5150. It is about 0.3 east of the center of section 14, T. 34 N., R. 7 W. Kurtak and others (2002) include a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals:

Gangue minerals: Epidote

Geologic description:

The Mike prospect was staked by Placid Oil Company in 1972 and explored by them until 1977 (Kurtak and others, 2002). The prospect was one of the deposits listed in a report by Ventures Resources Corp. (1999) about their exploration of the Chandalar Copper Belt.

The Mike prospect is at the northeast end of the Chandalar Copper Belt. The rocks in the vicinity are Devonian calcareous schist and marble, in thrust contact with Devonian Hunt Fork Shale, Skajit Limestone, and greenschist (Brosgé and Reiser, 1964). The prospect consists of an outcrop of quartz-epidote skarn about 20 feet by 50 feet in area (Kurtak and others, 2002) A select sample contained 29 parts per billion gold, 0.8 parts per million (ppm) silver, and 167 ppm copper. Kurtak and others (2002) searched the area between the Mike prospect and the Pilgrim prospect (CH099), about 1.5 miles to the south-southeast, but found little outcrop and no skarn. Newberry and others (1986) classify the Mike prospect as a copper (-zinc-silver) skarn, and Newberry and others (1997) classify it as a calcic copper skarn.

Alteration:

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Cu skarn deposits (Cox and Singer, 1986; model 18b).

Site name(s): Luna

Site type: Prospect

ARDF no.: CH101

Latitude: 67.76 **Quadrangle:** CH D-5

Longitude: 149.1633

Location description and accuracy:

The Luna prospect is about 6.5 miles at an azimuth of 6 degrees from the west peak of Horace Mountain. It covers much of the northeast quarter of section 20, T. 34 N., R. 7 W. Kurtak and others (2002) include detailed maps of the geology of the prospect, the regional geology of the area, and the location of this and other deposits of the Chandalar Copper Belt.

Commodities:

Main: Cu

Other: Ag, Au, Co, Zn

Ore minerals: Arsenopyrite, bornite, chalcopyrite, magnetite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Actinolite, chlorite, epidote, garnet, pyroxene, quartz, sericite

Geologic description:

The Luna prospect was discovered by Bear Creek Mining Company in 1968 and they explored it until 1973 by detailed mapping, geochemical and geophysical surveys, trenching, and sampling. Exploration continued at intervals until at least 1997 by Midwest Oil Company; by WGM Inc. who core drilled 5 holes totaling 1,500 feet in 1978-1979; and by Arctic Resources Inc. and Ventures Resource Corp. in 1997. The prospect has been mapped and sampled in detail several times and is covered by several generations of geochemical and geophysical surveys.

The rocks in the vicinity of the Luna prospect are interbedded Cambrian or Ordovician schist, marble, and skarn, overlain by Silurian and Devonian, Skajit Limestone. Quartz-sericite schist closely associated with the ore bodies is thought to be the sheared margin of a metamorphosed igneous body (Kurtak and others, 2002). The structure of the area is complex with thrust faulting and at least two generations of folding. The schists are isoclinally folded with shallow-plunging northeast-trending axes and they form a broad synform, which follows Roberts Creek.

Most of the mineralization is in quartz-sericite schist and calcareous quartz(+/-sericite)-chlorite schist. It consists of bodies of massive pyrrhotite, pyrite, chalcopyrite, magnetite, and sphalerite, in stringers and disseminations (Kurtak and others, 2002). Several notable intercepts were cut in the five, 1978-1979 drill holes: 1) 6.1 feet that contained 6.3 percent copper, 0.5 percent zinc, and 1.0 ounce of silver per ton; 2) 2.2 feet that contained 1.9 percent copper, and 1.0 percent zinc; and 3) 3.6 feet that contained 2.0 percent copper and 7.0 percent zinc. Samples collected by Nicholson (1990) contained up to 1,129 parts per billion (ppb) gold, 10.2 percent copper, and 8,447 ppm zinc. Kurtak and others (2002) collected samples of the same tenor and Ventures Resource Alaska reported samples over widths of 20 to 30 feet with 3 percent or more copper (Swainbank and others, 1997).

There are several interpretations of the mineralization at the Luna prospect. Newberry and others (1986, 1997) group it with the many skarn deposits of the Chandalar Copper Belt that is northwest of and genetically related to the Devonian(?) granitic plutons at Horace Mountain. Many of those skarns exhibit both garnet-pyroxene prograde and epidote-actinolite retrograde mineral assemblages. They conclude that the mineralogy, mineralization, and alteration indicate that most of them are continental-margin, porphyry-related copper skarns. In particular, they classify the Luna deposit as a copper-zinc-silver skarn or a calcic

copper skarn.

Nicholson (1990) suggests that at least part of the mineralization is volcanogenic based on the presence of massive, stringer, and disseminated sulfides, even if there are 'distal' copper-zinc skarns at Luna as well. Ventures Resource Corporation (1999) conclude that the mineralization at Luna is stratabound and consists principally of chalcopyrite and lesser amounts of bornite and sphalerite in altered calc-silicate schist associated with small bodies of meta-diorite and granodiorite. Ventures describes the deposit as including: a) stratabound volcanogenic sulfides; b) strata-controlled massive pyrite-chalcopyrite-magnetite skarns; c) strata- and shear-controlled massive chalcopyrite-bornite-sphalerite replacements; and d) a 2-foot-thick massive pyrrhotite-arsenopyrite replacement(?) in marble.

Using two different models, Nicholson (1990) estimated that the Luna deposit contains a resource of 1.8 million tons or 70,000 tons, in both cases with an average grade of 0.9 percent copper, 0.03 percent zinc, and 0.25 ounce of silver per ton.

Alteration:

Chloritic alteration of schists and silicic alteration of metamorphosed dikes and sills.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Cu skarn deposit or Kuroko massive sulfide? (Cox and Singer, 1986; models 18b? and 28a?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b? or 28a?

Production Status: None

Site Status: Active

Workings/exploration:

The Luna prospect was discovered by Bear Creek Mining Company in 1968 and they explored it until 1973 by detailed mapping, geochemical and geophysical surveys, trenching, and sampling. Exploration continued at intervals until at least 1997 by Midwest Oil Company; by WGM Inc. who core drilled 5 holes totaling 1,500 feet in 1978-1979; and by Arctic Resources Inc. and Ventures Resource Corp. in 1997. The prospect has been mapped and sampled in detail several times and is covered by several generations of geochemical and geophysical surveys.

Production notes:

None.

Reserves:

Using two different models, Nicholson (1990) estimated that the Luna deposit contains a resource of 1.8 million tons or 70,000 tons, in both cases with an average grade of 0.9 percent copper, 0.03 percent zinc, and 0.25 ounce of silver per ton.

Additional comments:

This prospect is on Doyon Ltd. selected lands; for more information, contact Doyon Ltd., Fairbanks, Alaska.

Site name(s): Big Jim Creek

Site type: Occurrence

ARDF no.: CH106

Latitude: 67.8587 **Quadrangle:** CH D-6

Longitude: 149.9522

Location description and accuracy:

This site is at an elevation of about 3,500 feet, approximately 0.6 mile north-northwest of the mouth of Big Jim Creek on Jim Creek. It is about 0.5 mile west of the center of section 13, T. 35 N., R. 11 W. The location is accurate to within a half mile.

Commodities:

Main: Cu, Pb

Other:

Ore minerals: Azurite, chalcopyrite, galena, malachite

Gangue minerals: Quartz

Geologic description:

This occurrence was originally described as galena and copper sulfides with malachite-azurite staining in Upper Devonian phyllite with some siltstone and sandstone (Brosgé and Reiser, 1964). Kurtak and others (2002) identified a 50-foot-wide zone of quartz veins that are exposed along strike for about 100 feet. There are two sets of veins; one parallel to the foliation of the phyllite host rock, and the other one crosscuts it. Both are deformed by post-mineralization folding. A sample of a 3-foot-wide quartz vein with chalcopyrite and a trace of galena contained 0.36 percent copper.

Alteration:

None noted.

Age of mineralization:

Late Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Quartz vein with chalcopyrite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only limited sampling by government agencies.

Production notes:

None.

Reserves:

None.

Additional comments:

This occurrence is in the Gates of the Arctic National Park which is closed to prospecting and mining.

Site name(s): Willow Creek

Site type: Mine?

ARDF no.: CH109

Latitude: 67.6632 **Quadrangle:** CH C-4

Longitude: 148.9764

Location description and accuracy:

Willow Creek is a 5-mile-long, headwater tributary to Robert Creek, approximately 7 miles north-northeast of the north end of Twin Lakes. There is an early reference to placer prospecting on Willow Creek but no information on its location along the creek. Arbitrarily, this site is located about 2 miles upstream from the mouth of the creek, near the northeast corner of section 30, T. 33 N., R. 6 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Reed (1938) reported that very good placer gold prospects were found in Willow Creek in the early 1900s. A small amount of gold was probably produced during the prospecting. Kurtak and others (2002) note that 28 placer claims were staked and kept current on Willow Creek from 1982 to 1986. They saw no evidence, however, of past or ongoing mining along the creek. Some of their panned concentrates from the creek contained small amounts of gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Inactive

Workings/exploration:

Reed (1938) reported that very good placer gold prospects were found in Willow Creek in the early 1900s. Kurtak and others (2002) note that 28 placer claims were staked and kept current on Willow Creek from 1982 to 1986. They saw no evidence, however, of past or ongoing mining along the creek.

Production notes:

A small amount of gold was probably recovered during prospecting.

Reserves:

None.

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Mikado vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and as of early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite.

Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults.

Several veins are exposed in trenches and pits on the ridge just southwest of Crystal Peak (Barker and Bundtzen, 2004; Barker, 2006, 2007; Barker and others, 2009). The veins are aligned along or a component of the Pioneer Fault zone which can be traced for almost 6 miles and is probably the most continuous structural feature in the Chandalar district; it trends about N65-75W. At least two veins are exposed in the Pioneer workings; they consist of discontinuous lenses of shattered quartz, sericite, and clay from a few inches to three feet thick, generally in the footwall of the Pioneer fault. The host rocks are quartz-muscovite schist of the Upper Plate unit. Float and outcrop samples contained up to 7.54 ounces of gold per ton (Strandberg, 1990). However, systematic channel samples across the veins assayed 0.02 to 2.523 ounces of gold per ton (Swanson and Ashworth, 1981).

The Pioneer fault continues northwest across Little Squaw Creek to the Grubstake East and Prospector East (CH111) prospects. The Grubstake East prospect is about 0.8 mile northwest of the Pioneer prospects in the valley of Little Squaw Creek. There is no outcrop at the Grubstake East prospect nor up the hillside to the Pioneer prospects. There is a small caved adit at the Grubstake East prospect and several prospect trenches. A single float sample of scorodite-stained quartz contained 5.18 parts per million gold.

The gold veins in the Chandalar district are considered mesothermal (Barker and others, 2004) by comparison similar deposits elsewhere and in consideration of fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1983; Rose and others, 1988; Gacetta and Church, 1989).

Alteration:

Not specifically noted.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

The work includes trenches, several prospect pits, and considerable surface sampling and examination over many years in several episodes of work by industry. In early 2010, this is one of the sites that was being studied by Goldrich Mining Company during their intensive exploration of the Chandalar area.

Production notes:

None.

Reserves:

None.

Other:

Ore minerals: Galena, gold

Gangue minerals: Quartz

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2005; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941. Those properties were taken over in 1946 into what became the Little Squaw Mining Company in 1959 and the Little Squaw Gold Mining Company in 1968. In 2008, the Little Squaw Gold Mining Company became the Goldrich Mining Company, the operator as of early 2010 (Goldrich Mining Company, 2010). From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1980 from the Mikado Mine by the Chandalar Gold Mining and Milling Company. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the know deposits in the Chandalar area and as of early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a major thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two major units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a major thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-Greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-Greenschist facies metamorphic rocks, mainly metamorphosed volcanic agglomerates, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone,

metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often occur along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional set of north-northeast-trending conjugate faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults.

The vein at the Prospect East prospect is not exposed but can be traced northwest for about 400 feet in shallow trenches and a short caved adit. In the Chandalar district, it is uniquely a silver prospect (Barker and Bundtzen, 2004, Barker, 2006; Barker, 2007; Barker and others, 2009). Two samples contained 171 and 740 parts per million (ppm) silver, 2.94 and 2.50 ppm gold, and up to 11.65 percent lead, 1,120 ppm bismuth, and 104 ppm cadmium. Barker (2009) considers the mineralization to be the northwest extension along the Pioneer fault of the mineralization at the Pioneer and Grubstake East prospects (CH110). The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004) by comparison with similar deposits elsewhere and consideration of fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1983; Rose and others, 1988; Gacetta and Church, 1989).

Alteration:

Not noted specifically.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Silver-lead-gold-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

A few old trenches and a short, caved adit. As of early 2010, this is one of the sites being studied by Goldrich Mining Company in their intensive exploration of the Chandalar area.

Production notes:

None.

Reserves:

None.

Site name(s): Crystal

Site type: Mine

ARDF no.: CH112

Latitude: 67.5449 **Quadrangle:** CH C-3

Longitude: 148.164

Location description and accuracy:

The Crystal Mine is in a low saddle on the ridge about 0.9 mile southwest of Crystal Peak. It is about 0.6 mile northwest of the center of section 2, T. 31 N., R. 3 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold, pyrite

Gangue minerals: Quartz

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins including the Crystal vein had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone,

metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. The Crystal Mine is in schist of the Upper Plate and occurs along the Little Squaw faults that continues across Little Squaw Creek to the Little Squaw Mine (CH040) (Barker and others, 2009).

The Crystal Mine was discovered by 1909 and developed by a prospect shaft and short crosscut (Barker and Bundtzen, 2005; Barker 2006; Barker and others, 2009). As then described, the Crystal vein was 6.5 to 9 feet thick and grab samples assayed 10.0 to 43.2 ounces of gold per ton. The vein is has several distinct bands, one of which has a ribbon structure; the vein consist of quartz with pyrite (arsenopyrite?). A 1908 report indicates that 4.5 tons of ore was processed at the Little Squaw mill. By 2005, the old shaft and workings were sloughed or covered by talus. Little Squaw Gold Mining Company drilled two holes but failed to intersect the vein because of unexpected faults.

Alteration:

Not specifically noted. However, many of the veins in the area such as Crystal are aligned along major faults that are marked by much clay and gouge.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Developed by a shaft and a short crosscut by 1909. Two holes drilled in 2006. In early 2010, this was one of the sites being studied by Goldrich Mining Company in their intensive exploration of the Chandalar area (Goldrich Mining Company, 2010).

Production notes:

A 1908 report indicates that 4.5 tons of ore was processed at the Little Squaw mill.

Reserves:

None.

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate,

chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. The St Marys prospect is in the upper plate rocks along the Mikado fault, one of the prominent west-northwest trending fault zones in the region.

Oxidized quartz veins in fault gouge were found on bedrock during placer mining on St Marys Creek in 1993 (Barker and Bundtzen, 2004) There are at least two veins (Barker, 2007). One is in the creek bottom; it is up to 10 feet thick and parallels a body of quartz-iron oxide breccia, 6 feet or more thick. The other only can be traced in float. None of the samples carried significant gold. However, an unpublished company report in the Goldrich Mining Company records cites a sample that contained 0.24 ounce of gold per ton across an 11-foot-wide quartz vein in the bed of St Marys Creek.

Barker and others (2009) propose that this prospect is at the southeast end of a belt of mineralization 4,000 or more feet long that extends to here from the Mikado Mine (CH045) along the Mikado fault. Numerous trenches between the Mikado Mine and this prospect have uncovered quartz veins with gold values. They suggest that the greatest economic potential of this belt is the extensive lower grade and probably relatively continuous mineralization that surrounds the rich gold-quartz lenses along the belt such as were mined at the Mikado Mine.

Alteration:

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite.

Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. The rocks in the Rachet Ridge prospect area are part of the Upper Plate.

There was no record of work at the Rachet prospect until it was explored by Little Squaw Gold Mining Company in 2006. They found a short adit and several hand-dug pits that probably date to the early days of the district. In 2006, they excavated a trench on the prospect and drilled three reverse-circulation holes.

The rocks at the prospect are similar to those at the nearby Summit Mine (CH041), black carbonaceous schist overlain by light-gray, muscovite-chlorite-quartz schist. The Summit fault, one of the west-northwest-striking regional faults, is along the south side of the prospect. The veins at the prospect splay from the Summit fault and strike about N70E. There are at least 5 veins; where exposed they are about 2 feet thick. A quartz-vein sample with arsenopyrite and galena contained 2.88 parts per million (ppm) gold. One drill hole showed considerable pyrrhotite, arsenopyrite, and pyrite for 20 feet. Another had a 5-foot intercept with 0.28 ppm gold and a 10-foot interval with 0.32 ppm gold.

Alteration:

Not specifically mentioned.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

An old adit and several pits probably date to the early 1900s. No record of any work until Little Squaw Gold Mining Company examined and sampled the prospect, did a magnetic survey, dug a trench, and drilled three, reverse-circulation holes in 2006.

Production notes:

None.

Reserves:

None.

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker, and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). There was some earlier small lode production from the district but the first documented gold produced from the lodes was 870 ounces produced from 1967 to 1971 from the Mikado and Summit mines by the Chandalar Gold Mining and Milling Company. Subsequently, Chandalar Development produced 8,169 ounces of lode gold from the Mikado and Summit Mines but recovery was poor. In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2010, that effort continued (Goldrich Mining Company, 2010).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite.

Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. The Kiska and Chiga prospect are in Upper Plate rocks near the contact of black, carbonaceous phyllite and schist of the Mikado Phyllite with muscovite-chlorite-quartz schist.

The Kiska and Star veins are typical of those in the district; they are gold quartz veins with a few percent sulfides, mainly arsenopyrite and some galena. Barker (2007) show that both the Kiska and Star veins trend west- northwest, i.e., parallel to the regional faults in the district that often control the mineralization.

No rocks crop out at the Kiska prospect and the old trenches that probably date to before WWII have sloughed (Barker, 2007). Two veins were identified by float of quartz vein and breccia material spread over an area about 1,600 feet long and up to 600 feet wide. The veins strike west-northwest. Fine gold can be panned from the frost boils in the vicinity of the veins and soil sampling shows strong gold and arsenic anomalies over the veins. The fine fraction of soil collected over the veins contained 0.4 to more than 2 parts per million (ppm) gold. Seven holes were drilled on the prospect in 2006. The drilling indicated that the mineralization is discontinuous and only a few short intercepts were cut that contained no more than 2 parts per million gold. After the drilling, a trench was dug over one of the drill holes. Discontinuous pods and lenses of weathered quartz were exposed. One sample contained 422 ppm gold. Another assayed 0.378 ppm gold but when reanalyzed by a metallic-screen assay, it assayed 71.7 ppm gold. The Kiska veins were traced for about 2,500 feet as a magnetic low.

Just north of the Kiska prospect, lenses of black dolomite are found along a fault zone. The dolomite appears to be hydrothermal and samples contain anomalous arsenic.

The nearby Chiga prospect is covered by thick alluvium, talus, and solifluction lobes. Some quartz float is on the surface and soil samples had up to 242 ppm antimony. One trench was cut on the Chiga prospect. One interval in an intensely altered shear zone averaged 1.1 ppm gold across 24 feet. Pods of massive stibnite occur along a fault zone. The Chiga gold and antimony soil anomalies can be traced for 3,200 feet. The high antimony values suggest a style of mineralization that is different from the other vein deposits in the Chandalar district. Most of the veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004) by comparison with similar deposits elsewhere and in consideration of the fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1983, 1984; Rose and others, 1988; Gacetta and Church, 1989). However, the Chiga may be epithermal.

Alteration:

Not noted specifically. The mineralization is associated with fault zones that have much gouge and clay.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a; stibnite vein (Cox and Singer, 1986, model 27d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a, 27d

Production Status: None

Site Status: Active

Workings/exploration:

Several old hand-dug prospect pits and trenches that probably date to before WWII. Soil and geophysical surveys, 7 drill holes, and several trenches in 2006.

Production notes:

None.

Reserves:

None.

Geologic description:

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and in early 2012 that effort continued (Goldrich Mining Company, 2012).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2007 [map]; 2007 [83 p.]). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist, quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending

faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. This prospect in the cirque at the head of Little Squaw Creek is covered by alluvium, landslide material, glacial deposits, and thick soil with much solifluction. However, the rocks on both sides of the cirque are part of the Upper Plate unit and the rocks under the surficial material in the cirque probably are mostly Mikado Phyllite.

Before 2002 there was no record of mineralization on the prominent rock glacier in the cirque at the head of Little Squaw Creek. During the work by Little Squaw Mining Company (Barker and Bundtzen, 2004; Barker, 2006; Barker, 2007; Barker and others, 2009) an area about 800 feet long and 150 feet wide on the western side of the lower part of the rock glacier was found to be littered with cobbles and boulders of quartz-vein material and of altered argillized and brecciated schist similar to that found at many of the veins in the Chandalar area. A random chip sample of the white quartz contained 4.06 parts per million gold. The quartz float is so abundant that it points to an undiscovered zone of mineralization in the cirque.

Reconstruction of the source of the float indicates that it probably is associated with one of the west-northwest-trending shear zones along which most of the gold deposits in the Chandalar district are located. In this case, it is probably a fault that extends from the Eneveloe Mine (CH046) to the northwest and the Rachet Ridge prospect (CH114) to the southeast. Ground magnetic surveys and geochemical surveys over the likely site of the source of the float suggest that it consists of at least 4 and perhaps 6 veins. In 2011, Goldrich Mining Corp. drilled 5 holes on the Rock Glacier prospect that totaled 850 meters. Of the 15 intercept 0.3 to 11.3 meters long that contained more than 0.5 gram of gold per tonne, the best were 2.1 meters with 6.02 grams of gold per tonne and 1.5 meters with 4.17 grams of gold per tonne.

Alteration:

Abundant quartz-vein float associated with rubble of argillized schist.

Age of mineralization:

Possibly mid-Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986, model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

The work on the Rock Glacier prospect from 2004 to 2009 included sampling and geophysical and geochemical surveys. In 2011, Goldrich Mining Corp. drilled 5 holes on the Rock Glacier prospect that totaled 850 meters.

Production notes:

None.

Reserves:

None.

Site name(s): McLellan Creek

Site type: Mines

ARDF no.: CH117

Latitude: 67.5532 **Quadrangle:** CH C-3

Longitude: 148.0216

Location description and accuracy:

The most prominent area of placer tailings near McLellan Creek is about 0.4 mile north-northeast of the junction of the Little McLellan and McLellan Creeks. The area is about 0.5 mile east-southeast of the center of section 32, T. 32 N., R. 2 W. The coordinates are at this location. Another area nearby is along Little McLellan Creek about 0.9 mile west of the junction of Little McLellan and McLellan Creeks. The locations are accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Other than word-of-mouth, there is little known about placer mining on Little McLellan Creek (Barker and Bundtzen, 2004). However, on their geologic map, Bundtzen and Laird (2009a, 2009b) show two areas of placer tailings near the junction of Little McLellan and McLellan Creeks. The area is covered by glacial till and outwash of two stages of the Itkillik Glaciation and by Quaternary colluvial talus deposits.

The most obvious area that is probably a placer mine is an area about 0.4 mile north-northeast of the junction of the two creeks (Bundtzen, and Laird, 2009a). Satellite imagery available on the Internet (e.g. at www.mapper.acme.com) shows an area about 500 feet long with little vegetation and signs of relatively recent mining(?) activity. The area is about 100 feet higher than McLellan Creek and if it is a placer mine, it may be a bench deposit. It is in an area of glacial till and outwash of the Itkillik II Glaciation.

Bundtzen and Laird (2009a, 2009b) show another area of placer tailings about 0.4 mile long along McLellan Creek, about 0.9 mile west of the junction of Little McLellan and McLellan Creeks. On the Internet satellite imagery, the area is heavily vegetated and placer mining is not obvious. They suggest that this placer may be derived from glacial outwash immediately below a terminal ice position of of the Itkillik II Glaciation.

In early 2010, these placer tailings were on the land being explored by Goldrich Mining Company (2010) in their study of the lodes and placers of the Chandalar district.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Active

Workings/exploration:

Areas of tailings indicate placer mining in the past.

Production notes:

Some gold was possibly produced but there is no published record of it.

Reserves:

Probably none.

Primary Reference: Bundtzen and Laird, 2009a and 2009b

Reporter(s): D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-02

Site name(s): Pallasgreen

Site type: Prospect

ARDF no.: CH118

Latitude: 67.562 **Quadrangle:** CH C-3

Longitude: 148.1158

Location description and accuracy:

The Pallasgreen prospect is at an elevation of about 3,000 feet, 0.8 mile northeast of Crystal Peak and about 0.5 mile north-northwest of the center of section 36, T. 32 N., R. 3 W., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: As, Au, Pb

Other:

Ore minerals: Arsenopyrite, galena, gold, limonite

Gangue minerals: Quartz

Geologic description:

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2009a, 2009b). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist; quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone, metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults.

Although the Pallasgreen prospect was discovered in the early 1900s, there was little more than a few bits of old company information about it prior to the work of Little Squaw Mining Company in 2005 (Barker, 2006 and 2007). A prominent, iron-stained quartz hogback about 25 feet wide that strikes 100-105 degrees with a steep south dip is exposed at the prospect. The footwall of the vein is feldspathic schist; the hanging wall is black graphitic schist. As mapped by Bundtzen and Laird (2009a, 2009b) the host rocks are part of the finely laminated, fine grained, quartz-mica schist unit of the Upper Plate.

Brecciated quartz-limonite zones and several joint sets cut the vein. Wispy bands of chlorite and arsenopyrite are common along the footwall and hanging wall contacts. Samples showed little gold. However, float quartz rock and a prospect pit about 300 feet west of the hogback suggest one or more parallel bands or zones of quartz-limonite breccia or quartz veins. The float quartz contain clots and grains of arsenopyrite and galena up to 3 cm. Soil samples in the vicinity contained up to 1.91 parts per million

(ppm) gold; rock-chip samples contained up to 12.12 ppm gold. Chips of quartz in the tundra that surround the outcrop suggest that the vein and quartz breccia may be extensive. The gold veins in the Chandalar district are considered mesothermal (Barker and Bundtzen, 2004; Barker, 2006, 2007; Barker and others, 2009) by comparison with similar deposits elsewhere and consideration of fluid inclusion and oxygen and lead isotope studies of the Chandalar mineralization (Ashworth, 1984; Rose and others, 1988; Gacetta and Church, 1989).

Alteration:

Quartz vein is heavily oxidized to limonite.

Age of mineralization:

Possibly Middle Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Only limited surface sampling by industry.

Production notes:

None.

Reserves:

None.

Last report date: 2010-04-02

Site name(s): Unnamed (near Horace Mountain)

Site type: Prospect

ARDF no.: CH119

Latitude: 67.6535 **Quadrangle:** CH C-5

Longitude: 149.1799

Location description and accuracy:

The center of this prospect is about 1.3 miles north-northeast of the mouth of Sheep Creek on Robert Creek. It is near the center of section 29, T. 33 N., R 7 W. However, similar mineralization is widespread on the north and south side of Horace Mountain. Kurtak and others (2002) include a map showing the regional geology of the area and the location of this and the other deposits of the Chandalar Copper Belt.

Commodities:

Main: Ag, As, Au, Cu, Mo, Pb, Zn

Other:

Ore minerals: Arsenopyrite, pyrite

Gangue minerals:

Geologic description:

A color and geochemical anomaly that suggested mineralization in this area was first identified in 1983 (Nichol, 1983). In the early 1990s, Central Alaska Gold Company (1992) mapped and sampled the prospect, and Kurtak and others (2002) visited it and collected samples widely on the slopes of Horace Mountain.

A east-northeast-trending, Devonian meta-granodiorite intrusion about 7 miles long and a mile wide makes up most of the central part of Horace Mountain (Dillon and others, 1996; Kurtak and others, 2002). It is flanked by Ordovician quartz-sericite schist, calcareous chlorite schist, felsic schist, and thin-bedded marble. The quartz-sericite schist is thought to be highly-altered metamorphosed intrusive rock.

Red-and-yellow-stained, quartz-sericite schist with zones of 2 to 3 percent pyrite is conspicuous near the meta-granodiorite on both sides of Horace Mountain (Kurtak and others, 2002). This schist probably outcrops continuously along the south side of Horace Mountain. On the west flank of Horace Mountain below peak 5540, samples of quartz-sericite schist with 4 percent pyrite and minor arsenopyrite, and a float sample of siliceous mica schist, averaged 127.5 parts per billion (ppb) gold, 15.7 parts per million (ppm) silver, 1,119 ppm copper, 510 ppm lead, 291 ppm zinc, and 1.16 percent arsenic. On the east flank of Horace Mountain below peak 5192, a 75- to 100-foot-thick outcrop of sericite-quartz schist contains zones of pyrite up to a foot thick. Select samples with 2 to 5 percent pyrite contained up to 62 ppb gold, 1.4 ppm silver, 116 ppm molybdenum, and 134 ppm arsenic.

The mineralization on the flanks of Horace Mountain is probably related to the meta-granodiorite in the center of the mountain and has much the same genesis as the other skarn deposits in the Chandalar Copper Belt (Newberry and others, 1986).

Alteration:

Not noted.

Age of mineralization:

Devonian(?) based on Early Devonian Pb/Pb zircon ages from the nearby Baby Creek batholith and Horace Mountain plutons (Dillon and others, 1996).

Generic deposit model:

Deposit model:

Mineralized quartz-sericite schist adjacent to a meta-granodiorite pluton.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only mapping and sampling by government agencies and industry from 1983 to 2002.

Production notes:

None.

Reserves:

None.

Additional comments:

This prospect is on Doyon Ltd. selected lands; for more information, contact Doyon Ltd., Fairbanks, Alaska.

Last report date: 2010-04-18

Site name(s): Unnamed (along Willow Creek)

Site type: Occurrence

ARDF no.: CH120

Latitude: 67.666 **Quadrangle:** CH C-4

Longitude: 148.9968

Location description and accuracy:

This occurrence is about 1.5 miles above the mouth of Willow Creek. The creek is a 5-mile-long, headwater tributary to Robert Creek. The occurrence is about 0.4 mile southwest of the center of section 19, T. 33 N., R. 6 W.

Commodities:

Main: As, Cu, Zn

Other:

Ore minerals: Arsenopyrite, chalcopyrite, malachite, pyrite

Gangue minerals:

Geologic description:

Kurtak and others (2002) examined the canyon of Willow Creek, about 1.5 miles above its mouth. The rocks in the area are Devonian chlorite-muscovite schist in thrust contact with quartz-muscovite-chlorite schist. Two iron-stained exposures of sericite schist up to 25 feet wide contain pyrite bands that average 0.8 foot thick and parallel the schistosity. The bands also contain arsenopyrite and trace chalcopyrite and malachite. A 7-foot chip sample across pyrite bands up to 0.5 foot thick contained 1,679 parts per million (ppm) copper and 367 ppm zinc. None of the samples contained precious metals.

Alteration:

Iron staining of pyritiferous schist.

Age of mineralization:

Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Schist with bands of pyrite and minor copper and zinc.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only limited sampling by the U.S. Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Reporter(s): D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-18

Site name(s): Limestone Creek

Site type: Prospect

ARDF no.: CH121

Latitude: 67.5722 **Quadrangle:** CH C-5

Longitude: 149.3837

Location description and accuracy:

Limestone Creek is a south-flowing tributary to the Bettles River. The mouth of the creek is about 6 miles north of the center of Bob Johnson Lake (formerly known as Big Lake) near the center of section 29, T. 32 N., R. 8 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

There is no record of mining on Limestone Creek (Kurtak and others, 2002). However, Reed (1938) reported that an 18-foot shaft was sunk near the mouth of the creek with indifferent results. Kurtak and others (2002) found remnants of a boom dam and cabin near the mouth of the creek that may indicate some unreported mining. They panned the creek at several locations for about 2 and a half miles above its mouth; none of their pans showed visible gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Evidence of prospecting for placer gold near the mouth of the creek prior to 1938.

Production notes:

Possibly a small amount of gold was produced in the course of prospecting but there is no recorded production and little sign of mining.

Reserves:

None.

Additional comments:

This prospect is on Doyon Ltd. selected lands; for more information, contact Doyon Ltd., Fairbanks, Alaska.

Site name(s): Canyon Creek

Site type: Mine

ARDF no.: CH122

Latitude: 67.5187 **Quadrangle:** CH C-6

Longitude: 149.6056

Location description and accuracy:

There is little information about placer mining along Canyon Creek but Kurtak and others (2002) reported mining in 2000 'near the narrows'. That feature is probably about 1.3 miles upstream from the mouth of Canyon Creek where the creek cuts through a low ridge. This location is about 0.5 mile north of the center of section 17, 32 N. R. 7 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

In his detailed list of the placer deposits of the Koyukuk area, Reed (1938) found no evidence of mining or prospecting on Canyon Creek. Kurtak and others (2002) reported claim staking in 1978 and 1982-1983, and mining in 1986 and 2000.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Undetermined

Workings/exploration:

Apparently the first claims were staked in 1978; more were staked in 1982-1983; and there was placer mining in 1986 and 2000.

Production notes:

Some production in 1986 and 2000.

Reserves:

Probably none.

Site name(s): Wizard

Site type: Prospect

ARDF no.: CH123

Latitude: 67.3798 **Quadrangle:** CH B-5

Longitude: 149.1554

Location description and accuracy:

This prospect is at the head of Dennys Gulch at an elevation of about 2,950 feet, near the center of section 32, T. 30 N., R. 7 W.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other:

Ore minerals: Gold, iron

Gangue minerals:

Geologic description:

This record describes the lode deposit at the head of the Dennys Gulch. Both this lode prospect and a placer mine (CH019) in Dennys Gulch are associated with Denny O'Keefe, who had claims and explored the area from 1948 to 1957; much of the work on the lode and placer probably coincided (Kurtak and others, 2002). A magnetometer survey was run over Dennys Gulch and Sawlog Creek in 1951 (Williams, 1952); there was uranium exploration by the U.S. Geological Survey in 1956 (Freeman, 1963); 6 lode claims were staked in 1955 (Heiner and Wolff, 1968); and WGM Inc. explored in the area from 1975 to 1976, and in 1983 (Dashevsky, 1986).

The rocks in Dennys Gulch are mainly Devonian quartz-mica schist and schistose quartzite intercalated with beds of greenschist and greenstone; the mineralization is associated with a thrust fault separating graphitic schist and quartz-muscovite schist. As described by Kurtak and others (2002), the rocks in upper Dennys Gulch are intensely stained dark red and are cut by numerous thin quartz veins. None of their samples of the quartz veins contained significant metal values, but there were reports that gold 'colors' could be panned 'at will' in the altered, quartz-veined rocks. Native iron is common in small, bright fragments, green copper staining is present, and the bitter taste of the water in the stream is attributed to arsenic. A panned-concentrate sample collected in the upper part of Dennys Gulch contained 235 parts per million (ppm) gold, 21.2 ppm silver, 133 ppm lead, 222 ppm zinc, and 116 ppm barite. Some of the rocks read as much as 0.035 milliroentgens per hour; these values are anomalous but probably do not indicate a body of economic uranium ore (Freeman, 1963).

Alteration:

Schist in upper Dennys Gulch is intensely stained dark red.

Age of mineralization:

Generic deposit model:

Deposit model:

Unclear.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Site name(s): Aurora

Site type: Prospect

ARDF no.: CH124

Latitude: 67.5505 **Quadrangle:** CH B-4

Longitude: 148.1798

Location description and accuracy:

The Aurora prospect is about 0.9 mile east-northeast of Little Squaw Peak and about 0.5 mile south-southeast of the center of section 34, T. 32 N., R. 3 W. The location is accurate.

Commodities:

Main: Au

Other: Ag, Cu, Pb, Sb, Zn

Ore minerals: Arsenopyrite, galena, gold, pyrite, scorodite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Aurora prospect is one of the numerous gold-vein occurrences in the Chandalar district that prior to 2011 didn't seem to merit a specific identify. It was drilled in 2011 by Goodrich Mining Corp. (2011) with notable results. Little specific information is available for the Aurora prospect but its geology and mineralization is almost certainly the same as the many of the prospects in the district.

Placer gold was discovered in the Chandalar area on Little Squaw Creek (CH039) in 1902 (Barker and Bundtzen, 2004; Barker, 2007; Barker and others, 2009). By 1909, four quartz veins had been discovered and many more were located prior to WWI. Most of the important properties in the district were consolidated by William Sulzer from 1909 to 1941; the Mikado Mine was one of the prominent deposits of the Chandalar area and was included. Those properties were taken over in 1946 to form the Little Squaw Mining Company in 1959, which in turn became the Little Squaw Gold Mining Company in 1968. From 1967 to 1999, Little Squaw Gold Mining Company leased some of their Chandalar lode and placer ground for mining and/or exploration to a succession of companies, notably the Chandalar Gold Mining and Milling Company (1967-1971), Noranda Mining (1974-1976), the Chandalar Development Corporation (1980-1983), and Gold Dust Mines (1989-1999). In 2003, Little Squaw Gold Mining Company and its direct descendent Goldrich Mining Company began an aggressive exploration program for lode and placer deposits over a large block of land that covers almost all of the known deposits in the Chandalar area and that effort continued through 2012 (Goldrich Mining Company, 2012).

The geology of the Chandalar area is dominated by a system of west-northwest-trending regional faults including a prominent thrust fault in the southern part of the district and a series of major high-angle faults through the center of the area (Bundtzen and Laird, 2007 [map]; 2007 [83 p.]). These faults separate the rocks into two principal units, a west-northwest-trending Upper Plate unit about 3 miles wide in the center of the area and a Lower Plate unit to the north and south. The contact of the two units is a thrust fault on the south side of the Upper Plate rocks and a high-angle fault on the north side. Most of the Upper Plate rocks consist of Devonian upper-greenschist-facies metamorphic rocks, mainly carbonaceous schist, quartz-chlorite-muscovite schist, schist and phyllite derived from turbidites that comprise the Mikado Phyllite, metamorphosed calcareous sandstone, and quartz-muscovite schist. The Lower Plate rocks consist of Devonian, upper-greenschist-facies metamorphic rocks, mainly metamorphosed volcanic agglomerate, chlorite-rich tuffaceous schist, quartz-mica schist derived from mudstone, mica-quartz schist, and quartzite. Both the Upper and Lower Plate rocks are cut by irregular masses, dikes and sills of greenstone,

metagabbro, and metadiorite of unknown age. Most of the mineral deposits in the Chandalar area are in the Upper Plate rocks and the deposits often are along the regional, steep-to-vertical, west-northwest-trending faults. There is an additional conjugate set of north-northeast-trending faults that offset the Upper Plate rocks and at least some of the mineralization may be localized at the intersections of the regional west-northwest-trending faults and the conjugate faults. This prospect in the cirque at the head of Little Squaw Creek is covered by alluvium, landslide material, glacial deposits, and thick soil with much solifluction. However, the rocks on both sides of the cirque are part of the Upper Plate unit and the rocks under the surficial material in the cirque probably are mostly Mikado Phyllite.

In 2011, Goldrich drilled 4 holes at the Aurora prospect that totaled 784 meters (Goldrich Mining Co., 2011). Of the 17 intervals 0.6 to 3.0 meters wide that contained more than 0.55 grams of gold per tonne, the best were 0.9 meters with 5.32 grams of gold per tonne, 0.6 meters with 4.14 grams of gold per tonne, 1.5 metes with 4.39 grams of gold per tonne, 1.5 meters with 6.57 grams of gold per tonne, and 0.9 meters with 4.44 grams of gold per tonne.

Alteration:

Not specifically noted. However, many of the veins in the area are aligned along major faults that are marked by much clay and gouge.

Age of mineralization:

Possibly mid-Cretaceous based on the assertion of Dillon (1982) that the gold-quartz veins of the central Brooks Range are that age. However, there is no definitive data for the age of the veins of the Chandalar area.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Four holes drilled in 2011.

Production notes:

None.

Reserves:

None.

Last report date: 2012-04-01

Site name(s): 88 Group

Site type: Prospect

ARDF no.: CI001

Latitude: 65.4375 **Quadrangle:** CI B-2

Longitude: 144.7532

Location description and accuracy:

The 88 Group prospect is about 5 miles southwest of Circle Hot Springs, near the divide between the head of Half Dollar Creek and Ketchem Creek. In 2008, the 88 Group is part of an approximately 5,000-acre property that was being explored by Millrock Resources Inc. as a single endeavor. The outline of the claim block and the site of recent exploration is uncertain but the coordinates near the northwest corner of section 18, T. 7 N., R. 14 E., are within the block, if not near the center of it .

Commodities:

Main: Au

Other: As, Cu, Sn

Ore minerals: Arsenopyrite, cassiterite, chalcopyrite

Gangue minerals: Quartz

Geologic description:

The 88 Group prospect is in a dark, mafic peripheral phase of a Cretaceous, coarse-grained porphyritic granitic pluton. Both lode and placer gold is found at these claims (Vetter, 1995). Wiltse and others (1995) mapped the bedrock in the area and described the pluton as a chloritized porphyritic (hornblende-)biotite monzogranite to syenogranite. They also mapped a mafic dike in the area as black to dark gray, aphanitic to slightly porphyritic rock with major plagioclase, augite, hornblende and magnetite.

Gold mineralization occurs in heavily Fe-oxide stained, quartz-rich greisen zones up to six feet across, within fractures, and in stockwork veins. A significant aspect of the prospect is the large amount of grus that covers the area to a depth of 10 to 20 feet and pans considerable gold. Other heavy minerals found in the panned concentrates include abundant sphalerite, and small amounts of arsenopyrite, chalcopyrite, cassiterite(?), and monazite(?).

Gold occurs in samples of mineralized exposures along about 2,000 feet of ditch along the Portage Creek road. The mineralization is within heavily Fe-oxide stained, quartz-filled greisen zones that average about 3 inches wide. Phyllic and argillic alteration is present along vein margins and is also controlled by fractures. Strong zinc anomalies, up to 0.5 percent, and moderate arsenic values were noted. Tin was not detected in the rock samples but two panned-concentrate samples contained anomalous tin values. The dominant trend in mineralization is N50W with near vertical dips (Bakke, 1991).

As described by Millrock Resources Inc. (2008), the 88-Group mineralization consists of gold-bearing quartz veins and stockworks that occur in three structurally controlled zones 3 to 25 meters wide. Placer Dome USA and AMAX Exploration previously sampled the property and drilled three holes. The drilling intersected numerous zones with anomalous gold values up to 745 parts per billion gold. One of the zones in altered granite that was sampled at the surface contained 8.92 grams of gold per tonne across a width of 25 meters. Several other prospects are on the property. The mineralization at the Silver Chalice prospect consists of quartz-sulfide veinlets in altered sedimentary rocks; grab samples contained up to 32.0 grams of gold per tonne. The Portage prospect is similar. The Silver Chalice and Portage prospects may be recent names for two sites previously included in ARDF, a nearby unnamed occurrence (DI065) and the Top Dollar occurrence (DI058). These occurrences are probably all within the property that was being explored

by Millrock in 2008.

Alteration:

Mineralization occurs within heavily Fe-stained, quartz-filled greisen zones that average about 3 inches wide. Phyllic and argillic alteration is present along vein margins and also along fractures (Bakke, 1991).

Age of mineralization:

Probably related to the Cretaceous granitic intrusion that hosts at least some of the mineralization.

Generic deposit model:

Deposit model:

Auriferous greisen zones and gold-quartz veins in granitic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Surface sampling beginning in the 1991 or before; three holes drilled. Being explored by Millrock Resources in 2008.

Production notes:

None.

Reserves:

None.

Site name(s): Little Champion Creek

Site type: Prospect

ARDF no.: CI051

Latitude: 65.438 **Quadrangle:** CI B-6

Longitude: 146.588

Location description and accuracy:

The location is the approximate center of a large claim group along the NW margin of the Mt. Prindle pluton. This record is a general description of the Mt. Prindle pluton uranium occurrences. Separate entries for individual sites are as follows: ARDF no. CI076, CI067, and CI069.

Commodities:

Main: U

Other: REE

Ore minerals: Allanite, bastnaesite, monazite, thorianite, thorite, uraninite, xenotime

Gangue minerals: Topaz, tourmaline

Geologic description:

This area contains significant uranium-rare earth mineralization.
There are numerous uranium prospects, uraniferous springs and stream-sediments in the area (Barker and Clautice, 1977). Mt. Prindle pluton is a tourmaline- and topaz-bearing porphyritic biotite granite that crops out over a 50-square-km area. Country rock is quartzite and micaceous quartzite with subordinate quartz-mica schist, phyllitic schist and calcareous schist, thermally metamorphosed to upper hornblende facies near the pluton contact. The pluton is cut by three major NE-trending faults, and several quartz porphyry, aplite and pegmatite dikes.

Fissure veins containing allanite, bastnaesite, monazite, thorianite, thorite, uraninite, and xenotime occur in Cretaceous porphyritic biotite syenite and alkali granite. The deposit contains significant La, Cd, Nd, Pr, Yd, and fluorite. Hematitic alteration of wall rock and leaching of magnetite occurs in host rocks. Samples contain up to 0.1 percent U-308 and 15 percent rare-earth elements (Burton, 1981).

Some exploration and limited drilling was carried out on Little Champion Creek, but no further development has taken place. Claims were active from 1977 through at least 1981 (Menzie and others, 1983, p. 56).

Alteration:

There is hematitic alteration of wall rock and leaching of magnetite in host rocks (Burton, 1981).

Age of mineralization:

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Some exploration and limited drilling was carried out on Little Champion Creek, but no further development has taken place. Claims were active from 1977 through at least 1981 (Menzie and others, 1983, p. 56).

Production notes:

None.

Reserves:

None.

Site name(s): Top Dollar

Site type: Prospect

ARDF no.: CI058

Latitude: 65.4433 **Quadrangle:** CI B-2

Longitude: 144.7586

Location description and accuracy:

The location is the approximate center of 20 mining claims about 5 miles southwest of Circle Hot Springs and about 0.6 mile southeast of the center of section 12, T. 7 N., R. 14 E. The location is generally accurate and probably well within the claim boundaries.

Commodities:

Main: Au

Other:

Ore minerals: Arsenopyrite, gold

Gangue minerals: Quartz

Geologic description:

Note: This prospect is probably within a large block of ground that is currently (2008) being explored by Millrock Resources Inc. (2008). The geology and past exploration within the block is discussed in the ARDF site for the '88 group' (CI001).

The Top Dollar claims are in the Paleozoic metamorphic rocks intruded by Cretaceous to Tertiary granitic rocks . The region is transected by regional-scale, northeast-trending shear zones and northeast-trending mafic dikes.

Gold mineralization occurs as gold-arsenopyrite-quartz veins and stockwork zones in massive, hornfelsed, micaceous quartzite and schist. The mineralization is near the intrusive contact of the Cretaceous 'Two Bit' granite pluton; possibly as mineralized pendants above the pluton. Rock, samples contain up to 14 parts per million gold, highly anomalous arsenic and antimony, and variably anomalous bismuth and base metals (D.D. Adams, written communication, 1998).

Alteration:

Silicification, quartz-sericite, chlorite, and iron-oxides.

Age of mineralization:

Possibly genetically related to the nearby Cretaceous granitic pluton.

Generic deposit model:

Deposit model:

Gold-arsenopyrite veins in hornfels and schist.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:
Only surface sampling.

Production notes:
None.

Reserves:
None.

Site type: Occurrence

ARDF no.: CI065

Latitude: 65.4394 **Quadrangle:** CI B-2

Longitude: 144.7275

Location description and accuracy:

This occurrence is the site of sample 3MZ0007b, plate 1, of U.S. Geological Survey, Open-File Report 84-479 (Foster and others, 1984). It is approximately 1 mile southwest of VABM 3125, about 5 miles southwest of Circle Hot Springs, near the northeast corner of section 18, T. 7 N., R. 14 E. The location is accurate.

Commodities:

Main: Au

Other: Ag

Ore minerals: Arsenopyrite

Gangue minerals: Quartz

Geologic description:

A sample of quartzite with arsenopyrite contained 3.2 ppm Au and 0.5 ppm Ag (Foster and others, 1984). This prospect is probably within a large block of ground that is currently (2008) being explored by Millrock Resources Inc. (2008). The geology and past exploration within the block is discussed in the ARDF record for the '88 group' (CI001).

Alteration:

Not specified.

Age of mineralization:

May be genetically related to a nearby Cretaceous granitic pluton.

Generic deposit model:

Deposit model:

Auriferous arsenopyrite-bearing quartzite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Only a surface sampling.

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Harrison Creek

Site type: Prospect

ARDF no.: CI090

Latitude: 65.3803 **Quadrangle:** CI B-2

Longitude: 144.8593

Location description and accuracy:

The placer prospect consists of 4 claims that extend along Harrison Creek from near the mouth of Bottom Dollar Creek, upstream to near the mouth of Squaw Creek; the location is in about the center of the claims. The claims extend along the northern half of sections 3 and 4, T. 6 N., R. 14 E. The location is accurate.

Commodities:

Main: Au, Sn, W

Other:

Ore minerals: Cassiterite, gold, wolframite

Gangue minerals:

Geologic description:

Jim Halloran in an unpublished report (2007) reports placer gold in Harrison Creek along 4 claims that extend from near the mouth of Squaw Creek downstream to near the mouth of Bottom Dollar Creek. His report is based on drilling by E.N. Wolf in 1995; Wolf's work consisted of 28 holes along 7 lines. Based on his samples, Wolf estimated that there is about 2.9 million cubic yards of auriferous gravels on the claims with an average grade of 0.032 ounce of gold per cubic yard. Earlier drilling by the United States Smelting, Refining, and Mining Company in 1938, which wholly or in part may not coincide with the later Wolf drilling, gave much lower values. Halloran, however, suggests that the Wolf numbers are conservative because his drilling apparently did not reach bedrock where the most gold is likely to be located. Cassiterite and wolframite also occur in the concentrates.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer gold (Singer and Cox, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Active

Workings/exploration:

Jim Halloran in an unpublished report (2007) reports placer gold in Harrison Creek along 4 claims that extend from near the mouth of Squaw Creek downstream to near the mouth of Bottom Dollar Creek. His report is based on drilling by E.N. Wolf in 1995; Wolf's work consisted of 28 holes along 7 lines. Earlier drilling by the United States Smelting, Refining, and Mining Company in 1938, which wholly or in part may not coincide with the later Wolf drilling, gave much lower values.

Production notes:

There is no record of gold production on Harrison Creek. However, there were at least 100 claims on the creek in 1897 just before the rush to the Klondike in 1898. A small amount of gold may have been produced then but there is no indications of any substantial production since and no production from the Halloran claims.

Reserves:

Based on 28 drill samples along 7 lines, E.N. Wolf estimated that there is about 2.9 million cubic yards of auriferous gravels on the four claims with an average grade of 0.032 ounce of gold per cubic yard. Earlier drilling by the United States Smelting, Refining, and Mining Company in 1938, which wholly or in part may not coincide with the later Wolf drilling, gave much lower values. Halloran, however, suggests that the Wolf numbers are conservative because his drilling apparently did not reach bedrock where the most gold is likely to be.

Last report date: 2008-06-05

Site name(s): Unnamed (beside Cobblestone Creek)

Site type: Occurrence

ARDF no.: CL006

Latitude: 68.5097 **Quadrangle:** CL C-1

Longitude: 150.3917

Location description and accuracy:

The occurrence is in bluffs and outcrops on the west side of Cobblestone Creek at an elevation of about 2300 feet. It is about 15.7 kilometers south of Arc Mountain near the northwest corner of section 12, T. 11 S., R. 7 E.

Commodities:

Main: Mn

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Shale and silty mudstone of the Lower Cretaceous Torok Formation are exposed along Cobblestone Creek in bluffs and outcrops just west of the creek. Greenish-brown mudstone and shale locally display intense manganese staining (Kurtak and others, 1995). Four samples across a zone 6.5 meters thick contained 2.4 to 11.7 percent manganese. Another sample across a zone 4.5 meters wide contained 5.5 percent manganese. A sample examined by the U.S. Bureau of Mines contained 61.9 percent iron, 15.2 percent silica, 7.4 percent aluminum, 5.8 percent calcium, 4.8 percent manganese, and 4.0 percent phosphorus (Barnwell and others, 1989). The main mineral in the sample is siderite; no specific manganese mineral was identified. Similar manganese-stained rocks occur along a northeast-trending zone about 2.3 kilometers long.

Alteration:

Age of mineralization:

Early Cretaceous host rock.

Generic deposit model:

Deposit model:

Sedimentary manganese.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling by government agencies.

Production notes:

None.

Reserves:

None.

Additional comments:

MAS No. 0020220011.

Last report date: 2010-04-18

Site name(s): Unnamed (at head of Siksikpuk River)

Site type: Occurrence

ARDF no.: CL014

Latitude: 68.271 **Quadrangle:** CL B-4

Longitude: 152.3296

Location description and accuracy:

The location of this occurrence is somewhat ambiguous in Kurtak and others (1995) but it is probably about 8.5 miles northwest of Inualurak Mountain in the southeast part of section 34, T. 13 S., R. 2 W. The location is probably accurate to within a half mile.

Commodities:

Main: Pb, Zn

Other: Ba

Ore minerals: Galena, marcasite, pyrite, sphalerite

Gangue minerals: Calcite, quartz, siderite

Geologic description:

This occurrence is in a 42.9-meter-thick fissile, carbonaceous black shale member of the Kayak Shale between a lower argillaceous member and an upper red limestone member. The black shale member contains red-brown, cherty ironstone nodules or concretions that vary from rounded forms about 4 centimeters in diameter to elongate forms about 8 by 38 centimeters in size. The concretions consist of quartz, calcite, siderite, pyrite (or marcasite?), minor sphalerite, and rare galena (Kurtak and others, 1995). There are also 2.5- to 5-centimeter sulfide-bearing beds in the black shale. Several samples of the concretions from a 6-meter-thick section of the black shale contained up to 13,152 parts per million (ppm) zinc, more than 2,000 ppm barium, and 52 ppm lead. Samples from a 10-centimeter-thick, cherty ironstone bed at the base of the black shale member contained up to 1,357 ppm zinc.

Although this record describes a specific site, Kurtak and others (1995) note that it is representative of similar sulfide occurrences in a member of the Early Mississippian Kayak Shale that outcrops for several hundred kilometers along the north side of the Brooks Range.

Alteration:

Age of mineralization:

Syngenetic deposit in Early Mississippian black shale.

Generic deposit model:

Deposit model:

Stratiform zinc(-lead) deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only sampling by government agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (near Pin Peak, Coronation Island)

Site type: Mine

ARDF no.: CR001

Latitude: 55.9126 **Quadrangle:** CR D-7

Longitude: 134.3311

Location description and accuracy:

Several adits are on the east side of Pin Peak at elevations between about 700 and 980 feet. The site is near the center of the area of workings, about 0.2 mile southwest of the center of section 2, T. 69 S., R. 71 E. The location is accurate.

Commodities:

Main: Ag, Au, Pb

Other: As, Hg, Sn, Zn

Ore minerals: Cerussite, galena, hydrozincite, limonite, smithsonite, sphalerite, tetrahedrite

Gangue minerals: Calcite

Geologic description:

This mine is in limestone of the Silurian Heceta Limestone (Moerlein and others, 1971-1973; Eberlein and others, 1983; Brew, 1996). A small Cretaceous granitic pluton is nearby. The deposit consists of irregular, scattered masses of galena with sphalerite and tetrahedrite (Wright and Wright, 1908; Roehm, 1940; Twenhofel and others, 1949; Wedow and others, 1952). Some of the ore is oxidized to limonite, hydrozincite, cerussite, and smithsonite. The maximum dimension of the ore bodies was about 20 feet. The largest was about 8 feet by 12 feet by 18 feet; one 1- to 4-foot-thick body extended for about 100 feet. The deposit was mined from three adits at elevations of about 700 feet, 860 feet, and 980 feet; the underground workings total about 800 feet. A sample from the highest adit contained 9.7 percent lead, 0.16 ounce of gold per ton, and 20.8 ounces of silver per ton.

Roppel (1991) presents a detailed history of the development and mining. Galena was discovered in 1900 and ten claims were staked. By 1901, several hundred bags of ore had been mined. A test shipment of 16 tons of ore proved to have a value of $88 per ton in lead and silver. Possibly as much as 400 tons of ore was then shipped. Mining continued intermittently until 1905 when 5 tons of ore was sent to the smelter and another 25 tons of ore was stacked on the beach. The claims were restaked several times until at least 1928 and there were several more small test shipments. Phelps Dodge mapped much of Coronation Island in the early 1970s, sampled the workings and held their claims until 1973 (Moerlein and others, 1971-1973; Still and others, 2002) and drilled several holes. There is no record of any significant discovery in their drilling.

The Bureau of Land Management located many of the old working and collected numerous samples in the adits and from the dumps in the late 1990s (Still and others, 2002). The highest grade sample they collected from below the number 2 adit was of oxidized gossan with knots of galena. It contained 13.95 parts per million (ppm) gold, 682 ppm silver, more than 1 percent lead, 3.58 percent zinc, more than 1 percent arsenic, 39.3 ppm mercury, and 307 ppm tin. They concluded that the ore was mainly in irregular pods and that most of the mineralization found in the underground work had been mined out.

Alteration:

Some of the ore was oxidized to limonite, hydrozincite, cerussite, and smithsonite.

Age of mineralization:

The deposit is younger than the Silurian host rock.

Generic deposit model:

Deposit model:

Galena masses in limestone.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Roppel (1991) presents a detailed history of the development and mining. Galena was discovered in 1900 and ten claims were staked. By 1901, several hundred bags of ore had been mined. A test shipment of 16 tons of ore proved to have a value of $88 per ton in lead and silver. Possibly as much as 400 tons of ore was then shipped. Mining continued intermittently until 1905 when 5 tons of ore was sent to the smelter and another 25 tons of ore was stacked on the beach. The claims were restaked several times until at least 1928 and there were several more small test shipments. Phelps Dodge mapped much of Coronation Island in the early 1970s (Moerlein and others, 1971-1973) and drilled several holes but there is no indication of any significant discovery. The Bureau of Land Management found and mapped several of the old working and collected numerous samples in the late 1990s.

Production notes:

Most references indicate that about 100 tons of ore was shipped but there are indications that production may have been higher.

Reserves:

None.

Additional comments:

All of Coronation Island is now a Forest Service Wilderness Area and is closed to exploration and mining.

Site type:

Mine

ARDF no.: CR028

Latitude: 55.6514

Quadrangle: CR C-1

Longitude: 132.0041

Location description and accuracy:

The Gold Standard Mine has a long and complex history dating back to before 1900. The workings are in two distinct areas that were part of the same claim group. Managerially and operationally they were always were tied together and they share the same geology. There is an 'upper', early set of workings (in the Craig C-1 quadrangle); the upper workings are about 0.3 mile northwest of the 'lower', younger workings (in the Ketchikan C-6 quadrangle) which consist of several glory holes undercut by a long adit. The coordinates are for the lower workings which are just back from the shoreline about 1.3 miles northwest of the the north end of Forss Island in Helm Bay. The location is near the northeast corner of section 12, T. 72 S., R. 87 E. Figure 46 of Maas and others (1995) shows the location of the upper and lower workings and Figure 47 has detailed maps of the lower workings.

Commodities:

Main: Ag, Au

Other: Pb, Te

Ore minerals: Galena, gold, pyrite, tetradymite, tetrahedrite

Gangue minerals: Calcite, chlorite, quartz

Geologic description:

The original discovery in 1897 on what was to become the Gold Standard mine was at the so-called upper workings about 0.3 miles back from the sea shore, when 17 claims were staked over the property. The gold occurred near or at the surface, either as a creek placer or as a residual deposit over a quartz vein, or both (Brooks, 1902, Maas and others, 1995; Roppel, 2005). Some pans were said to contain up to $100 in gold and 120 ounces of gold was soon recovered. A small arrastre using a water nozzle to move the ground into it was built and by the end of the 1898 season the upper workings had produced $20,000 (almost certainly in gold at $20.67 per ounce). The discovery aroused considerable interest and in 1898, the Alaska Gold Standard Mining Company was incorporated. By the fall of 1899, a camp had been built, a 5-stamp mill powered by a Pelton wheel was in operation at the upper workings, a tram was built to the coast, and the workings consisted of a 260-foot tunnel from a 50-foot shaft. The mill began operating in December 1899 and by April, 1901, 2,430 tons of ore had been run through it with a net yield of $10,540. There was very little work in the upper workings from 1902 to 1906. By 1907, depending on the source $150,000 or $75,000 had been invested in the property with a return of only $35,000. There was intermittent activity from 1902 to 1914, mainly changes in the principals of the company. Several leasers examined or did some work on the upper workings, and several mining companies examined the property. In 1914, a new slate of officers was in place and interest shifted to what would become the lower workings, where three holes were diamond. drilled. In 1921, a leaseholder took out $28,000 (almost certainly in gold) from 2 tons of material in a rich pocket in the lower workings; larger bodies of lower-grade material were also identified. In 1922, a 1,600-foot tunnel was started under what would become two glory holes that were the focus of mining by several leasers from 1922 to the start of WWII. Detailed production records are not available but the ore

was processed in the old 5-stamp mill that was moved from the upper workings to a mill site near the sea shore.

Maas and others (1995, p. 192) did considerable sample and mapping of the mine, especially the lower workings (Figure 47), as part of a Bureau of Mines regional mineral assessment. They also reported that the adit at the lower workings was sampled by private interests in 1993 but the gold values were subeconomic.

The rocks in the vicinity are are andesitic and basaltic metavolcanic rocks that are gradationally interbedded with flysch like metasedimentary rocks (Berg and others, 1988, p. 18). The strata were regionally metamorphosed to greenschist-grade phyllite and semischist in Late Cretaceous time (Brew, 1996, p. 27). The premetamorphic age of the strata is uncertain. Berg and others (1988, p. 17) report that they closely resemble Jurassic to Cretaceous strata nearby on Gravina Island.

According to Brooks (1902) and Wright and Wright (1908), the mineralization at the upper workings consisted of two sets of quartz veins in metamorphosed greenstone and greenschist. One set, typified by the principal vein, is parallel to the schistosity of the host rocks. It strikes about N25W and dips 60E and varies from 6 inches to 6 feet thick. The other set consists of gash veins that extend from the main vein; they also strike about N25W but dip 60-75 SW. The veins are faulted and there is considerable gouge along the footwalls. The veins are mainly quartz with subordinate chlorite and calcite. Free gold occurs in the veins with minor pyrite, tetrahedrite, and galena; the telluride tetradymite is reported in the gash veins. The ore is free milling and was said to run about $5 to $15 per ton in gold (at $20.67 per ounce). Bittenbender and others (1993) and Maas and others (1995) sampled the upper workings. The average content of their samples, taken along 40 meters of vein that averages 0.73 meter thick, was 3,713 parts per billion (ppb) gold. A sample across 0.43 meters of the 'Folwarzny vein' contained 5,500 ppb gold.

The Lakeview prospect described by Maas and others (1995) is about 0.1 mile west of the upper workings of the Gold Standard Mine. The deposit is probably similar. The average gold content of samples taken over a length of 550 feet of a vein that averages about 20 inches wide was 3,103 ppb. The only workings are trenches and prospect pits.

The mineralization of the lower workings is similar in character and orientation to that of the upper workings. The walls of the veins are well defined by slickensides, with gouge on the footwall side and by a seam filled with calcite carrying free gold along the hanging wall. Locally, the wallrock next to the veins is bleached and impregnated with pyrite (Maas and others, 1995, p. 183). Maas and others (1995, table 25) collected numerous samples in the lower workings, they averaged 10.4 parts per million (ppm) gold, 99 ppm copper, 7.4 ppm lead, 48 ppm zinc, 2.3 ppm tellurium, and 9.6 ppm tin. Two samples of quartz contained 8.12 and 8.71 ppm gold, and the gold content in several samples of pyritic schist was 17.0 and 35.9 ppm. The sampling by Maas and others (1995, p. 184) shows a distinct northward plunge to the ore zone, which is cut off by a fault that strikes NE and dips 45SE. The continuation of the ore zone past this fault has not yet been determined.

Fluid inclusion studies of quartz vein material from several of the Helm Bay lodes suggest that the veins formed at temperatures and pressures consistent with conditions during the Late Cretaceous greenschist-grade regional metamorphism (Maas and others, 1995, p. 184).

Alteration:

Locally, the wallrock next to the veins in at least the lower workings is bleached and impregnated with pyrite (Maas and others, 1995).

Age of mineralization:

The quartz veins cut country rocks that may be as young as Cretaceous or as old as Paleozoic.

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

The original discovery in 1897 on what was to become the Gold Standard mine was at the so-called upper workings about 0.3 miles back from the sea shore, when 17 claims were staked over the property. The gold occurred near or at the surface, either as a creek placer or as a residual deposit over a quartz vein, or both (Brooks, 1902, Maas and others, 1995; Roppel, 2005). Some pans were said to contain up to $100 in gold and 120 ounces of gold was soon recovered. A small arrastre using a water nozzle to move the ground into it was built and by the end of the 1898 season the upper workings had produced $20,000 (almost certainly in gold at $20.67 per ounce). The discovery aroused considerable interest and in 1898, the Alaska Gold Standard Mining Company was incorporated. By the fall of 1899, a camp had been built, a 5-stamp mill powered by a Pelton wheel was in operation at the upper workings, a tram was built to the coast, and the workings consisted of a 260-foot tunnel from a 50-foot shaft. The mill began operating in December 1899 and by April, 1901, 2,430 tons of ore had been run through it. There was very little work in the upper workings from 1902 to 1906. By 1907, depending on the source $150,000 or $75,000 had been invested in the property with a return of only $35,000. There was intermittent activity from 1902 to 1914, mainly changes in the principals of the company. Several leasers examined or did some work on the upper workings, and several mining companies examined the property. In 1914, a new slate of officers was in place and interest shifted to what would become the lower workings, where three holes were diamond. drilled. In 1921, a leaseholder took out $28,000 (almost certainly in gold) from 2 tons of material in a rich pocket in the lower workings; larger bodies of lower-grade material were also identified. In 1922, a 1,600-foot tunnel was started under what would become two glory holes that were the focus of mining by several leasers from 1922 to the start of WWII. Detailed production records are not available but the ore was processed in the old 5-stamp mill that was moved from the upper workings to a mill site near the sea shore.

Maas and others (1995, p. 192) did considerable sample and mapping of the mine, especially the lower workings (Figure 47), as part of a Bureau of Mines regional mineral assessment. They also reported that the adit at the lower workings was sampled by private interests in 1993 but the gold values were subeconomic.

Production notes:

Maas and others (1995, p. 192) estimate that the combined production from the lower and upper Gold Standard mines from about 1898 to 1941 was 310 kg or more of gold, and 33 kg or more of silver. The production figures for the lower workings alone are not available. Judging from the assay values and the extent of the workings, the production from the upper and lower workings may have been about equal.

Reserves:

None.

Location description and accuracy:

The Flagstaff Mine is a well known property on the east side of Granite Mountain. The workings are extensive and the location used here is the main adit of the mine at an elevation of about 1,400 feet. This adit is shown on the USGS 1:63,360-scale topographic map; it is about 0.5 mile southwest of the center of section 16, T. 73 S., R. 84 E.

Commodities:

Main: Ag, Au, Pb

Other: Cu, Zn

Ore minerals: Bornite, chalcocite, chalcopyrite, copper, covellite, galena, gold, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the vicinity of the Flagstaff Mine are part of a large granodiorite-quartz diorite stock (Sainsbury, 1961; Eberlein and others, 1983; Brew, 1996). Early workers considered the stock to be Mesozoic or Cretaceous, but recent radiometric dating indicates that it is Devonian (S.M. Karl, oral communication, 2003). The granitic rocks are cut by diabase dikes of unknown age.

Roppel (2005) provides much detail on the history of the mine. The property was originally staked in 1902 as the Treasure group; by 1905, it had been developed by a lower 400-foot adit and an upper 50-foot adit and a road had been built from Karta Bay to Salmon Lake and from Salmon Lake to the mine. The 400-foot tunnel became the main adit of the mine (Wright and Wright, 1908; Twenhofel and others, 1949; Stewart, 1938, 1944; Maas and others, 1991, 1995). By 1908, the original locator of the property relinquished it and in 1912, the claims were restaked by T.N. Steven as the Last Chance Group; he would hold the property for the next 22 years. By 1935, Stevens or leaseholders had extended the upper tunnel to 432 feet and the lower tunnel to 987 feet. In 1937, the Flagstaff Mining Company was formed to develop the property and they rebuilt the road, built several buildings at the property and a 2,000-foot tramway to the main adit, and built a 25-ton mill at the bottom of the tramway. The mill was run intermittently in 1936 and 1938 but the recovery of gold was poor. Mining and milling continued intermittently until the fall of 1941 when the property reverted to its original owners and the mine closed. Poor gold and silver recovery in the mill is cited as a major cause of the closure. There is no record of production since 1941 but several companies have examined the property; among the more intensive efforts, El Paso Mining and Milling Company examined the property in the mid-70s and Killick Gold Company, Ltd. optioned the property and did geological mapping and geochemical surveys from 1980 to 1988.

The property has two vein systems. The main workings of the mine are on a quartz vein, the lower or Flagstaff vein, that can be traced for nearly a mile through a vertical extent of at least 1,300 feet. The vein strikes about N55W and dips 60-86NE. The footwall of the vein is a diabase dike more than 8 feet thick that near the vein is almost completely altered to calcite, chlorite, and brown clay. Twenhofel and others (1949) describe the hanging wall as diorite and gabbro. Detailed maps of the main vein are on Plate 1 of Twenhofel and others (1949) and on several appendices in Stewart (1944). The vein varies from less than an inch to more than 36 inches thick; it averages about 18 inches thick but the thickness often varies abruptly. The vein

is white, vuggy quartz with free gold and locally abundant sulfide minerals that in many places are banded parallel to the vein. The sulfide minerals include galena, chalcopyrite, pyrite, bornite, and sphalerite. Native copper, covellite and chalcocite occur and may be secondary. The sulfides average 1-2 percent of the vein but may form up to 5 percent locally. The main vein has been sampled several times (see Stewart, 1944, in particular). There are high gold and silver values, but the data are not systematic enough to provide their average values in the vein. The mill operators told Stewart (1938) that the ore was running about $25 to $35 in gold and silver (with gold at $35 per ounce). Maas and others (1991) sampled the main vein. One sample across 2.5 feet of the vein contained 0.35 ounce of gold per ton, 10.77 ounces of silver per ton, and 7.04 percent lead. The weighted average of 4 other samples was 0.15 ounce of gold and 1.75 ounce of silver per ton across an average width of 1.9 feet.

The upper vein is exposed west of the main workings of the mine between about 2, 600 to 2,800 feet elevation near the top of Granite Mountain. This vein strikes about N25E and dips about 20NW, but it is cut by several cross faults and/or deflects markedly and varies in strike and dip. It varies in width from about 1 to 3 feet. The upper vein is similar to the lower vein, but it is mainly in quartz diorite. The intersection of the two veins has not been found. The upper vein has less sulfides but more free gold than the lower vein.

Maas and others (1995) give the total production of the Flagstaff Mine as 257 ounces of gold, 1,980 ounces of silver, 2,864 pounds of copper, and 5,926 pounds of lead from 873 tons of ore; however, they cite another report that gives the total production from 1938 to 1940 as 1,305 tons of ore.

Alteration:

Diabase dikes are almost totally altered to chlorite, calcite, and brown clay near the veins.

Age of mineralization:

Unknown, other than that the veins are in Devonian granitic rocks.

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

Roppel (2005) provides much detail on the history of the mine. The property was originally staked in 1902 as the Treasure group; by 1905, it had been developed by a lower 400-foot adit and an upper 50-foot adit and a road had been built from Karta Bay to Salmon Lake and from Salmon Lake to the mine. The 400-foot tunnel became the main adit of the mine (Wright and Wright, 1908; Twenhofel and others, 1949; Stewart, 1938, 1944; Maas and others, 1991, 1995). By 1908, the original locator of the property relinquished it and in 1912, the claims were restaked by T.N. Steven as the Last Chance Group; he would hold the property for the next 22 years. By 1935, Stevens or leaseholders had extended the upper tunnel to 432 feet and the lower tunnel to 987 feet. In 1937, the Flagstaff Mining Company was formed to develop the property and they rebuilt the road, built several buildings at the property and a 2,000-foot tramway to the main adit, and built a 25-ton mill at the bottom of the tramway. The mill was run intermittently in 1938 and 1938 but the recovery of gold was poor. Mining and milling continued intermittently until the fall of 1941 when the property reverted to its original owners and the mine closed. Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-03-04

Site name(s): North Pole Hill

Site type: Prospects

ARDF no.: CR047

Latitude: 55.6364 **Quadrangle:** CR C-2

Longitude: 132.60411

Location description and accuracy:

There are several prospects in the large gabbro-pyroxenite pluton that forms North Pole Hill (Sainsbury, 1961). There are numerous pits and mineral occurrences scattered on the hill and this site is somewhat arbitrarily located at about the center of the hill, near the southwest corner of section 7, T. 72 S., R. 84 E., of the Copper River Meridian. The accuracy of this location is within 500 feet.

Commodities:

Main: Ag, Au, Cu, Pd

Other:

Ore minerals: Bornite

Gangue minerals:

Geologic description:

The gabbro and pyroxenite that makes up North Pole Hill is an extension of the pluton at the Salt Chuck Mine (CR049), where it has been dated at 429 Ma (Loney and others, 1987).

In 1954 and 1955, Juan Munoz carried out geophysical and geochemical surveys on North Pole Hill and dug several prospects pits that showed bornite in the gabbro and pyroxenite (Munoz, 1955; Sainsbury, 1961). In 1969, and perhaps other years, Munoz drilled several holes on the body (D.J. Grybeck, field visit, 1969). Although not well documented, North Pole Hill has been examined and prospected repeatedly since the 1970s because of its proximity and similar geology to the Salt Chuck Mine. Santoy Resources Ltd. was active on North Pole Hill (http://www.santoy.ca/index.html; Sept. 2003). They had one showing on the north flank of the hill ('Geoff showing') with samples that contained 1.1 percent copper and 0.19 gram of palladium per ton. They also located a previously unknown small adit (at an unspecified location on the hill); grab samples from the dump contained 2.67 percent copper, 0.63 gram of palladium per ton, 2.42 grams of gold per ton, and 14.03 grams of silver per ton.

In his 1954 and 1955 work, Munoz also located several pyritiferous quartz veins, 6 to 18 inches thick, near a prominent fault. They contained about $7.00 in gold (at $35 per ounce). Those veins are probably at the prospect (shown on Plate 33 of Sainsbury, 1961) at about the center of section 7, T. 72 S., R. 84 E., of the Copper River Meridian.

From 2010 to 2014, Pure Nickel Inc. has been exploring at North Pole Hill as part of their Salt Chuck Project. Work they have performed includes IP surveying, soil sampling, and drilling. A 2012 drilling program resulted in high grade intersections of up to 127.8 grams of gold per tonne, 57.6 grams of silver per tonne, and 2.78 percent copper over 0.35 meter apparent width. Pure Nickel's 2014 drill program is to test continuity of high grade gold-copper mineralization (Pure Nickel Inc., 2014).

Alteration:

Not reported.

Age of mineralization:

The gabbro on North Pole Hill has been dated at 429 Ma (Loney and others, 1987); the bornite deposit is

probably cogenetic with the intrusion of the gabbro.

Generic deposit model:

Deposit model:

Disseminated bornite in gabbro.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Prospect pits and at least two drill holes. Site type: Mine

ARDF no.: CR049

Latitude: 55.6339 **Quadrangle:** CR C-2

Longitude: 132.5602

Location description and accuracy:

The Salt Chuck Mine is labeled at the wrong location on the USGS 1:63,360-scale topographic map. The principal workings of the mine are about 0.3 mile west of the mine symbol on the map, or about 0.5 mile north-northeast of the center of section 17, T. 72 S., R. 84 E., of the Copper River Meridian. The location of the underground workings and glory holes of the mine are shown in detail on the maps and diagrams of Gault (1945) and Gault and Wahrhaftig (1992). The location is accurate to within 1/2 mile.

Commodities:

Main: Ag, Au, Cu, Pd, Pt

Other: Sb, Te

Ore minerals: Bornite, chalcocite, chalcopyrite, covellite, digenite, gold, hessite, isomertieite, kotulskite, magnetite, pyrite, pyrrhotite, sopcheite, sperrylite, stibiopalladonite, temagamite

Gangue minerals: Calcite, clinopyroxene, epidote, plagioclase

Geologic description:

The Salt Chuck Mine is in a mafic pluton about 4.5 miles long and up to a mile wide in outcrop. The pluton consists of gabbro, clinopyoxenite, and diorite; most workers believe that the pluton is roughly cogenetic with the mineral deposit (Gault, 1945; Sainsbury, 1961; Gault and Wahrhaftig, 1992; Loney and others, 1987). Detailed studies by Watkinson and Melling (1992) and by Loney and Himmelberg (1992) describe the rocks in the vicinity of the mine as layered gabbro intruded by magnetite-bearing pyroxenite. The host rocks at the deposit are variably altered to epidote, actinolite, chlorite, sericite, titanite, and calcite. The pluton has been dated at 429 Ma (Loney and others, 1987). It intrudes metamorphosed volcanic and sedimentary rocks of the Descon Formation of Silurian and Devonian age (Eberlein and others, 1983; Brew, 1996).

The deposit consists chiefly of bornite, chalcopyrite, and platinum-group minerals that occur as disseminations or as veinlets and irregular masses in the gabbro and clinopyroxenite (Wright 1915; Mertie, 1921; Buddington and Chapin, 1929; Gault, 1945; Sainsbury, 1961; Page and others, 1973). The ore bodies are generally pods, lenses, and irregular masses with higher-grade cores. Numerous small faults cut the ore bodies. Most of the sulfides are in clinopyroxenite near its contact with gabbro. The ore minerals include varying amounts of digenite, chalcocite, and covellite that often rim bornite and chalcopyrite; they are mainly in irregular disseminated masses but some are in pyrite-pyrrhotite veins, and in epidote or calcite veinlets. The platinum-group minerals are mainly kotulskite (PdTe) or sperrylite ($PtAs_2$), with minor amounts of the palladium-antimony minerals stibiopalladonite and isomertieite. The kotulskite is variably altered to temanganite (Pd_3HgTe_3) or intergrown with or rimmed by sopocheite ($Pd_3Ag_4Te_4$) and hessite (Ag_2Te). The platinum-group minerals occur in small grains and masses in epidote, at sulfide grain boundaries, and, in decreasing order of abundance, in chalcopyrite, digenite, chalcocite, and covellite. Argentian gold occurs in chalcopyrite, in complex intergrowths with platinum-gourp minerals, and in epidote rims on clinopyroxene.

The deposit probably formed in two stages: 1) magmatic deposition of sulfides and platinum-group minerals, probably near the contact between layered gabbro and clinopyroxenite; and 2) remobilization of

the sulfides and platinum-group minerals by low-temperature deuteric, or externally derived, chlorine-rich fluids with redeposition near gabbro-clinopyroxenite contacts. As of late 2009, the Salt Chuck mine is being evaluated by EPA for listing in the National Priorities List as a site that would be cleaned up under the Superfund program (Environmental Protection Agency, 2009).

The deposit at the Salt Chuck Mine was discovered in 1906 and produced copper, silver, gold, and palladium intermittently until 1941 (Wright and Wright, 1908; Wright, 1915; Mertie, 1921; Gault, 1945; Holt and others, 1948; Roppel, 1991; Maas and others, 1995). In 1915, platinum was discovered in the ore but it wasn't until 1917 that palladium was recognized. A succession of companies operated the mine: the Goodro Mining Company from 1907 to 1916; the Salt Chuck Mining Company from 1918 to 1920; the Alaska Palladium Company from 1924 to 1926; the Solar Development Company from 1929 to 1931; and the Alaska Gold and Metals Company from 1935 to 1941. For most of its life, the mine was the only producer of palladium in the United States and the price of palladium, which varied markedly, was a key factor in the profitability of the mine. During World War II, the U.S. Geological Survey and the U.S. Bureau of Mines studied the deposit in detail, drilled 13 holes, and reinterpreted 7 holes that had been drilled earlier by Solar Development Company (Gault, 1945; Holt and others, 1948; Gault and Wahrhaftig, 1992).

The workings of the mine are shown in detail on the maps and diagrams of Gault (1945) and Gault and Wahrhaftig (1992). The deposit was mined in three glory holes connected by an intricate network of raises, stopes, and drifts at three levels. The workings connected to a main haulage tunnel at the 300-foot level that led to a mill (described in detail by Mertie, 1921) on the shore of the salt chuck at the head of Kasaan Bay.

Since at least the late 1970s, the deposit has been almost continuously active with varying degrees of intensity. Orbex Resources, in a joint venture with Alaska Platinum Company, did extensive mapping and geochemical work on the property from 1980 to 1989 and drilled several holes (Nevin and Reader, 1979; Peterson and Stevens, 1981; Payne, 1985; Goodall and Fox, 1988, 1989). Stealth Ventures worked at the property in 1997 and 1998 and Santoy Resources Ltd. was active on the property in the early part of the 2000s. In 2007, Pure Nickel Inc. (2007) did surface mapping and sampling over a 2,200-acre block of claims that covers the deposit. In late 2009, the Salt Chuck mine was being evaluated by EPA for listing in the National Priorities List as a site that would be cleaned up under the Superfund program (Environmental Protection Agency, 2009).

According to Gault (1945), the total production (from incomplete records) from 1907 to to 1941 was about 300,000 tons of ore. The ore averaged 0.9 percent copper, 0.01 ounce of gold per ton, 0.10 ounce of silver per ton, and 0.05 ounce of palladium per ton. In its later years of production under the Alaska Gold and Metals Company, the ore contained 0.94 percent copper, 0.04 ounce of gold per ton, 0.15 ounce of silver per ton, and 0.065 ounce of palladium per ton. Bundtzen and others (1988) indicated that the work by American Platinum Company defined several zones that contain up to 7.8 percent copper, 0.7 ounce of gold per ton, 0.25 ounce of palladium per ton, and 0.007 ounce of platinum per ton. Maas and others (1995) give the total production of the mine as about 6.2 million pounds of copper, 55,620 ounces of silver, 20,540 ounces of palladium, and 11,740 ounces of gold. According to almost all of the literature, the platinum content of the ore was negligible or not mentioned, but Mertie (1969) indicates that there may have been much more platinum in the ore than is generally recognized.

Gault (1945) gives a detailed analysis of the ore reserves at the mine. At a 0.2 percent cutoff for copper, the total reserves in three ore bodies are 251,000 tons of material with 0.65 to 0.92 percent copper, 0.005 to 0.25 ounce of gold per ton, 0.07 to 0.26 ounce of silver per ton, and 0.0 to 0.13 ounce of platinum-group elements per ton. The reserves are smaller at higher copper grades. Nevin and Reader (1979) estimate that the total resources and reserves of the deposit are about 244,000 tons of material with 0.6 percent copper, 0.45 parts per million (ppm) gold, 5.55 ppm silver, and 0.1 ppm palladium.

At various times over the life of the mine, it or claims that were eventually incorporated into the property have been given several names, including the Goodro, Stevens, Joker, and Leibrant.

Alteration:

The host rocks are variably altered to epidote, actinolite, chlorite, sericite, titanite, and calcite.

Age of mineralization:

The deposit is probably cogenetic with the 429 Ma gabbro-clinopyroxenite body that hosts it (Loney and others, 1987).

Generic deposit model:

Deposit model:

Cu and platinum-group minerals in gabbro-clinopyroxene intrusion.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes

Site Status: Active

Workings/exploration:

The workings of the Salt Chuck Mine are shown in detail on the maps and diagrams of Gault (1945) and Gault and Wahrhaftig (1992). The deposit was mined in three glory holes connected by an intricate network of raises, stopes, and drifts at three levels. The workings connected to a main haulage tunnel at the 300-foot level that led to a mill (described in detail by Mertie, 1921) on the shore of the salt chuck at the head of Kasaan Bay.

Since at least the late 1970s, the deposit has been almost continuously active with varying degrees of intensity. Orbex Resources, in a joint venture with Alaska Platinum Company, did extensive mapping and geochemical work on the property from 1980 to 1989 and drilled several holes (Nevin and Reader, 1979; Peterson and Stevens, 1981; Payne, 1985; Goodall and Fox, 1988, 1989). Stealth Ventures worked at the property in 1997 and 1998, and Santoy Resources Ltd. was active on the property in the early part of the 2000s. In 2007, Pure Nickel Inc. (2007) did surface mapping and sampling over the 2,200 acres of land that covers the deposit. As of late 2009, the Salt Chuck mine is being evaluated by EPA for listing in the National Priorities List as a site that would be cleaned up under the Superfund program (Environmental Protection Agency, 2009).

Production notes:

The deposit at the Salt Chuck Mine was discovered in 1906 and produced copper, silver, gold, and palladium intermittently until 1941 (Wright and Wright, 1908; Wright, 1915; Mertie, 1921; Gault, 1945, Holt and others, 1948; Roppel, 1991; Maas and others, 1995). In 1915, platinum was discovered in the ore but it wasn't until 1917 that palladium was recognized. A succession of companies operated the mine: the Goodro Mining Company from 1907 to 1916; the Salt Chuck Mining Company from 1918 to 1920; the Alaska Palladium Company from 1924 to 1926; the Solar Development Company from 1929 to 1931; and the Alaska Gold and Metals Company from 1935 to 1941. For most of its life, the mine was the only producer of palladium in the United States and the price of palladium, which varied markedly, was a key factor in the profitability of the mine. During World War II, the U.S. Geological Survey and the U.S. Bureau of Mines studied the deposit in detail, drilled 13 holes, and reinterpreted 7 holes that had been drilled earlier by Solar Development Company (Gault, 1945; Holt and others, 1948; Gault and Wahrhaftig, 1992).

According to Gault (1945), the total production (from incomplete records) from 1907 to to 1941 was about 300,000 tons of ore. The ore averaged 0.9 percent copper, 0.01 ounce of gold per ton, 0.10 ounce of silver per ton, and 0.05 ounce of palladium per ton. In its later years of production under the Alaska Gold and Metals Company, the ore contained 0.94 percent copper, 0.04 ounce of gold per ton, 0.15 ounce of silver per ton, and 0.065 ounce of palladium per ton. Bundtzen and others (1988) indicated that the work by American Platinum Company defined several zones that contain up to 7.8 percent copper, 0.7 ounce of gold per ton, 0.25 ounce of palladium per ton, and 0.007 ounce of platinum per ton. Maas and others (1995) give the total production of the mine as about 6.2 million pounds of copper, 55,620 ounces of silver, 20,540 ounces of palladium, and 11,740 ounces of gold. According to almost all of the literature, the platinum content of the ore was negligible or not mentioned, but Mertie (1969) indicates that there may have been much more platinum in the ore than is generally recognized.

Reserves:

Gault (1945) gives a detailed analysis of the ore reserves at the mine. At a 0.2 percent cutoff for copper,

the total reserves in three ore bodies are 251,000 tons of material with 0.65 to 0.92 percent copper, 0.005 to 0.25 ounce of gold per ton, 0.07 to 0.26 ounce of silver per ton, and 0.0 to 0.13 ounce of platinum-group elements per ton. The reserves are smaller at higher copper grades. Nevin and Reader (1979) estimate that the total resources and reserves of the deposit are about 244,000 tons of material with 0.6 percent copper, 0.45 parts per million (ppm) gold, 5.55 ppm silver, and 0.1 ppm palladium.

Additional comments:

As of late 2009, the Salt Chuck mine is being evaluated by EPA for listing in the National Priorities List as a site that would be cleaned up under the Superfund program (Environmental Protection Agency, 2009).

Site name(s): Iron King; Iron King No. 1

Site type: Prospects

ARDF no.: CR059

Latitude: 55.5452 **Quadrangle:** CR C-2

Longitude: 132.4248

Location description and accuracy:

The Iron King prospects are about 0.4 mile north-northwest of Sunny Hat Point, and about 0.5 mile west-southwest of the northeast corner of section 13, T. 73 S., R. 85 E. The geology and workings at the Iron King prospects are shown on figure 32 of Warner and others (1961).

Commodities:

Main: Au, Cu, Fe

Other:

Ore minerals: Chalcopyrite, magnetite, pyrite

Gangue minerals: Calcite, epidote, garnet

Geologic description:

The Iron King prospect is in folded and metamorphosed greenstone that is cut by northeast- and north-trending dikes of basalt, andesite, and dacite (Warner and others, 1961). Near the deposit, the greenstone is epidotized. The deposit is an irregular zone about 150 feet long and 10-15 feet wide that trends about N15 E and dips 64NW; it is probably localized along a fault. Magnetite locally makes up 50 percent of the mineralized zone, and chalcopyrite, pyrite, and magnetite are disseminated widely in it. The U.S. Bureau of Mines diamond drilled four holes which did not cut mineralization; their surface sampling indicates that the mineralized zone contains about 2 percent copper. The deposit has been explored by several trenches and prospect pits; most of the area is covered by glacial drift, alluvium, and vegetation. As of early 2011, the Iron King prospect is being developed primarily for its magnetite by Eagle Industrial Minerals (2011). They indicate that the prospect has about 3 million tons of 'good quality magnetite with small but recoverable amounts of copper and gold'.

Recent sampling shows an unusually high gold content in the deposit. Hedderly-Smith (1999 [Inventory]) cites a high-grade sample with over 10 percent copper and 37 percent iron, that contained 19.3 parts per million (ppm) gold, and 79.5 ppm silver. Several other samples across 17 feet of old trench contained 0.246 to to 0.301 ounce of gold per ton and 13.8 to 20.7 ounces of silver per ton. These and other samples contained 2.22 to 3.68 percent copper, and 31.2 to 50.97 percent iron. Hedderly-Smith (1999 [Inventory]) estimates that the deposit has one or more million tons of material that contains 2 to 4 percent copper, one-quarter of an ounce of gold per ton, and more than 35 percent iron.

The Iron King prospect is one of many copper-iron deposits on the Kasaan Peninsula having similar geology and origin (Warner and others, 1961; Eberlein and others, 1983; Brew, 1996). The rocks on the peninsula consist mainly of andesite ('greenstone' in much of the older literature) interbedded with about 25 percent sedimentary rocks comprising approximately equal amounts of limestone or marble, calcareous mudstone and sandstone, and graywacke and conglomerate. These units are part of the Luck Creek Breccia of Silurian and Devonian age, but many of the sedimentary units are similar to and probably grade into rocks of the Silurian and Ordovician, Descon Formation. The bedded rocks are intruded by a profusion of Silurian or Ordovician dikes, sills, and irregular masses of porphyritic gabbro, basalt, andesite, diorite, dacite, and granodiorite. Near some of the deposits, these intrusions may make up 20 percent or more of the outcrop and usually are associated with the development of tactite and alteration of the greenstone. The area

subsequently was intruded by several large Silurian or Ordovician plutons; they are mainly granodiorite but locally are diorite and gabbro.

The ore deposits are typically small and of irregular shape; often the ore bodies form lenses or mantos. Some of the deposits conform to the layering in the greenstone and sedimentary rocks. The principal ore minerals are chalcopyrite, pyrite, and magnetite; hematite is often present and a little molybdenite occurs in some deposits. Most of the deposits are associated with tactite or skarn with varying amounts of actinolite, calcite, chlorite, garnet, diopside, epidote, and hornblende. There was significant by-product silver and gold in the ore that was mined in the past, and the gold values in some deposits are high enough to have encouraged exploration in recent years. Marble is more common in the deposits in the western part of the peninsula, where the gold values are generally higher as well (Wright and Wright, 1908; Wright, 1915; Warner and others, 1961; Myers, 1985; Bond, 1993; Maas and others, 1995).

Early interpretations of the ore deposits on the Kasaan Peninsula emphasize their contact metamorphic origin and their probable Mesozoic age (for example, Warner and others, 1961). However, recent radiometric dating and mapping indicate that the deposits formed in a Silurian or Ordovician, arc-related environment characterized by deposition of andesite and submarine sedimentary rocks that were intruded by swarms of dikes of varying composition, mineralized, and then intruded by large granodiorite plutons (Hedderly-Smith, 1999 [Inventory]).

The copper deposits of the Kasaan Peninsula were known to the Russians and the first claim was staked in 1867. Most of the production and development occurred from about 1900 to 1918, especially from 1905 to 1907, when copper prices soared and a smelter was built at Hadley on the north side of the Kasaan Peninsula. After World War I, copper supply exceeded demand, prices fell, and there has been no further copper production since 1918 (Wright, 1915; Warner and others, 1961; Roppel, 1991; Maas and others, 1995). However, because of the intense and widespread mineralization on the peninsula, the area has repeatedly been re-examined for copper, iron, and gold, notably during WW II (Warner and others, 1961) and in the last several decades.

Alteration:

Greenstone is altered to epidote. Development of calc-silicate skarn.

Age of mineralization:

The deposit formed in a Silurian or Ordovician, submarine arc-related environment characterized by the deposition of volcanic and sedimentary rocks, the intrusion of swarms of dikes of diverse composition, and the emplacement of several large plutons.

Generic deposit model:

Deposit model:

Cu-Fe skarn (Cox and Singer, 1986; model 18d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18d

Production Status: None

Site Status: Active

Workings/exploration:

The deposit has been explored by several trenches and prospect pits. During WW II, the U.S. Bureau of mines diamond drilled 4 holes that did not cut mineralization. Recent sampling shows an unusually high gold content in the deposit. As of early 2011, the Iron King prospect is being developed primarily for its magnetite by Eagle Industrial Minerals (2011).

Production notes:

None.

Reserves:

Hedderly-Smith (1999 [Inventory]) estimates that the deposit has one or more million tons of material that contains 2 to 4 percent copper, one-quarter of an ounce of gold per ton, and more than 35 percent iron. As of early 2011, the Iron King prospect is being developed primarily for its magnetite by Eagle Industrial Minerals (2011). They indicate that the prospect has about 3 million tons of 'good quality magnetite with small but recoverable amounts of copper and gold'.

Additional comments:

The Iron King prospects are on or surrounded by land whose subsurface rights are held by the Sealaska Corporation.

Site name(s): Mount Andrew

Site type: Mine

ARDF no.: CR071

Latitude: 55.5167 **Quadrangle:** CR C-1

Longitude: 132.3021

Location description and accuracy:

The location of the Mount Andrew Mine is shown on the USGS 1:63,360-scale topographic map. It is about 0.5 mile north-northwest of the center of section 26, T. 73 S., R. 86 E. The extensive surface and underground workings of the Mount Andrew Mine and the geology of the mine area are shown on plates 7 to 11 of Warner and others (1961).

Commodities:

Main: Cu, Fe

Other: Ag, Au

Ore minerals:

Gangue minerals: Calcite, epidote, garnet, hornblende

Geologic description:

The Mount Andrew is one of the principal mines on the Kasaan Peninsula (Wright and Wright, 1908; Wright, 1915; Wright and Tolonen, 1947; Warner and others, 1961; Maas and others, 1995; Hedderly-Smith, 1999 [Inventory]). The host rocks are mainly greenstone, largely altered to tactite composed of garnet, epidote, and hornblende, and scattered small marble lenses. The dominant structure in the deposit is a syncline that outcrops over an area at least 600 feet long and 550 feet wide, and exposes about 550 feet of layered rocks. The syncline trends about N10W. Nearly half the rock in the syncline is massive magnetite in conformable layers or mantos a few feet to 50 feet thick, interlayered with the greenstone. The greenstone and magnetite layers are cut by numerous north-trending, steeply dipping dikes of alkalic granodiorite, gabbro, andesite, and diorite porphyry. Pyrite and chalcopyrite are disseminated widely in the tactite and magnetite; there were probably local concentrations of chalcopyrite-rich ore, but most such high-grade pockets were probably mined prior to 1919.

The Mount Andrew Mine comprises three adits, 4 glory holes, several winzes, and a sublevel, to a depth of about 250 feet. The geology and workings are shown in detail on plates 7 to 11 of Warner and others (1991). The deposit was discovered in 1898 and the first ore was shipped in 1906 to the Tacoma smelter (Wright and Wright, 1915; Warner and others, 1961; Roppel, 1991). There was intermittent production until 1918, but none since. In 1944, the U.S. Bureau of Mines trenched the deposit and drilled 14 holes. The U.S. Geological Survey mapped the deposit in detail from 1942 to 1944. Utah Construction and Mining did geologic mapping and geophysical surveys in 1957 and drilled the deposit from 1960 to 1962 and in 1968.

In 2006, Full Metal Minerals began work at Mount Andrew and they drilled 5 shallow holes that totaled 481 meters to test the periphery of the old surface and underground workings (Full Metal Minerals, 2008, Mount Andrew Property). The holes cut several zones of mineralization including: 1) 13.2 meters that contained 1.41 percent copper, 0.25 gram of gold per ton, and 5.33 grams of silver per ton, 2) 18.0 meters that contained 1.05 percent copper, 0.13 gram of gold per ton, and 4.06 grams of silver per ton, 3) 13.8 meters that contained 1.01 percent copper, 0.11 gram of gold per ton, and 4.40 grams of silver per ton, 4) 7.7 meters that contained 1.53 percent copper, 0.08 gram of gold per ton, and 5.15 grams of silver per ton, and 5) 38.7 meters that contained 0.42 percent copper, 0.09 gram of gold per ton, and 1.40 gram of silver per ton. The work suggests that the mineralization is of the iron oxide-copper-gold deposit in andesitic

volcanic rocks and intermediate intrusive rocks that are cut by post-mineralization dikes. In 2007, Full Metal drilled 1,500 meters in another 13 holes and cut several intervals with strong chalcopyrite-magnetite mineralization (Full Metal Minerals, 2008, Mount Andrew Property; 2008, Mount Andrew drilling; 2008, Mount Andrew locations). Some notable intercepts were: 4.89 meters with 4.45 percent copper, 15.25 grams of silver per ton, and 0.89 grams of gold per tonne and 2.95 meters with 3.75 percent copper and 12.44 grams of silver per tonne (with gold values yet to be received).

There have been several estimates of the remaining resources in the Mount Andrew, Stevenstown (CR072), and Mamie (CR073) mines. Warner and others (1961) and Wright and Tolonen (1947) estimate a collective resource of 2,684,000 long tons of ore, of which about 80 percent is in the Mount Andrew deposit. The weighted average grade of this resource is 47.8 percent iron, 0.32 percent copper, and 0.011 ounce of gold and 0.55 ounce of silver per ton (Wright and Tolonen, 1947). Twenhofel (1953) estimated that about 3,500,000 tons of ore remain in the deposits. Carr and Dutton (1959) estimated that the deposits still contain about 2.3 million tons of indicated magnetite ore with 50 percent iron, and 0.91 million tons of inferrred ore. The total production from the Mount Andrew, Stevenstown, and Mamie mines from 1905 to 1918 was about 270,000 tons of ore with an average grade of 2.37 percent copper, and 0.026 ounce of gold and 0.212 ounce of silver per ton (Warner and others, 1961). Little copper-rich ore such as was mined prior to 1919 probably remains.

Warner and others (1961) and Maas and others (1995) describe several geologically similar, small deposits east of the Mount Andrew Mine. They were originally under the same management as the Mount Andrew Mine and some produced small amounts of ore. These include the Peacock, Rico, North Star, Glory, and Good Luck claims, and the Good Luck-Mayflower group.

The Mount Andrew Mine is one of many copper-iron deposits on the Kasaan Peninsula having similar geology and origin (Warner and others, 1961; Eberlein and others, 1983; Brew, 1996). The rocks on the peninsula consist mainly of andesite ('greenstone' in much of the older literature) interbedded with about 25 percent sedimentary rocks comprising approximately equal amounts of limestone or marble, calcareous mudstone and sandstone, and graywacke and conglomerate. These units are part of the Luck Creek Breccia of Silurian and Devonian age, but many of the sedimentary units are similar to and probably grade into rocks of the Silurian and Ordovician, Descon Formation. The bedded rocks are intruded by a profusion of Silurian or Ordovician dikes, sills, and irregular masses of porphyritic gabbro, basalt, andesite, diorite, dacite, and granodiorite. Near some of the deposits, these intrusions may make up 20 percent or more of the outcrop and usually are associated with the development of tactite and alteration of the greenstone. The area subsequently was intruded by several large Silurian or Ordovician plutons; they are mainly granodiorite but locally are diorite and gabbro.

The ore deposits are typically small and of irregular shape; often the ore bodies form lenses or mantos. Some of the deposits conform to the layering in the greenstone and sedimentary rocks. The principal ore minerals are chalcopyrite, pyrite, and magnetite; hematite is often present and a little molybdenite occurs in some deposits. Most of the deposits are associated with tactite or skarn with varying amounts of actinolite, calcite, chlorite, garnet, diopside, epidote, and hornblende. There was significant by-product silver and gold in the ore that was mined in the past, and the gold values in some deposits are high enough to have encouraged exploration in recent years. Marble is more common in the deposits in the western part of the peninsula, where the gold values are generally higher as well (Wright and Wright, 1908; Wright, 1915; Warner and others, 1961; Myers, 1985; Bond, 1993; Maas and others, 1995).

Early interpretations of the ore deposits on the Kasaan Peninsula emphasize their contact metamorphic origin and their probable Mesozoic age (for example, Warner and others, 1961). However, recent radiometric dating and mapping indicate that the deposits formed in a Silurian or Ordovician, arc-related environment characterized by deposition of andesite and submarine sedimentary rocks that were intruded by swarms of dikes of varying composition, mineralized, and then intruded by large granodiorite plutons (Hedderly-Smith, 1999 [Inventory]).

The copper deposits of the Kasaan Peninsula were known to the Russians and the first claim was staked in 1867. Most of the production and development occurred from about 1900 to 1918, especially from 1905 to 1907, when copper prices soared and a smelter was built at Hadley on the north side of the Kasaan Peninsula. After World War I, copper supply exceeded demand, prices fell, and there has been no further copper production since 1918 (Wright, 1915; Warner and others, 1961; Roppel, 1991; Maas and others, 1995). However, because of the intense and widespread mineralization on the peninsula, the area has repeatedly been re-examined for copper, iron, and gold, notably during WW II (Warner and others, 1961)

and since 1990.

Alteration:

Pervasive development of tactite.

Age of mineralization:

The deposit formed in a Silurian or Ordovician, submarine arc-related environment characterized by the deposition of volcanic and sedimentary rocks, the intrusion of swarms of dikes of diverse composition, and the emplacement of several large plutons.

Generic deposit model:

Deposit model:

Cu-Fe skarn (Cox and Singer, 1986; model 18d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18d

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

The Mount Andrew Mine comprises three adits, 4 glory holes, several winzes, and a sublevel, to a depth of about 250 feet. The geology and workings are shown in detail on plates 7 to 11 of Warner and others (1991). The deposit was discovered in 1898 and the first ore was shipped in 1906 to the Tacoma smelter (Wright and Wright, 1915; Warner and others, 1961; Roppel, 1991). There was intermittent production until 1918, but none since. In 1944, the U.S. Bureau of Mines trenched the deposit and drilled 14 holes. The U.S. Geological Survey mapped the deposit in detail from 1942 to 1944. Utah Construction and Mining did geologic mapping and geophysical surveys in 1957 and drilled the deposit from 1960 to 1962 and in 1968. In 2006, Full Metal Minerals began work at Mount Andrew ; they drilled 5 shallow holes that totaled 481 meters to test the periphery of the old surface and underground workings (Full Metal Minerals, 2008, Mount Andrew Property). In 2007, Full Metal drilled 1,500 meters in another 13 holes and cut several intervals with strong chalcopyrite-magnetite mineralization (Full Metal Minerals, 2008, Mount Andrew Property; 2008, Mount Andrew drilling; 2008, Mount Andrew locations).

Production notes:

No figures are available solely for the production of the Mount Andrew Mine. However, the cumulative production from it and the nearby Stevenstown (CR072) and Mamie (CR073) mines from 1905 to 1918 was about 270,000 tons of ore with an average grade of 2.37 percent copper, and 0.026 ounce of gold and 0.212 ounce of silver per ton (Warner and others, 1961).

Reserves:

There have been several estimates of the remaining resources of the Mount Andrew, Stevenstown (CR72), and Mamie (CR73) mines. Warner and others (1961) and Wright and Tolonen (1947) estimate a collective resource of 2,684,000 long tons of ore, of which about 80 percent is in the Mount Andrew deposit. The weighted average grade of this resource is 47.8 percent iron, 0.32 percent copper, and 0.011 ounce of gold and 0.55 ounce of silver per ton (Wright and Tolonen, 1947). Twenhofel (1953) estimated that about 3,500,000 tons of ore remain in the deposits. Carr and Dutton (1959) estimated that the deposits still contain about 2.3 million tons of indicated magnetite ore with 50 percent iron, and 0.91 million tons of inferrred ore. Little copper-rich ore such as was mined prior to 1919 probably remains.

Additional comments:

The Mount Andrews Mine is covered by patented claims. The Sealaska Corporation holds the subsurface

rights to the land around it.

Site name(s): Harris River; Julia; Rogers; Dunton

Site type: Mine

ARDF no.: CR098

Latitude: 55.4615 **Quadrangle:** CR B-3

Longitude: 132.709

Location description and accuracy:

The Harris River Mine is on the north bank of the Harris River, about 0.5 mile above its mouth. It is about 0.6 mile south-southwest of the center of section 7, T. 74 S., R. 84 E. and is marked by old mining equipment in the river. Several early geologists, notably Wright and Wright (1908), and Roppel (2005) combine their descriptions of the Harris River Mine and the Dawson Mine (CR099) about a half mile to the north. They were mined at different periods by different parties however, and are described separately in ARDF.

Commodities:

Main: Ag, Au, Cu, Pb

Other: Te?

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

Much of the history of the mines near the mouth of the Harris River was compiled by Roppel (2005). The first claims were staked in 1899 but soon allowed to lapse. The property was restaked in 1905 as the Julia claims which extended over an uncertain area but what was to become the Harris River Mine, and then or later probably the area to the north that included what became the Dawson Mine (CE099).

The early workings on these claims was concentrated on the Harris River Mine along the Harris River. The claims were purchased by C.H. Dunton in 1906 who sank an inclined shaft near the Harris River. By 1912, there was a 5-stamp mill run by hydro power on the property and 3,000 tons of ore had been mined that yielded $37,000 (probably all in gold at $20.67 per ounce). Another leaser worked the property from 1913 to 1919 and produced 7,000 tons of ore with a gross value of $81,570. When visited by Sales (1916), the workings consisted of a 280-foot shaft inclined at 30 degrees, with levels at 50, 100, and 200 feet. About 4,000 to 6,000 tons of ore had been produced; the ore averaged about $7.00 per ton in gold (at $20.67 per ounce), and some ran as high as $60 in gold per ton. In 1919, the Kasaan Gold Mining Company took the property over and built a 60-ton-a-day mill powered by a new hydroelectric plant on the Harris River. From 1920 to 1928, the Kasaan company produced about $160,000, probably all in gold (at $20.67 per ounce).

In 1930, the company was reorganized as the Kasaan Mining Company. What were then called the Handy claims (to the north of the Harris River) were leased to Wendell Dawson who shifted the mining to what is now called the Dawson Mine (CR099) about a half mile north of the Harris River Mine. There apparently was no further mining at the Harris River Mine.

The Harris River Mine is in a band of black graphitic slate and quartzite; however, most of the rocks exposed along the river for several hundred yards above and below the mine are massive to schistose, intermediate to felsic volcanic rocks of the Silurian and Ordovician Descon Formation (Sales, 1916; Herreid and Rose, 1966; Wilcox, 1938 [PE 119-5]; D.J. Grybeck, unpublished field notes, 1984). The deposit consists of quartz-cemented brecciated slate and conformable quartz veins and lenses in the slate; the width of the mineralized zone varies from 1 to 12 feet and averages about 6 feet (Sales, 1916; Wilcox, 1938 [PE 119-5]; Herreid and Rose, 1966). Fine-grained to porphyritic dikes commonly are conformable to the

foliation but crosscut the veins. The individual quartz veins and lenses are several inches to 1 or 2 feet thick. Sulfides, mainly disseminated pyrite and rare galena and sphalerite, are sparse; the best ore was associated with the most abundant pyrite. Tellurides were reported but have not been verified in recent studies.

The total production was substantial but uncertain because the mill treated ore from other mines in the area. Maas and others (1991) indicate that the total production from 1910 to 1929 (from the mine or the mill?) was 5,814 ounces of gold, 6,457 ounces of silver, 4,390 pounds of copper, and 1,159 pounds of lead from 8,173 tons of ore. However, the production was probably greater in so much as the Kasaan Gold Mining Company produced about $160,000 of ore from 1920 to 1928 from the Harris River Mine.

Alteration:

Age of mineralization:

Site type: Mine

ARDF no.: CR099

Latitude: 55.4705 **Quadrangle:** CR B-3

Longitude: 132.70527

Location description and accuracy:

The Dawson Mine is named on the USGS 1:63,360-scale topographic map. It is about 0.1 mile north of the center of section 7, T. 74 S., R. 84 E. The workings extend south to just north of the Hollis-Klawock road. Herreid and Rose (1966, figure 3) provide a map of the workings. Several early geologists, notably Wright and Wright (1908), and Roppel (2005), combine their descriptions of the Dawson and the Harris River (CR098) Mines because for much of their history they shared the same ownership. They have different histories, however, and are are described separately in ARDF.

Commodities:

Main: Ag, Au, Cu, Pb

Other: As, Sb

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

Much of the history of the mines near the mouth of the Harris River was compiled by Roppel (2005). The first claims were staked in 1899 but soon allowed to lapse. The property was restaked in 1905 as the Julia claims, which covered an uncertain area but certainly the area that included what was to become the Harris River Mine (CE098) and then or later probably the area to the north that included what became the Dawson Mine.

The early workings on these claims was concentrated at the Harris River Mine (CE098) and its mill along the Harris River that was in operation until about 1929 by the Kasaan Gold Mining Company. In 1930, the company was reorganized as the Kasaan Mining Company and what were then called the Handy claims were leased to Wendell Dawson who shifted the mining about a half mile north of the Harris River Mine to what is now called the Dawson Mine. Dawson mined intermittently until 1952. There apparently was no further mining at the Harris River Mine. The Dawson mine was restaked in 1976, and from 1979 to 1981, MAPCO, Inc. explored the property and drilled several holes. Discovery Gold Explorations, Inc. drilled 5 holes in 1984 and several more holes in 1985 (Harris, 1985). The drilling defined a resource of 43,800 tons of ore averaging about 1 ounce of gold per ton. In 2008, the Dawson Mine is being explored under an agreement between Full Metals Minerals and Altair Ventures Inc. (Altair Ventures, Inc., 2008; Full Metal Minerals, 2008). and they drilled 3 holes in 2007.

Herreid and Rose (1966) mapped the rocks in the vicinity of the Dawson Mine as graywacke, banded siltstone and argillite with minor slate, limestone, and phyllite. They are part of the Descon Formation of Silurian and Ordovician age (Eberlein and others, 1983; Brew, 1996).

The deposit consists of quartz veins and stringers that generally strike about N35E and dip northwest at about 28 degrees (Smith, 1914; Mertie, 1921; Roehm, 1936 [PE 119-2]; Wilcox, 1938 [119-5]). The veins are in a zone 2 to more than 6 feet thick. Most of the value is in free gold that occurs along contacts between quartz stringers and slate; minor amounts of sulfides including pyrite, sphalerite, chalcopyrite, and galena are disseminated in the veins and country rocks. Pyritized, fine-grained felsic dikes parallel and crosscut the veins. Two principal veins were mined, the Freegold and Humboldt. Only the Freegold vein was mined; it

extends for about 210 feet along strike but it is segmented by several near-horizontal faults.

In the 1980s and 1990s, a considerable area was stripped and trenched just north of the Hollis-Klawock road (D.J. Grybeck, unpublished field notes, 1984 and 1991). Three veins, 10-24 inches thick, were exposed that dip west at about 26-55 degrees. The veins are in deformed black shale with graphitic partings; the footwalls for up to several feet from the veins are highly sheared gouge zones. The veins contain up to 1 percent sulfides, mainly pyrite and sphalerite. Three short(?) adits were driven on the veins in this area. In the 1990s, a road had been cleared to the older workings and mill site to the north. About 200 feet higher in elevation, there were several drill sites in the vicinity of the old workings and the mill. Several selected samples of quartz vein material from dumps at the old mill site contained up to 1,000 parts per million (ppm) silver, 700 ppm arsenic, 3,000 ppm copper, 1,000 ppm antimony, more than 1 percent zinc, and 59 ppm gold, but most values were much lower.

Maas and others (1991) sampled most of the accessible workings. Their samples had a wide range of values, but several of the quartz veins contained 0.3 to more than 5 ounces of gold per ton, up to several ounces of silver per ton, and lead, zinc, and copper values that reflect as much as 1 to 2 percent sulfides in the veins.

In the 1930s, the Dawson mine was developed by 2 short crosscut tunnels and at least 150 feet of underground workings. In 1938, Roehm (1936 [PE 119-2]) reported that about $22,000 in gold (at $35 per ounce?) had been produced since 1933; the ore ran about $20 to $30 in gold per ton. Wilcox (1938 [PE 119-5]), who may have been describing the Harris River Mine (CR098) to the south, indicated that the total production was about $16,000 to $17,000 in gold (at $35 per ounce?). His samples assayed up to about $30 in gold per ton across 5 feet. Maas and others (1995) indicate that the Dawson Mine operated intermittently from the 1930s to 1952, with a total production of nearly 10,000 ounces of gold, 7,000 ounces of silver, and minor lead and copper. There was a small mill on the property.

As of 2008, the Crackerjack mine and several nearby properties are being explored under an agreement between Full Metals Minerals and Altair Ventures Inc. (Altair Ventures, Inc., 2008; Full Metal Minerals, 2008, CJ property). The drilled 3 holes on the veins at the Dawson Mine as well as two holes at the Hollis tunnel near the Crackerjack mine (CR101) and three holes at the Crackerjack mine itself to test the mineralization along a belt several miles long. Some of the notable mineralized intercepts cut in the drilling at the Dawson mine included 2.05 meters that contained 9.56 grams of gold per tonne and 76.7 grams of silver per tonne.

Alteration:

None specifically mentioned, although the felsic dikes that cross the veins commonly are bleached and altered.

Age of mineralization:

Unknown, other than that the veins are in Silurian or Ordovician black shale and graywacke.

Generic deposit model:

Deposit model:

Gold-quartz vein (Cox and Singer, 1986, model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Much of the history of the mines near the mouth of the Harris River was compiled by Roppel (2005). The first claims were staked in 1899 but soon allowed to lapse. The property was restaked in 1905 as the Julia claims, which covered an uncertain area but certainly the area that included what was to become the Harris

River Mine (CE098) and then or later probably the area to the north that included what became the Dawson Mine.

The early workings on these claims was concentrated at the Harris River Mine (CE098) and its mill along the Harris River that was in operation until about 1929 by the Kasaan Gold Mining Company. In 1930, the company was reorganized as the Kasaan Mining Company and what were then called the Handy claims were leased to Wendell Dawson who shifted the mining about a half mile north of the Harris River Mine to what is now called the Dawson Mine. Dawson mined intermittently until 1952. There apparently was no further mining at the Harris River Mine. The Dawson mine was restaked in 1976, and from 1979 to 1981, MAPCO, Inc. explored the property and drilled several holes. Discovery Gold Explorations, Inc. drilled 5 holes in 1984 and several more holes in 1985 (Harris, 1985). The drilling defined a resource of 43,800 tons of ore averaging about 1 ounce of gold per ton. In 2008, the Dawson Mine is being explored under an agreement between Full Metals Minerals and Altair Ventures Inc. (Altair Ventures, Inc., 2008; Full Metal Minerals, 2008, CJ property) and they drilled 3 holes in 2007.

Production notes:

In 1938, Roehm (1936 [PE 119-2]) reported that about $22,000 in gold (at $35 per ounce?) had been produced at the Dawson Mine since 1933; the ore ran about $20 to $30 in gold per ton. Wilcox (1938) indicated that the total production was about $16,000 to $17,000 in gold (at $35 per ounce?). His samples assayed up to about $30 in gold per ton across 5 feet. Maas and others (1995) indicate that the mine operated intermittently from the 1930s to 1952, with a total production of nearly 10,000 ounces of gold, 7,000 ounces of silver, and minor lead and copper.

Reserves:

Discovery Gold Explorations, Inc. drilled 5 holes in 1984 and several more holes in 1985 (Harris, 1985). The drilling defined a resource of 43,800 tons of ore averaging about 1 ounce of gold per ton.

Primary Reference: Herreid and Rose, 1966

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-03-04

Site name(s): Crackerjack

Site type: Mine

ARDF no.: CR101

Latitude: 55.48956

Quadrangle: CR B-3

Longitude: 132.70226

Location description and accuracy:

The main adit of the Crackerjack Mine, Adit No. 2, is at an elevation of about 800 feet, about 0.5 mile south of the Puyallup Mine, which is shown on the USGS 1:63,360-scale topographic map. The adit is on what is locally called Crackerjack Creek, near the middle of the south boundary of section 31, T. 73 S., R. 84 E. The property consists of ten claims and numerous workings that are shown on figure 2 of Herreid and Rose (1966) and on figure 18 of Mass and others (1995).

Commodities:

Main: Ag, Au

Other: As, Cu, Pb, Sb, Zn

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite, tetrahedrite

Gangue minerals: Quartz

Geologic description:

The rocks in the vicinity of the Crackerjack Mine are mainly thin beds of interlayered black slate and black siltstone with subordinate argillite and graywacke, that are part of the Descon Formation of Silurian and Ordovician age (Herreid and Rose, 1966). The mineralization at the Crackerjack Mine consists of two parallel quartz veins about 100 feet apart that closely follow two porphyry dikes for over a mile (Wright and Wright, 1908; Roehm, 1938, PE 119-7; Herreid and Rose, 1966; Maas and others, 1991; Maas and others, 1995). The veins and dikes strike about N20-30W and dip 20-48SW. Different workers have variously called the dikes gray porphyritic diorite, green porphyry, greenstone, or dacite porphyry. Near the veins, the dikes are intensely altered to quartz, pyrite, calcite, chlorite, and epidote. The quartz veins are banded and vary from 1 to 5 feet wide. They contain free gold, and, in order of abundance: pyrite, chalcopyrite, galena, sphalerite, tetrahedrite, and an antimony or bismuth sulfosalt. The gold content of the ore is tied to the abundance of the sulfides. The ore occurs in shoots that Roehm (1938, PE 119-7) suggests rake gently to the west; they were formed along rolls or irregularities in shear zones along the veins.

The Crackerjack Mine was discovered prior to 1902 (Brooks, 1902). By 1938, there were 8 tunnels and numerous open cuts and trenches for about 6,000 feet along the west side of what is locally called Crackerjack Creek (Roehm, 1938; Herreid and Rose, 1966, figure 2). Most of the workings apparently were driven before 1909. Maas and others (1991; 1995, figure 18) mapped and sampled extensively in the workings; the gold content of their samples varied widely from almost nothing to several ounces per ton. Roehm's map (1938) shows the location of 176 samples across the veins; they contained from a trace to 14.14 ounces of gold per ton and a trace to 29.41 ounces of silver per ton. He also cites an old report that shows 185 channel samples that averaged $7.50 per ton in gold (at $20.67 per ounce). Apparently there has been no production since 1908 (Maas and others, 1995). A mill was in operation before 1905 at the nearby Puyallup Mine (CR103); that mill processed ore from both the Puyallup and Crackerjack mines (Wright and Wright, 1905). Bureau of Mines production records cited by Maas and others (1991) indicate that from 1900 to 1916, the two mines produced an estimated 10,466 ounces of gold; the average grade was 0.840 ounce of gold per ton and 0.668 ounce of silver per ton.

As of 2008, the Crackerjack mine and several nearby properties were being explored under an agreement

between Full Metals Minerals and Altair Ventures Inc. (Altair Ventures, Inc., 2008; Full Metal Minerals, 2008). In 2007, they drilled 3 holes on the vein at the Crackerjack mine, two holes at the Hollis tunnel about 800 meters to the southeast and 2 holes at the Dawson Mine (CR099) about a mile to the south; the drilling totaled 1,105 meters. The drilling on the Crackerjack vein cut several intervals of mineralization including: 3.21 meters that contained 4.94 grams of gold per ton and 5.7 grams of silver per ton; 3.60 meters with 4.23 grams of gold per ton and 11.4 ounces of silver per ton; and 6.26 meters with 2.74 grams of gold per ton and 42.7 grams of silver per ton. The best intercept at the Hollis Tunnel was 2.05 meters that contained 9.56 ounces of gold per ton and 76.7 ounces of silver per ton. Additional drilling began in March, 2008.

Alteration:

The dikes that are associated with the gold-quartz veins are intensely altered to quartz, pyrite, calcite, chlorite, and epidote near the veins.

Age of mineralization:

Unknown, other than that the veins are in Silurian or Ordovician rocks.

Generic deposit model:

Deposit model:

Gold-quartz veins (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Crackerjack Mine was discovered prior to 1902 (Brooks, 1902). By 1938, there were 8 tunnels and numerous open cuts and trenches for about 6,000 feet along the west side of what is locally called Crackerjack Creek (Roehm, 1938, PE 119-7; Herreid and Rose, 1966, figure 2). Most of the workings apparently were driven before 1909. Apparently there has been no production since 1908 and little activity until recently, other than patenting the claims in 1926 (Maas and others, 1995). Maas and others (1991; 1995, figure 18) mapped and sampled extensively in the workings.

As of 2008, the Crackerjack mine and several nearby properties are being explored under an agreement between Full Metals Minerals and Altair Ventures Inc. (Altair Ventures, Inc., 2008; Full Metal Minerals, 2008). In 2007, they drilled 3 holes on the vein at the Crackerjack mine, two holes on the Hollis tunnel about 800 meters to the southeast and 3 holes on the Dawson Mine (CR099) about a mile to the south. Additional drilling began in March, 2008.

Production notes:

A mill was in operation before 1905 at the nearby Puyallup Mine (CR103); the mill processed ore from both the Puyallup and Crackerjack mines (Wright and Wright, 1905). Bureau of Mines production records cited by Maas and others (1991) indicate that from 1900 to 1916, the two mines produced an estimated 10,466 ounces of gold; the average grade was 0.840 ounce of gold per ton and 0.668 ounce of silver per ton. Apparently there has been no production since 1908 from the Crackerjack Mine.

Reserves:

Probably none.

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-06-05

Site name(s): Khayyam; Kiam; Cayenne

Site type: Mine

ARDF no.: CR129

Latitude: 55.29603 **Quadrangle:** CR B-2

Longitude: 132.39288

Location description and accuracy:

The Khayyam Mine is incorrectly located on the USGS 1:63,360-scale topographic map. It is at an elevation of about 2,500 feet, about 0.3 mile southwest of the mine symbol on the topographic map and about 0.3 mile east-northeast of the center of section 7, T. 76 S., R. 86 E. This location is accurate.

Commodities:

Main: Ag, Au, Cu, Zn

Other: Pb

Ore minerals: Chalcopyrite, copper, gahnite, magnetite, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

The first claims were staked on the deposit at the Khayyam Mine in 1898 and most of the development work took place between 1901 and 1907 (Brooks, 1902; Wright and Wright, 1908; Roppel, 1991; Maas and others, 1995). The mine has 8 adits with a total of about 1,800 feet of underground workings, and numerous pits, trenches, and open cuts. The mine was serviced by aerial and surface trams that connected to the head of McKenzie Inlet. The mine produced 177,769 pounds of copper, 1,711 ounces of silver, and 129 ounces of gold in 1907. In 2007, The Niblack Mining Corp. acquired the Khayyam Mine and the Stumble-on prospect (CR13) and they are being explored together as the Cayenne property (Niblack Mining Corp., 2008). In 2007, Niblack carried out geologic mapping, collected rock samples, and did a geophysical ground, resistivity survey along 2.5 kilometers of line. Their samples (at the Khayyam?) included a 2-meter chip sample of massive sulfides that contained 0.88 percent copper, 9.66 percent zinc, 6.2 grams of silver per tonne, and 0.30 gram of gold per tonne. Several large boulders from the mine dump contained up to 14.6 percent zinc, 15.4 percent copper, 109 grams of silver per tonne, and 5.72 grams of gold per tonne.

Recent detailed mapping (Barrie, 1984; Barrie and Kyle, 1988) indicate that the deposits at the Khayyam Mine are stratiform, massive-sulfide lenses in Late Proterozoic or Cambrian metamorphic rocks of the Wales Group. The host rocks are mainly schist of volcanic origin. The main units are: felsic plagioclase-quartz-chlorite-biotite schist; intermediate (hornblende-quartz-)chlorite-plagioclase schist; and mafic (chlorite-)hornblende-plagioclase schist. The rocks consistently strike about N75W and dip steeply to the north and south. Minor amounts of garnet, sericite, stilpnomelane, and epidote are possibly related to hydrothermal alteration from a nearby Cretaceous diorite intrusion.

The deposit consists of at least 6 massive sulfide lenses in a 200-foot- thick layer of mafic and intermediate schist that grades laterally into felsic schist. Individual massive-sulfide lenses are up to 22 feet thick and can be traced for up to 230 feet along strike. The lenses consist of 50-95 percent pyrite with varying amounts of chalcopyrite, sphalerite, and pyrrhotite. Gahnite occurs in the schist near the massive sulfide layers. Copper, gold, and silver are distributed irregularly through the deposit; zinc is enriched at the periphery. The deposit is associated with coarse, fragmental volcanic rocks that were at or near hydrothermal, submarine vents. The ore lenses characteristically have chloritic alteration in their footwall, and the mafic and intermediate schist is silicified near the vents. Recent detailed geochemical and isotopic work by Slack and others (2002) confirm that the deposit is of Late Proterozoic or Cambrian age.

The deposit was extensively sampled by the U.S. Bureau of Mines in 1944 and 1945 (Fosse, 1946). They defined an inferred resource of 84,000 tons of material that contains an average of 1.71 percent copper, 0.93 percent zinc, 0.06 ounce of gold per ton, and 0.30 ounce of silver per ton. Banner Mining Company drilled 14 holes in 1971 at the Khayyam Mine and 11 holes at the Mammoth (Stumble-On) prospect (CR130). Cominco Exploration mapped and sampled the property in 1972 and 1973. Homestake Mining Company examined the property in 1975 (Hite, 1976). More recently, the deposit was sampled by the U.S. Bureau of Mines (Maas and others, 1995), who collected 41 samples. Their best values were 2.14 parts per million (ppm) gold, 43.7 ppm silver, 9.5 percent copper, 1.66 percent zinc, and minor lead; most values were much lower.

Alteration:

The ore lenses characteristically have chloritic alteration in their footwall, and the mafic and intermediate schist is silicified near the vents.

Age of mineralization:

Massive sulfide deposit in Late Proterozoic or Cambrian metamorphic rocks.

Generic deposit model:

Deposit model:

Besshi massive-sulfide deposit (Cox and Singer, 1986; model 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The first claims were staked on the deposit at the Khayyam Mine in 1898 and most of the development work took place between 1901 and 1907 (Brooks, 1902; Wright and Wright, 1908; Roppel, 1991; Maas and others, 1995). The mine has 8 adits with a total of about 1,800 feet of underground workings, and numerous pits, trenches, and open cuts. The mine was serviced by aerial and surface trams that connected to the head of McKenzie Inlet. The deposit was extensively sampled by the U.S. Bureau of Mines in 1944 and 1945 (Fosse, 1946). Banner Mining Company drilled 14 holes in 1971 at the Khayyam Mine and 11 holes at the Mammoth (Stumble-On) prospect (CR130). Cominco Exploration mapped and sampled the property in 1972 and 1973. Homestake Mining Company examined the property in 1975 (Hite, 1976). The deposit was sampled by the U.S. Bureau of Mines in the mid-1990s (Maas and others, 1995).

In 2007, The Niblack Mining Corp. acquired the Khayyam Mine and the Stumble-on prospect (CR013) and they are being explored together as the Cayenne property (Niblack Mining Corp., 2008). In 2007, Niblack carried out geologic mapping, collected rock samples, and did a geophysical ground, resistivity survey along 2.5 kilometers of line.

Production notes:

The mine produced 177,769 pounds of copper, 1,711 ounces of silver, and 129 ounces of gold in 1907.

Reserves:

The U.S. Bureau of Mines estimated an inferred resource of 84,000 tons of material that contains an average of 1.71 percent copper, 0.93 percent zinc, 0.06 ounce of gold per ton, and 0.30 ounce of silver per ton (Fosse, 1946).

Site type: Prospect

ARDF no.: CR130

Latitude: 55.29674 **Quadrangle:** CR B-2

Longitude: 132.37202

Location description and accuracy:

The Stumble-on prospect is at an elevation of about 1,300 feet, 0.8 mile east-southeast of the mine symbol for the Khayyam Mine on the USGS, 1:63,360 scale topographic map. (The Khayyam Mine is not at the symbol; see CR129 for its actual location.) The Stumble-on prospect is about 0.2 mile north-northeast of the center of section 8, T. 76 S., R. 86 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The deposit at the Stumble-on Mine was discovered in about 1899, probably at the same time as the nearby Khayyam Mine (CR129) (Brooks, 1902; Wright and Wright, 1908; Fosse, 1946; Bufvers, 1967; Barrie, 1984; Barrie and Kyle, 1988; Roppel, 1991; Maas and others, 1995). The Stumble-on, first called the Mammoth, was developed by 2 adits with about 530 feet of workings, an open cut, and several trenches. There is no record of production.

In 2007, The Niblack Mining Corp. acquired the Stumble-on prospect and the Khayyam Mine (CR129) and they are being explored together as the Cayenne property (Niblack Mining Corp., 2008) In 2007, Niblack carried out geologic mapping, collected rock samples, and did a geophysical ground, resistivity survey along 2.5 kilometers of line. Their Cayenne samples (at the Khayyam Mine?) included a 2-meter chip sample of massive sulfides that contained 0.88 percent copper, 9.66 percent zinc, 6.2 grams of silver per tonne, and 0.30 gram of gold per tonne. Several large boulders from the mine dump contained up to 14.6 percent zinc, 15.4 percent copper, 109 grams of silver per tonne, and 5.72 grams of gold per tonne.

Detailed mapping (Barrie, 1984; Barrie and Kyle, 1988) indicates that the deposit at the Stumble-on prospect is a stratiform, massive-sulfide lens in Late Proterozoic or Cambrian metamorphic rocks of the Wales Group. The host rocks consist mainly of schist of volcanic origin. The main units are (hornblende-quartz-)chlorite-plagioclase schist and (chlorite-)hornblende-plagioclase schist. The rocks consistently strike about N75W and dip steeply to the north and south. Minor amounts of garnet, sericite, stilpnomelane, and epidote also occur in the schist. Recent detailed geochemical and isotopic work by Slack and others (2002) confirm that the deposit is of late Proterozoic or Cambrian age.

The deposit at the Stumble-on prospect consists of a single, massive-sulfide lens about 6 feet thick that is exposed for about 560 feet (Barrie, 1984; Barrie and Kyle, 1984; Maas and others, 1995). The lens consists mainly of pyrite with subordinate chalcopyrite, pyrrhotite, and magnetite. A ground geophysical survey (VLF-EM) indicates that the body continues to the east under surficial material. The deposit is essentially the same as the one at the nearby Khayyam Mine (CR129), and much of the geologic and exploration work there probably extends to the area of the Stumble-on prospect. Bedrock between the two deposits is largely covered by surficial material, but they may be on the same stratigraphic horizon. The Stumble-on prospect has been sampled many times with similar results that vary mostly by the sample selection. Maas and

others (1995), for example, sampled extensively. Their best samples contained 5.96 percent copper, 3.61 percent zinc, 43.7 parts per million (ppm) silver, and 3.916 ppm gold; the average value of their 24 samples was 0.92 percent copper, 0.20 percent zinc, 691 ppm silver, and 1.12 ppm gold.

Alteration:

Probably similar to that at the Khayyam Mine (CR129).

Age of mineralization:

Volcanogenic, massive sulfide deposit in late Proterozoic or Cambrian metamorphic rocks.

Generic deposit model:

Deposit model:

Besshi massive-sulfide deposit (Cox and Singer, 1986; model 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b

Production Status: None

Site Status: Active

Workings/exploration:

The Stumble-on prospect was developed by 2 adits with about 530 feet of workings, an open cut, and several trenches. Banner Mining Company drilled 14 holes in 1971 at the Khayyam Mine (CR129) and 11 holes at the Mammoth (Stumble-On) prospect. Cominco Exploration mapped and sampled the property in 1972 and 1973. Homestake Mining Company examined the property in 1975 (Hite, 1976). The deposit was sampled by the U.S. Bureau of Mines (Maas and others, 1995). Last report date: 2008-06-05

Site name(s): Polymetal; Ruby Tuesday; Research; Chomly; Ketchikan Copper Company

Site type:

Prospects

ARDF no.: CR169

Latitude: 55.2157 **Quadrangle:** CR A-1

Longitude: 132.3248

Location description and accuracy:

This property was staked prior to 1902 by the Ketchikan Copper Company and it is so named in several old reports. A 297-foot adit was driven under the mineralization and the ARDF site is at the portal of that adit. The adit is at an elevation of about 1,300 feet, about 2.5 miles southwest of the mouth of the South Arm of Cholmondeley Sound, and near the southwest corner of section 4, T. 77 S., R. 87 E. After WW II, the property was restaked several times by several parties and there was considerable exploration in the 1980's and early 1990's, when the property consisted of more than 70 claims. Most of the work was in an area about 1,800 feet in diameter centered near the location of the original claims.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

This property was staked before 1902 (Brooks, 1902) by the Ketchikan Copper Company and it is so named in the early reports. A tunnel was driven for about 300 feet to intersect the ore body at depth, but apparently stopped short of it. The deposit was restaked as the Polymetal Lode in 1948 and was explored by one or more shallow drill holes in the mid-50s (Maas and others, 1991, 1995). It was restaked in 1973 and drilled by ASARCO under lease. Noranda restaked a large area around it in 1978 and 1979 as the Ruby Tuesday claim block. LAC Minerals (USA) Incorporated gained a controlling interest in the property in 1988 and brought in Kennecott Exploration as a partner in 1993. There were at least 11 holes totaling more than 7,300 feet drilled on the property through early 1993 (LAC Minerals (USA) Incorporated, 1989). There has been no production and no reserve figures have been published. In 2007, the property which consists of 120 claims was acquired by the Niblack Mining Corporation (2007).

The rocks in the area consist of intricately folded and faulted, greenschist-grade, chlorite schist, sericite schist, marble, siliceous and graphitic pelitic rocks, felsic tuff, and undivided pelitic and volcaniclastic rocks (Herreid and others, 1978; Kucinski, 1987; Maas and others, 1991, 1995). The rocks are part of the Wales Group of Late Proterozoic and/or Cambrian age. The main deposit, the Polymetal, is a stratiform volcanogenic massive-sulfide deposit that consists of thin stringers and layers of sphalerite, pyrite, galena, and chalcopyrite in siliceous felsic tuff near its contact with black argillaceous chert. Recent detailed geochemical and isotopic work by Slack and others (2002) confirm that the deposit is of Late Proterozoic and/or Cambrian age. Fowler (1949) sampled the outcrop of a 20-foot-thick mineralized zone; it averages 11.1 percent zinc, 3.1 percent lead, and a trace of silver. The nearby Chomly deposit is in a different stratigraphic horizon; it consists of patches of sphalerite and galena up to 4 inches thick and 3 feet long in black argillaceous chert.

Alteration:

Intense alteration was noted in one report but was not described specifically. The mineralized zone is oxidized and iron stained at the surface.

Age of mineralization:

Probably contemporaneous with the deposition the Late Proterozoic or Cambrian host rocks.

Generic deposit model:

Deposit model:

Volcanogenic Cu-Pb-Zn massive sulfide deposit (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active

Primary Reference: Kucinski, 1987

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-06-05

Site name(s): Valpariso

Site type: Mine

ARDF no.: CR197

Latitude: 55.1456 **Quadrangle:** CR A-1

Longitude: 132.0793

Location description and accuracy:

The Valpariso Mine is near the north shore of Paul Lake, about 0.4 mile southwest of Dolomi Mountain. It is not at the mine symbol that is misplaced about a half mile to the west on the USGS 1:63,360-scale topographic map. Instead, it is about 0.3 mile south-southeast of the center of section 36, T. 77 S., R. 88 E. The Paul or Jessie prospect (CR200) to the east is an extension of the vein at the Valpariso Mine and descriptions of that prospect sometimes have been combined with that of the mine; they were often managed by the same company. The underground workings of the mine are shown on figure 30 of Maas and others (1995).

Commodities:

Main: Ag, Au

Other: Cu, Pb, Sb, Zn

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite, tetrahedrite

Gangue minerals: Calcite, quartz

Geologic description:

The Valpariso Mine was the most productive mine in the Dolomi area and has been described in many publications (for example: Brooks, 1902; Wright and Wright 1905, 1906, 1908; Smith, 1914; Smith, 1934a, Smith, 1934b, ; Galloway, 1952; Dyer, 1952, 1956; Herreid, 1967; Maas and others, 1991, 1995). By 1902, the mine had been developed by two shafts and three ore shipments of 31, 50, and 60 tons has been made to a smelter in California. Development and production took place intermittently from 1898 to 1920, and the deposit was mined by a lessor in 1927 and again in 1932. The surface mine plant and mill were extensively rebuilt in 1935 and again from 1946 to 1948 but no ore was produced before funds ran out. Roppel (2005) presents a detailed historical survey of the mine from its earliest days and the many legal, personality , water, and power problems, and management changes that repeatedly stymied mining.

The workings consisted of two (four?) shafts, the deepest of which was 400 feet deep, and extensive workings on at least three levels. Smith (1934a, 1934b) and Dyer (1952, 1956) reported that the mine produced about 5,000 ounces of gold to 1933. U.S. Bureau of Mines records document the production of about 730 ounces of gold and 521 ounces of silver from 1914 to 1933 (Maas and others, 1991, 1995). Galloway (1952) estimated that the total production from the mine was about $100,000 (plus some production, probably small, from leasers), mostly from 1901 to 1908. In 1983 and 1984, Houston Oil and Mineral Exploration Corporation drilled 21 holes at the mine and at the Paul Lake (CR200), Amazon (CR209), and Boston (CR207) properties (Oliver and Adams, 1984).

The host rocks at the Valpariso Mine are marble and schist of the Wales Group of Late Proterozoic and Cambrian age (Eberlein and others, 1983). The deposit consists of a vein up to 14 feet thick of quartz, quartz breccia, and quartz-marble breccia cemented by calcite; the vein is locally faulted and the marble is extensively silicified. The vein is conformable to the bedding of a thick marble layer. In an adit about 600 feet west of the mill, the marble is in contact with chlorite schist and quartzite or jasperoid. The vein strikes about N55W and dips 30-70N; it can be traced for as much as 6,000 feet to the east, to and beyond the Paul or Jessie prospect (CR200). The vein typically contains about 1 percent ore minerals, including free gold,

tetrahedrite, pyrite, chalcopyrite, galena, and sphalerite. Some of the ore was very rich; some ore mined in early 1900s ran $200-$250 a ton in gold (at $20.67 an ounce) and silver (Brooks, 1902). Samples of veins and old dumps collected in 1934 ran $5.50 to $42.07 a ton in gold (at $35 per ounce) and silver (Smith, 1934). In 1934, after the last mining, Smith estimated that the deposit contained 22,500 tons of probable ore in place with an average grade of 0.28 ounce of gold per ton and minor silver. Maas and others (1991) collected 34 samples in the underground workings. Their gold values varied greatly; the best was 4.660 ounces of gold per ton across 1.2 feet, but most samples contained much less. The highest silver value was 6.18 ounces of silver per ton.

Alteration:

The vein is locally faulted and the marble is extensively silicified.

Age of mineralization:

The vein is younger than the Late Proterozoic or Cambrian host rocks.

Generic deposit model:

Deposit model:

Low-sulfide, brecciated gold-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

The workings consisted of two (four?) shafts, the deepest of which was 400 feet deep, and there were extensive workings on at least three levels. In 1983 and 1984, Houston Oil and Mineral Exploration Corporation drilled 21 holes at the mine and at the Paul Lake (CR200), Amazon (CR209), and Boston (CR207) properties (Oliver and Adams, 1984).

Production notes:

Smith (1934) and Dyer (1952, 1956) reported that the mine produced about 5,000 ounces of gold to 1933. U.S. Bureau of Mines records document the production of about 730 ounces of gold and 521 ounces of silver from 1914 to 1933 (Maas and others, 1991, 1995). Galloway (1952) estimated that the total production from the mine was about $100,000 (plus some production, probably small, from leasers), mostly from 1901 to 1908.

Reserves:

In 1934, after the last mining, Smith estimated that the deposit contained 22,500 tons of probable ore in place with an average grade of 0.28 ounce of gold per ton and minor silver.

Additional comments:

Roppel (2005) includes an extensive bibliography of the history of the mine.

Last report date: 2008-03-04

Site name(s): Golden Fleece

Site type: Mine

ARDF no.: CR201

Latitude: 55.1519 **Quadrangle:** CR A-1

Longitude: 132.0542

Location description and accuracy:

This site marks the portals of the two main adits of the Golden Fleece Mine, about 0.2 mile north of the north end of James Lake. It is about 0.2 mile east-northeast of the center of section 31, T. 77 S., R. 89 E. Maas and others (1995) provide a detailed map of the underground workings.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Gold, pyrite, tetrahedrite

Gangue minerals: Quartz

Geologic description:

The Golden Fleece Mine was discovered in 1899,. By 1902, a 5-stamp mill was erected at the north end of James Lake, and the mine was developed by considerable underground workings (Brooks, 1902; Wright and Wright, 1908; Bufvers, 1967; Herreid, 1967; Maas and others, 1992, 1995). The mine was active from 1901 to 1905, and produced ore that contained about $40 to $60 in gold per ton (at $20.67 per ounce). Roppel (2005) recounts much of the early history of the mine and the many legal and financial problems that swirled around the actual mining. Bufvers (1967) indicated some mining in 1933 but the production was probably minor. Production records are not available. As mapped by Maas and others (1992, 1995), the underground workings included a lower adit 428 feet long, an upper adit 195 feet long, a raise 222 feet long that connects the two levels, and stopes that extend to the surface.

The deposit consists of auriferous quartz veins along two parallel faults that trend north-northwest to north and dip about 20-50E (Brooks, 1902; Wright and Wright, 1908; Maas and others, 1991, 1995). The faults are marked by quartz lenses inches to more than 8 feet thick that pinch and swell along the trend. The faults follow the contact between blue marble and white marble; the marble is silicified and cut by diabase dikes. Several large natural caverns also are along the faults. The quartz contains minor pyrite, chalcopyrite, tetrahedrite, and native gold. Maas and others (1991, 1995) collected 15 samples in the underground workings. Most assayed between 328 and 2,493 parts per billion gold, but several samples across 0.5 to 3 feet of a quartz-rich portion of an old stope contained 0.550 to 1.585 ounces of gold per ton.

The rocks in the Dolomi area are part of the Wales Group of Late Proterozoic and Cambrian age (Herreid, 1967). They are folded into a large dome centered over the eastern third of Paul Lake, and consist of several marble layers 200 to 1300 feet thick, interbedded with calcareous chlorite schist and marble.

Alteration:

Silicification of marble.

Age of mineralization:

The mineralization is younger than the Late Proterozoic or Cambrian host rocks.

Generic deposit model:

Deposit model:
Low-sulfide gold-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
36a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:
As mapped by Maas and others (1991, 1995), the underground workings included a lower adit 428 feet long, an upper adit 195 feet long, a raise 222 feet long, and several stopes that extend to the surface.

Production notes:
The mine was most active from 1901 to 1905, and produced ore that contained about $40 to $60 in gold per ton (at $20.67 per ounce). Bufvers (1967) indicated some mining in 1933.

Reserves:
None.

Site name(s): Niblack

Site type: Mine

ARDF no.: CR216

Latitude: 55.0666 **Quadrangle:** CR A-1

Longitude: 132.1475

Location description and accuracy:

This site is the old Niblack Mine that operated from 1902 to 1909. It is just above the shoreline at the head of Niblack Anchorage. It is identified on the USGS 1:63,360-scale topographic map by the name of the old settlement, and it is about 0.6 mile east-northeast of the center of section 33, T. 78 S., R. 88 E.

From the late 1970's to the present (2004), there has been nearly continuous exploration of several geologically similar deposits in an area of about a square mile southeast of the old Niblack Mine. Those deposits are described separately (CR217-223), but in the recent literature, the Niblack Mine and other deposits in the area are commonly grouped together under the name 'Niblack,' or 'Niblack project'. In 2010, most of the work is concentrated on an orebody near the old Lookout prospect (CR221) which is often identified as the 'Niblack project' or 'Niblack'.

Commodities:

Main: Ag, Au, Cu, Zn

Other: Pb

Ore minerals: Chalcopyrite, galena, hematite, pyrite, sphalerite

Gangue minerals:

Geologic description:

The deposit at the Niblack Mine was first developed in 1902 and soon was put in production (Brooks, 1902; Wright and Wright, 1908; Berg and Cobb, 1967). Production continued until 1909, when the mine was closed due to legal actions and it has not produced since. The total production (from incomplete records) is 1,400,000 pounds of copper, 1,100 ounces of gold, and 15,000 ounces of silver. The mine was worked from several shafts, one to a depth of 300 feet. There were 5 levels of workings with a total of about 5,500 feet of drifts, raises, and winzes. Roppel (1991) provides a fascinating study of the personalities and the travails of mining at Niblack.

The deposit that was mined consisted of three large masses of sulfides, 90 to 200 feet long, 5 to 20 feet thick, and 50 to 100 feet deep, that were cut by numerous faults. The ore bodies consisted largely of pyrite and chalcopyrite, with minor sphalerite, galena, and hematite. In the older publications, the host rocks are described as greenstone schist with bands of quartzite, metamorphosed sandstone, and quartz-sericite schist.

Beginning in the mid-70s, a succession of companies, including Cominco-Alaska, Inc., Anaconda Minerals, Noranda Exploration, Houston Oil and Minerals, Lac Minerals, Abacus Minerals Corp., Niblack Mining Corp., Committee Bay Resources Ltd., and the operator as of early 2010, CBR Gold Corporation (2010) have carried out extensive exploration on several deposits in the Niblack Mine area (CR217-223), testing the now widely accepted theory that they are volcanogenic, stratabound, massive-sulfide deposits (Ghayemghamian, 2010). Those deposits are commonly referred to as the 'Niblack' or 'Niblack Project'. However most of the work since at least 2005, has been concentrated on mineralization near the old Lookout prospect (CR221) that is best know and studied deposits. There has apparently been little recent work at the old Niblack Mine although Cominco-America drilled 6 holes near it in the mid-1970s.

The rocks in the area are part of the Ordovician to Lower Silurian, Moira Sound unit. Locally, the rocks consist of footwall dacite and rhyodacite; the Lookout rhyolite that hosts the massive-sulfide mineralization;

and hanging wall, mafic volcanic and volcaniclastic rocks (Maas and others, 1995; Ghayemghamian and others, 2010). Rhyolite from near the Lookout prospect has a U-Pb age of 476.7 +/- 1.5 Ma (Ordovician) (Karl and others, 2009). The rocks are metamorphosed to greenschist facies. The structure in the area is dominated by several large north-verging folds and two major faults are known. Karl and others (2009) interpret the environment of deposition as a rifted, oceanic arc.

The sulfide mineralization was emplaced on the sea floor in porous, unconsolidated fragmental, volcanic sediments, resulting in zones of semi-massive and massive sulfide bodies up to 20 feet thick, dominated by chalcopyrite, pyrite, and sphalerite, that generally follow the sedimentary layering (Maas and others, 1995; Ghayemghamian and others, 2010). The massive-sulfide bodies often grade laterally into disseminated, stringer, and replacement sulfides. The main metals of economic significance are copper, zinc, gold, and silver; lead is low and arsenic, antimony, cadmium, mercury, and selenium are too low to pose a metallurgical problem.

Alteration:

Not specifically noted, but probably typical of volcanogenic massive-sulfide deposits.

Age of mineralization:

The Lookout rhyolite that hosts the mineralization has been dated at 476.7 +/- 1.5 Ma (Ordovician).

Generic deposit model:

Deposit model:

Besshi-type volcanogenic Ag-Au-Cu massive-sulfide deposit (Cox and Singer, 1986; model 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The deposit at the Niblack Mine was first developed in 1902 and soon was put in production (Brooks, 1902; Wright and Wright, 1908). Production continued until 1909, when the mine was closed due to legal actions and it has not produced since. Roppel (1991) provides a fascinating study of the personalities and the travails of the early mining at Niblack.

Beginning in the mid-70s, a succession of companies, including Cominco-Alaska, Inc., Anaconda Minerals, Noranda Exploration, Houston Oil and Minerals, Lac Minerals, Abacus Minerals Corp., Niblack Mining Corp., Committee Bay Resources Ltd., and the operator as of early 2010, CBR Gold Corporation (2010) have carried out extensive exploration on several deposits in the Niblack Mine area (CR217-223), testing the now widely accepted theory that they are volcanogenic, stratabound, massive-sulfide deposits (Ghayemghamian, 2010). Those deposits are commonly referred to as the 'Niblack' or 'Niblack Project'. However most of the work since at least 2005, has been concentrated on mineralization near the old Lookout prospect (CR221) that is best know and studied deposits. Apparently, there has been little recent work at the old Niblack Mine although Cominco-America drilled 6 holes near it in the mid-1970s.

Production notes:

The total production of the Niblack Mine from 1902 to 1909 (based on incomplete records) was 1,400,000 pounds of copper, 1,100 ounces of gold, and 15,000 ounces of silver.

Reserves:

Apparently none at this, the old Niblack Mine, but considerable at what is being called the 'Niblack' or 'Niblack project', near the nearby, old Lookout prospect (CR221).

Site name(s): Niblack; Lookout; Conundrum; Trio

Site type: Prospect

ARDF no.: CR221

Latitude: 55.0576 **Quadrangle:** CR A-1

Longitude: 132.1461

Location description and accuracy:

The old Lookout prospect is at an elevation of about 1,800 feet, about 0.2 mile northeast of elevation 2230 and about 0.1 mile north-northeast of the southwest corner of section 34, T. 78 S., R. 88 E.

From the late 1970s to the present (late 2011) there has been nearly continuous exploration of several geologically similar deposits in an area of about a square mile southeast of the pre-World War I, Niblack Mine (CR216). Those deposits are described separately (CR217-223). However, the bodies of mineralization that are receiving most of the current (early 2012) attention and are being explored together are near the old Lookout and Trio prospects (CR222). In the recent media and professional publications, the property is generally referred to as the 'Niblack project' or just 'Niblack'.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, covellite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Lookout prospect as described by Brooks (1902) and Wright and Wright (1908) was a mineralized zone up to 300 feet thick in quartz-sericite schist. Within the zone, mineralized bands consist largely of covellite, chalcopyrite, and pyrite. Locally, there are quartz veinlets that have gold values. As of 1908, the workings consisted of two adits, one 160 feet long and the other 60 feet long, and several trenches.

Beginning in the mid-1970s, a succession of companies, including Cominco-Alaska, Inc., Anaconda Minerals, Noranda Exploration, Houston Oil and Minerals, Lac Minerals, Abacus Minerals Corp., Niblack Mining Corp., Committee Bay Resources Ltd., CBR Gold Corporation, and Heatherdale Resources Ltd., the operator in early 2012, have extensively explored the several deposits in the Niblack Mine area (CR217-223), testing the now widely accepted theory that they are volcanogenic, stratabound, massive-sulfide deposits (Ghayemghamian, 2010). Those deposits are commonly grouped with the old Niblack Mine under the name 'Niblack' or 'Niblack Project'. However, most of the work since at least 2005, has been concentrated near the old Lookout prospect described in this record and the Trio prospect (CR222) which now are nearly always referred to as the Niblack project or just Niblack.

From the mid-1970s to 2008, 218 holes were drilled on the Niblack-Lookout deposit from the surface and 28 holes were drilled underground; these total 59,289 meters (Ghayemghamian and others, 2010). There was more drilling in 2009 (but these holes were not included in the 2010 Ghayemghamian resource estimate). In 2008, an 880-meter exploration drift was completed to test the deposit at depth. The various companies have also done considerable surface mapping and sampling and carried out numerous geochemical and geophysical surveys.

In July, 2009, Heatherdale optioned the property from CBR Gold Corporation (Heatherdale Resources Ltd., 2011). A 25,000-foot underground drill program in 2010 expanded the extent of the known mineralization and they had begun a 50,000-foot drill program to test the limits of the ore body.

The rocks in the area are part of the Ordovician to Lower Silurian, Moira Sound unit. At the deposit, the

rocks consist of footwall dacite and rhyodacite; the Lookout rhyolite, which hosts the massive-sulfide mineralization; and hanging wall, mafic volcanic and volcaniclastic rocks (Maas and others, 1995; Ghayemghamian and others, 2010). The age of the rocks in the area has been variously interpreted. Eberlein and others (1983) mapped the strata as locally metamorphosed graywacke of Silurian or Ordovician age, near a large Paleozoic or Mesozoic granitic intrusion. Gehrels (1992) and Maas and others (1995) mapped them as pre-Ordovician metamorphosed volcanic and sedimentary rocks near a Silurian or Ordovician granitic intrusion. Brew (1996) saw the host rocks as part of the Late Proterozoic and Cambrian Wales Group schist, phyllite, and marble, near a Tertiary granitic intrusion of intermediate composition. Most recently, Slack and others (2002) and S.M. Karl (oral communication, 2003) mapped the strata as Silurian and Ordovician, low-grade, regionally metamorphosed sedimentary and volcanic rocks. However, the most recent date based on 3 zircon analyses from flows and volcaniclastic rocks immediately above and below the mineralized horizon using CA-TIMS U/Pb techniques is that the mineralization is Neoproterozoic, 565 +/- 3 Ma (Oliver and others, 2011).

The rocks are metamorphosed to greenschist facies. The structure in the area is dominated by several large, north-verging, overturned folds and two major faults. The Lookout body of mineralization is on the overturned limb of a large syncline. Karl and others (2009) interpret the environment of deposition as a rifted, oceanic arc.

The sulfides precipitated on the sea floor in porous, unconsolidated fragmental, volcanic sediments, resulting in zones of semi-massive and massive sulfide bodies up to 20 feet thick. The dominant sulfides are chalcopyrite, pyrite, and sphalerite which generally follow the sedimentary layering (Maas and others, 1995; Ghayemghamian and others, 2010). The massive-sulfide bodies often grade laterally into disseminated, stringer, and replacement sulfides. The main metals of economic significance are copper, zinc, gold, and silver; lead is low, and arsenic, antimony, cadmium, mercury, and selenium values are too low to pose a metallurgical problem.

There have been several increasingly-better estimates of the resources of the Niblack-Lookout deposit as the drilling and exploration has progressed.

As of November 29, 2011, Heatherdale Resources Ltd. (2011) announced that at a cut-off grade of $50, the Lookout deposit has an indicated resource of 5,638,000 tonnes of material with a grade of 0.95 percent copper, 1.75 grams of gold per tonne, 1.73 percent zinc, and 29.52 grams of silver per tonne. The Lookout deposit has an inferred resource of 2,370,000 tonne of material with a grade of 0.73 percent copper, 1.42 grams of gold per tonne, 1.17 percent zinc, and 21.63 grams of silver per tonne. The Trio deposit (which is usually aggregated with the Lookout deposits in referring to 'Niblack' has an inferred resource of 1,023,000 tonnes of material with a grade of 1.00 percent copper, 1.11 grams of gold per tonne, 1.56 percent zinc, and 16.56 grams of silver per tonne. This resource estimate is based on 373 holes drilled to November 4, 2011. As then known, the Lookout deposit was about 2,200 by 1,700 feet in size with an average thickness of 70 feet; the Trio deposit was about 1,100 by 350 feet in size with an average thickness of 220 feet.

Alteration:

Not specified, but probably typical of volcanogenic massive-sulfide deposits.

Age of mineralization:

The age of the rocks in the area has been variously interpreted. Eberlein and others (1983) mapped the strata as locally metamorphosed graywacke of Silurian or Ordovician age, near a large Paleozoic or Mesozoic granitic intrusion. Gehrels (1992) and Maas and others (1995) mapped them as pre-Ordovician metamorphosed volcanic and sedimentary rocks near a Silurian or Ordovician granitic intrusion. Site type: Prospect

ARDF no.: CR222

Latitude: 55.05752 **Quadrangle:** CR A-1

Longitude: 132.13734

Location description and accuracy:

The Trio prospect is about 0.5 mile east-northeast of hill 2230 and about 0.5 mile south of the center of section 34, T. 78 S., R. 88 E. From the late 1970s to the present (2004), there has been nearly continuous exploration of several geologically similar deposits in an area of about a square mile southeast of the old Niblack Mine (CR216). Those deposits are described separately (CR217-223), but in the recent literature, the Trio prospect and other deposits in the area are commonly grouped together under the name 'Niblack' or 'Niblack project' (CR221).

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The deposit on the Trio claims was described by Brooks (1902) as similar to the deposit at the nearby Lookout prospect (CR221); the only workings were a short crosscut that exposed a 10-foot-wide ore body.

Beginning in the mid-1970s, a succession of companies, including Cominco-Alaska, Inc., Anaconda Minerals, Noranda Exploration, Houston Oil and Minerals, Long Lac Minerals, and, beginning in 1995, Abacus Minerals, have carried out extensive exploration on several deposits in the Niblack Mine area (CR217-223), testing the now widely accepted theory that they are volcanogenic, stratabound, massive-sulfide deposits. Those deposits are commonly grouped with the old Niblack Mine under the name 'Niblack' or 'Niblack Project'.

The exact location of most of the recent exploration in the Niblack area, including several generations of drilling, is not well documented in the public literature. Anaconda Minerals drilled at least two holes in 1978. Green and others (1989) note that Noranda and Lac Minerals drilled 24,000 feet on the deposits in the Niblack area through 1988, and Abacus Minerals drilled 39,000 feet in 1996 (1997?) (Swainbank and others, 1998). The exploration has been mentioned frequently in the annual reports of the Alaska Division of Geological and Geophysical Surveys since the early 80s. In their most recent annual report (Swainbank, and others, 2002), the deposits are grouped under the name 'Niblack'. The area currently is being explored by Abacus Minerals, and information about their work can be found on their web site (www.amemining.com/properties/niblack_project/; Jan. 26. 2004).

As described by Lac Minerals USA Inc. (1989) and Maas and others (1995), and from a cross-section by Abacus Minerals (www.abacusminerals.com/niblackxsec.htm; April 18, 2000), the area features several large folds that trend west-northwest. The folds consist of a layered sequence of rhyolitic flows and volcaniclastic rocks that host the ore deposits, a hanging wall of mafic flows and sedimentary rocks, and a foot wall of amygdaloidal mafic flows. All of the rocks are regionally metamorphosed to greenschist grade. Maas and others (1991) describe three types of deposits at the Lookout prospect (CR221). It is the best-known deposit and probably typifies the other deposits in the area, including the one at the Niblack Mine. The three types are: 1) volcanogenic massive-sulfide bodies up to 20 feet thick with values of up to 4.9

percent copper, 8.0 percent zinc, 0.265 ounce of gold per ton, and 4.6 ounces of silver per ton; 2) stringer-type sphalerite mineralization in lithic tuffs in the footwalls of the massive sulfide bodies; and 3) auriferous, pyrite-bearing volcaniclastic rocks and polylithic breccia that typically contain about 0.05 ounce of gold per ton, 0.5 to 1.0 ounce of silver per ton, and 1 percent combined copper-zinc across widths of more than 50 feet.

Maas and others (1992, 1995) collected several samples at the Trio prospect that contained up to 215 parts per billion gold, 1.2 parts per million (ppm) silver, 7,874 ppm copper, and 418 ppm zinc. Abacus Minerals drilled at least one hole on the Trio prospect in 1996 or 1997; 16.1 feet of that hole averaged 0.069 ounce of gold per ton, 1.35 ounce of silver per ton, 6.96 percent copper, and 8.18 percent zinc (www.amemining.com/properties/niblack_project/ Jan. 26, 2004).

The age of the rocks in the area has been variously interpreted. Eberlein and others (1983) mapped the strata as locally metamorphosed graywacke of Silurian or Ordovician age, near a large Paleozoic or Mesozoic granitic intrusion. Gehrels (1992) and Maas and others (1995) mapped them as pre-Ordovician metamorphosed volcanic and sedimentary rocks near a Silurian or Ordovician granitic intrusion. Brew (1996) saw the host rocks as part of the Late Proterozoic and Cambrian Wales Group schist, phyllite, and marble, near a Tertiary granitic intrusion of intermediate composition. Most recently, Slack and others (2002) and S.M. Karl (oral communication, 2003) mapped the strata as Silurian and Ordovician, low-grade, regionally metamorphosed sedimentary and volcanic rocks. But see the record for the nearby and probably contiguous NIblack deposit (CR221) that has recently been dated as Neoproterozoic, 565 +/- 3 Ma.

As of late 2011, the Trio deposit is often aggregated with the Lookout deposit and referred to as the Niblack deposit (CR221), for instance in the November 2011 estimate of the resources of the Niblack deposit (CR221) (Heatherdale Resources Ltd., 2011).

Alteration:

Not specifically noted, but probably typical of volcanogenic massive-sulfide deposits.

Age of mineralization:

The age of the rocks in the area has been variously interpreted. Generic deposit model:

Deposit model:

Besshi-type volcanogenic Ag-Au-Cu massive-sulfide deposit (Cox and Singer, 1986; model 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b

Production Status: None

Site Status: Active

Workings/exploration:

A short adit was driven prior to 1902; at least one hole was diamond drilled in 1996 or 1997. As of late 2011, the Trio deposit was being explored as part of the Niblack prospect (CR221). By that time, 343 holes had been drilled on the modern Niblack that mainly consisted of the old Lookout and Trio deposits (Heaterdale Resources Ltd., 2011).

Production notes:

None.

Reserves:

The Trio deposit (which is usually aggregated with the Lookout deposits in referring to 'Niblack' (CR221) has an inferred resource of 1.023,000 tonnes of material with a grade of 1.00 percent copper, 1.11 grams of gold per tonne, 1.56 percent zinc, and 16.56 grams of silver per tonne. This Niblack resource estimate is based on 373 drill holes drilled to November 4, 2011. As know then, the Lookout deposit was about 2,200 by 1,700 feet in size with an average thickness of 70 feet; the Trio deposit was about 1,100 by 350 in size with an average thickness of 220 feet.

Primary Reference: Maas and others, 1995

Reporter(s): D.J. Grybeck (Contractor, USGS)

Last report date: 2012-04-01

Site name(s): Unnamed (near Alikula Bay)

Site type: Prospect

ARDF no.: CR225

Latitude: 55.9184 **Quadrangle:** CR D-7

Longitude: 134.2985

Location description and accuracy:

This prospect is near the shore on the east side of Alikula Bay near its mouth. It is about 1.3 miles east-northeast of Pin Peak and about 0.2 mile northeast of the center of section 1, T. 69 S., R. 72 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

This prospect was briefly noted by Roehm (1942, 1943) but it was largely unrecognized until it was later described and mapped in detail by Still and others (2002). The host rock is Silurian Heceta Limestone that is intruded by an intermediate Cretaceous intrusion a few hundred feet away from the mineralization and mafic dikes up to 50 feet thick. (Eberlein and Churkin, 1983). The mineralization consists of irregular masses of sulfides exposed over a diameter of about 50 feet. The largest surface exposure is about 10 feet by 28 feet in size. The sulfide masses consist of about 80 percent pyrite with pyrrhotite and sphalerite. Still and others (2002) collected 7 samples; the richest taken across 8 feet contained 8,483 parts per billion (ppb) gold, 22.5 parts per million (ppm) silver, 1,173 ppm copper, 7,515 ppm lead, and 4.85 percent zinc. Of the seven samples, six had gold values over 1,200 ppb, all had silver over 10 ppm, lead was over 2,500 ppm in all, and one had more than 1 percent lead. Four of the seven had over 1.4 percent zinc and one had 8.69 percent zinc. All had bismuth over 40 ppm, one had 336 ppm bismuth, and all had high arsenic, antimony and mercury. The sulfides are locally oxidized to gossan but there are no skarn minerals.

Alteration:

Age of mineralization:

Probably related to a nearby Cretaceous intermediate pluton.

Generic deposit model:

Deposit model:

Polymetallic replacement deposit in limestone.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Known (and staked?) before 1942 but went unrecognized for decades; rediscovered, mapped, and sampled by staff of the U.S. Bureau of Land Management in the late 1990s.

Production notes:

None.

Reserves:

None.

Additional comments:

This prospect is now in a Forest Service Wilderness that is closed to mineral exploration and mining.

Site name(s): Reynolds-Alaska Development Co.

Site type: Mine

ARDF no.: CV007

Latitude: 60.833 **Quadrangle:** CV D-8

Longitude: 146.628

Location description and accuracy:

The map site of this mine is at the position of the main tunnel, which is at sea level on the east side of Boulder Bay. The site is in the S1/2 sec. 27, T. 11 S., R 8 W., of the Copper River Meridian. The location is accurate to within 1000 ft. This mine is shown as #7 in Cobb (1972: MF-392) and as C-87 in Jansons and others (1984).

Commodities:

Main: Cu, Zn

Other: Ag

Ore minerals: Chalcopyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

The country rocks at this mine are mafic volcanic rocks and sedimentary rocks of the Tertiary Orca Group (Nelson and others, 1985). The deposit consists of massive sulfide lenses, and sulfide veins, disseminations, and thin selvages in shear zones (Jansons and others, 1984). The sulfide minerals are chalcopyrite, pyrrhotite, and sphalerite. The ore minerals are restricted to north-trending and steeply-dipping shears at the contact of volcanic and sedimentary rock.

Grant and Higgins (1909) report that some large beach boulders were shipped as ore. Chip samples collected in the 1980s contained 0.6 to 1.7 percent Cu, 225 parts per million (ppm) to 0.6 percent Zn, and 2.4 ppm to 8.9 ppm Ag; grab samples contained 60 ppm to 6 percent Cu, 67 ppm to 1.7 percent Zn, and 1.1 ppm to 13 ppm Ag (Jansons and others, 1984).

Three grab samples were collected in 2014 for analyses. Sample 1 contained 0.93 ppm Au, 10.9 ppm Ag, 1.67 percent Cu, and 0.1520 percent Zn. Sample 2 contained 0.396 ppm Au, 1.01 ppm Ag, 0.13 percent Cu, and 0.506 percent Zn. Sample 3 contained 0.077 ppm Au, 1.24 ppm Ag, 0.691 percent Cu, and 0.164 percent Zn (Angel, 2014).

Alteration:

Oxidation of copper minerals (Angel, 2014).

Age of mineralization:

Probably Tertiary based on the age of the host rocks (Nelson and others, 1985).

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and Singer, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

The mine was developed in the early 1900s by 2100 feet of drifts (main tunnel), numerous crosscuts, winzes and raises, and at least 500 ft. of additional tunnels (Capps and Johnson, 1915). One 200 ft. tunnel was caved by the early 1980s (Jansons and others, 1984). Grant and Higgins (1909) report that some large beach boulders were shipped as ore. Chip samples collected in the 1980s contained 0.6 to 1.7 percent Cu, 225 parts per million (ppm) to 0.6 percent Zn, and 2.4 ppm to 8.9 ppm Ag; grab samples contained 60 ppm to 6 percent Cu, 67 ppm to 1.7 percent Zn, and 1.1 ppm to 13 ppm Ag (Jansons and others, 1984).

Field work including sampling was performed in 2014. Three grab samples were collected in 2014 for analyses. Sample 1 contained 0.93 ppm Au, 10.9 ppm Ag, 1.67 percent Cu, and 0.1520 percent Zn. Sample 2 contained 0.396 ppm Au, 1.01 ppm Ag, 0.13 percent Cu, and 0.506 percent Zn. Sample 3 contained 0.077 ppm Au, 1.24 ppm Ag, 0.691 percent Cu, and 0.164 percent Zn (Angel, 2014).

Production notes:

215,000 pounds of copper were recovered from 2,850 tons of ore (Jansons and others, 1984).

Reserves:

Inferred reserves of 600 tons at 1.37 percent Cu, 0.28 percent Zn, and 6.67 ppm Ag (Jansons and others, 1984).

Additional comments:

Nelson and others (1985) interpret the country rocks as accreted ocean crust. Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Last report date: 2015-01-14

Site name(s): Galena Bay Mining Co. (Vesuvius Valley)

Site type: Prospect

ARDF no.: CV011

Latitude: 60.878 **Quadrangle:** CV D-7

Longitude: 146.594

Location description and accuracy:

This site represents several prospects in a roughly circular, half-mile-square, area at about 2000 feet elevation on the northeast face of Bells Butte. The area is in the N1/2 secs. 26 and 35, T. 11 S., R. 8 W., of the Copper River Meridian. The location is accurate to within 1000 ft. This area of prospects is shown in Cobb (1972: MF-392) as sites #9 and #10; in Jansons and others it is shown as site C-83.

Commodities:

Main: Cu, Zn

Other: Ag, Au

Ore minerals: Chalcopyrite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The country rocks at these prospects are mafic volcanic rocks and sedimentary rocks of the Tertiary Orca Group (Nelson and others, 1985). The deposit consists of shear-zone-hosted masses of calcite, quartz, chalcopyrite, pyrite, pyrrhotite, and sphalerite. Capps and Johnson (1915) reported that most of the ore was found in numerous 1- to 20-ft.-wide shear zones in pillow basalt (greenstone). The shear zone containing most of the early workings is 1000 ft. long.

Jansons and others (1984) collected chip samples that contained 58 parts per million (ppm) to 13 percent Cu, 46 ppm to 2 percent Zn, and <0.1 ppm to 32.8 ppm Ag; their grab samples contained 80 ppm to 6.1 percent Cu, 790 ppm to 20.1 percent Zn, and 1.1 ppm to 20 ppm Ag. Small amounts of gold were reported in earlier assays (Capps and Johnson, 1915).

Four grab samples were collected in 2014 at approximately 60.886 N 146.601 W. Three samples were taken from an ore stockpile below an adit, the other sample was collected above the adit, at an exploration trench. The trenching was conducted on a quartz rich epithermal breccia. Sample 1 from ore stockpile contained 0.056 ppm Au, 25.6 ppm Ag, 3.57 percent Cu, and 5.4 percent Zn. Sample 2 contained 0.178 ppm Au, 74.2 ppm Ag, 10.65 percent Cu, and 2.15 percent Zn. Sample 3 contained 0.021 ppm Au, 5.81 ppm Ag, 0.692 percent Cu, and 0.772 percent Zn. Sample 4 taken from the trench contained 0.013 ppm Au, 3.13 ppm Ag, 0.449 percent Cu and 1.36 percent Zn (Angel, 2014).

Alteration:

Age of mineralization:

Probably Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and Singer, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: None

Site Status: Inactive

Workings/exploration:

Capps and Johnson (1915) reported nine adits with a total of about 3000 ft. of underground workings, and some open cuts and buildings. The longest (2200 ft) adit was caved by the early 1980s (Jansons and others, 1984). Jansons and others (1984) collected chip samples that contained 58 parts per million (ppm) to 13 percent Cu, 46 ppm to 2 percent Zn, and <0.1 ppm to 32.8 ppm Ag; their grab samples contained 80 ppm to 6.1 percent Cu, 790 ppm to 20.1 percent Zn, and 1.1 ppm to 20 ppm Ag. Small amounts of gold were reported in earlier assays (Capps and Johnson, 1915).

Field work including sampling was performed in 2014. Four grab samples were collected in 2014 at approximately 60.886 N 146.601 W. Three samples were taken from an ore stockpile below an adit, the other sample was collected above the adit, at an exploration trench. The trenching was conducted on a quartz rich epithermal breccia. Sample 1 from ore stockpile contained 0.056 ppm Au, 25.6 ppm Ag, 3.57 percent Cu, and 5.4 percent Zn. Sample 2 contained 0.178 ppm Au, 74.2 ppm Ag, 10.65 percent Cu, and 2.15 percent Zn. Sample 3 contained 0.021 ppm Au, 5.81 ppm Ag, 0.692 percent Cu, and 0.772 percent Zn. Sample 4 taken from the trench contained 0.013 ppm Au, 3.13 ppm Ag, 0.449 percent Cu and 1.36 percent Zn (Angel, 2014).

Production notes:

None.

Reserves:

Inferred reserves of 5,800 tons at 7.9 percent Cu, 1.3 percent Zn, and 5 ppm Ag (Jansons and others, 1984).

Additional comments:

Nelson and others (1985) interpret the country rocks as accreted ocean crust. Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Last report date: 2014-09-09

Site name(s): Falck

Site type: Prospect

ARDF no.: CV015

Latitude: 60.866 **Quadrangle:** CV D-7

Longitude: 146.569

Location description and accuracy:

The Falck prospect is at an elevation of about 2400 ft., about 0.5 mile east of Copper Mountain. It is in S1/2 sec. 36, T. 11 S., R. 8 W., of the Copper River Meridian. The location is accurate to within 1000 ft. This prospect is shown as #12 in Cobb (1972: MF-392) and as C-78 in Jansons and others (1984).

Commodities:

Main: Cu, Zn

Other: Ag

Ore minerals: Chalcopyrite, pyrite, pyrrhotite, native Cu, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The country rocks at this prospect are mafic volcanic rocks and sedimentary rocks of the Tertiary Orca Group (Nelson and others, 1985). The deposit consists of sulfide minerals and native copper in veinlets and as disseminations in a northwest-striking, steeply-dipping shear zone in the volcanic and sedimentary rocks (Capps and Johnson, 1915). The sulfides are chalcopyrite, pyrite, pyrrhotite, and sphalerite.

Analyses of chip samples contained 0.11percent to 7.5 0.11percent Cu, 240 parts per million (ppm) to 0.68 0.11percent Zn, and 0.7 ppm to 18.3 ppm Ag (Jansons and others, 1984).

A 2014 grab sample collect near the Falck prospect contained 0.034 ppm Au, 0.11 ppm Ag, 112 ppm Cu, and 100 ppm Zn. Another grab sample collected roughly 1000 ft to the east of the Falck prospect coordinates contained 0.04 ppm Ag, 122.5 ppm Cu, and 94 ppm Zn (Angel, 2014).

Alteration:

Age of mineralization:

Probably Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and Singer, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: None

Site Status: Inactive

Workings/exploration:

Capps and Johnson (1915) report a 25 ft. adit and a 15 ft. adit, along with minor surface cuts. In the 1980s only the 25 ft. adit was still accessible (Jansons and others, 1984). Analyses of chip samples contained 0.11percent to 7.5 0.11percent Cu, 240 parts per million (ppm) to 0.68 0.11percent Zn, and 0.7 ppm to 18.3 ppm Ag (Jansons and others, 1984).

Field work including sampling was performed in 2014. A 2014 grab sample collect near the Falck prospect contained 0.034 ppm Au, 0.11 ppm Ag, 112 ppm Cu, and 100 ppm Zn. Another grab sample collected roughly 1000 ft to the east of the Falck prospect coordinates contained 0.04 ppm Ag, 122.5 ppm Cu, and 94 ppm Zn (Angel, 2014).

Production notes:

None.

Reserves:

Inferred reserves of 200 tons at 2.03 percent Cu, 0.23 percent Zn, 13 ppm Ag (Jansons and others, 1984).

Additional comments:

Nelson and others (1985) interpret the country rocks as accreted ocean crust. Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Last report date: 2014-09-09

Site name(s): Standard Copper Mines Co.

Site type: Mine

ARDF no.: CV016

Latitude: 60.862 **Quadrangle:** CV D-7

Longitude: 146.577

Location description and accuracy:

This mine is at an elevation of about 1800 feet, about 0.5 mile southeast of Copper Mountain. It is in the NW1/4 sec. 1, T. 12 S., R. 8 W., of the Copper River Meridian. The location of the site is accurate to within 1000 ft. This site is loc. 13 in Cobb (1972: MF-392) and loc. C-77 in Jansons and others (1984).

Commodities:

Main: Cu, Zn

Other: Ag, Au

Ore minerals: Chalcopyrite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The country rocks at this mine are mafic volcanic rocks and sedimentary rocks of the Tertiary Orca Group (Nelson and others, 1985). The deposit consists of quartz, calcite, and massive sulfides in shear zones cutting the volcanic rocks. A 6 ft. x 32 ft. lens of massive sulfide was observed by Mihelich and Wells (1957), but most of the sulfide bodies are smaller (Jansons and others, 1984). The sulfide minerals are chalcopyrite, pyrite, pyrrhotite, and sphalerite.

Chip samples collected in 1955 (Mihelich and Wells, 1957) contained 0.07 percent to 6.1 percent Cu. Jansons and others (1984) report that three chip samples from the 660-ft.-long adit contained 280 ppm to 0.89 percent Cu, 200 ppm to 0.9 percent Zn, 0.01 parts per million (ppm) to 0.11 ppm Au, and 0.5 ppm to 2.5 ppm Ag. Three grab samples from the adit contained 0.70 percent to 2 percent Cu, 200 ppm to 2 percent Zn, 0.08 ppm to 0.19 ppm Au, and 2.3 ppm to 6.1 ppm Ag.

A 2014 grab sample contained 0.175 ppm Au, 5.35 ppm Ag,1.145 percent Cu, and 4.43 percent Zn. A stream sediment sample from below the historical workings contained 0.008 ppm Au, 0.24 ppm Ag, 729 ppm Cu, and 160 ppm Zn (Angel, 2014).

Alteration:

Age of mineralization:

Probably Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and Singer, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: Yes

Site Status: Inactive

Workings/exploration:

Grant and Higgins (1909) report five adits on the steep slopes of Copper Mountain and a tram to an ore bunker on the shore of Landlocked Bay. Only three of the adits could be located in the 1980s (Jansons and others, 1984). Chip samples collected in 1955 (Mihelich and Wells,1957) contained 0.07 percent to 6.1 percent Cu. Jansons and others (1984) report that three chip samples from the 660-ft.-long adit contained 280 ppm to 0.89 percent Cu, 200 ppm to 0.9 percent Zn, 0.01 parts per million (ppm) to 0.11 ppm Au, and 0.5 ppm to 2.5 ppm Ag. Three grab samples from the adit contained 0.70 percent to 2 percent Cu, 200 ppm to 2 percent Zn, 0.08 ppm to 0.19 ppm Au, and 2.3 ppm to 6.1 ppm Ag.

Field work including sampling was performed in 2014. A 2014 grab sample contained 0.175 ppm Au, 5.35 ppm Ag,1.145 percent Cu, and 4.43 percent Zn. A stream sediment sample from below the historical workings contained 0.008 ppm Au, 0.24 ppm Ag, 729 ppm Cu, and 160 ppm Zn (Angel, 2014).

Production notes:

32,000 lbs. Cu, 518 oz. Ag, and 36 oz. Au were recovered from 1,100 tons of ore. However, it is felt that not all the recovered gold and silver were reported (Mihelich and Wells, 1957).

Reserves:

Inferred reserves of 4,300 tons at 2.89 percent Cu (Jansons and others, 1984).

Additional comments:

Nelson and others (1985) interpret the country rocks as accreted ocean crust. Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Chugach Alaska Corporation, Anchorage, Alaska has control of these lands.

Last report date: 2014-09-08

Site name(s): Montezuma (Threeman Mining Co.)

Site type: Prospect

ARDF no.: CV017

Latitude: 60.862 **Quadrangle:** CV D-7

Longitude: 146.568

Location description and accuracy:

The Montezuma prospect is at an elevation of about 1500 feet, about 0.5 mile southeast of Copper Mountain. It is in the N1/2 sec. 1, T. 12 S., R. 8 W., of the Copper River Meridian. The site location is accurate to within 1000 ft. This prospect is shown as site C-76 in Jansons and others (1984) and as site #13 in Cobb (1972: MF-392).

Commodities:

Main: Cu

Other: Ag, Au

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The country rocks at this prospect are mafic volcanic rocks and sedimentary rocks of the Tertiary Orca Group (Nelson and others, 1985). The deposit consists of irregular lenses of quartz, chalcopyrite, pyrite, and pyrrhotite in several highly mineralized shear zones in the volcanic rocks (Mihelich and Wells, 1957).

A sample from a quartz-filled shear zone one foot wide in volcanic rocks contained 0.5 percent Cu, 0.08 oz. Ag/ton, and 0.18 oz. Au/ton (Mihelich and Wells, 1957). Jansons and others (1984) report that chip samples contained 0.74 percent to 3.2 percent Cu, 3.2 parts per million (ppm) to 20 ppm Ag, and grab samples contained 125 ppm to 0.75 percent Cu, and 0.92 ppm to 10 ppm Ag.

A 2014 stream sediment sample collected below the workings contained 0.008 ppm Au, 0.23 ppm Ag, 804 ppm Cu, and 207 ppm Zn (Angel, 2014).

Alteration:

Age of mineralization:

Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and Singer, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: None

Site Status: Inactive

Workings/exploration:

Mihelich and Wells (1957) report more than 300 feet of underground workings and 900 feet of surface stripping. A sample from a quartz-filled shear zone one foot wide in volcanic rocks contained 0.5 percent Cu, 0.08 oz. Ag/ton, and 0.18 oz. Au/ton (Mihelich and Wells, 1957). Jansons and others (1984) report that chip samples contained 0.74 percent to 3.2 percent Cu, 3.2 parts per million (ppm) to 20 ppm Ag, and grab samples contained 125 ppm to 0.75 percent Cu, and 0.92 ppm to 10 ppm Ag.

Field work including sampling was performed in 2014. A 2014 stream sediment sample collected below the workings contained 0.008 ppm Au, 0.23 ppm Ag, 804 ppm Cu, and 207 ppm Zn (Angel, 2014).

Production notes:

None.

Reserves:

Inferred reserves of 200 tons at 1.67 percent Cu and 9.88 ppm Ag (Jansons and others, 1984).

Additional comments:

Nelson and others (1985) interpret the country rocks as accreted ocean crust. Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Chugach Alaska Corporation, Anchorage, Alaska has control of these lands.

Last report date: 2014-09-09

Site name(s): Threeman (Standard Copper)

Site type: Mine

ARDF no.: CV020

Latitude: 60.855 **Quadrangle:** CV D-7

Longitude: 146.537

Location description and accuracy:

The mine is at an elevation of about 300 feet above the north shore of inner Landlocked Bay, and about 0.25 mile north-northeast of VABM Dick. It is in the S1/2 sec. 6, T. 12 S., R. 7 W., of the Copper River Meridian. The site location is accurate to within 1000 ft. The location corresponds to site C-73 in Jansons and others (1984) and to #14 in Cobb (1972: MF-392).

Commodities:

Main: Cu, Zn

Other: Ag, Au, Co

Ore minerals: Chalcopyrite, cubanite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

The deposit at this mine is in mafic volcanic and sedimentary rocks of the Tertiary Orca Group (Nelson and others, 1985). It consists of two sulfide lenses up to about 6 ft wide and over 300 ft. long in pillow basalt and sedimentary rocks (Mihelich and Wells, 1957). Sulfide minerals include chalcopyrite, cubanite, galena, pyrite, pyrrhotite, and sphalerite.

Chip and grab samples contained 53 parts per million (ppm) to 5.25 percent Cu, 40 ppm to 2.85 percent Zn, <0.02 ppm to 0.10 ppm Au, <1 ppm to 22 ppm Ag, and 5 to 700 ppm Co (Jansons and others, 1984). Sixteen chip samples taken in 1955 contained 0.3 percent to 8.6 percent Cu, 0.05 percent to 0.64 percent Zn, trace to 0.07 oz. Au/ton and trace to 0.78 oz. Ag/ton (Mihelich and Wells, 1957).

A 2014 grab sample contained 0.025 ppm Au, 8.63 ppm Ag, 4.09 percent Cu, and 1.62 percent Zn. A stream sediment sample collect roughly 1000 ft to the northeast contained 0.25 ppm Ag, 330 ppm Cu, and 482 ppm Zn (Angel, 2014).

Alteration:

Age of mineralization:

Probably Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and Singer, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: Yes; medium

Site Status: Inactive

Workings/exploration:

There are several thousand feet of workings on three levels. Three adits were caved when visited by this reporter in 1974 and 1986 (also see Sainsbury, 1993). Chip and grab samples contained 53 parts per million (ppm) to 5.25 percent Cu, 40 ppm to 2.85 percent Zn, <0.02 ppm to 0.10 ppm Au, <1 ppm to 22 ppm Ag, and 5 to 700 ppm Co (Jansons and others, 1984). Sixteen chip samples taken in 1955 contained 0.3 percent to 8.6 percent Cu, 0.05 percent to 0.64 percent Zn, trace to 0.07 oz. Au/ton and trace to 0.78 oz. Ag/ton (Mihelich and Wells, 1957).

Field work including sampling was performed in 2014. A 2014 grab sample contained 0.025 ppm Au, 8.63 ppm Ag, 4.09 percent Cu, and 1.62 percent Zn. A stream sediment sample collect roughly 1000 ft to the northeast contained 0.25 ppm Ag, 330 ppm Cu, and 482 ppm Zn (Angel, 2014).

Production notes:

1,159,660 lbs. Cu, 101 oz. Au, 5,308 oz. Ag from 6,196.5 tons ore (Mihelich and Wells, 1957).

Reserves:

Inferred reserves of 1,902,000 tons at 1.05 percent Cu (Sainsbury, 1953).

Additional comments:

Nelson and others (1985) interpret the country rocks as accreted ocean crust. Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Last report date: 2014-09-09

Site name(s): Hoodoo and South Landlocked Bay Mining Co.

Site type: Mine

ARDF no.: CV021

Latitude: 60.848 **Quadrangle:** CV D-7

Longitude: 146.549

Location description and accuracy:

This site represents a mine and a prospect along the south shore of Landlocked Bay. The map site is at an elevation of about 150 feet, just inland from the bay. It is in the NW1/4 sec. 7, T. 12 S., R. 7 W., of the Copper River Meridian. The site location is accurate to within 2000 ft. This site combines both sites C-70 and C-71 of Jansons and others (1984) and site #15 of Cobb (1972: MF-392). The site location was updated from a 2014 site visit.

Commodities:

Main: Cu, Zn

Other: Ag, Au

Ore minerals: Chalcopyrite, native copper, sphalerite

Gangue minerals: Quartz

Geologic description:

The mineral deposits at this site are in mafic volcanic rocks (greenstone) of the Tertiary Orca Group (Nelson and others, 1985) and consist of massive sulfide lenses in shear zones 1.5 ft. to 3 ft. wide (Jansons and others, 1984). The ore minerals are mainly chalcopyrite and sphalerite; native copper is also reported.

Development work began in 1904 (Cobb, 1979: OFR 79-973). Extensive surface stripping at 230 feet elevation exposed about 75 feet of a 3-foot-wide mineralized zone in metavolcanic rock striking N45W, and dipping 60 NE. Four tunnels were driven, the longest of which was 180 feet (Capps and Johnson, 1913). In 1953 one tunnel was inaccessible (Mihelich and Wells, 1957). Early assays contained 0.48 to 1.06 oz. Au/ton. Recent sampling (Jansons and others, 1984) of five chip samples from one adit contained 0.11 ppm to 2.9 percent Cu, 680 ppm to 0.95 percent Zn, <0.03 to 0.03 parts permillion (ppm) Au, and 0.2 to 13.9 ppm Ag. Three grab samples contained 1.14 percent to 19.3 percent Cu, 0.95 to 2.25 percent Zn, 0.15 ppm to 44 ppm Au, and 0.23 ppm to 34 ppm Ag.

A 2014 grab sample contained 0.075 ppm Au, 39.2 ppm Ag, 8.7 percent Cu, and 3.26 percent Zn (Angel, 2014).

Alteration:

Age of mineralization:

Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and SInger, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Development work began in 1904 (Cobb, 1979: OFR 79-973) Extensive surface stripping at 230 feet elevation exposed about 75 feet of a 3-foot-wide mineralized zone in metavolcanic rock striking N45W, and dipping 60 NE. Four tunnels were driven, the longest of which was 180 feet (Capps and Johnson, 1913). In 1953 one tunnel was inaccessible (Mihelich and Wells, 1957). Early assays contained 0.48 to 1.06 oz. Au/ton. Site name(s): Threeman Mining Co.; Billygoat Mountain

Site type: Prospect

ARDF no.: CV023

Latitude: 60.8281 **Quadrangle:** CV D-7

Longitude: 146.5133

Location description and accuracy:

This prospect is at an elevation of about 1750 feet, about 0.1 mile east of the summit of Billygoat Mountain. It is in the SW1/4 sec. 17, T. 12 S., R. 7 W., of the Copper River Meridian. The location of the site is accurate to within 100 ft. This prospect was located in the field in 2014. This prospect is shown as site C-68 by Janson and others (1984) and as #18 by Cobb (1972: MF-392).

Commodities:

Main: Cu, Zn

Other: Ag

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

This prospect consists of two sulfide-bearing shear zones in mafic volcanic rocks of the Tertiary Orca Group (Nelson and others, 1985). The zones range in width from a few inches to five feet and contain lenses and stringer zones of chalcopyrite, pyrite, and pyrrhotite. Samples grade up to 6 percent Cu (Capps and Johnson, 1913).

Capps and Johnson (1913) reported adits at 1150 ft. and 1750 ft. elevation. The lower adit was 30 ft. long and the upper adit was 70 ft. long. Jansons and others (1984) reported that a grab sample from the 70 ft. adit contained 3.8 percent Cu, 0.2 percent Zn, and 7.5 parts per million (ppm) Ag. Gossan from the area contained 1.55 percent Cu, 0.4 percent Zn, and 13 ppm Ag.

A 2014 grab sample from below the upper 1750 ft adit contained 0.04 percent Cu, 0.01 percent Zn and a trace of Ag at 0.006 ppm. A stream sediment sample collected approximately 1000 ft east of the 1750 ft adit contained 0.024 ppm Au, 0.17 ppm Ag, 0.02 percent Cu, and 0.0082 percent Zn (Angel, 2014).

Alteration:

Local oxidation of sulfide minerals.

Age of mineralization:

Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Cyprus massive sulfide (Cox and Singer, 1986; model 24a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24a

Production Status: None

Site Status: Inactive

Workings/exploration:

Capps and Johnson (1913) reported adits at 1150 ft. and 1750 ft. elevation. The lower adit was 30 ft. long and the upper adit was 70 ft. long. Jansons and others (1984) reported that a grab sample from the 70 ft. adit contained 3.8 percent Cu, 0.2 percent Zn, and 7.5 ppm Ag. Gossan from the area contained 1.55 percent Cu, 0.4 percent Zn, and 13 ppm Ag.

A 2014 grab sample from below the upper 1750 ft adit contained 0.04 percent Cu, 0.01 percent Zn and a trace of Ag at 0.006 ppm. A stream sediment sample collected approximately 1000 ft east of the 1750ft adit contained 0.024 ppm Au, 0.17 ppm Ag, 0.02 percent Cu, and 0.0082 percent Zn (Angel, 2014).

Production notes:

None.

Reserves:

None.

Additional comments:

Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Chugach Alaska Corporation, Anchorage, Alaska has control of these lands.

In 2014 the coordinate location was updated and is accurate for the upper 1750 ft adit. The lower adit couldn't be located (Angel, 2014).

Site name(s): Fidalgo-Alaska; Schlosser

Site type: Mine

ARDF no.: CV028

Latitude: 60.774 **Quadrangle:** CV D-7

Longitude: 146.417

Location description and accuracy:

The Fidalgo-Alaska mine is at an elevation of about 500 feet, about 0.8 mile east of the mouth of Irish Cove and 0.5 mile north of peak 1430. It is in the NW1/4 sec. 2, T. 13 S., R. 7 W., of the Copper River Meridian. The site is accurately located to within 1000 ft. This mine is shown as site C-28 in Jansons and others (1984) and site #19 in Cobb (1972: MF-392).

Commodities:

Main: Cu, Zn

Other: Ag, Au

Ore minerals: Chalcopyrite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

This deposit consists of sulfide-bearing quartz-calcite veins in 150- to 300-foot-wide shear zones in folded and sheared slate and graywacke of the Tertiary Orca Group (Nelson and others, 1985). The sulfide minerals include chalcopyrite, pyrite, pyrrhotite, and sphalerite.

This mine was developed and productive from 1913 to about 1920 (Cobb, 1979: OF 79-973). Five adits with the following lengths are reported (Jansons and others, 1984): 1800 ft., 540 ft., 410 ft., 250 ft., and 50 ft. U.S Bureau of Mines samples from various adit levels and of surface materials contained 0.02 percent to 19.5 percent Cu, 150 parts per million (ppm) to 29 percent Zn, 2 ppm to 15 ppm Ag, and <0.02 ppm to 5.8 ppm Au. Industry evaluation of the property was undertaken in 1986 (B. Ellis, personal communication, 2000).

A grab sample taken in 2014 contained 1.095 ppm Au, 11.55 ppm Ag, 1.84 percent Cu, and 0.086 percent Zn (Angel, 2014).

Alteration:

Oxidation of copper minerals (Angel, 2014).

Age of mineralization:

Early Tertiary age based on the age of the host rocks (Nelson and others, 1985).

Generic deposit model:

Deposit model:

Besshi massive sulfide (Cox and Singer, 1986; model 24b)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

This mine was developed and productive from 1913 to about 1920 (Cobb, 1979: OF 79-973). Five adits with the following lengths are reported (Jansons and others, 1984): 1800 ft., 540 ft., 410 ft., 250 ft., and 50 ft. U.S Bureau of Mines samples from various adit levels and of surface materials contained 0.02 percent to 19.5 percent Cu, 150 parts per million (ppm) to 29 percent Zn, 2 ppm to 15 ppm Ag, and <0.02 ppm to 5.8 ppm Au. Industry evaluation of the property was undertaken in 1986 (B. Ellis, personal communication, 2000).

Field work including sampling was performed in 2014. A grab sample taken in 2014 contained 1.095 ppm Au, 11.55 ppm Ag, 1.84 percent Cu, and 0.086 percent Zn (Angel, 2014).

Production notes:

4,160,820 lbs. Cu and 1,384 oz Ag were produced from 21,434 tons of ore. Average grade was 10 percent Cu.

Reserves:

Jansons and others (1984) report indicated reserves of 25,625 tons at 3 percent Cu and inferred reserves of 224,000 tons at 3.18 percent Cu.

Additional comments:

Crowe and others (1992; 1993) and Sainsbury (1993) discuss the genesis of the volcanogenic massive sulfide deposits in this area.

Site name(s): Fidalgo Mining Co. (Blackney Prospect)

Site type: Mine

ARDF no.: CV030

Latitude: 60.7951 **Quadrangle:** CV D-7

Longitude: 146.2947

Location description and accuracy:

This mine is at an elevation of about 500 feet on the south side of Port Fidalgo, about 1.5 miles northwest of the head of Matthews Bay. It is in the SE1/4 sec. 28, T. 12 S., R. 6 W., of the Copper River Meridian. The location is accurate to within 500 ft. This mine is shown as site #21 in Cobb (1972: MF-392) and C-63 in Jansons and others (1984).

Commodities:

Main: Cu

Other: Ag, Au

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

Most of the ore mined from this deposit was from two lens-shaped bodies of massive sulfides. The ore bodies were localized in a shear zone in interbedded volcanic and sedimentary rocks of the Tertiary Orca Group (Nelson and others, 1985; Moffit and Fellows, 1950). Sulfide minerals include chalcopyrite, pyrite, and pyrrhotite. Underground study by Jansons and others (1984) reported three main shear zones up to 30 feet wide and traceable for 4000 feet parallel to bedding.

Most of the mining activity took place in 1913. The average copper grade was 13 percent. The mine continued to be active until 1920 (Moffit and Fellows, 1950). Workings included four adits having the following lengths: 1200 ft., 735 ft., 350 ft., and 175 ft. The following assays are reported by Jansons and others (1984). Four chip samples from the 735-foot-long adit contained from 175 parts per million (ppm) to 0.23 percent Cu; nine chip samples across the main shear zone in the 1200-foot-long adit contained 0.12 percent to 1.25 percent copper; fifteen chip samples from the rest of the adit contained 9 ppm to 0.29 percent Cu; and three chip samples from the 175-foot-long adit contained 300 ppm to 0.73 percent Cu; three chip samples from the 350-foot-long adit contained 0.17 percent to 0.73 percent Cu. Grab samples from the dump contained 1 percent to 6.3 percent Cu. Industry evaluation of the property was undertaken in 1986 (B. Ellis, personal communication, 2000).

A 2014 grab sample contained 0.117 ppm Au, 3.96 ppm Ag, 0.819 percent Cu, and 0.236 percent Zn (Angel, 2014).

Alteration:

Age of mineralization:

Tertiary based on the age of the host rocks.

Site name(s): Sunday Lake

Site type: Prospect

ARDF no.: DE017

Latitude: 54.9295 **Quadrangle:** DE D-1

Longitude: 132.1724

Location description and accuracy:

The Sunday Lake prospect is at an elevation of about 750 feet, about 1.2 miles northwest of Bokan Mountain and about 0.7 mile east-southeast of the center of section 17, T. 80 S., R. 88 E. Its location relative to the other uranium and REE prospects in the vicinity of Bokan Mountain is best shown on Plate 1 of MacKevett (1963).

Commodities:

Main: Cb, Ce, Dy, Er, Eu, Gd, Ho, La, Lu, Nd, Pm, Pr, Sm, Tb, Th, Tm, U, Y, Yb, Zr

Other:

Ore minerals: Allanite, REE minerals

Gangue minerals:

Geologic description:

This and several other nearby uranium-thorium-REE deposits (DE015, DE016, and DE18 to DE031) are spatially and genetically related to a stock of Jurassic, peralkaline granite about 2 miles in outcrop diameter centered on Bokan Mountain. It commonly is referred to as the Bokan Mountain peralkaline granite or Bokan Mountain complex. The intrusion and its deposits have been mapped in detail several times using slightly different subdivisions of the granite (MacKevett, 1963; Thompson and others, 1980, 1982; Saint-Andre and others, 1983; Gehrels, 1992; Thompson, 1997). This description largely follows Gehrels' (1992) map units. The intrusion is a ring-dike complex with an outer border zone up to 14 meters thick of pegmatite and aplite; a nearly complete intermediate zone of aegirine granite porphyry, 15 to 180 meters thick; and a core of several varieties of riebeckite granite porphyry. It has been dated by several methods at 151 Ma to 191 Ma (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997). The peralkaline granite mainly intrudes a regionally extensive body of Silurian or Ordovician quartz monzonite, granite, and quartz diorite that makes up much of the southeast tip of Prince of Wales Island. The south and west sides of the peralkaline granite are in contact with a band up to about 3,000 feet wide of shale and argillite of the Silurian or Ordovician Descon Formation. The Bokan Mountain complex and surrounding Paleozoic rocks are cut by numerous pegmatite, andesite, dacite, and aplite dikes. The dikes are genetically related to the complex and commonly are associated with the uranium, thorium, and REE deposits. The deposits are marked by intense albitization, pervasive or fracture-controlled chloritization, calcite-fluorite replacement of aegirine, and hematitization. Three types of U-Th-REE deposits occur in the Bokan Mountain complex: 1) irregular cylindrical pipes; 2) steep, shear-zone-related pods or lenses ('veins'); and 3) quartz veins.

The Sunday Lake prospect has been explored by two short trenches and a small pit (Warner and Barker, 1989), and three holes were drilled in the fall of 2009 (Ucore Uranium, 2009b). The deposit is controlled by steeply dipping, north-northwest-trending shear zones and fractures which can be traced for about 300 feet in riebeckite granite. Allanite is locally abundant. Where exposed, the deposit is 3 to 7 feet thick and consists of highly radioactive, mottled, iron- and manganese-stained gouge and crushed rock.

In 2009, Ucore Uranium announced that samples taken at or near this prospect contained a significant content of heavy and light rare-earth elements (Ucore Uranium, 2009a). The analyses of the samples were

reported as the light rare-earth-element oxides or LREO (lanthanum, cerium, praseodymium, neodymium, and samarium) and the heavy rare-earth-element oxides or HREO (europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, and yttrium); together they are termed the TREO, the total rare-earth-element oxides. The two samples contained 7.19 and 0.37 percent HREO and 2.39 and 15.17 percent HREO. The analyses indicate that nearly all of the rare-earth-element oxides are the heavy rare-earth-element oxides. By early fall of 2009, two of the three Ucore holes cut high grade intercepts of rare-element minerals (Ucore Uranium, 2009b). The notable intercepts were 4.80 meters with 0.10 percent LREO and 1.93 percent HREO, 0.80 meters with 0.13 percent LREO and 3.82 percent HREO, and 1.72 meters with 0.07 percent LREO and 0.81 percent HREO. In other words, 92 to 97 percent of the rare-earth-element oxides were the heavy rare-earth-element oxides.

According to Warner and Barker (1989), the deposit has an inferred resource of 27,000 short tons of material that contains 26,000 pounds of columbium, 1,728,000 pounds of thorium, 270,000 pounds of uranium, 437,000 pounds of yttrium, 151,000 pounds of zirconium.

Alteration:

This prospect and the other uranium, thorium, and REE deposits associated with the Bokan Mountain peralkaline granite are marked by albitization, chloritization, and argillization. Minor calcite, fluorite, quartz, sulfide minerals, and tourmaline are common in the altered rocks and hematite often occurs in the periphery of high-grade ore zones.

Age of mineralization:

Genetically related to the Jurassic, Bokan Mountain peralkaline granite stock.

Generic deposit model:

Deposit model:

U-Th-REE deposit associated with peralkaline granite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Two short trenches and a small prospect pit to 2008. In 2009, Ucore Uranium sampled the prospect and drilled three holes.

Production notes:

None.

Reserves:

According to Warner and Barker (1989), the deposit has an inferred resource of 27,000 short tons of material that contains 26,000 pounds of columbium, 1,728,000 pounds of thorium, 270,000 pounds of uranium, 437,000 pounds of yttrium, 151,000 pounds of zirconium.

Site name(s): I and L; I and L Nos. 3-5

Site type: Prospects

ARDF no.: DE023

Latitude: 54.913 **Quadrangle:** DE D-1

Longitude: 132.1345

Location description and accuracy:

The I & L Nos. 3-5 prospects cover an area about 1,000 feet in diameter centered about 0.9 mile east-southeast of Bokan Mountain. The center of the area is just north of the midpoint of the south boundary of section 22, T. 80 S., R. 88 E, of the Copper River Meridian. As known in 2011, it is at the northwest end of the prospects along the Dotson dike and its persistent mineralization. The location of these prospects relative to the other uranium and REE prospects in the vicinity of Bokan Mountain is best shown on Plate 1 of MacKevett (1963). The location is accurate, though the degree of accuracy is not reported.

Commodities:

Main: Cb, Ce, Dy, Er, Eu, Gd, Ho, La, Lu, Nd, Pm, Pr, Sm, Tb, Th, Tm, U, Y, Yb, Zr

Other:

Ore minerals: Aeschynite, allanite, bastnaesite, brannerite, columbite-tantalite, euxenite-polycrase, fergusonite, fluorite, galena, monazite, parisite, phenakite, pyrite, samarskite, sphalerite, synchysite, tengerite, thalenite, thorite, unnamed REE fluorocarbonate, uranothorite, xenotime, zircon

Gangue minerals: Albite, calcite, fluorite, hematite, quartz, tourmaline

Geologic description:

This and several other nearby uranium-thorium-REE deposits (DE015 to DE022 and DE024 to DE031) are spatially and genetically related to a stock of Jurassic, peralkaline granite about 2 miles in diameter centered on Bokan Mountain. It commonly is referred to as the Bokan Mountain peralkaline granite or Bokan Mountain complex. The intrusion and its deposits have been mapped in detail several times using slightly different subdivisions of the granite (MacKevett, 1963; Thompson and others, 1980, 1982; Saint-Andre and others, 1983; Gehrels, 1992; Thompson, 1997). This description largely follows Gehrels' (1992) map units. The intrusion is a ring-dike complex with an outer border zone up to 14 meters thick of pegmatite and aplite; a nearly complete intermediate zone of aegirine granite porphyry, 15 to 180 meters thick; and a core of several varieties of riebeckite granite porphyry. It has been dated by several methods at 151 Ma to 191 Ma (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997). The peralkaline granite mainly intrudes a regionally extensive body of Silurian or Ordovician quartz monzonite, granite, and quartz diorite that makes up much of the southeast tip of Prince of Wales Island. The south and west sides of the peralkaline granite are in contact with a band up to about 3,000 feet wide of shale and argillite of the Silurian or Ordovician Descon Formation. The Bokan Mountain complex and surrounding Paleozoic rocks are cut by numerous pegmatite, andesite, dacite, and aplite dikes. The dikes are genetically related to the complex and commonly are associated with the uranium, thorium, and rare-earth-element (REE) deposits. The deposits are marked by intense albitization, pervasive or fracture-controlled chloritization, calcite-fluorite replacement of aegirine, and hematitization. Three types of U-Th-REE deposits occur in the Bokan Mountain complex: 1) irregular cylindrical pipes; 2) steep, shear-zone-related pods or lenses ('veins'); and 3) quartz veins.

As described by MacKevett (1963) and Warner and Barker (1989), the I and L prospects are on six principal and many smaller northwest-trending, quartz-cored, pegmatite dikes that cut riebeckite granite porphyry and aegirine granite of the Bokan Mountain peralkaline stock near its southeast border. Transverse

pegmatite dikes are also present. The dikes contain scattered concentrations and discrete grains of uranium, thorium, and REE minerals. The largest and northernmost dike (the No. 1 dike) is at least 900 feet long and up to 18 feet thick. The other dikes are parallel, vary from 100 to 500 feet in length, and are a few inches to 6 feet thick. The dikes are generally vertical but drilling on the No. 1 dike indicates that it is irregular in width and shape, and bends markedly at depth. Intense argillic alteration is common along the contacts of the dikes, and the better mineralization is generally associated with faults.

In a study of the mineralogy of the IL & M dikes, Staatz (1978) found that the uranium is generally in thorium-bearing uraninite, whereas brannerite predominates in some transverse dikes. Thorite is the principal thorium mineral in the northwest and central parts of the prospect area; allanite predominates in the southeastern part of the area and in transverse dikes. Rare earth minerals include bastnaesite, xenotime, monazite and an unidentified fluorocarbonate. The distribution of the individual rare earth minerals varies markedly. One part of a dike may contain predominantly cerium-group minerals, for example bastnaesite; another part may contain predominantly yttrium-bearing minerals, for example xenotime. Small amounts of sulfides including galena, sphalerite, and pyrite are common in many of the dikes. Zircon and fluorite are commonly present in minor amounts and two samples contained the beryllium mineral phenacite. The gangue is mostly quartz and albite. Scanning electron microscope study by Warner and Barker (1989) shows that the REE minerals are mainly thalenite, bastnaesite, and allanite; tengerite, parisite, synchysite, an unnamed REE flurocarbonate mineral, monazite, and xenotime also occur. The columbium-bearing mineral is mainly euxenite-polycrase, although columbite-tantalite, samarskite, fergusonite, and aeschynite are present. The main radioactive mineral is thorite but uranothorite is also present.

In 2007 and 2008, Ucore Uranium drilled 27 holes on the I&L vein system (Ucore Uranium, 2010). All the holes intersected uranium mineralization. Some of the best values were a 50.24-meter intercept with 0.47 percent U308, including a 3.90-meter intercept with 2.43 percent U3O8; a 46.72-meter intercept with 0.16 percent U3O8; a 5.11-meter intercept with 0.46 percent U308; a 7.56 meter intercept with 0.59 percent U3O8; and a 15.23-meter intercept with 0.42 percent U3O8. In conjunction with the drilling, an airborne geophysical survey was flown over the Bokan Mountain area in 2007 and channel samples were cut across the I & L vein system to guide the drilling. The drilling and channel sampling indicated that the uranium mineralization extends along strike for at least 100 meters, to a depth of at least 35 meters, and is open both along strike and dip (Ucore Uranium, 2008).

In 2010, Ucore drilled 20 more holes, including 13 infill holes along the Dodson Dike at roughly regular intervals from this prospect, now considered to be the northwest end of the dike, through the Atom Marietta prospect (DE024), to the Carol Ann prospect (DE027) (Ucore, 2010 [News release]; Ucore, 2011). They also dug 45 trenches across the dike. As known in early 2011, the Dodson dike has a strike length of at least 2,180 meters, averages 50 meters wide, extends from 300 meters above sea level to at least 150 meters below sea level, has remarkably persistent mineralization. and it is open along strike and down dip.

With this additional drilling on the Dodson dike, a new and considerably larger 'Conceptual Estimate' was made for the dike. The estimate was made using a model of the dike 2,425 meters long and 200 meters deep. The new figures are an 'Estimated contained mineralized tonnage' of from 3.5 to 6.5 million tonnes, with an 'Estimated grade TREO' of from 0.76 to 1.42 percent. (TREO = total rare earth elements.)

Alteration:

These prospects and the other uranium, thorium, and REE deposits associated with the Bokan Mountain peralkaline granite are marked by albitization, chloritization, and argillization. Minor calcite, fluorite, quartz, sulfide minerals, and tourmaline are common in the altered rocks and hematite often occurs in the periphery of high-grade ore zones. Intense argillic alteration is common along the contacts of the dikes, and the better mineralization is generally associated with faults (source not cited by previous reporter).

Age of mineralization:

Genetically related to the Jurassic, Bokan Mountain peralkaline granite (source not cited by previous reporter).

Generic deposit model:

Deposit model:

U-Th-REE deposit related to a peralkaline granite stock.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The prospects have been explored by numerous pits and trenches, and in 1977 were drilled to a depth of 260 feet. In 2007 and 2008, Ucore Uranium drilled 23 holes, cut several channel samples across the vein system, and completed an airborne geophysical survey over the area. In 2010, Ucore drilled 13 infill holes along the Dodson Dike at roughly regular intervals from the I and L prospect which was considered to be the northwest end of the dike, through the Atom Marietta prospect (DE024) to the Carol Ann prospect (DE027) (Ucore, 2010 [News release]; Ucore, 2011). They also dug 45 trenches across the dike. As known in early 2011 through systematic drilling, the Dodson dike has a strike length of at least 2,180 meters, averages 50 meters wide, extends from 300 meters above sea level to at least 150 meters below sea level, and it is open along strike and down dip.

In 2009 and 2010, Ucore conducted airborne total magnetic field and radiometric surveys in order to map radiogenic rocks in order to directly locate uranium and rare earth mineralization with the radiometric survey, and to map structure and stratigraphy indirectly with the total magnetic field survey. In 2009, Ground total magnetic field and radiometric surveys were performed to map these zones prior to drilling. An induced polarization (IP) survey was run to attempt to discern controls on mineralization intersected in drillholes at this site. In 2010, 3,214 m of core were drilled in 13 holes (Bentzen and others, 2013). This exploration work from 2008-2010 led to the 2013 Preliminary Economic Assessment (Bentzen and others, 2013) and a 2013 updated resource estimate (Ucore Rare Metals Inc., 2013).

Although no exploration work was conducted in 2016, Ucore Rare Metals Inc. conducted mineral-separation tests on ore from their Bokan-Dotson Ridge rare-earth-element (REE) project in Southeast Alaska. The first batch of pregnant leach solution (PLS) derived from Bokan ore was treated by the SuperLig®-One Molecular Recognition Technology plant at IBC Advanced Technologies, Inc.’s Utah facility. Successful separations include: 1) separation of REE from gangue metals in the PLS; 2) greater than 99 percent purity of separation of light REE from heavy REE at greater than 99 percent recovery; 3) greater than 99 percent purity of separation and recovery of the sub-groups samarium-dysprosium (Dy sub-group) and holmium-lutetium (Ho sub-group) from the heavy REE class consisting of samarium and lutetium; and 4) greater than 99 percent separation of dysprosium from the Dy sub-group (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

With the partial results of the 2010 infill drilling, a new and considerably larger 'Conceptual Estimate' was made for the Dodson dike. The estimate was made using a model of a dike 2,425 meters long and 200 meters deep. The new figures are an 'Estimated contained mineralized tonnage' of from 3.5 to 6.5 million tonnes, and an 'Estimated grade TREO' of from 0.76 to 1.42 percent. (TREO = total rare earth elements.)

In October 2013, an upgraded resource estimate was reported combining I and L, Carol Ann (DE027) and Atom Marietta (DE024). The estimate was made using a model via five alternative total rare earth oxide (TREO) cut-off grades with a baseline case employing a TREO cut-off of 0.4 percent. The deposit has indicated resources of 2,936,000 tonnes containing 39,731,596 pounds of TREO composed of 0.365 percent LREO, 0.249 percent HREO, and 0.614 percent TREO with a TREO cut-off of 0.4, and an additional inferred resources of 1,995,000 tonnes containing 26,601,729 pounds of TREO composed of 0.366 percent LREO, 0.239 percent HREO, and 0.605 percent TREO with a TREO cutoff of 0.40 (Ucore Rare Minerals Inc., 2013).

A 2013 preliminary economic assessment for Ucore Rare Metals’ Bokan property states an inferred

resource of 5.228 million tonnes grading 0.653 percent total rare-earth oxide (Bentzen and others, 2013); it includes the Dotson (DE027), and I-and-L zones (DE023).

Last report date: 2017-08-26

Site name(s): Atom Marietta

Site type: Prospect

ARDF no.: DE024

Latitude: 54.9122 **Quadrangle:** DE D-1

Longitude: 132.1283

Location description and accuracy:

The Atom Marietta prospect is about 1.1 miles east-southeast of Bokan Mountain, near the center of the west boundary of the SE1/4 SE1/4 section 22, T. 80 S., R. 88 E, of the Copper River Meridian. As known in 2011, it is one of the prospects along the Dodson dike and its persistent mineralization. Its location relative to the other uranium and REE prospects in the vicinity of Bokan Mountain is best shown on Plate 1 of MacKevett (1963). The location is accurate, though the degree of accuracy is not reported.

Commodities:

Main: Cb, Ce, Dy, Er, Eu, Gd, Ho, La, Lu, Nd, Pm, Pr, Sm, Tb, Th, Tm, U, Y, Yb, Zr

Other:

Ore minerals: Brannerite?, dravite?, uraninite, uranophane

Gangue minerals: Albite, calcite, chlorite, fluorite, hematite, quartz, tourmaline

Geologic description:

This and several other nearby uranium-thorium-REE deposits (DE015 to DE023 and DE025 to DE031) are spatially and genetically related to a stock of Jurassic, peralkaline granite about 2 miles in diameter centered on Bokan Mountain. It commonly is referred to as the Bokan Mountain peralkaline granite or Bokan Mountain complex. The intrusion and its deposits have been mapped in detail several times using slightly different subdivisions of the granite (MacKevett, 1963; Thompson and others, 1980, 1982; Saint-Andre and others, 1983; Gehrels, 1992; Thompson, 1997). This description largely follows Gehrels' (1992) map units. The intrusion is a ring-dike complex with an outer border zone up to 14 meters thick of pegmatite and aplite; a nearly complete intermediate zone of aegirine granite porphyry, 15 to 180 meters thick; and a core of several varieties of riebeckite granite porphyry. It has been dated by several methods at 151 Ma to 191 Ma (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997). The peralkaline granite mainly intrudes a regionally extensive body of Silurian or Ordovician quartz monzonite, granite, and quartz diorite that makes up much of the southeast tip of Prince of Wales Island. The south and west sides of the peralkaline granite are in contact with a band up to about 3,000 feet wide of shale and argillite of the Silurian or Ordovician Descon Formation. The Bokan Mountain complex and surrounding Paleozoic rocks are cut by numerous pegmatite, andesite, dacite, and aplite dikes. The dikes are genetically related to the complex and commonly are associated with the uranium, thorium, and REE deposits. The deposits are marked by intense albitization, pervasive or fracture-controlled chloritization, calcite-fluorite replacement of aegirine, and hematitization. Three types of U-Th-REE deposits occur in the Bokan Mountain complex: 1) irregular cylindrical pipes; 2) steep, shear-zone-related pods or lenses ('veins'); and 3) quartz veins.

The Atom Marietta prospect consists of a few hand-dug cuts and pits on several claims located in 1955 (MacKevett, 1963). The prospect is in aplite near the southeastern edge of the Bokan Mountain peralkaline complex. The deposit is near the intersection of a major northeast-trending fault zone with a group of steep northwest faults. The deposit is associated with intensely altered and fractured dacite dikes that cut the aplite in or near the fault zones. The uranium-thorium minerals occur in narrow veinlets, as disseminations, and as irregular, sublinear masses. The primary radioactive mineral is uranothorite, although uraninite and other

unidentified minerals, possibly brannerite or davite, also occur. Secondary uranophane is present.

In 2008 and 2009, Ucore Uranium drilled a line of 24 holes for rare-earth elements at roughly equal intervals from near this prospect to the Carol Ann prospects (DE027), a distance of about 2,000 meters (Ucore Uranium, 2010). The line of holes follows the Dodson dike system. The analyses for the samples were reported as the light rare-earth-element oxides or LREO (lanthanum, cerium, praesodymium, neodymium, and samarium) and the heavy rare-earth-element oxides or HREO (euroipium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, and yttrium); together they are termed the TREO, the total rare-earth-element oxides. Some of the notable intercepts are: 1) 0.2 meter with 5.7 percent TREO, 0.4 meter with 3.0 percent TREO; 2) 0.3 meter with 3.3 percent TREO, 0.8 meter with 3.5 percent TREO; 3) 0.3 meter with 3.2 percent TREO; 4) 0.25 meter with 4.4 percent TREO; 5) 0.33 meter with 3.0 percent TREO: 6) 0.83 meter with 5.4 percent TREO; 7) 0.5 meter with 6.3 percent TREO; 8) 0.6 meter with 4.5 percent TREO); 9) 0.4 meter with 3.4 percent TREO; 10) 0.5 meter with 4.0 percent TREO; and 11) 0.4 meter with 3.4 percent TREO. Several of the holes had multiple intercepts of rare-earth-element mineralization which is notable persistent along the whole line of holes. The ratio of the the HREO to the TREO in the better intercepts varied from about 24 percent to about 70 percent, but roughly about half of the rare-earth elements in the samples are the heavy rare-earth elements.

In 2010, Ucore drilled 20 more holes, including 13 infill holes along the Dodson dike at roughly regular intervals from the I and L prospect (DE023), through this site, to the Carol Ann prospect (DE 027) (Ucore, 2010 [News release]; Ucore, 2011). They also dug 45 trenches across the dike. As known in early 2011, the Dodson dike has a strike length of at least 2,180 meters, averages 50 meters wide, extends from 300 meters above sea level to at least 150 meters below sea level, has remarkably persistent mineralization, and it is open along strike and down dip.

With this additional drilling on the Dodson dike, a new and considerably larger 'Conceptual Estimate' was made for it. The estimate was made using a model of a dike 2,425 meters long and 200 meters deep. The new figures are an 'Estimated contained mineralized tonnage' of from 3.5 to 6.5 million tonnes, with an 'Estimated grade TREO' of from 0.76 to 1.42 percent. (TREO = total rare earth elements.)

In October 2013, an upgraded resource estimate was reported combining Atom Marietta, I and L (DE023), and Carol Ann (DE027). The estimate was made using a model via five alternative total rare earth oxide (TREO) cut-off grades with a baseline case employing a TREO cut-off of 0.4 percent. The deposit has 1) indicated resources of 2,936,000 tonnes containing 39,731,596 pounds of TREO composed of 0.365 percent LREO, 0.249 percent HREO, and 0.614 percent TREO with a TREO cut-off of 0.4, and 2) inferred resources of 1,995,000 tonnes containing 26,601,729 pounds of TREO composed of 0.366 percent LREO, 0.239 percent HREO, and 0.605 percent TREO with a TREO cutoff of 0.40 (Ucore Rare Minerals Inc., 2013).

Alteration:

These prospects and the other uranium, thorium, and REE deposits associated with the Bokan Mountain peralkaline granite are marked by albitization, chloritization, and argillization. Minor calcite, fluorite, quartz, sulfide minerals, and tourmaline are common in the altered rocks and hematite often occurs in the periphery of high-grade ore zones.

Age of mineralization:

Genetically related to the Jurassic, Bokan Mountain peralkaline granite (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997).

Deposit model:

U-Th-REE deposit associated with peralkaline granite stock.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Only several hand-dug pits and trenches prior to 2008. In 2008 and 2009, Ucore Uranium drilled a line of 24 holes for rare-earth elements at roughly equal intervals from near this prospect to the Carol Ann prospects (DE027), a distance of about 2,000 meters (Ucore Uranium, 2010). The line of holes follows the Dodson dike system. In 2010, Ucore drilled 13 infill holes along the Dodson Dike at roughly regular intervals from the I and L prospect (DE023), through the Atom Marietta prospect to the Carol Ann prospect (DE027) (Ucore, 2010 [News release]; Ucore, 2011). They also dug 45 trenches across the dike.

In 2009 and 2010, Ucore conducted airborne total magnetic field and radiometric surveys in order to map radiogenic rocks in order to directly locate uranium and rare earth mineralization with the radiometric survey, and to map structure and stratigraphy indirectly with the total magnetic field survey. In 2009, Ground total magnetic field and radiometric surveys were performed to map these zones prior to drilling. An induced polarization (IP) survey was run to attempt to discern controls on mineralization intersected in drillholes at this site. In 2010, 3,214 m of core were drilled in 13 holes (Bentzen and others, 2013). This exploration work from 2008-2010 led to the 2013 Preliminary Economic Assessment (Bentzen and others, 2013) and a 2013 updated resource estimate (Ucore Rare Metals Inc., 2013).

Production notes:

None.

Reserves:

With the partial results of the 2010 infill drilling, a new and considerably larger 'Conceptual Estimate' was made for the Dodson dike. The estimate was made using a model of a dike 2,425 meters long and 200 meters deep. The new figures are an 'Estimated contained mineralized tonnage' of from 3.5 to 6.5 million tonnes, and an 'Estimated grade TREO' of from 0.76 to 1.42 percent. (TREO = total rare earth elements.)

In October 2013, an upgraded resource estimate was reported combining Atom Marietta, I and L (DE023), and Carol Ann (DE027). The estimate was made using a model via five alternative total rare earth oxide (TREO) cut-off grades with a baseline case employing a TREO cut-off of 0.4 percent. The deposit has an indicated resources of 2,936,000 tonnes containing 39,731,596 pounds of TREO composed of 0.365 percent LREO, 0.249 percent HREO, and 0.614 percent TREO with a TREO cut-off of 0.4. It has an additional inferred resources of 1,995,000 tonnes containing 26,601,729 pounds of TREO composed of 0.366 percent LREO, 0.239 percent HREO, and 0.605 percent TREO with a TREO cutoff of 0.40 (Ucore Rare Minerals Inc., 2013).

Prospects

ARDF no.: DE027

Latitude: 54.9053 **Quadrangle:** DE D-1

Longitude: 132.1072

Location description and accuracy:

The three Carol Ann prospects are at the southeast end of the Dodson dike and its persistent. The coordinates are at near the center of the prospect area, about 1.9 miles southeast of Bokan Mountain, near the middle of the N1/2 section 26, T. 80 S., R. 88 E of the Copper River Meridian. The locations of the Carol Ann prospects relative to the other uranium and REE prospects in the vicinity of Bokan Mountain are best shown on Plate 1 of MacKevett (1963). The location is accurate, though degree of accuracy is not reported.

Commodities:

Main: Cb, Ce, Dy, Er, Eu, Gd, Ho, La, Lu, Nd, Pm, Pr, Sm, Tb, Th, Tm, U, Y, Yb, Zr

Other:

Ore minerals: Aeschynite, allanite, bastnaesite, columbite-tantalite, euxenite-polycrase, fergusonite, fluorite, monazite, parisite, pyrite, samarskite, synchysite, tengerite, thalenite, thorite, unnamed REE fluorocarbonate, uranothorite, xenotime, zircon

Gangue minerals: Albite, calcite, fluorite, hematite, quartz, tourmaline

Geologic description:

This and several other nearby uranium-thorium-REE deposits (DE015 to DE026 and DE028 to DE031) are spatially and genetically related to a stock of Jurassic, peralkaline granite about 2 miles in outcrop diameter centered on Bokan Mountain. It commonly is referred to as the Bokan Mountain peralkaline granite or Bokan Mountain complex. The intrusion and its deposits have been mapped in detail several times using slightly different subdivisions of the granite (MacKevett, 1963; Thompson and others, 1980, 1982; Saint-Andre and others, 1983; Gehrels, 1992; Thompson, 1997). This description largely follows Gehrels' (1992) map units. The intrusion is a ring-dike complex with an outer border zone up to 14 meters thick of pegmatite and aplite; a nearly complete intermediate zone of aegirine granite porphyry, 15 to 180 meters thick; and a core of several varieties of riebeckite granite porphyry. It has been dated by several methods at 151 Ma to 191 Ma (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997). The peralkaline granite mainly intrudes a regionally extensive body of Silurian or Ordovician quartz monzonite, granite, and quartz diorite that makes up much of the southeast tip of Prince of Wales Island. The south and west sides of the peralkaline granite are in contact with a band up to about 3,000 feet wide of shale and argillite of the Silurian or Ordovician Descon Formation. The Bokan Mountain complex and surrounding Paleozoic rocks are cut by numerous pegmatite, andesite, dacite, and aplite dikes. The dikes are genetically related to the complex and commonly are associated with the uranium, thorium, and REE deposits. The deposits are marked by intense albitization, pervasive or fracture-controlled chloritization, calcite-fluorite replacement of aegirine, and hematitization. Three types of U-Th-REE deposits occur in the Bokan Mountain complex: 1) irregular cylindrical pipes; 2) steep, shear-zone-related pods or lenses ('veins'); and 3) quartz veins.

MacKevett (1963) describes three prospects under the name Carol Ann as surface pits on three claims located in 1955. The prospects are on a series of steep, subparallel, allanite-bearing andesite dikes that strike

about N60-75W for at least 3,500 feet. The dikes radiate out from the Bokan Mountain peralkaline granite into Silurian or Ordovician quartz monzonite.

Warner and Barker (1989) describes these prospects under the name Dotson and extend the dikes northwest to the I & L Nos. 3-5 prospects (DE023) at the periphery of the Bokan Mountain alkaline granite. Several parallel dikes occur over a width of less than 100 feet to 200 feet; the individual dikes vary in width from 0.6 feet to 3.1 feet. To northwest, near the Bokan Mountain granite, the dikes are pegmatitic; to the southeast, they generally are medium- to fine-grained and equigranular. The mineralization occurs in microfractures or in the interstices between silicate grains. The dominant radioactive mineral is allanite. Scanning electron microscope study shows that the REE minerals are mainly thalenite, bastnaesite, and allanite, with subordinate tengerite, parisite, synchysite, an unnamed REE flurocarbonate mineral, monazite, and xenotime. The columbium-bearing mineral is mainly euxenite-polycrase, accompanied by subordinate columbite-tantalite, samarskite, fergusonite, and aeschynite. The main radioactive mineral is thorite but uranothorite is also present.

In 2008 and 2009, Ucore Uranium drilled a line of 24 holes for rare-earth elements at roughly equal intervals from near this prospect to the Atom Marietta prospect (DE024), a distance of about 2,000 meters (Ucore Uranium, 2010). The line of holes follows the Dodson dike system. The analyses for the samples were reported as the light rare-earth-element oxides or LREO (lanthanum, cerium, praesodymium, neodymium, and samarium) and the heavy rare-earth-element oxides or HREO (euroipium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, and yttrium); together they are termed the TREO, the total rare-earth-element oxides. Some of the notable intercepts are: 0.2 meter with 5.7 percent TREO, 0.4 meter with 3.0 percent TREO, 0.3 meter with 3.3 percent TREO, 0.8 meter with 3.5 percent TREO, 0.3 meter with 3.2 percent TREO, 0.25 meter with 4.4 percent TREO, 0.33 meter with 3.0 percent TREO, 0.83 meter with 5.4 percent TREO, 0.5 meter with 6.3 percent TREO, 0.6 meter with 4.5 percent TREO), 0.4 meter with 3.4 percent TREO, 0.5 meter with 4.0 percent TREO, and 0.4 meter with 3.4 percent TREO. Several of the holes had multiple intercepts of rare-earth-element mineralization and it is notable persistent along the whole line of holes. The ratio of the the HREO to the TREO in the better intercepts varied from about 24 percent to about 70 percent, but roughly about half of the rare-earth elements in the samples are the heavy rare-earth elements.

In 2010, Ucore drilled 20 more holes, including 13 infill holes along the Dodson Dike at roughly regular intervals from the I and L prospect (DE023), through the Atom Marietta prospect (DE024), to this prospect. (Ucore, 2010 [News release]; Ucore, 2011). They also dug 45 trenches across the dike. As known in early 2011, the Dodson dike has a strike length of at least 2,180 meters, averages 50 meters wide, extends from 300 meters above sea level to at least 150 meters below sea level, has remarkably persistent mineralization, and it is open along strike and down dip.

With this additional drilling on the Dodson dike, a new and considerably larger 'Conceptual Estimate' was made for the dike. The estimate was made using a model of a dike 2,425 meters long and 200 meters deep. The new figures are an 'Estimated contained mineralized tonnage' of from 3.5 to 6.5 million tonnes, with an 'Estimated grade TREO' of from 0.76 to 1.42 percent. (TREO = total rare earth elements.)

Alteration:

Age of mineralization:

Genetically related to the Jurassic, Bokan Mountain peralkaline granite (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997).

Generic deposit model:

Deposit model:

U-Th-REE deposit associated with peralkaline granite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Only prospect pits to 2008. In 2008 and 2009, Ucore Uranium drilled a line of 24 holes for rare-earth elements at roughly equal intervals from near this prospect to the Atom Marietta prospect (DE024), a distance of about 2,000 meters (Ucore Uranium, 2010). In 2010, Ucore drilled 13 infill holes along the Dodson Dike at roughly regular intervals from the I and L prospect (DE023), through the Atom Marietta prospect (DE024), to this prospect. (Ucore, 2010; Ucore, 2011). They also dug 45 trenches across the dike.

In 2009 and 2010, Ucore conducted airborne total magnetic field and radiometric surveys in order to map radiogenic rocks in order to directly locate uranium and rare earth mineralization with the radiometric survey, and to map structure and stratigraphy indirectly with the total magnetic field survey. In 2009, Ground total magnetic field and radiometric surveys were performed to map these zones prior to drilling. An induced polarization (IP) survey was run to attempt to discern controls on mineralization intersected in drillholes at this site. In 2010, 3,214 m of core were drilled in 13 holes (Bentzen and others, 2013). This exploration work from 2008-2010 led to the 2013 Preliminary Economic Assessment (Bentzen and others, 2013) and a 2013 updated resource estimate (Ucore Rare Metals Inc., 2013).

Although no exploration work was conducted in 2016, Ucore Rare Metals Inc. conducted mineral-separation tests on ore from their Bokan-Dotson Ridge rare-earth-element (REE) project in Southeast Alaska. The first batch of pregnant leach solution (PLS) derived from Bokan ore was treated by the SuperLig®-One Molecular Recognition Technology plant at IBC Advanced Technologies, Inc.’s Utah facility. Successful separations include: 1) separation of REE from gangue metals in the PLS; 2) greater than 99 percent purity of separation of light REE from heavy REE at greater than 99 percent recovery; 3) greater than 99 percent purity of separation and recovery of the sub-groups samarium-dysprosium (Dy sub-group) and holmium-lutetium (Ho sub-group) from the heavy REE class consisting of samarium and lutetium; and 4) greater than 99 percent separation of dysprosium from the Dy sub-group (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

With partial results from the 2010 infill drilling, a new and considerably larger 'Conceptual Estimate' was made for the Dodson dike. The estimate was made using a model of a dike 2,425 meters long and 200 meters deep. The new figures are an 'Estimated contained mineralized tonnage' of from 3.5 to 6.5 million tonnes, with an 'Estimated grade TREO' of from 0.76 to 1.42 percent. (TREO = total rare earth elements.)

In October 2013, an upgraded resource estimate was reported combining Carol Ann, I and L (DE023), and Atom Marietta (DE024). The estimate was made using a model via five alternative total rare earth oxide (TREO) cut-off grades with a baseline case employing a TREO cut-off of 0.4 percent. The deposit has an indicated resources of 2,936,000 tonnes containing 39,731,596 pounds of TREO composed of 0.365 percent LREO, 0.249 percent HREO, and 0.614 percent TREO with a TREO cut-off of 0.4, and an additional inferred resources of 1,995,000 tonnes containing 26,601,729 pounds of TREO composed of 0.366 percent LREO, 0.239 percent HREO, and 0.605 percent TREO with a TREO cutoff of 0.40 (Ucore Rare Minerals Inc., 2013).

A 2013 preliminary economic assessment for Ucore Rare Metals’ Bokan property states an inferred resource of 5.228 million tonnes grading 0.653 percent total rare-earth oxide (Bentzen and others, 2013); it includes the Dotson (DE027), and I-and-L zones (DE023).

Site name(s): Cheri; Cheri No. 1

Site type: Prospects

ARDF no.: DE029

Latitude: 54.8924 **Quadrangle:** DE D-1

Longitude: 132.1035

Location description and accuracy:

The Cheri prospects are centered about 0.7 mile south-southeast of the head of the West Arm of Kendrick Bay, near the center of the NE1/4 section 35, T. 80 S., R. 88 E., of the Copper River Meridian. Their locations relative to the other uranium and REE prospects in the vicinity of Bokan Mountain are best shown on Plate 1 of MacKevett (1963).

Commodities:

Main: Be, Cb, Ce, Dy, Er, Eu, Gd, Ho, La, Lu, Nd, Pm, Pr, Sm, Tb, Th, Tm, U, Y, Yb, Zr

Other:

Ore minerals: Allanite, hematite, magnetite, pyrite

Gangue minerals: Albite, quartz

Geologic description:

This and several other nearby uranium-thorium-REE deposits (DE015 to DE028 and DE030 to DE031) are spatially and genetically related to a stock of Jurassic, peralkaline granite about 2 miles in outcrop diameter centered on Bokan Mountain. It commonly is referred to as the Bokan Mountain peralkaline granite or Bokan Mountain complex. The intrusion and its deposits have been mapped in detail several times using slightly different subdivisions of the granite (MacKevett, 1963; Thompson and others, 1980, 1982; Saint-Andre and others, 1983; Gehrels, 1992; Thompson, 1997). This description largely follows Gehrels' (1992) map units. The intrusion is a ring-dike complex with an outer border zone up to 14 meters thick of pegmatite and aplite; a nearly complete intermediate zone of aegirine granite porphyry, 15 to 180 meters thick; and a core of several varieties of riebeckite granite porphyry. It has been dated by several methods at 151 Ma to 191 Ma (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997). The peralkaline granite mainly intrudes a regionally extensive body of Silurian or Ordovician quartz monzonite, granite, and quartz diorite that makes up much of the southeast tip of Prince of Wales Island. The south and west sides of the peralkaline granite are in contact with a band up to about 3,000 feet wide of shale and argillite of the Silurian or Ordovician Descon Formation. The Bokan Mountain complex and surrounding Paleozoic rocks are cut by numerous pegmatite, andesite, dacite, and aplite dikes. The dikes are genetically related to the complex and commonly are associated with the uranium, thorium, and REE deposits. The deposits are marked by intense albitization, pervasive or fracture-controlled chloritization, calcite-fluorite replacement of aegirine, and hematitization. Three types of U-Th-REE deposits occur in the Bokan Mountain complex: 1) irregular cylindrical pipes; 2) steep, shear-zone-related pods or lenses ('veins'); and 3) quartz veins.

MacKevett (1963) identified small pits and trenches at the Cheri prospects on several claims staked in 1956. The rocks in the vicinity consist of Ordovician, albitized quartz diorite and diorite, and a pendant of quartzite of the Descon Formation that cannot be delineated exactly in the heavily vegetated cover. The deposit at the Cheri prospects consists of system of radioactive andesite(?) dikes that strike about N 45 W and can be traced for at least 3,000 feet along strike (Warner and Barker, 1989). The zone of dikes is about 100 feet wide; it consists of several parallel dikes, 0.8 to 1.3 feet thick. The dikes are fine grained and siliceous. At one location, pyroxene-rich masses with minor pyrite, rare fluorite, and secondary uranium

minerals, occur in a dike. Chlorite, magnetite, pyrite, and epidote commonly occur at the margins of the dikes. Allanite is the principal radioactive mineral and the mineralogy is probably similar to that at the nearby Carol Ann/Dotson prospects (DE027), where similar dikes occur. The radioactive minerals are mainly concentrated in quartz veinlets or along mineralized fractures. At the Cheri No. 1 prospect, allanite in the interstices of quartzite is accompanied by abundant hematite and less-abundant albite, quartz, calcite, epidote, and chlorite.

In 2009, Ucore Uranium (2010) drilled two holes near the Cheri prospect for rare-earth elements. The analyses for the samples were reported as the light rare-earth-element oxides or LREO (lanthanum, cerium, praesodymium, neodymium, and samarium) and the heavy rare-earth-element oxides or HREO (europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, and yttrium); together they are termed the TREO, the total rare-earth-element oxides. The two most notable intercepts in one of the holes was 0.5 meter with 4.0 percent TREO, and 0.4 meter with 3.4 percent TREO. The ratio of the the HREO to the TREO in the two intercept was 39.4 and 46.1 percent; in other words nearly half of the rare-earth elements in the samples are the heavy rare-earth elements.

Warner and Barker (1989) estimate an indicated resource of 73,000 tons of rock in two portions of the Cheri dike system that contain 91,000 pounds of columbium, 32,000 pounds of thorium, 109,000 pounds of zirconium, 13,000 pounds of beryllium, 15,000 pounds of uranium, and 349,000 pounds of REE. There is an additional indicated resource of 458,000 short tons of rock in another portion of the dike system that contains 1,122,000 pounds of columbium, 338,000 pounds of thorium, 1,602,000 pounds of yttrium, 4,397,000 pounds of zirconium, 101,000 pounds of beryllium, 153,000 pounds of uranium, and 3,593,000 pounds of REE.

Alteration:

Age of mineralization:

Genetically related to the Jurassic, Bokan Mountain peralkaline granite.

Generic deposit model:

Deposit model:

U-Th-REE deposit in dikes associated with peralkaline granite stock.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

Only a few prospect pits to 2008. In 2009, Ucore Uranium drilled two holes for rare-earth elements.

Production notes:

None.

Reserves:

Warner and Barker (1989) estimate an indicated resource of 73,000 tons of rock in two portions of the Cheri dike system that contain 91,000 pounds of columbium, 32,000 pounds of thorium, 109,000 pounds of zirconium, 13,000 pounds of beryllium, 15,000 pounds of uranium, and 349,000 pounds of REE. Reporter(s): D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-02

Site name(s): Shore

Site type: Occurrence

ARDF no.: DE030

Latitude: 54.896 **Quadrangle:** DE D-1

Longitude: 132.0935

Location description and accuracy:

The Shore occurrence is in the intertidal zone in the vicinity of the point that juts out into the West Arm of Kendrick Bay near the northwest corner of section 36, T. 80 S., R. 88 E. The location of this occurrence relative to the other uranium and REE prospects in the vicinity of Bokan Mountain is best shown on Plate 1 of MacKevett (1963).

Commodities:

Main: Be, Cb, Ce, Dy, Er, Eu, Gd, Ho, La, Lu, Nd, Pm, Pr, Sm, Tb, Th, Tm, U, Y, Yb, Zr

Other: Pb, Sn, Sr, Ta

Ore minerals: Allanite?, pyrite, REE minerals?

Gangue minerals: Albite, quartz

Geologic description:

This and several other nearby uranium-thorium-REE deposits (DE015 to DE029 and DE031) are spatially and genetically related to a stock of Jurassic, peralkaline granite about 2 miles in outcrop diameter centered on Bokan Mountain. It commonly is referred to as the Bokan Mountain peralkaline granite or Bokan Mountain complex. The intrusion and its deposits have been mapped in detail several times using slightly different subdivisions of the granite (MacKevett, 1963; Thompson and others, 1980, 1982; Saint-Andre and others, 1983; Gehrels, 1992; Thompson, 1997). This description largely follows Gehrels' (1992) map units. The intrusion is a ring-dike complex with an outer border zone up to 14 meters thick of pegmatite and aplite; a nearly complete intermediate zone of aegirine granite porphyry, 15 to 180 meters thick; and a core of several varieties of riebeckite granite porphyry. It has been dated by several methods at 151 Ma to 191 Ma (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997). The peralkaline granite mainly intrudes a regionally extensive body of Silurian or Ordovician quartz monzonite, granite, and quartz diorite that makes up much of the southeast tip of Prince of Wales Island. The south and west sides of the peralkaline granite are in contact with a band up to about 3,000 feet wide of shale and argillite of the Silurian or Ordovician Descon Formation. The Bokan Mountain complex and surrounding Paleozoic rocks are cut by numerous pegmatite, andesite, dacite, and aplite dikes. The dikes are genetically related to the complex and commonly are associated with the uranium, thorium, and REE deposits. The deposits are marked by intense albitization, pervasive or fracture-controlled chloritization, calcite-fluorite replacement of aegirine, and hematitization. Three types of U-Th-REE deposits occur in the Bokan Mountain complex: 1) irregular cylindrical pipes; 2) steep, shear-zone-related pods or lenses ('veins'); and 3) quartz veins.

The Shore occurrence is in the intertidal zone on the south side of the West Arm of Kendrick Bay (Warner and Barker, 1989). Radioactive, granitic dike rubble and a few outcrops of dike occur along about 1,000 feet of shoreline. The dikes are in a 100-foot-wide zone near the contact of quartz monzonite and quartz diorite. The dikes strike N50W and dip steeply to vertical. They are generally 0.2 to 0.5 feet thick wide and there are intervals where thinner dikes closely parallel each other. The dikes vary from coarse grained to pegmatitic and commonly contain disseminated fluorite, pyrite, allanite(?), and REE(?) minerals. The quartz monzonite near the dikes locally is cut by pyritic, siliceous zones up to 30 feet wide. Samples

contained anomalously high columbium, uranium, thorium, REE, yttrium, zirconium, zinc, titanium, and beryllium. Some samples also contained elevated tin, tantalum, lead, and strontium. Three channel samples 1.1 feet long averaged 760 parts per million columbium. The dikes are unusually enriched in REE, especially cerium and neodymium; samples of dike material contained up to 2.5 percent REE.

In 2008, Ucore Uranium drilled one hole hear the Shore prospect for rare-earth elements along what they term the 'Geoduck trend' that is oriented northwest along the N50W granitic dike. In 2009, they drilled two more holes about 600 meters southeast along the trend at the Geoduck prospect (DE031).

Alteration:

Not specifically described; the dikes and their wallrocks are probably albitized and chloritized like those at the other REE deposits in the area.

Age of mineralization:

Genetically related to the Jurassic, Bokan Mountain peralkaline granite stock.

Generic deposit model:

Deposit model:

U-Th-REE deposit in dikes associated with peralkaline granite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Only surface sampling by government geologists to 2008. In 2008, Ucore Uranium drilled one hole for rare-earth elements.

Production notes:

None.

Reserves:

None.

Site name(s): Geoduck

Site type: Occurrences

ARDF no.: DE031

Latitude: 54.8887 **Quadrangle:** DE D-1

Longitude: 132.0853

Location description and accuracy:

The Geoduck occurrences are south of the West Arm of Kendrick Bay. They are related to a dike system that extends N40-50W for about 10,000 feet, nearly diagonally through the center of section 36, T. 80 S., R. 88 E. and into the NW1/4 of section 2, T. 81 S., R. 89 E. The site is approximately at the midpoint of the most continuous and thickest dike, where resource calculations have been made.

Main: Be, Cb, Ce, Dy, Er, Eu, Gd, Ho, La, Lu, Nd, Pm, Pr, Sm, Tb, Th, Tm, U, Y, Yb, Zr

Other:

Ore minerals: Allanite?, pyrite, REE minerals

Gangue minerals: Feldspar, quartz

Geologic description:

This and several other nearby uranium-thorium-REE deposits (DE015 to DE030) are spatially and genetically related to a stock of Jurassic, peralkaline granite about 2 miles in outcrop diameter centered on Bokan Mountain. It commonly is referred to as the Bokan Mountain peralkaline granite or Bokan Mountain complex. The intrusion and its deposits have been mapped in detail several times using slightly different subdivisions of the granite (MacKevett, 1963; Thompson and others, 1980, 1982; Saint-Andre and others, 1983; Gehrels, 1992; Thompson, 1997). This description largely follows Gehrels' (1992) map units. The intrusion is a ring-dike complex with an outer border zone up to 14 meters thick of pegmatite and aplite; a nearly complete intermediate zone of aegirine granite porphyry, 15 to 180 meters thick; and a core of several varieties of riebeckite granite porphyry. It has been dated by several methods at 151 Ma to 191 Ma (Lanphere and others, 1964; Saint-Andre and others, 1983; Armstrong, 1985; Gehrels, 1992; Thompson, 1997). The peralkaline granite mainly intrudes a regionally extensive body of Silurian or Ordovician quartz monzonite, granite, and quartz diorite that makes up much of the southeast tip of Prince of Wales Island. The south and west sides of the peralkaline granite are in contact with a band up to about 3,000 feet wide of shale and argillite of the Silurian or Ordovician Descon Formation. The Bokan Mountain complex and surrounding Paleozoic rocks are cut by numerous pegmatite, andesite, dacite, and aplite dikes. The dikes are genetically related to the complex and commonly are associated with the uranium, thorium, and REE deposits. The deposits are marked by intense albitization, pervasive or fracture-controlled chloritization, calcite-fluorite replacement of aegirine, and hematitization. Three types of U-Th-REE deposits occur in the Bokan Mountain complex: 1) irregular cylindrical pipes; 2) steep, shear-zone-related pods or lenses ('veins'); and 3) quartz veins.

The Geoduck occurrences are related to a system of equigranular, fine- to medium-grained, andesite dikes that strike N40-50W for about 10,000 feet, west of the head of Kendrick Bay (MacKevett, 1963; Warner and Barker, 1989). The dikes have steep to vertical dips, cut Silurian or Ordovician quartz monzonite, granite, and quartz diorite, and typically have wall rocks marked by chlorite and epidote alteration. The ore mineralogy has not been worked out in detail but it is probably similar to that in the mineralized dikes at the Carol Ann/Dotson prospects (DE027), which may be extensions of the Geoduck dikes. In the northwest part of the Geoduck dike system, individual dikes average about 1.4 feet thick; in the southeast part, they

average about 0.8 foot thick. Many samples contain elevated values of beryllium, thorium, yttrium, REE, columbium, uranium, and zirconium.

In 2009, Ucore Uranium (2010) drilled two holes near the Geoduck prospect for rare-earth elements. The holes are along what they term the 'Geoduck trend' that is oriented northwest along the andesite dike. The analyses for the samples were reported as the light rare-earth-element oxides or LREO (lanthanum, cerium, praesodymium, neodymium, and samarium) and the heavy rare-earth-element oxides or HREO (europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, and yttrium); together they are termed the TREO, the total rare-earth-element oxides. The most notable intercept in the two holes was 0.4 meter with 3.4 percent TREO. The ratio of the the HREO to the TREO in the three best intercepts varied between 41.9 and 46.6 percent; in other words nearly half of the rare-earth elements in the samples are the heavy rare-earth elements.

Warner and Barker (1989) estimate that a 3,000-foot section of the most continuous and thickest dike, which averages 1.5 feet thick, has an indicated resource of 1,378, 000 short tons of rock that contains 278,000 pounds of beryllium, 752,000 pounds of thorium, 8,116,000 pounds of yttrium, 8,786,000 pounds of REE, 2,844,000 pounds of columbium, 358,000 pounds of U, and 12,953,000 pounds of zirconium (Warner and Barker, 1989). There is a inferred reserve in 95,28,000 short tons of rock of 1,906,000 pounds of beryllium, 3,525,000 pounds of thorium, 29,975,000 pounds of yttrium, 14,864,000 pounds of columbium, 1,944,000 pounds of uranium, and 55,262,000 pounds of zirconium.

Alteration:

The dikes are probably albitized and chloritized; the wall rocks are marked by chlorite and epidote alteration.

Age of mineralization:

Associated with dikes that are genetically related to the Jurassic, Bokan Mountain peralkaline granite stock.

Generic deposit model:

Deposit model:

U-Th-REE deposit in dikes associated with peralkaline granite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Only surface sampling by government geologists to 2008. In 2009, Ucore Uranium drilled two holes.

Production notes:

None.

Reserves:

Warner and Barker (1989) estimate that a 3,000-foot section of the most continuous and thickest dike, which averages 1.5 feet thick, has an indicated resource of 1,378, 000 short tons of rock that contains 278,000 pounds of beryllium, 752,000 pounds of thorium, 8,116,000 pounds of yttrium, 8,786,000 pounds of REE, 2,844,000 pounds of columbium, 358,000 pounds of U, and 12,953,000 pounds of zirconium (Warner and Barker, 1989). ARDF no.: DI002

Latitude: 59.2751 **Quadrangle:** DI B-7

Longitude: 158.5342

Location description and accuracy:

The Red Top Mine is near the top of the southeastern peak of Marsh Mountain; the mine is plotted on the USGS B-7, 1:63,360-scale topographic map. It is at an elevation of about 1,100 feet, about 3.1 miles east of the village of Aleknagik, and about 0.6 mile south-southwest of the center of section 27, T. 10 S., R. 54 W. The location is accurate.

Commodities:

Main: Hg

Other:

Ore minerals: Cinnabar

Gangue minerals: Calcite, dickite, dolomite, hematite, limonite, quartz

Geologic description:

Placer cinnabar was discovered in 1941 in Arcana Creek, which drains east from the center of Marsh Mountain; follow-up exploration the next year discovered the lode deposits of the Red Top Mine (Sainsbury and MacKevett, 1965). The U.S. Defense Minerals Exploration Administration funded 10,000 feet of surface dozer trenching in 1952 and about 560 feet of underground workings in an adit and drifts in 1955. Subsequently, a lower adit and drifts totaling about 920 feet of underground workings were driven by mining companies. There was considerable drilling underground in the workings of the lower adit in 1958. C.L. Sainsbury mapped the surface and underground workings in 1959 (Sainsbury and MacKevett, 1965). Twenty-two flasks of mercury were produced from ore mined in the trenches and a total of 60 flasks of mercury were recovered by 1959. In 1959, the stockpiled ore was estimated to contain at least another 60 flasks of recoverable mercury (Sainsbury and MacKevett, 1965). Although Pennington (1959) reported that exploration had found ore that contained an estimated 1,400 flasks of mercury, production from the Red Top mine probably totaled about 100 flasks of mercury to the mid-1960s.

In 1969, Clayton Rasmusson leased the property and brought in a 20-ton mill (D.J. Grybeck, unpublished field notes, 1970). A 'raise', actually an irregular stope, was driven at the end of the lower adit from one of the better zones of mineralization. About 100 tons of ore was stockpiled that Rasmusson estimated to contain about one-half percent mercury. Some of the ore was concentrated at the mill and 3 flasks of mercury were retorted from it in Anchorage. Rasmussen estimated that the total production to 1970 was about 120 flasks of mercury. Apparently, there has been little work since 1971.

The host rocks for the Red Top cinnabar deposit are interbedded, very fine- to very coarse-grained graywacke, calcareous graywacke, and siltstone. Wilson and others (2006) include them in their 'Graywacke of Kululak Bay' unit of Middle and Upper Jurassic age. Individual beds vary from a few inches to several feet or more in thickness. The beds generally strike east to northeast and the rocks near the mine are broadly folded into a south-plunging syncline.

The principal controls on cinnabar mineralization are faults and breccia zones in massive graywacke. Faults in siltstone tend to be gouge-filled and tight; they commonly are not hosts for cinnabar deposits. The principal fault in the Red Top Mine strikes west to northwest and dips 45 to 80 degrees south. This arcuate reverse fault has had consistent right-lateral oblique slip, including some displacements that postdate

mineralization. It has been traced for a distance of about 1,250 feet at the surface and for 400 feet in the subsurface. Smaller subparallel faults and splays, generally striking west-northwest and dipping 40 to 50 degrees south, have been mapped in the subsurface, particularly in the hanging wall of the main fault (Sainsbury and MacKevett, 1965).

Cinnabar, the only sulfide mineral identified in the Red Top Mine, occurs in discrete small veins up to 4 inches thick that have been traced laterally up to 200 feet but are commonly only a few tens of feet long. Cinnabar also occurs as disseminations in fractured graywacke and in the carbonate gangue that cements graywacke breccia; as replacements of graywacke fragments and dolomite in breccia; and as breccia fragments in or along massive carbonate pods. Dolomite or ankeritic dolomite and later calcite are the most common gangue minerals. The carbonate minerals occur as discontinuous pods and lenses along the faults and as cement in breccia. Other gangue minerals include hematite, limonite, scarce quartz, and fairly common dickite (Sainsbury and MacKevett, 1965). The grade of mineralization varies greatly. Production has been from selected high-grade material. A sample of muck from a lower adit drift assayed 0.59 percent Hg, and a large grab sample from the lower adit dump assayed 1.09 percent Hg (Sainsbury and MacKevett, 1965). Two cinnabar-rich samples from the Red Top Mine contained less than 10 parts per billion gold Au and 150 and 7,000 parts per million antimony (Hawley and others, 1969).

Surface sampling of soils and nearby stream sediments suggests that the area surrounding the Red Top Mine on Marsh Mountain may contain other occurrences of mercury mineralization (Eakins, 1968). Cinnabar reported from Wood River gravels in the vicinity could have been derived from the Red Top deposit (Malone, 1962).

Alteration:

Hematite and limonite, closely associated with cinnabar and dickite, line the walls of some veins.

Age of mineralization:

Late Cretaceous or Tertiary. The Red Top deposit postdates regional deformation of the host Jurassic (?) sedimentary rocks and is probably similar in age to other mercury deposits of southwest Alaska that postdate regional deformation of Cretaceous sedimentary rocks.

Generic deposit model:

Deposit model:

Cinnabar vein and breccia deposits (Cox and Singer, 1986; model 27b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

27b

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

Placer cinnabar was discovered in 1941 in Arcana Creek, which drains eastward from the center of Marsh Mountain. Follow-up exploration the next year discovered the lode deposits that became the Red Top Mine (Sainsbury and MacKevett, 1965). The U.S. Defense Minerals Exploration Administration funded 10,000 feet of surface dozer trenching in 1952 and the driving of a upper adit and drifts totaling 560 feet of underground workings in 1955. Subsequently, a lower adit and drifts totaling about 920 feet of underground workings was driven by mining companies. Exploration drilling was completed from the lower adit workings in 1958. C. L. Sainsbury mapped the surface and underground workings in 1959 (Sainsbury and MacKevett, 1965).

In 1969, Clayton Rasmusson leased the property, revitalized the camp, and brought in a 20-ton mill (D.J. Grybeck, unpublished field notes, 1970). A 'raise', actually a irregular stope, was driven at the end of the lower adit from one of the better zones of mineralization. About 100 tons of ore was stockpiled that Rasmusson estimated to contain about 1/2-percent mercury. Some of the ore was concentrated at the mill

and 3 flasks of mercury were retorted from it in Anchorage.

Production notes:

Surface trenching exposed ore from which 22 flasks of mercury were recovered and a total of 60 flasks of mercury were recovered from surface and underground workings by 1959. In 1959, the stockpiled ore was estimated to contain at least another 60 flasks of mercury (Sainsbury and MacKevett, 1965). Although Pennington (1959) reported that exploration had found ore that contained an estimated 1,400 flasks of mercury. Clay Rasmussen (personal communication, 1970) estimated that the total production to 1970 was about 120 flasks of mercury. Apparently, there has been no production since 1971.

Reserves:

Pennington (1959) suggested that the Red Top Mine contained 1,4000 flasks of mercury. Three flasks were produced in the early 1970's but there has been no production since 1971.

Last report date: 2010-04-02

Site name(s): Humble; Kemuk

Site type: Prospect

ARDF no.: DI003

Latitude: 59.7203 **Quadrangle:** DI C-5

Longitude: 157.67

Location description and accuracy:

The Humble prospect is 12 miles east-northeast of the summit of Kemuk Mountain. The prospect is centered near the southwest corner of section 20, T. 5 S., R. 49 W. It is in an area of extensive surficial deposits with few conspicuous topographic features and little outcrop. The location is accurate to within 1 mile.

Commodities:

Main: Cu, Fe

Other: Ti, platinum-group metals?

Ore minerals: Titaniferous magnetite

Gangue minerals:

Geologic description:

The Humble prospect is above a pronounced 4-mile-square magnetic anomaly identified in an aeromagnetic survey flown for Humble Oil and Refining Company in 1959 (Berg and Cobb, 1967). The anomaly reflects a large composite mafic and ultramafic body beneath 90 to 140 feet of unconsolidated Quaternary deposits. The pluton was explored by 16 diamond drill holes as the Kemuk prospect, some holes down to a depth of almost 2,000 feet. It is a composite, tabular, southeast-dipping body of clinopyroxenite with some olivine-bearing and hornblende-bearing rocks ((Nokleberg and others, 1987; T. Hinderman, personal communication, 2000). The country rocks cut by the drilling are hornfels and quartzite. The body contains much titaniferous magnetite that probably occurs as segregations and disseminations in the clinopyroxenite. The body was estimated to have a resource of 2.4 billion long tons that average 15 to 17 percent total iron (Nokleberg and others, 1987). A beneficiation test indicates the feasibility of producing a concentrate containing 65 percent Fe, 2 to 3 percent SiO2, 0.005 to 0.016 percent P2O5, and 2 to 3 percent TiO2.

In 2010, Millrock Resources staked a large block of claims over the body, calling it the Humble prospect. Millrock with funding provided by Kinross Gold Corp., began drilling in August of 2011 (Millrock, 2012). The drilling was begun to test the idea that the body was similar to the gabbro body (IL005) peripheral to the large Pebble copper-gold porphyry deposit (IL007) which features similar geochemistry and geophysical characteristics. In September, 2011, Millrock reported that the drilling was not going well (Millrock Resources Inc., 2011).

Alteration:

Age of mineralization:

The age of the body is not known. The age of the country rocks is uncertain; from regional trends, they could be clastic sedimentary rocks of either Jurassic or Cretaceous age (Decker and others, 1994).

Generic deposit model:

Deposit model:

Titaniferous magnetite in clinopyroxenite; Alaska PGE? (Cox and Singer, 1986; model 9?); Porphyry Cu-Au-(Mo) (Cox and Singer, 1986; model 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

9?, 20c

Production Status: None

Site Status: Active

Location description and accuracy:

This prospect is within a block of 88 State of Alaska mining claims on the east side of the lower Mulchatna River about 10 miles northeast of its mouth. The center of the block is near the northeast corner of section 1, T. 9 S., R. 44 W., of the Seward Meridian.

Commodities:

Main: Cu?

Other: Au?

Ore minerals:

Gangue minerals:

Geologic description:

The D Block claims were originally staked by Rio Algom in 2000 on overlapping aeromagnetic and IP anomalies. The prospect is in an area of extensive alluvial deposits and bedrock is not exposed. Two drill holes were attempted in 2003 by the TNR Gold Corporation (Chapman, 2004). IL-D-01 reached a total depth of 129.3 meters (424 feet) in unconsolidated deposits and did not reach bedrock. Il-D-02 was inclined 80 degrees southeast from a location 1.5 km northwest of IL-D-01. This hole also did not reach bedrock after passing through 104.9 meters (344 feet) of unconsolidated deposits. The unconsolidated deposits in these two holes were mostly silt, and fine sand, with minor fine gravel. This prospect essentially remains a geophysical anomaly. Drilling equipment has been moved to the prospect as of April 27, 2006 and the plan is to drill at least 250-meter holes to test the geophysical anomaly (TNR Gold Corporation, 2006).

Workings/exploration:

The D Block prospect was discovered as a result of regional geophysical surveys in a search for Pebble-like (ARDF DI007) porphyry copper-gold deposits. Rio Algom contracted a 7,468-kilometer-long (4,640 mile) aeromagnetic survey; the flight line spacing was 1,600 meters and the survey was flown at an altitude of 300 meters. This survey was followed up by IP surveys over 7 anomalies identified by the aeromagnetic survey. Two of these anomalies, D Block and H Block (DI012) were subsequently staked. BHP-Billiton Minerals International controlled these prospects when they were optioned to TNR Gold Corp. in 2002. TNR Gold Corp. in turn optioned the D Block to Geocom Resources Inc. in 2003. Geocom completed two diamond drill holes (Il-D-01 and IL-D-02) on the D Block prospect in August and September 2003. Drilling equipment has been moved to the prospect as of April 27, 2006 and the plan is to drill at least 250-meter holes to test the geophysical anomaly (TNR Gold Corporation, 2006).

Production notes:

None.

Reserves:

None.

Site name(s): H Block

Site type: Prospect

ARDF no.: DI012

Latitude: 59.3898 **Quadrangle:** DI B-2

Longitude: 156.6868

Location description and accuracy:

The H Block prospect consists of 149 State of Alaska mining claims approximately centered at the northeast corner of section 22, T. 9 S., R. 44 W., of the Seward Meridian, i.e., at about the center of the township. The center of these claims is about 5.3 miles west of triangulation station Yellow Hill 2, which is about 22 miles north-northeast of the village of Lovelock.

Commodities:

Main: Cu

Other: Au

Ore minerals: Chalcopyrite, pyrite, pyrrhotite

Gangue minerals: Biotite, carbonate, chlorite, potassium feldspar, quartz, sericite

Geologic description:

The H Block prospect is in an area of extensive glacial outwash about 8 km west of a terminal moraine complex associated with the west end of Iliamna Lake. Because bedrock is not exposed, the geology of the prospect is only known from two diamond drill holes by TNR Gold Corporation (Chapman, 2004).

Il-H-01 is a vertical drill hole drilled in the center of a positive magnetic anomaly. It went through 67.1 meters (220 feet) of sand, silt, and fine gravel deposits to bedrock. Bedrock is a metasedimentary and metavolcanic (?) sequence that extended to the bottom of the hole at a depth of 208.8 meters (685 feet). The entire bedrock sequence was variably altered and mineralized. Petrographic descriptions (Chapman, 2004, Appendix B) indicate that at least some of these rocks are hornfels and calc-silicate rocks containing biotite-amphibole-plagioclase, plagioclase-clinopyroxene-quartz-sphene, and plagioclase-biotite-orthopyroxene assemblages. These rocks may be altered volcanic rocks and/or skarn. Granitic dikes were also encountered. The alteration varies from weak sericite, carbonate, and chlorite alteration to strong biotite veining and replacement. Secondary potassium feldspar was identified in and adjacent to some veins and fractures. Chalcopyrite, pyrite, and pyrrhotite occur both as disseminations and in veins and fractures but the veining is generally weakly developed. The sulfide-bearing veins commonly include quartz +/- carbonate. Some fractures contain sulfide linings and lack gangue minerals.

Drill hole Il-H-02 was located about 1 km west of Il-H-01 and inclined -70 degrees east. It targeted an IP anomaly on the flank of a positive magnetic anomaly. It intersected 85.4 meters (280 feet) of sand, silt, and fine gravel overlying medium- to coarse-grained granodiorite. This hole terminated in a fine- to medium-grained granitic intrusive (dike?) at a depth of 254.6 m (835 feet). The granodiorite varies from unaltered to extensively altered with chlorite, carbonate, and sericite replacement, local silicification, and secondary potassium feldspar and biotite adjacent to fractures. Sulfides in IL-H-02 are disseminated and fracture-controlled chalcopyrite, pyrite, and pyrrhotite similar in occurrence to that in IL-H-01.

Assay results are fairly consistent over long intervals in these holes (Chapman, 2004). In Il-H-01, 141.8 meters (465 feet) contained 0.0195 gram of gold per ton and 231 parts per million (ppm) copper. The bottom 73 m (240 feet) contained 0.02 gram of gold per ton and 244 ppm copper. The best assays were 0.068 gram of gold per ton and 601 ppm copper over 1.5 meter (5 feet) and 0.044 gram of gold per ton and 709 ppm copper over 3 meters (10 feet). In Il-H-02, the entire 168.6 meters (553 feet) of bedrock averaged

0.0484 gram of gold per ton and 212 ppm copper. The high values included 3 meters (10 feet) of 0.0535 gram of gold per ton and 235 ppm copper and 1.5 meter (5 feet) of 0.037 gram of gold per ton and 1,125 ppm copper.

The initial exploration shows that a porphyry copper-gold system is present at the H Block prospect. This system is buried by 200 feet or more of glacial outwash deposits where it has been drilled.

Alteration:

The granodiorite varies from unaltered to extensively altered, with chlorite, carbonate, and sericite replacement, local silicification, and secondary K-feldspar and biotite adjacent to fractures.

Age of mineralization:

The age of this mineralization is assumed to be Late Cretaceous or early Tertiary based on the general age of intermediate intrusive rocks north of the prospect (Wilson and others, 2003). The similar (?) Pebble porphyry copper-gold deposit (ARDF IL007) nearby has been dated at 89.7 Ma.

Generic deposit model:

Deposit model:

Porphyry Cu-Au (Cox and Singer, 1986, model 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

The H Block prospect was discovered as a result of regional geophysical surveys meant to locate Pebble-like (ARDF IL007) porphyry copper-gold deposits. In 2000, Rio Algom contracted a 7,468-kilometer-long (4,640 miles) aeromagnetic survey; the flight line spacing was 1,600 meters and it was flown at an altitude of 300 meters. This survey was followed up by ground IP surveys over 7 anomalies identified by the aeromagnetic survey. Two of these anomalies, H Block and D Block (DI011) were subsequently staked. BHP-Billiton Minerals International controlled these prospects when they were optioned to TNR Gold Corp. in 2002. TNR Gold Corp. in turn optioned the H Block to Geocom Resources Inc. in 2003. Geocom completed two diamond drill holes (Il-H-01 and IL-H-02) on the H Block prospect in August and September 2003. In late summer 2004, Geocom completed a 47 kilometer (28 miles) three-dimensional induced polarization-resistivity survey in the area of IL-H-01 and IL-H-02 in the H Block prospect. This survey identified several anomalies, some of which were tested in the fall of 2004 by five more drill holes (http://www.tnrgoldcorp.com/news/tnr_050605.asp; May 6, 2005). One of these holes, IL-H-06 encountered drilling problems and did not reach bedrock.

Site name(s): Unnamed (near tributary to Arcana Creek)

Site type: Mine

ARDF no.: DI013

Latitude: 59.28 **Quadrangle:** DI B-7

Longitude: 158.535

Location description and accuracy:

This placer mine is near the mouth of an unnamed tributary to Arcana Creek in the central part of Marsh Mountain. This is the small creek that drains north from the Red Top Mine (DI002) for about 0.4 mile. The placer mine is about about 0.3 mile west of the center of section 27, T. 10 S., R. 55 W., of the Seward Meridian.

Commodities:

Main: Hg

Other:

Ore minerals: Cinnabar

Gangue minerals:

Geologic description:

Placer cinnabar has been known on Arcana Creek since 1941, when the cinnabar was traced upstream to discover the Red Top Mine (DI002) ((Sainsbury and MacKevett, 1965). Apparently, however, no placer mining took place on Arcana Creek or its tributaries until 1969, when Clarence Wren of Dillingham operated a small placer mine about 0.4 mile north of the Red Top Mine on the creek that extends north from the mine (Clarence Wren, personal communication, 1970; D.J. Grybeck, unpublished field notes, 1970). Panned samples from the lower part of the creek were often exceptionally rich in cinnabar with nuggets up to 1/2 inch in size; pans in the upper part of the creek where it flowed on bedrock had only small amounts of cinnabar. In 1969, Wren mined with with indifferent results using a front-end loader, D6 tractor, and a sluice box. He attributed the results to inexperience and inappropriate recovery methods. About 5 gallons of cinnabar concentrate was produced. Apparently, there has been no mining since. The source of the cinnabar is almost certainly the Red Top deposit at the head of this creek.

The rocks in the area consist of interbedded, very fine- to very coarse-grained graywacke, calcareous graywacke, and siltstone. Wilson and others (2006) include them in their 'Graywacke of Kululak Bay' unit of Middle and Upper Jurassic age.

Alteration:

Age of mineralization:

Placer in Quaternary gravel.

Reporter(s): D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-02

Site name(s): Monk's Hood

Site type: Mine

ARDF no.: DI014

Latitude: 59.2814 **Quadrangle:** DI B-7

Longitude: 158.5427

Location description and accuracy:

The Monk's Hood Mine is about in the middle of the Marsh Mountain area, about 0.3 mile east of the center of section 28, T. 10 S., R. 55 W., of the Seward Meridian and about 0.6 mile northwest of the Red Top Mine (DI002). The location is accurate.

Commodities:

Main: Hg

Other:

Ore minerals:

Gangue minerals: Calcite, dolomite

Geologic description:

In 1969, William Carlson and Edward Gentzwill as the Arcana Creek Mining Company, began prospecting in the headwaters of Arcana Creek, northwest of the Red Top Mine (DI002). They employed the classical methods of digging pits to bedrock along the creek and panning the samples (D.J. Grybeck, unpublished field notes, 1970, after discussions with Carlson and Gentzwill). They followed encouraging pans that contained cinnabar up the headwater tributary of Arcana Creek which flows eastward in the center of section 28, and then dug pits up to 8 feet deep up the hillside to the south, about 0.3 mile east of the center of the section. (They also prospected up the tributary that extends northwest in the NE 1/4 of section 28; there was little cinnabar in the pans for a short distance and then none at all.)

The rocks in the area are interbedded, very fine- to very coarse-grained graywacke, calcareous graywacke, and siltstone. Wilson and others (2006) include them in their 'Graywacke of Kululak Bay' unit of Middle and Upper Jurassic age.

The pits and hand trenching on the hillside uncovered two good shows of mineralization. The best is a 1/2- to 3-inch vein of carbonates with disseminated and massive cinnabar that extends for at least 100 feet; it strikes N 80 E and dips 70S. The other is along a gouge zone several inches thick that strikes N 70 E and dips 18S; at one place along it there was a disseminated-cinnabar-bearing carbonate lens about 8 feet long, 4 feet deep, and about 18 inches thick. In 1969, about 700 pounds of ore was hand mined from these showings and a flask of mercury was retorted from it. Some trenching with a tractor was attempted in 1969 but the hillside has discontinuous permafrost and the trenching generally did not reach bedrock. It is unclear whether there was work after 1970 but Carlson and Gentzwill found considerable mineralized float above and below the pits that exposed the mineralization. The mineralization is similar to that at the nearby Red Top Mine (DI002).

Alteration:

Not specifically noted but probably similar to that at the better-known, nearby Red Top Mine (DI002).

Age of mineralization:

Jurassic or younger based on the age of the host rocks; probably Cretaceous or Tertiary by analogy with other mercury deposits in southwestern Alaska.

Generic deposit model:

Deposit model:

Cinnabar veins (Cox and Singer, 1986; model 27b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

27b

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

In 1969, William Carlson and Edward Gentzwill as the Arcana Creek Mining Company, began prospecting in the headwaters of Arcana Creek, northwest of the Red Top Mine (DI002). They employed the classical methods of digging pits to bedrock along the creek and panning the samples (D.J. Grybeck, unpublished field notes, 1970, after discussions with Carlson and Gentzwill). They followed encouraging pans that contained cinnabar up the headwater tributary of Arcana Creek which flows eastward in the center of section 28, and then dug pits up to 8 feet deep up the hillside to the south, about 0.3 mile east of the center of the section. (They also prospected up the tributary that extends northwest in the NE 1/4 of section 28; there was little cinnabar in the pans for a short distance and then none at all.) Some trenching with a tractor was attempted in 1969 but the hillside has discontinuous permafrost and the trenching generally did not reach bedrock. It is unclear whether there was work after 1970.

Production notes:

One flask of mercury was retorted from 700 pounds of ore mined by hand from surface pits.

Reserves:

Probably none.

Last report date: 2010-04-02

Site name(s): Red Dog; Qanaiyaq; Hilltop; Aqqaluk; Paalaaq

Site type: Mine

ARDF no.: DL001

Latitude: 68.0704 **Quadrangle:** DL A-2

Longitude: 162.8379

Location description and accuracy:

This record describes the main Red Dog deposit mined since 1989, and the nearby Qanaiyak (Hilltop), Aqqaluk, and Paalaaq deposits that are part of the Red Dog mine. The map site is at the open pit of the main deposit, 2 miles northwest of Deadlock Mountain in section 20, T. 31 N., R. 18 W., of the Kateel Meridian. The Qanaiyak (Hilltop) deposit is one mile south of the main deposit; Aqqaluk is 1,500 feet north of the Main deposit, across Red Dog Creek, and Paalaaq is just east-northeast of Aqqaluk. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Pb, Zn

Other: As, Ba, Cu, Sb

Ore minerals: Barite, bornite, boulangerite, chalcopyrite, covellite, galena, marcasite, polybasite, pyrite, pyrrhotite, sphalerite, tetrahedrite

Gangue minerals: Quartz

Geologic description:

The DeLong Mountains are characterized by stacked and folded, thrust allochthons (Ellersieck and others, 1990; Kelley and Jennings, 2004; [Supplemental map]). The structurally lower allochthons are composed of Devonian through Cretaceous clastic and chemical sedimentary rocks. The two uppermost allochthons contain Jurassic or older mafic and ultramafic igneous sequences. Minor igneous rocks of basic composition are exposed 0.6 mile northeast of Red Dog (Kulas, 1992).

The Red Dog deposit is a shale-hosted, sedimentary exhalite deposit (SEDEX) deposit (Kelley and Jennings, 2004). The deposit is in multiple, superimposed thrust fault slices of stratabound, massive sulfides and barren mudstones. The host rock is black, siliceous shale and chert of the Ikalukrok unit of the Mississippian to Pennsylvanian Kuna Formation (Dumoulin and others, 2004). The Kivalina unit, an interbedded calcarenite and calcareous shale, is the footwall of the deposit. Mineralization is syngenetic with respect to sediment deposition. Silicification occurs within and peripheral to the main mass of sulfides. A barite facies is concentrated toward the top and periphery of the deposit. Major sulfides in decreasing order of abundance are sphalerite, pyrite, marcasite, and galena. Rare disseminated chalcopyrite and pyrrhotite occur in the sphalerite. The ore textures are massive, fragmental, chaotic, and veined; they rarely show typical sedimentary layering (Kelley, Leach, and others, 2004). The upper portion of the ore body is oxidized. The deposit is weakly enriched upward in lead relative to zinc.

The Main deposit consists of two major mineralized thrust fault slices and one lesser mineralized fault slice. It extends 1,600 meters in a northwest direction and varies in width from 150 to 975 meters. High-grade portions of the deposit are up to 135 meters thick. The base of the Main deposit is a tectonic melange zone which separates it from the Cretaceous Okpikruak Formation.

The Qanaiyaq (the old Hilltop) ore body is a horizontal klippe of the same ore body as the Main deposit (Moore and others, 1986). The mineralized zone is 490 meters long by 245 meters wide and the exhalite package is less than 100 meters thick. The mineral assemblage is similar to that at the Main deposit except that it locally contains significant amounts of chalcopyrite, covellite, and bornite. The deposit contains 0.3

percent copper with gold values of about 1 gram per tonne. The presence of copper and gold may indicate that this deposit formed near a vent (Kulas, 1992).

The Aqqaluk ore body was discovered north of the main deposit across Red Dog Creek during a drilling program in 1995. The ore is similar to that at the Main deposit. Sphalerite and galena occur in silica rock, barite and shale. Sulfides are disseminated, semi-massive to massive, and rarely laminated. Late crosscutting sulfide veins and stringers occur in the host shale and occasionally in the exhalites.

The Paalaaq ore body is the newest and deepest exploration target in the Red Dog complex.

Kelley, Leach and others (2004) suggest that the mineralization took place by: 1) deposition of early brown sphalerite with abundant barite, minor pyrite, and trace galena immediately beneath the sea floor in unconsolidated mud; 2) deposition of yellow-brown sphalerite during subsea-floor hydrothermal recrystallization and coarsening of preexisting barite; 3) open-space deposition of barite, red-brown sphalerite and other sulfides in veins, and coeval replacement of barite; and 4) post-ore sulfide deposition, including the formation of late tan sphalerite breccias. Sedimentological, faunal, and geochemical data indicate that the Kuna Formation formed in slope and basin settings characterized by anoxic or dyosoxic bottom water (Dumoulin and others, 2004). The mineralization has been dated at 338 Ma by Re-Os methods but has been subject to later thermal overprinting during episodes of the Brooks Range orogeny (Romback and Layer, 2004).

Mineralization at Red Dog was first reported in 1968 by the U.S. Geological Survey (Tailleur, 1970). In 1975, the U.S. Bureau of Mines conducted a mineral examination of the Red Dog site. Active exploration of the site and adjacent area began in 1975 and the first claims were staked in 1978. In 1980, Cominco Alaska drilled 9 holes that totaled 915 meters; extensive surface mapping, sampling, and geochemical and geophysical surveys followed through the the 1980s. Mining began in 1989 from an open pit that is still in operation in early 2011. However, the main ore body of the Red Dog mine will be exhausted within a few years and mining has shifted to the Aqqaluk ore body where mining began in 2011 (Nana Regional Corp, 2011). The mine was developed under an innovative operating agreement between the NANA Regional Corporation, owned by the Inupiat people of Northwest Alaska, and Teck Alaska Incorporated, a U.S. subsidiary of Teck Resources Limited (Nana Regional Corp., 2011).

The mine has been in operation continually since 1989 and from 1999 to 2009 it has produced from about 3.2 to 3.7 tons of ore a year. The production in 2009 was 3.729 million tons of ore that recovered 642,096 tons of zinc, 144,954 tons of lead, and 8.12 million ounces of silver (Szumigala and others, 2010).

As of December, 2009, the Red Dog mine has: 1) 10.14 million tons of proven reserves with a grade of 20.0 percent zinc and 5.4 percent lead; 2) 57.52 tons of probable reserves with a grade of 16.6 percent zinc and 4.4 percent lead; 3) 6.50 million tons of indicated resources with a grade of 20.0 percent zinc and 6.6 per lead; and 4) 34.16 million tons of inferred resources with a grade of 11.0 percent zinc and 4.0 percent lead (Szumigala and others, 2010). The 2009 probable reserves are almost entirely in the Aqqaluk ore body whose 2011 reserves are 51.6 million tons with a grade of 16.7 percent zinc, and 4.4 percent lead (Nana Regional Corp., 2011). This Aqqaluk ore is thought to prolong the life of the mine to 2031. Red Dog indicated mineral resources as of December 31, 2006 for the Aqqaluk deposit are 3.0 million tonnes at 11.2 percent zinc, 4.0 percent lead, and 85 grams of silver per tonne and for the Qanaiyaq deposit indicated resources are 4.7 million tonnes at 23.7 percent zinc, 6.2 percent lead, and 127 grams of silver per tonne (Cinits and others, 2007).

Mining began in 1989 from an open pit called Red Dog Main pit; this was in operation until the first quarter of 2012, when it was exhausted. All future ore will come from the Aqqaluk deposit (Teck, 2014a). The mine life of the Aqqaluk deposit is expected to go through 2031. The Qanaiyaq deposit is higher grade than Aqqaluk and will supplement declining grades in later years from Aqqaluk with an expected mine life from 2016 to 2025 (Cinits and others, 2007).

In 2016, Teck Alaska Inc. mined the Aqqaluk deposit portion of their Red Dog deposit; zinc production increased to 583,000 tonnes compared with 567,000 tonnes in 2015, primarily due to increased mill throughput as softer ores were processed. The zinc grade was 17.1 percent, with an 82.8 percent recovery rate. Lead production in 2016 rose to 122,300 tonnes, compared to 117,600 tonnes in 2015, primarily due to higher mill throughput. The lead grade was 4.9 percent, with a 56.0 percent recovery rate. In 2016, Teck Alaska Inc. mined 13,704,000 tonnes of material and milled 4,250,000 tonnes of ore. In 2016, Teck began development of its Qanaiyaq deposit, a near-surface deposit located immediately south of the mined-out Red Dog Main pit. This high-grade deposit hosts 7.4 million tonnes of reserves averaging 24.7 percent Zn and 6.9 percent Pb; production at Qanaiyaq is scheduled to begin in early 2017 (Athey and Werdon, 2017).

Alteration:

Silicification of host mudstone (Kelley, Leach, and others, 2004).

Age of mineralization:

Mineralization is syngenetic to sediment deposition which has been dated to 338 Ma by Re-Os methods (Kelley, Leach, and others, 2004).

Generic deposit model:

Deposit model:

Sedimentary exhalative Zn-Pb (Cox and Singer, 1986; model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31a

Production Status: Yes; large

Site Status: Active

Workings/exploration:

Mineralization at Red Dog was first reported in 1968 by the U.S. Geological Survey (Tailleur,1970). In 1975, the U.S. Bureau of Mines conducted a mineral examination of the Red Dog site. Active exploration of the site and adjacent area began in 1975 and the first claims were staked in 1978. In 1980, Cominco Alaska drilled 9 holes that totaled 915 meters; extensive surface mapping, sampling, geochemical and geophysical surveys, and much additional drilling followed through the 1980s. Teck has been conducting ongoing exploration work, including geological mapping, geochemistry, geophysical surveys, and drilling, around the Red Dog Property except for a hiatus between 1990 and 1994. Various geophysical survey methods have been used including airborne electromagnetics (EM), induced polarization (IP), controlled source, audio-frequency magneto-tellurics (CSAMT), time-domain electromagnetics (TEM), University of Toronto electromagnetometer (UTEM), and gravity. The discovery of the Anarraaq deposit was attributed to the use of gravity (Cinits and others, 2007).

Mining began in 1989 from an open pit called Red Dog Main pit; this was in operation until the first quarter of 2012, when it was exhausted. All future ore will come from the Aqqaluk deposit (Teck, 2014a). The mine life of the Aqqaluk deposit is expected to go through 2031. The Qanaiyaq deposit is higher grade than Aqqaluk and will supplement declining grades in later years from Aqqaluk with an expected mine life from 2016 to 2025. Red Dog indicated mineral resources as of December 31, 2006 for the Aqqaluk deposit are 3.0 million tonnes at 11.2 percent zinc, 4.0 percent lead, and 85 grams of silver per tonne and for the Qanaiyaq deposit indicated resources are 4.7 million tonnes at 23.7 percent zinc, 6.2 percent lead, and 127 grams of silver per tonne (Cinits and others, 2007).

Teck Alaska Inc. continued to explore on their Noatak project near its' existing Red Dog mine in northwest Alaska in 2016. The project area includes the Anarraaq-Aktigiruq deposits, where Teck Alaska Inc. drilled a total of 29,800 feet (9,083m) (Athey and Werdon, 2017).

Production notes:

The mine was developed under an innovative operating agreement between the NANA Regional Corporation, owned by the Inupiat people of Northwest Alaska, and Teck Alaska Incorporated, a U.S. subsidiary of Teck Resources Limited (Nana Regional Corp., 2011). The mine has been in operation continually since 1989 and from 1999 to 2009, it has produced from about 3.2 to 3.7 million tons of ore a year. However, the main ore body of the Red Dog mine will be exhausted in a few years and mining has shifted to the Aqqaluk ore body, where mining began in 2011 (Nana Regional Corp., 2011). The production in 2009 was 3.729 million tons of ore that recovered 642,096 tons of zinc, 144,954 tons of lead, and 8.12 million ounces of silver (Szumigala and others, 2010).

The production in 2011 was 572,000 tonnes zinc concentrate (Teck, 2013). The production in 2012 was 529,000 tonnes zinc concentrate at 18.2 percent zinc and 96,700 tonnes lead concentrate at 3.9 percent lead.

The production in 2013 was 551,000 tonnes of zinc concentrate at 17.0 percent zinc and 95,400 tonnes lead concentrate at 4.6 percent lead (Teck, 2014b).

In 2016, Teck Alaska Inc. mined the Aqqaluk deposit portion of their Red Dog deposit; zinc production increased to 583,000 tonnes compared with 567,000 tonnes in 2015, primarily due to increased mill throughput as softer ores were processed. The zinc grade was 17.1 percent, with an 82.8 percent recovery rate. Lead production in 2016 rose to 122,300 tonnes, compared to 117,600 tonnes in 2015, primarily due to higher mill throughput. The lead grade was 4.9 percent, with a 56.0 percent recovery rate. In 2016, Teck Alaska Inc. mined 13,704,000 tonnes of material and milled 4,250,000 tonnes of ore. In 2016, Teck began development of its Qanaiyaq deposit, a near-surface deposit located immediately south of the mined-out Red Dog Main pit. This high-grade deposit hosts 7.4 million tonnes of reserves averaging 24.7 percent Zn and 6.9 percent Pb; production at Qanaiyaq is scheduled to begin in early 2017 (Athey and Werdon, 2017).

Reserves:

As of December, 2009, the Red Dog mine has 1) 10.14 million tons of proven reserves with a grade of 20.0 percent zinc and 5.4 percent lead; 2) 57.52 tons of probable reserves with a grade of 16.6 percent zinc and 4.4 percent lead; 3) 6.50 million tons of indicated resources with a grade of 20.0 percent zinc and 6.6 per lead; and 4) 34.16 million ton of inferred resources with a grade of 11.0 percent zinc and 4.0 percent lead (Szumigala and others, 2010). The 2009 probable reserves are almost entirely in the Aqqaluk ore body, whose 2011 reserves are 51.6 million tons with a grade of 16.7 percent zinc, and 4.4 percent lead (Nana Regional Corp., 2011). This Aqqaluk ore is thought to prolong the life of the mine to 2031.

In 2016, Teck Alaska Inc. began development of its Qanaiyaq deposit, a near-surface deposit located immediately south of the mined-out Red Dog Main pit. This high-grade deposit hosts 7.4 million tonnes of reserves averaging 24.7 percent Zn and 6.9 percent Pb; production at Qanaiyaq is scheduled to begin in early 2017. As of March 2016, total Red Dog proven and probable reserves are 56.6 million tonnes at 14.6 percent zinc and 4.1 percent Pb. Indicated resources include 200,000 tonnes at 11.5 percent zinc and 3.8 percent lead (Teck Alaska Inc., 2016).

Last report date: 2017-08-26

Site name(s): Lik; Sue

Site type: Prospect

ARDF no.: DL005

Latitude: 68.1664 **Quadrangle:** DL A-2

Longitude: 163.202

Location description and accuracy:

The Lik prospect is at an elevation of about 1,000 feet in the headwaters of east-flowing tributaries to Wulik River. The coordinates are at about the center of the prospect, near the southeast corner of section 15, T. 32 N., R. 20 W., of the Kateel River Meridian. The Sue deposit is the southern extension of the Lik deposit beyond the claims of the Zazu Metals Corporation, which was exploring the Lik deposit in early 2010. The accuracy is unknown.

Commodities:

Main: Ag, Pb, Zn

Other: Ba, Cd

Ore minerals: Boulangerite, bournonite, galena, marcasite, pyrite, sphalerite

Gangue minerals: Barite, calcite, dolomite, quartz

Geologic description:

In early 2010, the Lik deposit was on 296 unpatented federal mining claims, and the deposit was aggressively being explored by Zazu Metals Corporation (Zazu Metals Corporation, 2010; Gow and others, 2009; Britton, 2009; Scott and others, 2010). The Lik deposit was first staked in 1976 as a result of stream geochemical sampling by GCO and New Jersey Zinc Company. The deposit was drilled in 1977 by a joint venture of GCO, New Jersey Zinc, and WGM. HOMEX soon replaced New Jersey Zinc and by 1979, 103 holes had been drilled, many intersected lead-zinc mineralization. Noranda optioned the property in 1984, and in 1990 Moneta Porcupine Mines Inc. took control. By the end of 1992, 135 holes had been drilled that aggregated 26,237 meters. Zazu purchased their interest in the property in 2006 and drilled 69 holes in 2007 and 2008 that aggregated 8,223 meters (Gow and others, 2009; Scott and others, 2010).

The Lik deposit is in Kuna Formation of the Red Dog plate of the Endicott Mountain allochthon (Gow and others, 2009; Scott and others, 2010). Regionally, the Mississippian to Pennsylvanian Kuna Formation consists of at least 122 meters of thinly interbedded calcareous shale, calcareous spiculite, and bioclastic support stone, overlain by 30 to 240 meters of siliceous shale, mudstone, calcareous radiolarite, and calcareous turbidite. The Kuna Formation has two units, the Kivilina and the Ikalukrok which hosts the massive sulfide deposits in the area, including the Lik. At the Lik deposit, the Ikalukrok unit consists of carbonaceous and siliceous black shale with subordinate black chert and fine-grained limestone. These strata and their mineralized horizons generally strike north and dip 25 to 40 degrees west. The Lik mineralized horizon is overlain conformably by the Permian Siksikpuk Formation. The Lik mineralization is cut by numerous faults, notably the Main Break Fault that drops the northern end of the deposit down about 150 meters and separates the Lik South deposit from the Lik North deposit. The Lik South deposit is about 1,100 meters long and about 600 meters wide; the Lik North deposit is about 700 meters long and about 350 wide. The Lik deposit is open to the north and extends south beyond the Zazu claims to the Sue prospect, which is held by the Teck company that operates the nearby Red Dog mine (DL001).

The mineralization consists of irregular stratiform lenses of pyrite, marcasite, sphalerite, and galena with rare tetrahedrite, bournonite, and boulangerite. The mineralization was deposited in four distinct cycles that are better developed close to the hydrothermal sources of the mineralizing fluids. The thickest cycle is about

13.7 meters thick. Typically, the base of a cycle begins with the deposition of sphalerite, galena, and pyrite; the highest grades usually occur a few meters above the base of a cycle and the grade decreases upward. Locally, the mineralization is brecciated. The gangue consists of chert, clay minerals, carbonates, and barite.

Numerous high-grade intercepts of zinc-lead-silver mineralization were cut in many of the drill holes. As estimated by Gow and others (2009), Roscoe, and by Scott and others (2010), the mineral resources in Lik South consist of 18.74 million tonnes of 'Indicated Mineral Resources' with a grade of 8.08 percent zinc, 2.62 percent lead, and 52.8 grams of silver per tonne. There is an 'Inferred Mineral Resources' in Lik North of 1.23 million tonnes with a grade of 6.08 percent zinc, 2.12 percent lead, and 35 grams of silver per tonne; and' 'Inferred Mineral Resources' of 5.18 million tonnes with a grade of 9.65 percent zinc, 3.25 percent lead, and 51 grams of silver per tonne. An earlier 'reserve' estimate by Sterne and others (1984) was similar but did not meet modern standards of ore calculations, nor did it have the benefit of the more recent drilling.

Zazu completed a summer field program in 2011 including exploration, infill, and geotechnical drilling; metallurgy and associated environmental baseline, acid rock drainage, and infrastructure studies (Zazu Metals Corporation, 2011). The 2012 program focused on environmental baseline, acid rock drainage, and infrastructure studies, in addition to refined resource estimate, pit models, and metallurgical studies (Zazu Metals Corporation, 2012). In 2013, Zazu initiated the field portion of the acid rock drainage program, in addition to mine design, infrastructure, and metallurgical studies. The work completed by Zazu over these three years was compiled for a preliminary economic analysis (PEA), which was reported on April 23, 2014. Drilling completed in 2011 contributed to a new indicated mineral resource for Lik South of 16.85 million tonnes at 8.04 percent zinc, 2.70 percent lead, and 50.1 grams of silver per tonne. The PEA found that acid rock drainage and metal leaching related to waste rock and storage facilities are manageable and have no large environmental or permitting issues (Matter and others, 2014).

Alteration:

Host rocks are intensely silicified close to the sulfides (Gow and others, 2009).

Age of mineralization:

The mineralization is coeval with the deposition of the Mississippian host rocks (Gow and others, 2009; Scott and others, 2010).

Generic deposit model:

Deposit model:

Sedimentary exhalative Zn-Pb (Cox and Singer, 1986; model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31a

Production Status: None

Site Status: Active

Workings/exploration:

In early 2010, the Lik deposit was on 296 unpatented federal mining claims, and the deposit was being explored by Zazu Metals Corporation (Gow and others, 2009; Britton, 2009; Scott and others, 2010; Zazu Metals Corporation, 2010). The LIk deposit was first staked in 1976 as a result of stream geochemical sampling by GCO and New Jersey Zinc Company. The deposit was drilled in 1977 by a joint venture of GCO, New Jersey Zinc, and WGM. HOMEX soon replaced New Jersey Zinc and by 1979, 103 holes had been drilled on the deposit; many intersected lead-zinc mineralization. Noranda optioned the property in 1984, and in 1990 Moneta Porcupine Mines Inc. took control. By the end of 1992, 135 holes had been drilled that aggregated 26,236.6 meters. Zazu purchased their interest in the property in 2006 and drilled 69 holes in 2007 and 2008 that aggregated 8,223 meters (Gow and others, 2009; Scott and others, 2010).

Zazu completed a summer field program in 2011 including exploration, infill, and geotechnical drilling; metallurgy and associated environmental baseline, acid rock drainage, and infrastructure studies (Zazu

Metals Corporation, 2011). The 2012 program focused on environmental baseline, acid rock drainage, and infrastructure studies, in addition to refined resource estimate, pit models, and metallurgical studies (Zazu Metals Corporation, 2012). In 2013, Zazu initiated the field portion of the acid rock drainage program, in addition to mine design, infrastructure, and metallurgical studies. The work completed by Zazu over these three years was compiled for a preliminary economic analysis (PEA), which was reported on April 23, 2014. Drilling completed in 2011 contributed to a new indicated mineral resource for Lik South of 16.85 million tonnes at 8.04 percent zinc, 2.70 percent lead, and 50.1 grams of silver per tonne. The PEA found that acid rock drainage and metal leaching related to waste rock and storage facilities are manageable and have no large environmental or permitting issues (Matter and others, 2014).

Production notes:

None.

Reserves:

As estimated by Gow and others (2009), Roscoe, and by Scott and others (2010), the mineral resources in Lik South consist of 18.74 million tonnes of 'Indicated Mineral Resources' with a grade of 8.08 percent zinc, 2.62 percent lead, and 52.8 grams of silver per tonne. There is an 'Inferred Mineral Resources' in Lik North of 1.23 million tonnes with a grade of 6.08 percent zinc, 2.12 percent lead, and 35 grams of silver per tonne; and' 'Inferred Mineral Resources' of 5.18 million tonnes with a grade of 9.65 percent zinc, 3.25 percent lead, and 51 grams of silver per tonne. An earlier 'reserve' estimate by Sterne and others (1984) was similar but did not meet modern standards of ore calculations, nor did it have the benefit of the more recent drilling.

Drilling completed in 2011 by Zazu Metals Corporation contributed to a new indicated mineral resource published in a prelimary economic assessment report in 2014 for Lik South of 16.85 million tonnes at 8.04 percent zinc, 2.70 percent lead, and 50.1 grams of silver per tonne of potential open pit ore. The inferred mineral resource for open pit ore at Lik South is 0.74 million tonnes at 7.73 percent zinc, 1.94 percent lead, and 13.4 grams of silver per tonne. Indicated resources at Lik North are 0.44 million tonnes at 10.03 percent zinc, 2.77 percent lead, and 59.0 grams of silver per tonne and inferred resources are 2.87 million tonnes at 8.59 percent zinc, 2.68 percent lead, and 37.5 grams of silver per tonne (Matter and others, 2014).

Last report date: 2014-12-10

Site name(s): Anarraaq

Site type: Prospect

ARDF no.: DL016

Latitude: 68.155 **Quadrangle:** DL A-2

Longitude: 163.033

Location description and accuracy:

The Anarraaq prospect is about 9.6 miles northwest of Deadlock Mountain on a small tributary to the Wulik River. It is near the center of section 21, T. 32 N., R. 19 W., of the Kateel River Meridian. The location is accurate.

Commodities:

Main: Ag, barite, Pb, Zn

Other:

Ore minerals: Barite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Anarraaq prospect was found in 1999 by Teck Cominco by drilling a gravity anomaly (Kelley, Dumoulin, and Jennings, 2004). In plan view the deposit is about 300 by 400 meters in area and consists of a flat-lying lens of massive and banded sulfides up to about 100 meters thick, that is overlain stratigraphically by a thick, continuous layer of barite.

The Anarraag deposit is in shale, mudstone, and carbonate of the Mississippian Ikalukrok unit of the Kuna Formation, which is overlain by the Pennsylvanian to Permian Siksikpuk Formation (Kelley and Jennings, 2004, supplemental map; Kelley, Dumoulin, and Jennings, 2004). The Ikalukrok unit varies greatly in thickness from about 135 to 350 meters.

The sulfide zone at Anarraaq varies in thickness from a few meters to more than 100 meters. There are three types of mineralization: 1) low grade zones (less than 8 percent zinc) with sphalerite, galena, and up to 60 percent pyrite and marcasite; 2) banded sulfides with laminated sphalerite, galena, pyrite, marcasite, and quartz; and 3) massive sphalerite, galena, pyrite, and marcasite in breccias, contorted bands, and veins. The barite layer above the massive and banded sulfides is 65 to 140 meters thick under the entire drilled area and from the top down consists of modular barite, massive banded barite, and calcareous barite. Carbonate replacement by sulfides and barite played a critical role in localizing them.

The Anarraaq deposit is estimated to have a resource of as much as 1 billion tonnes of barite and 18 million tonnes of sulfide ore with a grade of 18 percent zinc, 5.4 percent lead, and 85 grams of silver per tonne (Kelley, Dumoulin, and Jennings, 2004).

Alteration:

Carbonate replacement by sulfides and barite played a critical role in localizing them.

Age of mineralization:

Mississippian based on the age of the host rock.

Generic deposit model:

Deposit model:

Sedimentary exhalative Zn-Pb (Cox and Singer, 1986; model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31a

Production Status: None

Site Status: Active

Workings/exploration:

The Anarraaq prospect was found in 1999 by Teck Cominco by drilling a gravity anomaly (Kelley, Dumoulin, and Jennings, 2004). There are 14 holes in the ore body and numerous holes peripheral to it.

Production notes:

None.

Reserves:

The Anarraaq deposit is estimated to have a resource of as much as 1 billion tonnes of barite and 18 million tonnes of sulfide ore with a grade of 18 percent zinc, 5.4 percent lead, and 85 grams of silver per tonne.

Site name(s): Lead Creek

Site type: Prospect

ARDF no.: EA057

Latitude: 58.96 **Quadrangle:** EA C-1

Longitude: 161.652

Location description and accuracy:

The Lead Creek prospect is located in the headwaters of Lead Creek, about 8 miles west-northwest of Liberty on the Taylor Highway. Lead Creek is not labeled on the U.S. Geological Survey topographic map of the Eagle C-1 quadrangle (1956). The coordinates are the approximate center of the 4-square-mile prospect area, located in the southwest corner of section 36, T. 4 S., R. 31 E., of the Fairbanks Meridian. The location is accurate. The hills around the head of Lead Creek (none named on the Eagle C-1 map) are, clockwise from west to east: Wizard Hill, Paradox Hill, Nodular Knob, Pebble Dike Hill, and Macarena Hill. Argent Creek is a small, west-flowing creek in the draw near the middle of section 5, T. 5 S., R. 32 E. between Pebble Dike Hill and Macarena Hill. The Lead Creek prospect is on Doyon, Ltd. selected or conveyed land.

Commodities:

Main: Ag, Pb, Zn

Other: As, Au, Bi, Cd, Cu, Hg, Sb

Ore minerals: Arsenopyrite?, chalcopyrite, galena, iron-oxide, manganese oxide, pyrite, sphalerite

Gangue minerals: Ankerite, dolomite, garnet, pyroxene, quartz, scorodite, siderite, wollastonite

Geologic description:

Rocks in the vicinity of the Lead Creek prospect include carbonaceous quartz-mica schist and phyllite; weakly metamorphosed silicified volcanic rocks, quartzite, marble, and metachert; unmetamorphosed limestone, sandstone, argillite, and tuff; slightly metamorphosed greenstone, basalt, and pillow basalt; and serpentinite (WGM Inc., 1998 [DLR 98-12]). The protolith ages for these rocks may be Triassic, Permian, or Mississippian and Devonian (Dusel-Bacon and others, 1998); they are tentatively correlated with Paleozoic rocks that host stratiform lead-zinc-silver deposits in the Yukon Territory. Granodiorite, diorite, and dacite intrusions of Tertiary to Mesozoic age also occur in the Lead Creek area.

The models proposed for the Lead Creek prospect include: lead-zinc stratiform massive sulfide (Schmidt, 1997); manto replacement silver-lead-zinc; breccia-hosted silver-lead-zinc; skarn-hosted lead-zinc-silver; pluton-hosted lead-zinc-copper-silver; or another type of deposit indicated by precious and base metals in siliceous nodules (WGM Inc., 1998 [DLR 98-12]). The prospect is defined by anomalous lead in soils over a 3-mile by 1.5-mile area. The mineralized system may be more extensive than indicated by soil sampling since favorable ore intervals pass under overlying units on the ridges (WGM Inc., 2000 [Champion property summary]).

Graphitic quartz-mica schist and phyllite crop out on top of Paradox Hill and Nodular Knob (WGM Inc., 1998 [DLR 98-12]). A strongly graphitic schist east of Nodular Knob contains siliceous nodules and iron(?) oxide-cemented concretions that are anomalous in precious and base metals. The graphitic schist and phyllite grade into, or are in fault contact with, underlying silicified volcanic rocks.

A steeply dipping, east-southeast-trending fault separates the silicified metavolcanic rocks on Nodular Knob from limestone on Pebble Dike Hill (WGM Inc., 1998 [DLR 98-12]). Sections of impure massive limestone were intersected in drill holes on the west side of Pebble Dike Hill. The limestone has been bleached, silicified, brecciated, and mineralized; it has a trace to greater than 20 percent combined pyrite,

galena, and sphalerite. A carbonaceous sequence of interlayered limestone, shale, argillite, siltstone, and sandstone underlies the massive limestones. Massive sulfides (50 percent or more galena, pyrite, and sphalerite) are present in strata-bound layers within the carbonaceous sedimentary rocks. Pillow basalts form prominent outcrops on the west side of Macarena Hill and are present northwest of Paradox Hill and in drill core.

Small granodiorite and quartz diorite bodies and numerous andesite, dacite, and feldspar porphyry dikes are scattered throughout the upper basin of Lead Creek (WGM Inc., 1998 [DLR 98-12]). Many of these intrusions are argillically altered, fractured, and sheared; the feldspar is altered to clays, and chlorite occurs along cleavage planes. Galena and sphalerite are sparsely disseminated in granodiorite in a drill hole on Wizard Hill. Fine-grained hornfels and skarn zones in limestone units contain garnet, wollastonite, and pyroxene. Skarns are generally small and spatially related to dikes and (or) sills. A 120-foot-thick intercept of hydrofracture breccia with greater than 25 percent disseminated pyrite that occurs in a drill hole on Pebble Dike Hill is possibly intrusion-related. A pebble dike cuts across limestone on Pebble Dike Hill.

Structural features at the Lead Creek prospect include Triassic to Jurassic thrust faults, folds, and later, north-south-trending and east-southeast-trending high-angle faults (WGM Inc., 1998 [DLR 98-12]). Airborne geophysical data indicate that Lead Creek is on the periphery of a semicircular magnetic zone that contains the Champion II (EA049), North Champion (EA046), East Champion (EA047), and Little Champion Creek (EA051) prospects. An arcuate trend of high conductivity follows topographic contours around the Lead Creek basin, possibly indicating a graphitic unit with the potential for stratiform sulfide mineralization (WGM Inc., 1998 [DLR 98-12]).

Sulfides at Lead Creek predominantly are galena, sphalerite, and pyrite, with trace chalcopyrite (WGM Inc., 1998 [DLR 98-12]). Sphalerite is typically reddish and coarse grained. Silver is closely associated with galena. Pyrite is the most widespread and abundant sulfide, and is present in all rock types. Silicification accompanies much of the sulfide mineralization and is especially strong in mineralized limestone. Carbonate alteration is marked by dolomite-ankerite and possibly siderite; the carbonates are primarily found in veins and breccia matrix.

There are four main target areas at the Lead Creek prospect: Nodular Knob, Argent Creek, Wizard Hill, and Paradox Hill (WGM Inc., 1998 [DLR 98-12]). Siliceous nodules and scorodite-cemented nodules in graphitic schist and phyllite immediately east of Nodular Knob are anomalous in gold, silver, lead, zinc, arsenic, antimony, cadmium, mercury, and bismuth. One nodule contains 2,000 parts per billion (ppb) gold, 31.4 parts per million silver, greater than 10,000 ppm arsenic, 6 ppm bismuth, 374 ppm antimony, 1,330 ppm copper, 2.82 percent lead, and 744 ppm zinc.

In the Argent Creek area, drilling intersected a stratiform massive sulfide horizon; a 47-foot interval averages 1.4 percent lead, 1.3 percent zinc, and 1.53 ounces of silver per ton (WGM Inc., 1998 [DLR 98-12]). Base metals and abundant pyrite occur in brecciated and sheared carbonaceous shale, argillite, and gray limestone, and are also found as semi-massive replacements of graywacke. Another drill hole (LC-14) in the Argent Creek area has a 31.5 foot intercept with 23.3 ounces of silver per ton and 6.4 percent lead. The Argent Creek fault has been identified as a possible ore control (Ventures Resource Corp., 2001). Quartz-vein float with iron and manganese oxides and sparse galena was found in sandstone and limestone north of Argent Creek; the float contains 2,500 ppm lead, 4,800 ppm zinc, and 1.8 ppm silver. A weakly developed skarn is exposed on Pebble Dike Hill. Step-out hole LC-15, drilled 430 feet to the southeast of 2000 hole LC-14, has a 50.6 foot intersect with 11.9 ounces of silver per ton, 5.1 percent lead, and 0.2 percent zinc in the same zone as hole LC-14. Mineralization is open west of hole LC-14; other 2001 holes tentatively indicate that it is to the east (Swainbank and others, 2002; Ventures Resource Corp., 2002).

Paradox Hill contains complex, siliceous, metavolcanic breccias with clasts of quartzite, limestone, siltstone, claystone, basalt, and tuffaceous material (WGM Inc., 1998 [DLR 98-12]). Galena and sphalerite are disseminated in the quartzite clasts and occur as replacements and open-space fillings in silicified breccia matrix and in quartz-carbonate veins. The veins contain as much as 2.82 percent lead, 2.84 percent zinc, and 0.79 ounce of silver per ton. A small amount of sulfide-bearing skarn is also present in core.

At Wizard Hill, sparse pyrite, galena, sphalerite, and chalcopyrite are associated with quartz-carbonate veins in quartzite and graphitic schist. Altered granodiorite contains minor disseminated pyrite, chalcopyrite, galena, and sphalerite (WGM Inc., 1998 [DLR 98-12]).

The Lead Creek prospect was originally identified by stream-sediment sampling conducted by the Alaska Division of Mines and Minerals in 1968 (Smith, 1968). Argentiferous galena float was found on the ridge south of Champion Creek (the west end of Wizard Hill) in 1968 (Foster and Clark, 1970). In 1976, WGM

Inc. conducted stream-sediment and soil sampling in the Lead Creek area (WGM Inc., 1998 [DLR 98-12]). In 1977 and 1978, WGM Inc. conducted soil sampling and gridded geophysical surveys, and drilled about 600 feet of core in three holes. Three EM conductors were identified during a 13.3-mile vertical-loop survey. Analyses of soil, stream-sediment, pan-concentrate, and rock samples from the Lead Creek area are reported in Burleigh and Lear (1994). In 1996, WGM Inc. carried out a mapping and sampling program at Lead Creek and identified new drilling targets. In 1997, WGM Inc. followed up an airborne EM-magnetics survey, carried out geologic mapping and sampling, and drilled a total of 3,853 feet in seven core holes. WGM Inc. drilled an additional 2,033 feet at Lead Creek in 2000 and 5,464 feet in 2001 and reported high-grade silver-lead mineralization (Ventures Resource Corp., 2001; Ventures Resource Corp., 2002). As of May 2006, the Lead Creek prospect was being examined by Full Metal Minerals under an agreement with Doyon Limited (Full Metal Minerals, 2008, 40 mile). Full Metals web site shows the location of the 22 drill holes on the property and the footages of the mineralized intercepts in them (Full Metal Minerals, 2008, Lead Creek).

Alteration:

Some limestones are bleached, silicified, brecciated, and (or) contain weak skarn alteration (WGM Inc., 1998 [DLR 98-12]). Metavolcanic rocks are locally silicified and altered to clay, but the relationship of alteration to mineralization is unclear. Granodiorite porphyry is argillically altered and contains green chlorite along fractures. Many intrusions are argillically altered, fractured, and sheared, with feldspars altered to clays; chlorite occurs along cleavages.

Age of mineralization:

Probably Mesozoic, as inferred from the presence of skarns adjacent to Mesozoic intrusions and a Cretaceous common lead age from galena (Dusel-Bacon and others, in press [in 2003]).

Generic deposit model:

Deposit model:

Possibly Zn-Pb skarn, polymetallic replacement, or sedimentary exhalative (Cox and Singer, 1986; models 18c, 19a, or 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18c, 19a, or 31a

Production Status: None

Site Status: Active

Workings/exploration:

The Lead Creek prospect was originally identified by stream-sediment sampling conducted by the Alaska Division of Mines and Minerals in 1968 (Smith, 1968). Argentiferous galena float was found on the ridge south of Champion Creek (the west end of Wizard Hill) in 1968 (Foster and Clark, 1970). In 1976, WGM Inc. conducted stream-sediment and soil sampling in the Lead Creek area (WGM Inc., 1998 [DLR 98-12]). In 1977 and 1978, WGM Inc. conducted soil sampling and gridded geophysics surveys and drilled about 600 feet of core in three holes at the prospect. Three EM conductors were identified during a 13.3-mile vertical-loop survey. Analyses of soil, stream -sediment, pan-concentrate, and rock samples from the Lead Creek area are reported in Burleigh and Lear (1994). In 1996, WGM Inc. carried out a mapping and sampling program at Lead Creek and identified new drilling targets. In 1997, WGM Inc. followed up an airborne EM-magnetics survey, carried out geologic mapping and sampling, and drilled a total of 3,853 feet in seven core holes. WGM Inc. drilled an additional 2,033 feet at Lead Creek in 2000 and 5,464 feet in 2001 (Ventures Resource Corp., 2001; Swainbank and others, 2002. As of May 2006, the Lead Creek prospect was being examined by Full Metal Minerals under an agreement with Doyon Limited (Full Metal Minerals, 2008, 40 mile). The Full Metals web site shows the location of the 22 drill holes on the property and the footages of the mineralized intercepts in them (Full Metal Minerals, 2008, Lead Creek).

Production notes:

None.

Reserves:

None.

Additional comments:

The Lead Creek prospect is located within Doyon, Ltd. selected or conveyed land. For more information contact Doyon, Ltd., Fairbanks, Alaska.

Last report date: 2008-03-04

Site name(s): Fish

Site type: Prospect

ARDF no.: EA062

Latitude: 64.2546 **Quadrangle:** EA B-4

Longitude: 142.7058

Location description and accuracy:

The Fish prospect is about 0.6 mile northwest of hill 4280 near the center of the southern boundary of the Eagle B-4 quadrangle. The coordinates are the location of a quartz-carbonate vein and gossan zone at the headwaters of Texas Creek in the northeast quarter of section 1, T. 8 S., R. 25 E.. Texas Creek, a small tributary of Fish Creek, is not labeled on the U.S. Geological Survey topographic map of the Eagle B-4 quadrangle (1956); its mouth is in the northeast quarter of section 24, T. 7 S., R. 25 E. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, smithsonite, sphalerite

Gangue minerals: Carbonate, quartz

Geologic description:

In upper Fish Creek, Paleozoic metasedimentary and metavolcanic rocks are intruded by Mesozoic to early Tertiary(?) biotite-hornblende quartz monzonite and granodiorite stocks (Dashevsky and others, 1986). Hornfelsed metamorphic rocks are common near the contact of a quartz monzonite pluton. The Fish prospect consists of quartz-carbonate veins and a gossan zone in the headwaters of Texas Creek (see EA061). Mineralization in one drainage appears to be associated with a 5- to 10-foot-wide gossan zone along a north-trending fault zone at a contact of granodiorite and metasedimentary rock. Gossan samples from the fault zone contain 8 to 24 percent zinc, as much as 2,000 parts per million (ppm) lead, and as much as 200 ppm copper. Samples of gossan and silicified zones contained more than 3 percent zinc, and up to 6,424 ppm lead and 12 ppm silver (U.S. Bureau of Mines, 1995). Five VLF lines run at right angles to the trend of the fault zone showed 'crossovers' probably related to the fault. The geology in the prospect area is considered permissive for skarn, structurally controlled, or stratabound deposits (Dashevsky and others, 1986). There has been placer gold prospecting on Fish Creek (EA059) and Texas Creek (EA061) to the north and west of this prospect.

Sulfides in the area were first noted by Foster (1976). Reconnaissance stream-sediment sampling was done in the upper Fish Creek drainage in 1976 by WGM Inc. (Dashevsky and others, 1986). Initial reconnaissance sampling detected elevated zinc and lead in stream sediments in several tributaries to Fish Creek. In 1977, WGM Inc. conducted reconnaissance mapping, sampled soils and rocks, and filled in the stream-sediment sampling grid. traverses and soil and rock sampling, and fill-in stream sediment sampling. In 1981, Arctic Resources Inc. conducted ridge line traverses and ran a soil-sampling line across the north-south-trending fault zone. Soils with elevated lead and zinc were found west of the fault in hornfels and quartzite, but no mineralization was observed. In 1991, Central Alaska Gold Co. conducted rock sampling in the area; no gold was detected in any samples (WGM Inc., 1998 [DLR 98-10]). The U.S. Bureau of Mines briefly examined the Fish Creek area in 1994. Soil sampling and mapping by WGM Inc. in 2001 resulted in defining a steeply dipping metal-enriched shear zone that persistently extends for 4,800 feet across a high ridge crest to the edge of the soil grid. The zone is defined by anomalous zinc, lead, silver,

copper, bismuth, arsenic, antimony, cadmium, and manganese. All the zinc values exceed 1,000 ppm for the entire 4,800 feet; zinc values exceed 5,000 ppm in 1,200 segments to each side of the ridge. Twenty-eight grab samples of rocks averaged 11.6 percent zinc, 0.13 percent lead, and 18.7 ppm silver. The mineralized zone is estimated to be 50 to 75 feet thick (Swainbank and others, 2002; Ventures Resource Corp., 2002).

Under an agreement with Doyon Ltd., Full Metal Minerals began work on the prospect in 2006 (Full Metal Minerals, 2006 [40 mile]). They described the mineralization as strongly oxidized massive sulfides up to 44 meters thick. They drilled a gossan 15 to 23 meters thick derived from intensely weathered massive to semi-massive sulfides. The zinc in the gossan occurs mainly as smithsonite. The gossan has been traced 1,500 meters along strike and 250 meters down dip. Through 2010, Full Metal has drilled 10 holes at Fish that total 1,629 meters (2007 Stevens, 2010). The mineralization remains open in depth and in both directions along strike. Some notable intercepts are: 1) 11 meters that averaged 205.2 grams of silver per tonne, 0.1 percent copper, 0.2 percent lead, and 4.2 percent zinc; 2) 12.9 meters that averaged 181.3 grams of silver per tonne, 0.1 percent copper, 0.4 percent lead, and 4.0 percent zinc; 3) 7.8 meters that averaged 114.8 grams of silver per tonne, 0.2 percent copper, 0.1 percent lead, and 2.7 percent zinc; 4) 8.2 meters that averaged 118.8 grams of silver per tonne, 0.1 percent copper, and 0.1 percent zinc; 5) 20.6 meters that averaged 52 grams of silver per tonne, 0.1 percent copper, 0.08 percent lead and 1.7 percent zinc; 6) 4.6 meters that averaged 46.7 grams of silver per tonne and 2.2 percent zinc; and 7) 2.1 meters that averaged 205 grams of silver per tonne and 0.3 percent zinc.

Alteration:

Age of mineralization:

Mineralization probably related to nearby Mesozoic to early Tertiary(?) biotite-hornblende quartz monzonite and granodiorite stocks in the upper Fish Creek drainage (Dashevsky and others, 1986).

Generic deposit model:

Deposit model:

Silver-zinc-lead skarn (Cox and Singer, 1986; model 18c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18c

Production Status: None

Site Status: Active

Workings/exploration:

Sulfides in the area were first noted by Foster (1976). Reconnaissance stream-sediment sampling was done in the upper Fish Creek drainage in 1976 by WGM Inc. (Dashevsky and others, 1986). In 1981, Arctic Resources Inc. conducted ridge line traverses and ran a soil sampling line across the north-south-trending fault zone that crosses the prospect. In 1991, Central Alaska Gold Co. conducted rock sampling in the area; no gold was detected in any samples (WGM Inc., 1998 [DLR 98-10]). The U.S. Bureau of Mines briefly examined the Fish Creek area in 1994. WGM carried out soil sampling and mapping. Under an agreement with Doyon Ltd., Full Metal Minerals began work on the prospect in 2006. They drilled 7 holes in 2006 and 3 holes in 2008 (Stevens, 2010).

Production notes:

None.

Reserves:

None.

Site name(s): Oscar

Site type: Prospect

ARDF no.: EA096

Latitude: 64.2279 **Quadrangle:** EA A-5

Longitude: 143.1174

Location description and accuracy:

The Oscar prospect covers about 5 square miles on the ridge west of Gold Bottom Creek. The coordinates are the approximate center of the prospect about 4 miles northwest of Mount Veta in the northeast quarter of section 14, T. 8 S., R. 23 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, magnetite, pyrrhotite, sphalerite

Gangue minerals: Calc-silicate minerals

Geologic description:

The Oscar prospect is at the contact between the Jurassic Mount Veta syenite and Paleozoic marble, calcareous schist, and quartzite (WGM Inc., 1998 [DLR 98-10]). Hypabyssal Tertiary felsic intrusions and volcanic rocks and Tertiary or Mesozoic quartz-monzonite plutons are also present. The relation of these younger intrusions to the Oscar prospect is not known. Ten outcrops of skarn occur at the prospect, but vegetation cover is extensive (WGM Inc., 2000 [Veta property summary]; WGM Inc., 1998 [DLR 98-10]). Ground magnetometer surveys indicate that several skarns are connected in the shallow subsurface and blind extensions continue beneath tundra cover.

Magnetite, pyrrhotite, galena, sphalerite, and chalcopyrite occur in calc-silicate rocks and hornfels (Dashevsky and others, 1986). Average grades are generally less than 11 percent combined lead and zinc, and as much as 3 ounces of silver per ton. A massive chalcopyrite-pyrrhotite boulder in rubble contained 18.8 percent copper and 18 ounces of silver per ton. A trench over a ground-magnetic anomaly revealed iron-stained and geochemically anomalous soils that contain as much as 3.8 percent lead, 10 ounces of silver per ton, 0.4 percent copper, 0.9 percent zinc, and 860 ppb gold. Rock samples collected in 1990 contain as much as 2,040 parts per billion (ppb) gold, 192 parts per million (ppm) silver, 9,134 ppm lead, greater than 1 percent copper, and greater than 1 percent zinc (WGM Inc., 1998 [DLR 98-10]). Four northeast-trending soil anomalies are as much as 2,000 feet long; they contain from 30 to greater than 7,000 ppb gold, 1 to 30 ppm silver, 100 to greater than 10,000 ppm copper, and 10,000 ppm or more zinc (WGM Inc., 2000 [Veta property summary]). Molybdenum- and silver-bearing calc-silicate inclusions in quartz monzonite occur across Gold Bottom Creek, east of the Oscar prospect skarns.

Bear Creek Mining Co. discovered the Oscar prospect in 1971; they conducted soil and rock sampling and a ground magnetic survey (Dashevsky and others, 1986). In 1975, WGM Inc. did stream sediment reconnaissance in the area; 1976 work by WGM Inc. included stream sediment sampling, reconnaissance geologic mapping, rock sampling, trenching, and soil sampling on a grid. In 1981, Arctic Resources Inc. extended the soil grid, and in 1982, Doyon, Ltd. traversed outlying ridges and slopes, sampled soils on a grid over a blind skarn, and conducted a ground magnetometer survey. In 1990, Central Alaska Gold Co. did geologic mapping and rock, soil, and stream-sediment sampling (WGM Inc., 1998 [DLR 98-10]). Work by WGM Inc. in 2001 was restricted to stream-sediment sampling near the peripheries of the prospect.

As of early 2012, the Oscar prospect was being explored by Heavy Metal Zinc under a lease agreement

with Doyon, Ltd. (Heavy Metal Zinc, 2012). They consider the deposit to be in skarn bodies in marble adjacent to a syenite stock. The deposit is roughly zoned with magnetite-chalcopyrite bodies near the syenite and galena-sphalerite bodies further away. There are only two outcrops. Thirty-eight samples from the lower outcrop contained from a trace to 3.8 percent copper and a trace to 356 grams of silver per tonne. Sixty-two samples from the upper outcrop contained from a trace to 1.0 percent copper, a trace to 34.1 grams of silver per ton, and up to 1.2 percent zinc. Samples from prospect pits contained up to 17 percent copper, 5.2 percent zinc, 4.4 percent lead, and 444 grams of silver per tonne. Full Metal drilled one hole in 2010 but it did not intersect any significant mineralization (Stevens, 2010).

Alteration:

Mineralization is associated with skarn bodies.

Age of mineralization:

Skarn mineralization is at the contact of the Jurassic, Mount Veta syenite.

Generic deposit model:

Deposit model:

Cu skarn or Zn-Pb skarn (Cox and Singer, 1986; models 18b or 18c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b or 18c

Production Status: None

Site Status: Active?

Workings/exploration:

Bear Creek Mining Co. discovered the Oscar prospect in 1971; they conducted soil and rock sampling and a ground magnetic survey (Dashevsky and others, 1986). In 1975, WGM Inc. did stream-sediment reconnaissance in the area; 1976 work by WGM Inc. included stream-sediment sampling, reconnaissance geologic mapping, rock sampling, trenching, and soil sampling on a grid. In 1981, Arctic Resources Inc. extended the soil grid, and in 1982, Doyon, Ltd. traversed outlying ridges and slopes, sampled soils on a grid over a blind skarn, and conducted a ground magnetometer survey. In 1990, Central Alaska Gold Co. did geologic mapping and rock, soil, and stream-sediment sampling (WGM Inc., 1998 [DLR 98-10]). Work by WGM Inc. in 2001 was restricted to stream-sediment sampling near the peripheries of the prospect (Ventures Resources, 2002). Beginning in 2006, the Oscar deposit was being explored by Full Metal Minerals and its successor Full Metal Zinc under a lease agreement with Doyon Ltd. Their work to early 2010 consisted mainly of sampling outcrops and hand-dug pits. They drilled one hole in 2010 that did not intersect any significant mineralization.

WGM Inc., 2000, Veta property summary, in Ventures Resource Alaska project overview and properties summary: Ventures Resource Corporation report.

Primary Reference: Stevens, 2010

Reporter(s): D.J. Grybeck (Contractor, USGS)

Last report date: 2012-04-01

Site name(s): Eva; Eva Creek; Ruby Silver

Site type: Prospect

ARDF no.: EA099

Latitude: 64.1057 **Quadrangle:** EA A-5

Longitude: 143.198

Location description and accuracy:

The center of the Eva prospect is at an elevation of about 3,900 feet on the ridge north of Eva Creek. The claims of the prospect extend several miles to the north and south into the Norvell Creek and Iron Creek drainages. The coordinates are the location of trenches in the central part of the Eva Creek prospect in section 23, T. 27 N., R. 11 E. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Au, Sb

Ore minerals: Argentiferous galena, azurite, cerussite, hematite, magnetite, malachite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, epidote, quartz

Geologic description:

The Eva prospect is in Paleozoic gneiss, schist, quartzite, and marble, that have been intruded by the Mount Veta syenite of Jurassic age (Foster, 1976). Other Tertiary to Mesozoic monzonite and granite intrusions are about 1 mile east of the prospect, and there are felsic and mafic dikes in the area (Dashevsky and others, 1986). The syenite to the east is epidotized and contains local altered zones near the contact (Foster and Clark, 1970). Several other prospects are spatially associated with the Mount Veta intrusive complex, including East Eva (EA098), Drumstick (EA166), Oscar (EA096), Oscar West (EA097), Little Enchilada (EA103), unnamed (north of Fish Creek) (EA062), Molly Creek (EA100), Little Whiteman Creek (EA060), and Mitchell (EA101).

At the Eva prospect, pyrite and pyrrhotite are disseminated grains in gneiss and schist. There are also scattered highly mineralized marble units that contained argentiferous galena, cerussite, sphalerite, azurite, and malachite filling vugs, boxworks, and quartz veinlets (Carter, 1981). Wedow and others (1954) reported quartz veins as much as several feet thick, most of which are highly fractured and stained with hematite. These veins contain pods of galena, partly altered to cerussite, and calcite. Rock samples from the Eva Creek prospect with galena, sphalerite, and malachite contained as much as 9.24 ounces of silver per ton, 29.13 percent lead, and 0.61 percent copper (Saunders, 1962). Mineralized rock samples from trenches contained 0.4 to 2 percent copper, 7 to 52 percent lead, 0.6 to 21 percent zinc, and 31 to 99 ounces of silver per ton. Other samples of vein material and gossan in trenches contain as much as 32.4 ounces of silver per ton, 0.18 percent copper, 896 parts per million antimony, 9.5 percent zinc, and 6.6 percent lead (U.S. Bureau of Mines, 1995). Samples from a vein that can be traced on the surface for at least 1,800 feet contains as much as 28.7 percent lead, 9.4 percent zinc, 0.28 percent copper, 0.003 ounce of gold per ton, and 19.4 ounces of silver per ton (Swainbank and others, 1998).

Metal anomalies in soils at the Eva prospect are elongated northeast (Dashevsky and others, 1986). CEM and VLF-EM geophysical surveys both detected narrow conductors up to 400 feet long striking north to northwest. Seven hundred feet northwest of the trenches at the Eva Creek prospect, soils have elevated copper in an area of strong response to IP and ground magnetic surveys. A drill hole penetrated pyrite- and magnetite-bearing, biotite schist, and calcite-filled breccia zones as much as 58 feet thick. At the head of

Iron Creek, two core holes totaling 404 feet were drilled in an area with anomalous magnetite and zinc; these holes intersected disseminated pyrite and chalcopyrite, iron oxides, and rare galena in banded marble and dolomite (Dashevsky and others, 1986).

About 18 miles of traverses were conducted for radioactive minerals in the area in 1949 but no significant radioactivity was detected in panned heavy-mineral concentrates (Wedow and others, 1954). Saunders (1962) examined prospects in the My Creek and Eva Creek area in 1960. Rock and stream-sediment samples were collected from the Molly Creek drainage in 1968 (Foster and Clark, 1970). Apex Exploration Ltd. conducted exploration in the Eva Creek area in the early 1970s (Dashevsky and others, 1986). Placid Oil Company explored in the area from 1975 to 1978; their work included float mapping, soil sampling on a grid, and ground magnetic, CEM, and VLF-EM geophysical surveys. They drilled three core holes in trenches at Eva Creek in 1977, and two core holes on Iron Creek in 1978. In 1981, Arctic Resources Inc., sampled rocks and soils at the Eva Creek prospect, and in 1982, Doyon Ltd. in 1982 ran two lines of IP-resistivity and magnetometer surveys.

Full Metal Minerals resumed exploration at the Eva prospect in 2007 and at an extension about 2,200 meters north called the Drumstick prospect (EA166) (Full Metal Minerals, 2008 [40 Mile district]; 2008 [LWM prospect]; 2008 [LWC drill sites]. They interpret the deposit as a carbonate replacement that consists of partially oxidized, massive, coarsely-crystalline sphalerite, with galena, and chalcopyrite. They collected 14 samples from outcrop and prospect pits. The samples contained 6.5 to 43.6 percent zinc, 4.1 to more than 25 percent lead, and 0.18 to 4.9 percent copper. The lowest silver value was 207 grams of silver per tonne; the highest three samples contained 3,730, 1,960, and 1,280 grams of silver per tonne.

Stevens (2010) shows several trenches spread along about 100 meters of marble, quartz-mica schist, amphibole schist, and gossan. Five holes were drilled in 2010 that totaled 632 meters. The best intercept was 1.1 meter that contained 70 grams of silver per tonne, 0.03 percent copper, 2.35 percent lead, and 1.43 percent zinc; four of the holes did not cut significant mineralization.

Alteration:

Not noted.

Age of mineralization:

Jurassic or younger if related to the nearby Mt. Veta syenite.

Generic deposit model:

Deposit model:

Silver-copper-lead-zinc replacement deposits in carbonate rocks (Cox and Singer, 1986; model 19a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

19a

Production Status: None

Site Status: Active

Workings/exploration:

About 18 miles of traverses were conducted for radioactive minerals in 1949 but no significant radioactivity was detected in panned heavy-mineral concentrates (Wedow and others, 1954). Saunders (1962) examined prospects in the My Creek and Eva Creek area in 1960. Rock and stream-sediment samples were collected from the Molly Creek drainage in 1968 (Foster and Clark, 1970). Apex Exploration, Ltd. conducted exploration in the Eva Creek area in the early 1970s (Dashevsky and others, 1986). Placid Oil Company explored in the area from 1975 to 1978; their work included float mapping, soil sampling on a grid, and ground magnetic, CEM, and VLF-EM geophysical surveys. They drilled three core holes in trenches at Eva Creek in 1977 and two core holes on Iron Creek in 1978. In 1981, Arctic Resources Inc. sampled rocks and soils and in 1982 Doyon Ltd. ran two lines of IP-resistivity and magnetometer surveys. Full Metal Minerals resumed exploration at the Eva prospect in 2007 and at an extension about 2,200 meters

north called the Drumstick prospect (EA166) (Full Metal Minerals, 2008 [40 Mile district]; 2008 [LWM prospect]; 2008 [LWC drill sites]). Full Metal drilled 4 holes in 2010.

Production notes:

None.

Reserves:

None.

Additional comments:

The Eva prospect is on Doyon, Ltd. selected or conveyed land. For more information contact Doyon, Ltd., Fairbanks, Alaska.

Site name(s): LWM; Little Whiteman; West LWM

Site type: Prospect

ARDF no.: EA102

Latitude: 64.2308 **Quadrangle:** EA A-4

Longitude: 142.8274

Location description and accuracy:

The LWM prospect covers 9 square miles in upper Little Whiteman Creek. The coordinates are at about the center of an area that has been drilled in section 8, T. 8 S., R. 25 E. The location is accurate within 1 mile.

Commodities:

Main: Ag, Pb, Zn

Other: Au, Hg, In, W

Ore minerals: Cerrusite, chalcopyrite, galena, hemimorphite, smithsonite, sphalerite

Gangue minerals: Calcite

Geologic description:

The rocks in upper Little Whiteman Creek consist of Paleozoic quartzite, schist, marble, and greenstone that have been intruded by the Mount Veta intrusive complex of Mesozoic granodiorite and quartz monzonite stocks and by Jurassic syenite dikes (Foster, 1976; WGM Inc., 1998). A northeast-trending greenstone belt underlies the ridge at the south end of the LWM prospect. Reconnaissance stream-sediment samples from Little Whiteman Creek are anomalous in lead, zinc, and silver, and panned heavy-mineral concentrates contain anomalous tungsten, silver, and mercury. The geochemical anomalies are spatially separated and perhaps reflect input from two different deposit types. Sulfides noted by Foster (1976) on the ridge east of Little Whiteman Creek and on the ridge line at the head of the creek are probable sources for the geochemical anomalies.

WGM Inc. conducted a regional stream-sediment reconnaissance in the upper Little Whiteman Creek area in 1975 (Dashevsky and others, 1986). In 1977, WGM Inc. carried out reconnaissance soil sampling, and did a reconnaissance magnetic survey; in 1978 they did a follow-up panned heavy-mineral-concentrate survey. In 1981, Arctic Resources Inc. mapped the ridges and collected soil samples in the area. Doyon, Ltd. conducted a placer reconnaissance in 1982. In 1990, Central Alaska Gold Co. mapped the geology and collected soil, rock, and stream-sediment samples (WGM Inc., 1998). In 2001, WGM Inc. sampled and hypothesized that the mineralization is hosted in gently dipping siliceous and carbonaceous phyllite. This target, which was open to the north, was well defined by a 6,000-foot by 1,200-foot soil anomaly in zinc, lead, and silver. The only mineralized rock that was found in the heart of the target area was rare gossan exposed in pits during soil sampling. Gossan samples contained up to 34 percent lead, 16 percent zinc, and 13.75 ounces of silver per ton (Swainbank and others, 2002; Ventures Resource Corp., 2002).

Under an agreement with Doyon Ltd., Full Metal Minerals began work on this prospect in 2006. Full Metal Minerals subsequently established a separate company, Full Metal Zinc, to explore their properties in the 40 Mile District.

As of March, 2012, Full Metal Zinc had drilled 72 holes on 50-meter centers at the LWM prospect and outlined a zone of mineralization that extends 970 meters along strike and 300 meters down dip (Full Metal Zinc, 2012 [40 Mile]; 2012 [LWM]). Twelve of these holes totaling 3,229 meters were drilled in 2011. Some notable intercepts were: 1) 44.6 meters that averaged 15.7 percent zinc, 5.3 percent lead, and 76 grams of silver per tonne; 2) 11.1 meters that averaged 26.3 percent zinc, 11.7 percent lead, and 169.8 grams

of silver per tonne; 5.6 meters that averaged 31.8 percent zinc, 19.9 percent lead, and 346.8 grams of silver per tonne; and 4) 17.7 meters that averaged 14.5 percent zinc, 11.1 percent lead, and 217.5 grams of silver per tonne.

Full Metal Zinc also drilled two holes totaling 260 meters on a geochemical anomaly at the West LWM prospect about 3,500 meters southwest of the LWM prospect. No significant mineralization was cut.

The mineralization at the LWM prospect consists of massive to semi-massive sphalerite, galena, and chalcopyrite in dolomitized marble and marble breccia. The primary mineralization is capped by a thick oxide zone with smithsonite, hemimorphite, and cerussite. The mineralization also includes notable indium; 9 samples that were analyzed for indium contained from a trace to 39.8 grams of indium per tonne, with an average of 16.1 grams of indium per tonne.

There are two mineralized zones. The lower zone extends the full length of the deposit; it is 970 meters long, 25-50 meters thick, and dips to the southeast. Near the center of the drilling, the upper zone is about 200 meters long and 0-30 meters thick. Stevens (2011), citing a company report from Full Metal Zinc classifies the deposit a carbonate replacement, a subset of the Mississippi Valley type of deposit. Full Metal Zinc considers the LWM a high-temperature carbonate-replacement deposit.

Alteration:

The deposit is partly oxidized near the surface.

Age of mineralization:

This carbonate replacement deposit may be related to nearby Mesozoic granodiorite or quartz monzonite intrusive plutons.

Generic deposit model:

Deposit model:

Ag-Pb-Zn replacement deposit in carbonates (Cox and Singer, 1986; model 19a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

19a

Production Status: None

Site Status: Active

Workings/exploration:

WGM Inc. conducted a regional stream-sediment reconnaissance in the upper Little Whiteman Creek area in 1975 (Dashevsky and others, 1986). In 1977, WGM Inc. carried out reconnaissance soil sampling, and did a reconnaissance magnetic survey; in 1978 they did a follow-up panned heavy-mineral-concentrate survey. In 1981, Arctic Resources Inc. mapped the ridges and collected soil samples in the area. Doyon, Ltd. conducted a placer reconnaissance in 1982. In 1990, Central Alaska Gold Co. mapped the geology and collected soil, rock, and stream-sediment samples (WGM Inc., 1998). In 2001, WGM Inc. sampled. Under an agreement with Doyon Ltd., Full Metal Minerals began work on this prospect in 2006. Full Metal Minerals subsequently established a separate company, Full Metal Zinc, to explore their properties in the 40 Mile District. As of March, 2012, Full Metal Zinc had drilled 72 holes on 50-meter centers at the LWM prospect and outlined a zone of mineralization that extends 970 meters along strike and 300 meters down dip (Full Metal Zinc, 2012 [40 Mile]; 2012 [LWM]).

Last report date: 2012-04-01

Site name(s): Main Zone; Saddle Zone; Trench 24; Napoleon

Site type: Prospect

ARDF no.: EA115

Latitude: 64.1643 **Quadrangle:** EA A-2

Longitude: 141.6352

Location description and accuracy:

This site consists of 3 discrete but adjacent mineralized zones, the Main Zone, the Saddle Zone, and the Trench 24 zone. These are often combined with the nearby Twin Peaks (EA167) and with the Burnt Ridge (EA168) prospects under the name Napoleon or Napoleon Block/claims. The three zones are near peak 3750 northwest of the head of Napoleon Creek and occupy much of the west half of section 35, T. 28 N., R. 19 E. The location is accurate.

Commodities:

Main: Ag, Au, Pd, Pt

Other:

Ore minerals: Gold, hematite, pyrite

Gangue minerals: Carbonate, chlorite, epidote, K-feldspar, quartz, sericite

Geologic description:

As described by Eden (2010), this site consists of three discrete but adjacent mineralized zones: the Main Zone, the Saddle Zone, and the Trench 24 zone. All are in the Napoleon pluton which is roughly equidimensional and about 4 miles wide. The pluton is mainly weakly to strongly foliated hornblende, quartz monzonite. Hornblende from this pluton gives a Jurassic 40Ar/39Ar plateau age of 186.5 +/- 1.3 Ma (Layer and others, 2002). The pluton contains small bodies of biotite clinopyroxenite and coarse-grained hornblende gabbro, which form inclusions, dikes, and/or marginal phases (Werdon and others, 2001). Clinopyroxenite bodies in the Napoleon pluton contain as much as 25 parts per billions (ppb) platinum and 6 ppb palladium (Werdon and others, 2000). Biotite clinopyroxenite dikes, which are compositionally and texturally similar to those in the northeastern Eagle quadrangle, give K-Ar ages of 184-185 Ma (Newberry and others, 1996). The Napoleon pluton and the inclusions/dikes of clinopyroxenite and hornblende gabbro are cut by minor, granite and aplite dikes of unknown age. The pluton intrudes amphibolite-facies amphibolite, quartzite, paragneiss, marble, orthogneiss, and minor schist (Werdon and others, 2001). The Napoleon pluton and surrounding country rocks are cut and offset by high-angle faults.

Airborne magnetic and resistivity surveys were flown in the Fortymile Mining district in 1998 (Alaska Division of Geological and Geophysical Surveys and others, 1999). The Alaska Division of Geological and Geophysical Surveys conducted 1:63,360-scale bedrock and surficial geologic mapping in the area from 1999 to 2001. The mineralization was discovered by Kennecott Exploration in 1998 and 1999 by detailed soil and rock sampling and airborne and ground geophysical surveys (Jones and Olson, 1999; Eden, 2010). In 1999, Kennecott drilled 9 holes on the Main Zone, 3 holes on the Saddle Zone, and 2 holes on the Trench 24 zone, and dug 24 trenches that totaled 464 meters. In 2000 and 2001, Tech Resources explored the property with ground and magnetic geophysical surveys and drilled 4 holes on the Main Zone and 3 holes on the Saddle Zone. A large block of claims was staked over the property in 2007 by Millrock Resources Inc., the current owners of the property (Millrock, 2011), and they have done considerable rock and soil sampling.

The mineralization is controlled by a major east-west trending shear zone that has been traced along strike for at least 4 miles (Eden, 2010). As best exposed in the Main Zone, this shear zone is at least 150 feet thick.

Along this shear zone, the Napoleon pluton is cut by several discrete concentrations of narrow quartz veins including the three that make up this site. These veins typically strike northwest or north-northeast and dip steeply south. The veins are up to 12 inches thick, and consist of mainly of quartz +/- pyrite +/- hematite +/- epidote +/- carbonate +/- rare visible gold. Samples from the quartz veins assayed as much as 15 ounces of gold per ton and rarely contained less than 0.2 ounces of gold per ton. Vein selvages commonly contain K-feldspar, some of which is partly replaced by sericite. Sericite-altered K-feldspar from the selvage of a gold-quartz vein gives a Cretaceous 40Ar/39Ar isochron age of 127.8 +/- 1.6 Ma (Layer and others, 2002); this is approximately 60 Ma younger than the Napoleon pluton and is tentatively interpreted to reflect the time of mineralization.

The best exposed mineralization and the focus of most of the exploration has been the Main Zone. The most notable drill intercepts on the Main Zone were two feet that contained 34.71 grams of gold per tonne and 2 feet that contained 17.74 grams of gold per tonne. The drilling at the Saddle Zone and Trench 24 zone tested a strong gold anomalies in soil. The best drill intercepts on the Saddle Zone were 3 meters with 8.49 grams of gold per tonne and 0.5 meters with 14.21 grams of gold per tonne. The best drill intercepts on the Trench 24 zone were 5 feet with 3.90 grams of gold per tonne, and 0.61 meters with 5.566 grams of gold per tonne.

Jones and Olson (1999) classified the prospect as a porphyry gold deposit. More recently, Eden (2010) classified it as a plutonic related gold-quartz vein deposit as defined by Lefebure and Hart (2005).

Alteration:

K-feldspar adjacent to quartz veins is partly altered to sericite.

Age of mineralization:

Sericite-altered K-feldspar from the selvage of a gold- quartz vein gave a Cretaceous 40Ar/39Ar isochron age of 127.8 +/- 1.6 Ma (Layer and others, 2002); this is tentatively interpreted to reflect the time of mineralization.

Generic deposit model:

Deposit model:

Plutonic related gold-quartz vein deposit (Lefebure and Hart, 2005).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The mineralization was discovered by Kennecott Exploration in 1998 and 1999 by detailed soil and rock sampling and airborne and ground geophysical surveys (Jones and Olson, 1999; Eden, 2010). In 1999, Kennecott drilled 9 holes on the Main Zone, 3 holes on the Saddle Zone, and 2 holes on the Trench 24 zone, and dug 24 trenches that totaled 464 meters. In 2000 and 2001, Tech Resources explored the property with ground and magnetic geophysical surveys and drilled 4 holes on the Main Zone and 3 holes on the Saddle Zone. A large block of claims was staked over the property in 2007 by Millrock Resources Inc., the current owners of the property (Millrock, 2011), and they have done considerable rock and soil sampling.

Production notes:

None.

Reserves:

None.

Site name(s): Boundary

Site type: Prospect

ARDF no.: EA152

Latitude: 64.0985 **Quadrangle:** EA A-1

Longitude: 141.028

Location description and accuracy:

The Boundary prospect covers about 2 square miles; it is bounded to the east by the Canadian border, to the south by the Top of the World Highway, to the west by Arkansas Creek, and to the north by the ridge north of Brophy Creek. The coordinates are the approximate center of the drillholes, in the northeast 1/4 section 26, T. 27 N., R. 22 E., of the Copper River Meridian; the location is accurate.

Commodities:

Main: Pb, Zn

Other: Ag, Cu

Ore minerals: Chalcocite?, chalcopyrite, covellite, galena, pyrite, sphalerite

Gangue minerals: Chlorite, quartz

Geologic description:

The Boundary prospect is interpreted to be a lead-zinc-copper-silver, volcanogenic massive-sulfide deposit. The prospect is in greenschist-facies metamorphic rocks, including quartz-white mica schist, and underlying quartz-chlorite-white mica schist and minor quartz-chlorite schist. Foliation and compositional layering generally dip 20 to 30 degrees to the north and northwest (Resource Associates of Alaska, 1977). These rocks are part of the Klondike Schist (the Klondike series of McConnell, 1905). The Klondike Schist has mid-Permian protolith ages determined by uranium-lead zircon dating (Mortensen, 1999). Because the Klondike Schist hosts mineralization that is probably syngenetic with its host rocks, the stratabound sulfide mineralization is probably mid-Permian. A galena sample taken from drill core from the Boundary prospect was analyzed for common lead values in two separate dissolutions. Both analyses fall within the middle of the field for galenas from other Permian Klondike Schist-hosted syngenetic occurrences in the area (J.K. Mortensen, written communication, 2002).

Klondike Schist near the Boundary prospect overlies carbonaceous schist and quartzite to the south that are part of the Nasina Series, which has a Mississippian protolith age (McConnell, 1905; Resource Associates of Alaska, 1977; Mortensen, 1999). Along the north side of the Boundary prospect, serpentinized ultramafic rocks (including an ultramafic body more than 1 square mile in area along Hall Creek) crop out along a thrust contact with the overlying Nasina Series rocks and extend across the border into Yukon Territory (Mortensen, 1988; R.L. Flynn, unpub. data, 2000). Two base-metal sulfide prospects in Klondike Schist are located across the border in the Yukon Territory: the Baldy prospect is 2 miles to the east, and the Pub prospect is 5 miles to the east of the Boundary prospect (Mortensen, 1988).

At the Boundary prospect, the Klondike Schist contains abundant quartz lenses; locally abundant iron oxides replace pods of pyrite and occur along the foliation (R.L. Flynn, unpub. data, 2000). Surface oxidation is extensive to depths of more than 300 feet in drillcore, and there are local gossan zones. Where sulfides are present in outcrop, they are generally found as thin laminations and include pyrite and minor galena, sphalerite, and covellite and possibly chalcocite (Resource Associates of Alaska, 1977). The sulfides most commonly occur in felsic schist. Sulfides in drillcore are found to below 300 feet and consist primarily of pyrite, with rare galena, sphalerite, and chalcopyrite (Resource Associates of Alaska, 1977). Whole-rock analyses of some felsic schists indicate that they have high magnesium and iron contents,

suggesting chlorite alteration; chlorite alteration is visible in some drillcore samples (Smit, 2000).
A lead-zinc-copper-silver geochemical anomaly occurs along the contact between felsic schists and mafic schists at the Boundary prospect (Smit, 2000). Rock samples from gossan zones commonly contain 3,000 to 5,000 parts per million (ppm) lead, 300 to 500 ppm zinc, 300 to 800 ppm copper, and 7 to 14 ppm silver; gold is below detection limits. Zinc is more dispersed than lead; a soil geochemistry anomaly approximately 6,000 by 2,000 feet in extent typically has 100 to 300 ppm lead, 300 to 700 ppm zinc, and 75 to 100 ppm copper, with less than 2 ppm silver. Stream sediments generally contain less than 50 ppm lead and copper, but they typically contain 400 to 900 ppm zinc (Resource Associates of Alaska, 1977). Several geochemically anomalous intervals were found in drillcore; a 48-foot section of pyritic chlorite schist has 241 ppm copper, 709 ppm lead, 1,933 ppm zinc, and 6.4 ppm silver (Smit, 2000).

Alteration:

Oxidation is extensive to depths of more than 300 feet, and there are local gossan zones (Resource Associates of Alaska, 1977). Whole-rock analyses of some felsic schists indicate that they have high magnesium and iron contents, suggesting chlorite alteration; chlorite alteration is visible in some drillcore samples (Smit, 2000).

Age of mineralization:

Because the Klondike Schist hosts mineralization that is probably syngenetic with its host rocks, the stratabound sulfide mineralization is probably mid-Permian. A galena sample taken from drillcore from the Boundary prospect was analyzed for common lead values in two separate dissolutions. Both analyses fall within the middle of the field for galenas from other Permian, Klondike Schist-hosted syngenetic occurrences in the area (J.K. Mortensen, written commun., 2002).

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Workings/exploration:

The area between Arkansas Creek (see EA150) and Brophy Creek was first identified as a potential lead-zinc deposit by R.R. Asher of the Alaska Division of Mines and Geology (Asher, 1970). Asher observed a gossan zone with limonite replacing pyrite, and several samples contain anomalous lead, zinc, and copper. In 1977, Resource Associates of Alaska conducted regional and detailed geologic mapping, sampled soil on a grid over about 2 square miles, and drilled four diamond drill holes totaling 1,560 feet near Brophy Creek. Recoveries were poor; only two of the drill holes reached target depth, and massive sulfides were not intersected. Most of this drillcore is now stored at the University of Alaska Museum, Fairbanks, Alaska. Resource Associates of Alaska (1977) suggested that the drillholes may have been collared in the footwall of a potential massive-sulfide deposit and the deposit may be to the north of Brophy Creek, down-dip and up-section. However, recent mapping (R.L. Flynn, unpub. data, 2000) suggests that near Brophy Creek, Nasina Series rocks have been thrust over the Klondike Schist that hosts the Boundary prospect. A horizontal-loop-EM (electromagnetic) survey with a penetration depth of about 140 feet was run on six grid lines by Resource Associates of Alaska in 1977, but no conductors were found.
Regional exploration was conducted by Anaconda in the Boundary area in 1978; about 70 square miles was mapped at a reconnaissance scale (Wiltse, 1978). In 1979, two holes totaling 1,004 feet were drilled by American Copper and Nickel Company in the same area, but they also failed to intersect massive-sulfide mineralization (Smit, 2000); most of this drillcore is still at the drill hole collars, but information about the

orientation of the holes has been lost. Limited work on the Boundary prospect in 1999 by Grayd Resource Corporation did not produce new exploration targets (Smit, 2000).

In 2010 Full Metal Minerals (FMM) staked the Boundary prospect and in 2011 completed soil sampling along the ridge north of the Top of the World Highway near Davis Dome. The following year FMM collected 107 more soil samples along the spurs around the Boundary prospect area. Results showed a copper and zinc anomaly in the chlorite-sericite schist. Rock samples collected in gossan zones near areas of historic drilling contained up to 1,025 parts per million (ppm) lead, 669 ppm copper, 392 ppm zinc, and 4.9 ppm silver (King, 2012).

Site name(s): Drumstick

Site type: Prospect

ARDF no.: EA166

Latitude: 64.1316 **Quadrangle:** EA A-5

Longitude: 143.2114

Location description and accuracy:

The Drumstick prospect is on the ridge about a half mile north of the mouth of Silas Pup, a short headwater tributary of My Creek. It is in about the middle of the west half of section 11, T. 27 N., R. 11 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals: Calcite

Geologic description:

Although mineralization at the Drumstick prospect was probably recognized earlier in several pits dug in conjunction with work at the nearby Eva prospect (EA099), it first cited as a separate prospect by Full Metal Minerals (2008 [40 mile]) in 2007.

The Drumstick prospect is in Paleozoic gneiss, schist, quartzite, and marble, that have been intruded by the Mount Veta syenite of Jurassic age (Foster, 1976). Other Tertiary to Mesozoic monzonite and granite plutons are about 1 mile east of the prospect, and there are felsic and mafic dikes in the area (Dashevsky and others, 1986). The granitic pluton to the east is epidotized and contains scattered altered zones near the contact (Foster and Clark, 1970).

Full Metal interprets the Drumstick prospect as an extension of the Eva prospect and like it a carbonate replacement deposit that consists of partially oxidized, coarsely crystalline sphalerite, with galena, and chalcopyrite. Three samples of the mineralization were collected from old prospect pits by Full Metal Minerals, (2008 [high grade]; 2008 [map]). Two of the samples contained 21.6 and 11.6 percent zinc, 19.1 and 8.1 percent lead, 222 and 863 grams of silver per tonne, and anomalous gold and copper. The Drumstick prospect is within a 1,100-meter-long by approximately 120-meter-wide soil anomaly marked by lead values of 100 to 7,980 parts per million. The anomaly coincides with subtle vegetation 'kill zones', similar to the one at the LWM prospect (EA 102), 22 kilometers to the northeast.

Stevens (2010) reports that 8 holes were drilled at the Drumstick prospect in 2008. Some notable intercepts are: 1) 1.4 meters that averaged 44.5 grams of silver per tonne, 2.27 percent lead, and 11.75 percent zinc; 2) 6.03 meters that averaged 3 grams of silver per tonne and 0.16 percent zinc; and 3) 1 meter that averaged 14 grams of silver per tonne, 0.39 percent lead, and 1.67 percent zinc.

Alteration:

Not specifically noted.

Age of mineralization:

Probably Jurassic or younger based on nearby Jurassic plutons.

Generic deposit model:

Deposit model:

Silver-lead-zinc carbonate replacement deposit (Cox and Singer, 1986; model 19a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

19a

Production Status: None

Site Status: Active

Workings/exploration:

Probably undocumented prospecting and sampling as far back as the 1980s. In 2008 being explored by Full Metal Minerals and they drilled 8 holes that year.

Production notes:

None.

Reserves:

None.

Site name(s): Twin Peaks; Napoleon

Site type: Prospect

ARDF no.: EA167

Latitude: 64.1698 **Quadrangle:** EA A-2

Longitude: 141.5601

Location description and accuracy:

This prospect is about 2.2 miles east of peak 3750, just northeast of the head of Napoleon Creek. It is about 0.5 mile north of the center of section 31,T. 28 N., R. 20 E. This prospect is often combined with the nearby Main Zone, Saddle Zone, and Trench 24 sites (EA115) and with the Burnt Ridge (EA168) prospects under the name Napoleon or Napoleon Block/claims.

Commodities:

Main: Ag, Au, Pd, Pt

Other:

Ore minerals: Gold, hematite, pyrite

Gangue minerals: Carbonate, chlorite, epidote, K-feldspar, quartz, sericite

Geologic description:

The Twin Peaks prospect is about 2 miles east of ARDF site EA115. Although it is a discrete mineralized area, it is along the same regional structure and shares the same characteristics and origin. The Twin Peaks prospect, like those to the west, is in the Napoleon pluton which is roughly equidimensional and about 4 miles wide. The pluton is mainly weakly to strongly foliated hornblende quartz monzonite. Hornblende from this pluton gives a Jurassic 40Ar/39Ar plateau age of 186.5 +/- 1.3 Ma (Layer and others, 2002). The pluton contains small bodies of biotite clinopyroxenite and coarse-grained hornblende gabbro, which form inclusions, dikes, and/or marginal phases (Werdon and others, 2001). Clinopyroxenite bodies within the Napoleon pluton contain as much as 25 parts per billion (ppb) platinum and 6 ppb palladium (Werdon and others, 2000). Biotite clinopyroxenite dikes, which are compositionally and texturally similar to those in the northeastern Eagle quadrangle, give K-Ar ages of 184-185 Ma (Newberry and others, 1996). The Napoleon pluton and the inclusions/dikes of clinopyroxenite and hornblende gabbro are cut by minor, granite aplite-pegmatite dikes of unknown age. The Napoleon pluton intrudes amphibolite-facies amphibolite, quartzite, paragneiss, marble, orthogneiss, and minor schist (Werdon and others, 2001). The Napoleon pluton and surrounding country rocks are cut and offset by high-angle faults.

Airborne magnetic and resistivity surveys were flown in the Fortymile Mining district in 1998 (Alaska Division of Geological and Geophysical Surveys and others, 1999). In 1998 and 1999, Kennecott Exploration did detailed soil- and rock sampling, and airborne and ground geophysical surveys which led to the discovery of the Twin Peaks mineralization (Jones and Olson, 1999; Eden, 2010). In 1999, Kennecott drilled 16 holes on similar mineralization to the west (EA115 and EA New G1002) but dug only one trench at Twin Peaks. Encouraged by strong geochemical anomalies, Teck Resources drilled one hole at Twin Peaks in 2001. A large block of claims was staked over the property in 2007 by Millrock Resources Inc., the current owners of the property (Millrock, 2011) and they have done considerable rock and soil sampling in the area.

While not as well known as the mineralization at site EA115 about two miles to the west, the Twin Peaks mineralization is almost certainly controlled by a major east-west trending shear zone that has been traced along strike for at least 4 miles (Eden, 2010). As best exposed in the Main Zone propsect (EA115), this shear zone is at least 150 feet wide. Along this shear zone, the Napoleon pluton is cut by several discrete

swarms of narrow quartz veins, including at this prospect. These veins typically strike northwest or north-northeast and dip steeply south. These veins are up to 12 inches thick, and consist of mainly of quartz +/- pyrite +/- hematite +/- epidote +/- carbonate +/- rare visible gold. Vein selvages commonly contain K-feldspar, some of which is partly replaced by sericite. Sericite-altered K-feldspar from the selvage of a gold + pyrite + quartz vein gave a Cretaceous 40Ar/39Ar isochron age of 127.8 +/- 1.6 Ma (Layer and others, 2002); this is approximately 60 Ma younger than the Napoleon pluton and is tentatively interpreted to reflect the time of mineralization. Quartz vein samples contained up to 15 ounces of gold per ton and rarely less than 0.2 ounce of gold per ton. The best intercept in the 2001 Teck drilling at Twin Peaks was 7.6 meters that contained 2.69 grams of gold per tonne.

Jones and Olson (1999) classified the prospect as a porphyry gold deposit. More recently, Eden (2010) classified it as a plutonic related gold-quartz vein deposit as defined by Lefebure and Hart (2005).

Alteration:

K-feldspar adjacent to quartz veins is partly altered to sericite.

Age of mineralization:

Sericite-altered K-feldspar from the selvage of a gold- quartz vein gave a Cretaceous 40Ar/39Ar isochron age of 127.8 +/- 1.6 Ma (Layer and others, 2002); this is tentatively interpreted to reflect the time of mineralization.

Generic deposit model:

Deposit model:

Plutonic related gold-quartz vein deposit (Lefebure and Hart, 2005).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 1998 and 1999, Kennecott carried out detailed soil- and rock sampling, and airborne and ground geophysical surveys which led to the discovery of the Twin Peaks prospect (Jones and Olson, 1999; Eden, 2010). In 1999, Kennecott drilled 16 holes on similar mineralization to the west (EA115 and EA168) but dug only one trench at Twin Peaks. Encouraged by strong geochemical anomalies, Teck Resources drilled one hole in 2001 at Twin Peaks. A large block of claims was staked over the property in 2007 by Millrock Resources Inc., the current owners of the property (Millrock, 2011) and they did considerable rock and soil sampling in the area.

Site name(s): Burnt Ridge; Napoleon

Site type: Prospect

ARDF no.: EA168

Latitude: 64.1554 **Quadrangle:** EA A-2

Longitude: 141.6189

Location description and accuracy:

This prospect is about 1 mile southeast of peak 3750, about 0.6 mile west of the fork at the head of Napoleon Creek. It is about 0.6 mile north-northeast of the center of section 2, T. 27 N., R.19 E. This prospect is sometimes combined with the nearby Main Zone, Saddle Zone, and Trench 24 prospects (EA115) and with the Twin Peaks (EA167) prospects under the name Napoleon or Napoleon Block/claims.

Commodities:

Main: Ag, Au, Pd, Pt

Other:

Ore minerals:

Gangue minerals: Carbonate, chlorite, epidote, K-feldspar, quartz, sericite

Geologic description:

The Burnt Ridge prospect like those at the nearby prospects EA115 and EA167 to the north is within the Napoleon pluton, a roughly roughly equidimensional stock about 4 miles wide. The pluton is mainly weakly to strongly foliated hornblende, quartz monzonite. Hornblende from this pluton gives a Jurassic 40Ar/39Ar plateau age of 186.5 +/- 1.3 Ma (Layer and others, 2002). The pluton contains small bodies of biotite clinopyroxenite and coarse-grained hornblende gabbro, which form inclusions, dikes, and/or marginal phases (Werdon and others, 2001). Clinopyroxenite bodies within the Napoleon pluton contain as much as 25 parts per billion (ppb) platinum and 6 ppb palladium (Werdon and others, 2000). Biotite clinopyroxenite dikes, which are compositionally and texturally similar to those in the northeastern Eagle quadrangle, give K-Ar ages of 184-185 Ma (Newberry and others, 1996). The Napoleon pluton and the inclusions/dikes of clinopyroxenite and hornblende gabbro are cut by minor, granite aplite-pegmatite dikes of unknown age. The Napoleon pluton intrudes amphibolite-facies amphibolite, quartzite, paragneiss, marble, orthogneiss, and minor schist (Werdon and others, 2001). The Napoleon pluton and surrounding country rocks are cut and offset by high-angle faults.

Airborne magnetic and resistivity surveys were flown in the Fortymile Mining district in 1998 (Alaska Division of Geological and Geophysical Surveys and others, 1999). In 1998 and 1999, Kennecott Exploration did detailed soil- and rock sampling, and airborne and ground geophysical surveys which led to the discovery of the Burnt Ridge mineralization (Jones and Olson, 1999; Eden, 2010). In 1999, they drilled 13 holes on similar mineralization to the north (EA115) and 3 holes on Burnt Ridge. A large block of claims was staked over the property in 2007 by Millrock Resources Inc., the current owners of the property (Millrock, 2011) and they have done considerable rock and soil sampling in the area.

While not as well known as the similar mineralization to the north at ARDF site EA115, the Burnt Ridge mineralization is probably related to a major east-west striking shear zone exposed to the north or a similar parallel structure. This shear zone is at least 150 feet thick and contains several swarms of narrow sulfide-bearing quartz veins. The veins typically strike northwest or north-northeast and dip steeply south. The veins are up to 12 inches thick, and consist of mainly of quartz +/- pyrite +/- hematite +/- epidote +/- carbonate +/- rare visible gold. Vein selvages commonly contain K-feldspar, some of which is partly replaced by sericite. Sericite-altered K-feldspar from the selvage of a gold + pyrite + quartz vein gave a

Cretaceous 40Ar/39Ar isochron age of 127.8 +/- 1.6 Ma (Layer and others, 2002); this is approximately 60 Ma younger than the Napoleon pluton and is tentatively interpreted to reflect the time of mineralization. Samples of the quartz veins contain up to 15 ounces of gold per ton and rarely contain less than 0.2 ounces of gold per ton. The best intercept in the 1999 Burnt Ridge drilling was 35 feet that averaged 1.413 grams of gold per tonne; it included 5 feet that contained 6.56 grams of gold per tonne.

Jones and Olson (1999) classified the prospect as a porphyry gold deposit. More recently, Eden (2010) classified it as a plutonic related gold-quartz vein deposit as defined by Lefebure and Hart (2005).

Alteration:

Age of mineralization:

Sericite-altered K-feldspar from the selvage of a gold- quartz vein gave a Cretaceous 40Ar/39Ar isochron age of 127.8 +/- 1.6 Ma (Layer and others, 2002); this is tentatively interpreted to reflect the time of mineralization.

Generic deposit model:

Deposit model:

Plutonic related gold-quartz vein deposit (Lefebure and Hart, 2005).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 1998 and 1999, Kennecott did detailed soil- and rock sampling in the area as well as airborne and ground geophysical surveys which led to the discovery of the Burnt Ridge mineralization (Jones and Olson, 1999; Eden, 2010). In 1999, they drilled 13 holes on similar mineralization to the north (EA115) and 3 hole on Burnt Ridge. The best intercept was 35 feet that averaged 1.413 grams of gold per tonne; it included 5 feet that contained 6.56 grams of gold per ton Teck Resources drilled one hole at the Burnt Ridge prospect in 2001. A large block of claims was staked over the property in 2007 by Millrock Resources Inc., the current owners of the property (Millrock, 2011) and they have done considerable rock and soil sampling in the area.

Site name(s): West Eva

Site type: Prospect

ARDF no.: EA169

Latitude: 61.134 **Quadrangle:** EA A-5

Longitude: 143.3377

Location description and accuracy:

The West Eva prospect is near hill 3812, about 2 miles northeast of the junction of My Creek and Molly Creek. Two holes were drilled about 0.5 mile apart and the coordinates are between them, about 0.3 mile west of the center of section 7, T. 27 N., R. 11 E. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Galena?, sphalerite?

Gangue minerals:

Geologic description:

There was little information about the West Eva prospect until Full Metal Minerals Inc. began to work in the area in 2006. The country rocks in the area are amphibolite-facies Paleozoic metamorphic rocks of the 40-Mile assemblage (Stevens, 2010). The West Eva prospect is marked by geochemical soil anomalies in lead, silver, zinc. Full Metal explored the anomalies with two holes that were drilled in 2010, one 192 meters deep and the other 298 meters deep. The best intercepts were three, 6-meter intervals with 15-30 grams of silver per tonne, 0.0 to 0.04 percent copper, 0.36 to 0.96 percent lead, and 0.04 to 0.6 percent zinc; and a 1.4 meter intercept with 23 grams of silver per tonne, 0.01 percent copper, 0.5 percent lead, and 0.33 percent zinc.

Alteration:

Not specified.

Age of mineralization:

Younger than the Paleozoic host rocks.

Generic deposit model:

Deposit model:

Insufficient information to assign.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Gridded geochemical sampling, surface mapping, and 2 holes drilled in 2010 by Full Metal Minerals Inc.

Production notes:

None.

Reserves:

None.

Additional comments:

The West Eva prospect is on Doyon, Ltd. selected or conveyed land. For more information contact Doyon, Ltd., Fairbanks, Alaska.

Last report date: 2012-04-01

Site name(s): Maple Leaf

Site type: Prospect

ARDF no.: EA170

Latitude: 64.4013 **Quadrangle:** EA B-6

Longitude: 143.9333

Location description and accuracy:

The Maple Leaf prospect is located 2 miles north of Eisenmenger Fork, Goodpaster River; 0.6 mile from the center of section 11, T. 6 S., R. 19 E., of the Fairbanks Meridian. This location is accurate to within 500 feet.

Commodities:

Main: Au

Other: As, Bi, Mo, Te

Ore minerals: Arsenopyrite, bismuthinite, gold, molybdenite

Gangue minerals: Quartz, sericite

Geologic description:

The Maple Leaf prospect is located in the eastern edge of the Goodpaster Mining District, and it was discovered during regional pan concentrate and stream sediment sampling conducted by Avalon Development Corp. for Evanachan Ltd. in the fall of 2006 (Freeman, 2015).

The primary host rocks at the Maple Leaf prospect are Cretaceous(?) age unfoliated biotite granite and biotite quartz monzonite. These rocks are fine- to medium-grained, equigranular and contain abundant quartz and biotite. There are numerous dikes of the biotite granite-quartz monzonite cutting the gneissic country rocks. Sulfide-bearing auriferous quartz veins are hosted in dikes of this unit. Maple Leaf is structurally bounded by numerous northeast-trending, near-vertical faults, which may control gold mineralization (Freeman, 2015).

Mineralization is characterized by sugary textured quartz veins and locally by vein stockworks of variable orientation associated with intrusive and country rock (gneisses) containing trace to 2 percent sulfides characterized by arsenopyrite +/- bismuthinite +/- molybdenite and, locally, visible gold. Outcrop in the area is limited and solifluction has clearly transported float boulders down slope. Vein widths range from less than 1.0 meter to vein stockworks over 1-3 meters. Large (0.5 by 0.25 meter) boulders containing bismuthinite-bearing veins noted from the prospective area have not yet been traced to their source although, given the topography, the source is likely local (Freeman, 2014).

Samples from work in 2006 of a quartz vein boulder float/train and from stream sediment and pan concentrate samples in surrounding drainages identified a 10 kilometer by 7.0 kilometer area with greater than 100 parts per million (ppm) arsenic stream silt and pan concentrate anomaly. Within this area quartz vein samples interpreted as bedrock or sub-crop returned anomalous gold (from trace up to 12 grams per tonne). Evanachan Ltd. was acquired by Rubicon Minerals in early 2007 and follow up work, including limited diamond drilling (1,105 meters in 4 holes), was conducted in 2007.

Assays of grab rock samples collected in 2007 returned gold values from trace to 19.1 grams per tonne with 19 samples (total 114 rock samples) containing gold in excess of 1.0 gram of gold per tonne with an average of 5.2 grams of gold per tonne. Gold is associated with elevated bismuth (up to 7,700 ppm), tellurium (up to 280 ppm) and variable arsenic (Freeman, 2014).

Alteration:

Moderate to weak sericite alteration in biotite quartz monzonite adjacent to sugary textured quartz veins, which host the gold mineralization (Freeman, 2015).

Age of mineralization:

Cretaceous or younger based on age of host rock (Freeman, 2015).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Inactive

Workings/exploration:

The Maple Leaf prospect was discovered during regional pan concentrate and stream sediment sampling conducted by Avalon Development Corp. for Evanachan Ltd. in the fall of 2006. Follow up rock and grab samples were collected that year (Freeman, 2014).

In 2007, Avalon Development managed a diamond core drilling program for Rubicon on the Maple Leaf prospect. The program included 1,105 meters of drilling in four holes. Drilling beneath surface gold-quartz vein showings intersected weakly anomalous (up to 0.25 gram of gold per tonne over 0.8 meter) but did not intersect vein style mineralization similar to that observed on the surface (Freeman, 2014). Values up to 19 grams of gold per tonne were assayed (Freeman, 2014).

The land was open to mineral entry until staked by Anglo Alaska Gold Corp. in 2011 and assessment-level work has been conducted by Anglo Alaska since 2011 (Freeman, 2014).

Production notes:

None.

Reserves:

None.

Additional comments:

According to Freeman (2015), after the 2007 drilling, no other work was conducted on the Maple Leaf prospect and in the fall of 2008, Rubicon dropped the claims covering these prospects. No significant mineral exploration has been conducted on the prospect since that time.

Site name(s): Ninja Jim

Site type: Occurrence

ARDF no.: EA171

Latitude: 64.0714 **Quadrangle:** EA A-2

Longitude: 141.8729

Location description and accuracy:

The Ninja Jim prospect is located 0.8 mile southeast from the center of section 33, T. 27 N., R. 18 E., of the Copper River Meridian. Ninja Jim is located 1.9 miles east from the town of Chicken. This location is accurate to within 30 feet of the center of the prospect.

Commodities:

Main: Au

Other: Cu, Pb, Sb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, cinnabar, gold, stibnite

Gangue minerals: Calcite, quartz

Geologic description:

Ninja Jim is a prospect within the Chicken (EA9901) claim block, composed of a claim block of 12 claims held by Millrock Resources Inc. in the Fortymile mining district. The Ninja Jim prospect is named after Alaskan prospector Jim McLaughlin, who discovered the Golden Eagle lode prospect on McKinley Creek (Still and others, 1991). This area is underlain by older metamorphic rocks and younger igneous rocks. The metamorphic rocks have been dated from upper Paleozoic to Devonian with several undated units considered to be Pre-Mississippian. Metamorphic protoliths include both sedimentary and igneous rocks. The metamorphic rocks are intruded by Cretaceous, equigranular to porphyritic, felsic to intermediate igneous bodies (Foster, 1970). Gold mineralization is most commonly found in quartz and calcite veins associated with arsenopyrite, chalcopyrite, cinnabar, stibnite and other sulfide minerals (Millrock Resources Inc., 2014).

Millrock has been working the Fortymile area since 2007 conducting geochemical sampling programs at the Chicken claim block (Millrock Resources Inc., 2014). In 2008, 25 rock samples collected over 400 meters along the stream reach at Ninja Jim averaged 0.6 part per million (ppm) gold. Two rock samples collected at the head of the stream measure 3.54 ppm gold and 3.39 ppm gold (Negri, K., Database/IT/GIS Manager, Millrock Resources Inc., written communication, 2014).

Alteration:

Age of mineralization:

Age of gold mineralization in the area is known to be prolific around 135 million years ago related to felsic to intermediate intrusions (Millrock Resources Inc., 2014).

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Site name(s): Tourmaline Ridge

Site type: Occurrence

ARDF no.: EA173

Latitude: 64.402 **Quadrangle:** EA B-6

Longitude: 143.987

Location description and accuracy:

The Tourmaline Ridge occurrence is located 1 mile northeast of the Eisenmenger Fork, Goodpaster River; about 0.5 mile north from the center of section 16, T. 6 S., R. 19 E., of the Fairbanks Meridian (Freeman, 2014). This location is approximate, although probably, accurate to within one mile.

Commodities:

Main: Au

Other: As, Bi

Ore minerals: Gold

Gangue minerals: Quartz, sericite, tourmaline

Geologic description:

The Tourmaline Ridge prospect is located in the eastern edge of the Goodpaster Mining District, and it was discovered in 2007 by Avalon Development Corporation. The upper 150 meters on this ridge, extending for about 800 meters along the ridge crest, is composed of tourmaline-bearing paragneiss containing massive tourmalinite (50 percent tourmaline) with lesser quartz veins and tourmaline-vein breccias. Numerous dikes of granite, ranging from less than 1 to 3 meters wide intrude the tourmaline-rich gneissic rocks and often contain tourmaline along the dike margins (Freeman, 2014).

Sampling of the tourmaline-rich rocks has returned weakly elevated gold (maximum 164 parts per billion (ppb)), up to 804 parts per million (ppm) bismuth and up to 2,620 ppm arsenic. The intensity and extent of tourmaline indicates that a fluid-rich intrusive-related mineralizing system is present on a large scale in the general Maple Leaf (EA9901) area (Freeman, 2014).

Alteration:

Age of mineralization:

Cretaceous or younger based on age of host rock (Freeman, 2014).

Site name(s): American Eagle

Site type: Occurrence

ARDF no.: EA174

Latitude: 64.4366 **Quadrangle:** EA B-6

Longitude: 143.8524

Location description and accuracy:

The American Eagle prospect is located 5 miles northeast from the of Eisenmenger Fork, Goodpaster River; about 0.1 mile southeast from the center of section 21, T. 5 S., R. 20 E., of the Fairbanks Meridian. This location is approximate although probably accurate to within one mile.

Commodities:

Main: Au

Other: As, Bi, Mo, Te

Ore minerals:

Gangue minerals: Quartz, sericite

Geologic description:

The American Eagle occurrence is located in the eastern edge of the Goodpaster Mining District, and it was discovered in 2007 during exploration work for Rubicon Minerals by Avalon Development Corp by a sampling program including steam sediment, pan concentrate samples, and rock sampling in the area.

The primary host rocks at the American Eagle prospect is Cretaceous(?) age unfoliated biotite granite and biotite quartz monzonite. These rocks are fine- to medium-grained, equigranular and contain abundant quartz and biotite. There are numerous dikes of this biotite granite-quartz monzonite cutting the gneissic country rocks. Sulfide-bearing auriferous sheeted white quartz veins ranging from 0.1 to 1.0 cm thick are hosted in dikes of this unit. Vein material makes up 5 percent-10 percent of the country rock over an area of 400 by 50 meters. Quartz veins at American Eagle host extremely course grained bismuthinite in flat,sometimes deformed tabular plates ranging up to 1.0 cm in maximum dimensions. The bismuth-bearing veins have not been seen in outcrop and occur on a coarse boulder-strewn talus slope just below a flat ridge line. Limited grab sampling along this ridge has returned gold values ranging from trace to 3.03 gpt gold, up to 3,880 ppm bismuth, up to 5,610 ppm arsenic and up to 494 ppm molybdenum. The full extent of this mineralization is unknown due to extensive talus cover (Freeman, 2014).

Samples from a quartz boulder train and from steam sediment and pan concentrate samples in surrounding drainages in 2006 identified a 10 kilometer by 7.0 kilometer, greater than 100 ppm arsenic stream silt and pan concentrate anomaly within which samples of quartz veins interpreted as bedrock or sub-crop returned anomalous gold (from trace up to 12 gpt) (Freeman, 2014).

Assays of grab rock samples collected in 2007 returned gold values from trace to 19.1 gpt with 17 percent of samples (total 114 rock samples) containing gold in excess of 1.0 gpt gold with an average of 5.2 gpt gold (Freeman, 2014).

Alteration:

Moderate to weak sericite alteration adjacent to sugary textured quartz veins which host the gold mineralization (Freeman, 2014).

Age of mineralization:

Cretaceous or younger based on age of host rock (Freeman, 2014).

Generic deposit model:

Deposit model:

Gold-quartz veins that contain bismuth and tellurium? (Cox and Singer, 1986; model 22c?)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Reporter(s): V.C. Zinno (Alaska Earth Sciences, Inc.)

Last report date: 2014-12-09

Site name(s): Unnamed (near Crescent Creek)

Site type: Occurrence

ARDF no.: EA175

Latitude: 64.9654 **Quadrangle:** EA D-6

Longitude: 143.6824

Location description and accuracy:

An unnamed tungsten occurrence is located on the north bank of Crescent Creek at the confluence of an unnamed northerly tributary stream. The site lies about 2 miles west of Beverly Creek, which is another tributary to Crescent Creek. All local drainages are to the Charley River, located east of the site. The occurrence is in the SE1/4 sec. 28, T. 2 N., R. 20 E., of the Fairbanks Meridian, and the location given is the approximate midpoint of an area of hornfels boulders. Accuracy of the location is about 1,000 feet.

Commodities:

Main: W

Other: Li, Sn

Ore minerals: Cassiterite, scheelite

Gangue minerals: Amphibole, chlorite, epidote, garnet, muscovite, quartz, sericite, tourmaline

Geologic description:

Local igneous rocks, mostly biotite-quartz monzonite and its more felsic segregations, are part of a much larger Mesozoic to Tertiary age intrusive complex in east-central Alaska (Foster and others, 1973; Foster, 1976; Brabb and Churkin, 1969). North of Crescent Creek the granitic rocks intrude biotite gneiss, amphibolite and subordinate quartz-biotite gneiss, schist, and marble (Foley and Barker, 1981). Near this site leucocratic aplite dikes are also common. Contact margins between these rocks are locally retrograded to plagioclase- and pyroxene-hornfels and banded calc-silicate.

Near the confluence of an unnamed creek with Crescent Creek green siliceous carbonate rock with scheelite occurring as layered and dissemination of aggregate grains is reported, as well as minor disseminated scheelite in some granitic boulders (Foley and Barker, 1981). Locally minor scheelite also occurs as isolated interstitial grains in aplite and within quartz veinlets cutting these dike rocks. Minor constituent minerals in the aplite groundmass include garnet, tourmaline, muscovite and epidote. Dravite-filled fractures in granitic rock and disseminated scheelite are noted in the vicinity. Lithium in the granitic rocks was also found substantially anomalous. Local areas of sericite greisen occur in the quartz monzonite along joints and faults. Placer scheelite occurs in the stream bed about two miles upstream (Foley and Barker, 1981).

Alteration:

Silicification and greisen formation with scheelite and minor cassiterite (Foley and Barker, 1981).

Age of mineralization:

Granitic rocks that host primary scheelite occurrences are believed to be Cretaceous with some subordinate granitic rocks of early Tertiary age (Brabb and Churkin, 1969; Foster, 1976). Mineralization appears concordant with the younger (Tertiary) intrusive phase.

Generic deposit model:

Deposit model:

Tungsten greisen (Cox and Singer, 1986; model 15c); Skarn tungsten (Cox and Singer, 1986; model 14a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

15c, 14a

Production Status: None

Site Status: Inactive

Workings/exploration:

This unnamed tungsten occurrence was selected for study by the U.S. Bureau of Mines in 1977 because reconnaissance sampling had defined a broad southeasterly trend of mostly poorly known or unreported tungsten occurrences beginning near Pinnell Mountain in the Circle mining district and extending eastward across the headwaters of the Charley and Seventy Mile Rivers (Barker, 1978; Foley and Barker, 1981). Stream sediment and heavy mineral surveys of the upper Charley River basin were part of the Bureau's land assessment surveys for the proposed Alaska Lands legislation. The occurrences of tungsten mineralization first reported in 1978, were later studied and reported in greater detail in 1981 (Foley and Barker, 1981) and included ultraviolet scanning of the occurrence near Crescent Creek. Twelve samples of granitic rocks from this site, located about 2 miles west of Beverly Creek, were analyzed for lithium and tungsten, yielding lithium values ranging from less than 20 to more than 1,000 parts per million (ppm). Tungsten values were generally less than 20 ppm, though one quartz monzonite sample yielded 1357 ppm tungsten and a hornfels sample 96 ppm tungsten.

Production notes:

None.

Reserves:

None.

Additional comments:

The assessment of the Crescent Creek tungsten occurrence was done in 1977-1978; the occurrence is now within the Yukon-Charley Rivers National Preserve and mineral development is prohibited.

Site name(s): Ryan Lode

Site type: Mine

ARDF no.: FB065

Latitude: 64.863 **Quadrangle:** FB D-2

Longitude: 147.99

Location description and accuracy:

The Ryan mine is on the ridge between Eva Creek and Saint Patrick Creek, on the southeast side of Ester Dome. The mine workings are marked on the Fairbanks D-2 topographic map in the NW1/4NE1/4 section 5, T. 1 S., R. 2 W., of the Fairbanks Meridian. The property can be reached from the Parks Highway by turning east on Gold Hill Road for about a quarter of a mile, then north and then west on Saint Patrick Road for about 2 miles. The extensive workings can be seen on both sides of the road. The mine is included in locality 18 of Cobb (1972 [MF 410]). This location is accurate to within 500 feet.

Commodities:

Main: Ag, Au

Other: Sb

Ore minerals: Arsenopyrite, gold, jamesonite, stibnite

Gangue minerals:

Geologic description:

The following is a summary of the Ryan Lode property prepared by Ryan Lode Mines, Inc. (Ryan Lode Mines, Inc., unpublished report, 1996). The Ryan lode is underlain by the Fairbanks Schist that consists of quartz-mica schist, mica schist, and calcareous schist. A small quartz monzonite intrusion is located in the southeast portion of the property. Prior to the intrusion, the rocks underwent several episodes of regional deformation. Post-intrusive brittle deformation resulted in pervasive near-vertical faulting. The dominant structural trend on the property parallels the regional trend of about N 45 E.

The ore reserves occur in two shear zones: the Ryan shear and the Curlew shear, which is just south of the Ryan shear. Both deposits are schist-hosted and structurally controlled. However, the Curlew shear is partially in a small quartz monzonite intrusion. A surface oxidation zone is present at both sites and varies in depth from 150 feet to more than 300 feet. Quartz veins in the shear zones contain gold, arsenopyrite, and minor pyrite and stibnite. The Ryan shear is of varied thickness and has an average strike of N 30 E. Where the shear zone trends N 35 E to N 55 E, secondary splays diverge from the main trunk at regular intervals along the shear. The dip of the Ryan shear varies between 50 and 80 degrees east. High-grade ore is found in pods which form at deflection points in the shear zone. As in the Ryan shear, the gold and sulfides in the Curlew shear are associated with quartz-filled voids in highly fractured rock. The intrusion (90 to 93 million years old) that hosts part of the Curlew shear appears to be sill-like, and in some places it is in fault contact with the surrounding schist. It has a core of quartz monzonite surrounded by a border of granodiorite to quartz diorite. There has been extensive sericitic alteration along shears and fractures within the intrusion. At least three alteration assemblages have been identified: quartz-muscovite-siderite, quartz-muscovite-chlorite, and silicification. White mica in the hydrothermal stockwork has been dated at 89.1 +/- 0.3 Ma (McCoy and others, 1997).

Gold ore was discovered at the Ryan lode in the early 1900s; the first production was recorded in 1911 (Brooks, 1912, p. 33). Work continued intermittently from 1911 to 1958. The gold varies from 814 to 834 fine (Glover, 1950). Between 1938 and 1942, more than 1,500 feet of shafts, 2,000 feet of drifts, adits and crosscuts, and more than 2,800 feet of trenching was completed (Warfield and Thomas, 1972). From 1987

to 1989, approximately 320,000 tons of ore were mined from an open pit (R. Hughes, written communication, 1996). In recent years, sampling of the Ryan and Curlew ore bodies has been accomplished by both reverse circulation and core drilling that began in 1990 and continued until 1993 (Ryan Lode Mines, Inc., unpublished report, 1996). From this drilling, a reserve of 8.27 million tons of material grading 0.077 ounce of gold per ton has been defined (Masterman and Campbell, 1993).

The 2002 resource estimate was an indicated resource of 3.0 million tonnes grading 2.37 grams of gold per tonne (Kinross Gold Corp., 2003).

Alteration:

A surface oxidation zone is present at both the Ryan and Curlew shears and varies in depth from 150 feet to more than 300 feet. There has been extensive sericitic alteration along shears and fractures within the quartz monzonite intrusion. At least three alteration assemblages have been identified: quartz-muscovite-siderite, quartz-muscovite-chlorite, and silicification (Ryan Lode Mines, Inc., unpublished report, 1996).

Age of mineralization:

McCoy and others (1997) dated both hydrothermal and intrusion-related minerals using the 40Ar/39Ar method. At the Ryan lode, hydrothermal white mica has been dated at 89.1 +/- 0.3 Ma, and white mica from hydrothermally altered schist has been dated at 87.6 +/- 0.3 Ma. The quartz diorite hornblende was dated at 90.6 +/- 0.3 Ma, and the quartz diorite biotite was dated at 90.2 +/- 0.3 Ma; both are cut by mineralized shear zones and thus are earlier than the mineralization.

Generic deposit model:

Deposit model:

Schist-hosted gold-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Work was reported on the property as early as 1911 (Brooks, 1912, p. 33). In 1913, a shaft was reported to be 90 feet deep (Smith, 1913 [B 525, p. 207]). By 1931, the workings consisted of shallow shafts and pits, a tunnel 300 feet long, and a shaft 200 feet deep (Hill, 1933, p. 135-138). In 1938, Bartholomae Oil Co. had control of the property and cleaned out the old shaft to a depth of 160 feet and drove 330 feet of drift and several hundred feet of crosscuts and raises (Smith, 1939 [B 917-A, p. 26]). In 1940, a large amount of development work was reported including trenching and geophysical work (Smith, 1942, p. 23). Between 1938 and 1942, more than 1,500 feet of shafts, 2,000 feet of drifts, adits and crosscuts, and more than 2,800 feet of trenching was completed (Warfield and Thomas, 1972). From 1954 to 1958, there was minor trenching and drlling (Warfield and Thomas, 1972). In 1969-70, the U.S. Bureau of Mines conducted a drilling program that was a pilot study to compare the cost and environmental damage of rotary drilling versus bulldozer trenching (Warfield and Thomas, 1972). Citigold Mining Company Ltd. acquired the project in 1985 and began a test heap leach, which was unsuccessful (Ryan Lode Mines, unpublished report, 1996). In 1986, La Teko Resources merged with Citigold, and a small, more successful heap leach test was conducted. Full scale production began in 1987. From 1987 to 1989, approximately 320,000 tons of ore were mined from the property by open pit methods (Rich Hughes, written communication, 1996). In recent years, sampling of the Ryan and Curlew ore bodies has been accomplished by both reverse circulation and core drilling, which began in 1990 and continued until 1993 (Ryan Lode Mines, Inc., unpublished report, 1996). In 1993, Citigold Alaska, Inc. was renamed Ryan Lode Mines, Inc. Exploration activity was suspended at the project at the end of 1993, although heap reclamation and detoxification efforts continue at the project site (Ryan Lode Mines, Inc., unpublished report, 1996). In 1997, over 8,000 feet of reverse-

circulation holes were drilled on the Ryan Lode (Swainbank and Clautice, 1998, p. 8). In 1999, the property was acquired by Kinross Gold Corporation. The deposit was idle while geology and development teams evaluate recent drilling and metallurgical studies (Kinross Gold Corporation, 2001a).

In 1999 Kinross Gold Corp. acquired La Teko and with it, their interests in the True North and Ryan Lode deposits. From 1999 until 2004, Kinross conducted drilling, resource estimates, and engineering of the Ryan Lode and adjacent Curlew deposits. Work in 2001 also included substantial confirmation and exploration drilling, and environmental baseline and geological and metallurgical studies (Kinross Gold Corp., 2001b). The 2002 resource estimate was an indicated resource of 3.0 million tonnes grading 2.37 grams of gold per tonne (Kinross Gold Corp., 2003).

In mid-2006 Kinross terminated its lease and relinquished Ryan Lode to the current owners, Gold Run Ltd. (Freeman, 2014).

Production notes:

The first shipment of ore was reported in 1911 (Brooks, 1912, p. 33). In 1938, Bartholomae Oil Co. cleaned out the old shaft and ore was taken out and milled (Smith, 1939 [B 917-A, p. 26]). There is no further production until the late 1980s when La Teko Resources mined approximately 320,000 tons of ore from a pit on the property from 1987 to 1989. This ore contained 19,220 ounces of gold and 14,330 ounces of silver (R. Hughes, written commun., 1996).

Reserves:

The 2002 resource estimate was an indicated resource of 3.0 million tonnes grading 2.37 grams of gold per tonne (Kinross Gold Corp., 2003).

In 2014, Freeman (2014) updated the resource estimate to 676,000 ounces of gold grading 0.066 ounce per ton in 10,167,000 tons of material, based on a 0.030 ounce per ton cut off.

Geologic description:

The following geologic description is summarized from a report by Sam Dashevsky (1993) on work done by American Copper and Nickel Company on the Eagle Creek property in the early 1990s. In the 1970s, an arsenic soil anomaly was identified in the area, and two samples were identified that contained more than 100 ppb gold. The soil anomaly is approximately 1,700 feet by 1,000 feet in area and contains anomalous levels of gold, antimony, arsenic, lead, and silver with erratic boron, copper and zinc values. The soil anomaly is underlain by quartz-mica schists, minor quartzite, and minor graphitic schist. This area was mapped by Newberry and others (1996) as Fairbanks Schist that consists of quartz-muscovite schist, quartzite, and chlorite-quartz schist. Silicification and quartz veining were noted in approximately half the soil pits. The trace of the anomaly follows the southern contact zone of a feldspar porphyry body. The soil anomaly diminishes over an intrusive. The igneous float in the area is altered to clay and locally silicifiied. A north-dipping fault has been inferred from airphotos and soil geochemistry. An east-northeast trending linear was traced from airphotos; the linear trends from the saddle between the east fork of Any Creek and Treasure Creek through the main body of the geochemical anomaly. Cross-cutting faulting is indicated by a sharp break in slope, suggestive of a fault scarp, that runs north-northeast through the anomalous area. Rock geochemistry on float fragments of the intrusive that were found in the soil pits indicates as much as 250 ppb gold. In a trench sample, rare quartz-stibnite-veined schist contains 6,050 ppb gold, 4.4 percent antimony, 2 ounces of silver per ton, and 758 ppm arsenic. Another specimen of silicified schist from the same location that is cross-cut by vuggy crustiform quartz veins contains 4,610 ppb gold, 4,601 ppm arsenic, 98 ppm antimony, and 3.5 ppm silver. Silicification and quartz veining are widespread throughout the anomaly. Iron staining, clay alteration, and bleaching of schist are noted in soil pit schist fragments. The quartz porphyry that marks the north edge of the anomaly is silicified and vuggy, and limonite fills vugs locally (Dashevsky, 1993).

Alteration:

Silicification and quartz veining are common in rock fragments found throughout the anomaly, as well as iron staining, clay alteration, and bleaching of schist. The quartz porphyry that marks the north edge of the anomaly is silicified and vuggy, and limonite fills vugs locally (Dashevsky, 1993).

Deposit model:
Schist-hosted gold- and antimony-bearing quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:
In the 1970s, Cantu Minerals conducted a soil-geochemistry survey of the area. In the 1980s, Tri-Con Mining, Inc. (the operating arm of CAN-EX Resources Inc.) reanalyzed some of the old soil sample pulps for gold and conducted some trenching. In 1990, American Copper and Nickel Company assumed interest in the Eagle Creek properties and sampled existing trenches and check-sampled across the previously defined gold-arsenic soil anomaly (Dashevsky, 1993).

In 2016, the Treasure Creek Partnership consolidated three, separately owned properties, including numerous prospects and occurrences (LG038; LG039; FB074; FB075; FB076; FB077; FB078; FB079; FB080; FB081) in the Treasure and Any Creek watersheds that potentially host plutonic-related, lode-gold mineralization contained in shear zones north of Fairbanks. Exploration activity in 2016 included conducting field work and reviewing and updating 1990s-era exploration information (Athey and Werdon, 2017).

Production notes:
None.

Reserves:
None.

Geologic description:

The following geologic description is summarized from a report by Sam Dashevsky (1993) on work done by American Copper and Nickel Company on the Eagle Creek property in the early 1990s. Soil samples anomalous in gold,arsenic,and antimony define a linear trend 2,000 feet long. A 1,000-foot portion near the crest of a loess ridge contains 1,500 ppb gold. The linear gold anomaly coincides with the northern limit of an isolated block of schist. This area was mapped by Newberry and others (1996) as Fairbanks Schist that consists of quartz-muscovite schist, quartzite, and chlorite-quartz schist. Rock fragments in float collected at various sample sites consisted of limonite-stained, altered, quartz-mica schist; chips of vein quartz were also noted. The schist fragments appear to be weakly argillized, are bleached, and contain quartz veins.

A strongly mineralized zone is present on the upper contact of a 25-foot-thick felsic sill; the sill dips shallowly to the north, is fine- to medium-grained, and is equigranular to weakly porphyritic. This upper contact appears to be a fault, the Redline shear, that contains calcite veining and limonite staining. A hornfelsed, 3-foot-thick siliceous schist marks the base of the sill. The mineralized fault contact was sampled and contains 10 feet of rock that assays 0.09 ounce of gold per ton. One hole was drilled on the Redline shear and assays from the samples showed values similar to those found in the soil samples: 120-165 ppb gold, 588-1,148 ppm arsenic, 26-50 ppm antimony. The Redline shear was recognized in the drill hole as argillized, black, silicified phyllite. The sheared upper intrusive contact is marked by carbonate and limonite alteration.

Alteration:

Schist fragments in soils appear to be weakly argillized, bleached, and veined with quartz. The Redline shear was recognized in the drill hole as argillized, black, silicified phyllite. The sheared upper contact of an intrusive body is marked by carbonate and limonite alteration (Dashevsky, 1993).

Latitude: 64.996 **Quadrangle:** FB D-2

Longitude: 147.775

Location description and accuracy:

The West Fork prospect is a soil anomaly approximately 2,500 feet by 1,500 feet in area. It is centered about 0.3 mile north of Old Murphy Dome Road in the southwest headwater tributary of Eagle Creek; it is in sec. 16, T. 2 N., R. 1 W., Fairbanks Meridian.

Commodities:

Main: Sb

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The following geologic description is summarized from a report by Sam Dashevsky (1993) on work done by American Copper and Nickel Company on the Eagle Creek property in the early 1990s. Five lines of soil samples spaced 600 feet apart define a 2,500-foot by 1,500-foot area of anomalous antimony; within it there is a 1,000-foot by 1,400-foot zone of weakly elevated silver. Rock fragments in soil are quartz-mica schist that is argillized, bleached, and veined with quartz. This area was mapped by Newberry and others (1996) as Fairbanks Schist that consists of quartz-muscovite schist, quartzite, and chlorite-quartz schist.

Alteration:

Schist fragments are weakly argillized, bleached, and veined with quartz (Dashevsky, 1993).

Age of mineralization:

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

In 1992, American Copper and Nickel Company conducted a soil survey that identified an area with anomalous antimony in the soil (Dashevsky, 1993).

In 2016, the Treasure Creek Partnership consolidated three, separately owned properties, including numerous prospects and occurrences (LG038; LG039; FB074; FB075; FB076; FB077; FB078; FB079; FB080; FB081) in the Treasure and Any Creek watersheds that potentially host plutonic-related, lode-gold mineralization contained in shear zones north of Fairbanks. Exploration activity in 2016 included conducting field work and reviewing and updating 1990s-era exploration information (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Site name(s): Scrafford; Treasure Creek

Site type: Mine

ARDF no.: FB077

Latitude: 64.999 **Quadrangle:** FB D-2

Longitude: 147.757

Location description and accuracy:

The Scrafford mine is located in the SE1/4 sec. 16, T. 2 N., R. 1 W., Fairbanks Meridian. This mine is accessible from the Elliott Highway and Old Murphy Dome Road. Approximately 4 miles down Old Murphy Dome Road, a steep, rough road leads 0.5 mile north to the Scrafford mine. The mine is just north of the southeast fork of Eagle Creek, a tributary of Treasure Creek.

Commodities:

Main: Sb

Other: Ag, Au, Pb

Ore minerals: Galena, gold, stibnite

Gangue minerals:

Geologic description:

The Scrafford mine is the largest producer of antimony ore in the Fairbanks mining district; production has been estimated at more than 2,700 tons of ore (Robinson and Bundtzen, 1982). Mining from open cuts took place from 1915 to 1916, in 1926, and from 1968 to 1970 (Cobb, 1976 [OFR 76-662, p. 169-170]). The deposit consists of massive stibnite localized along shear zones associated with stockwork-type quartz veinlets containing disseminated arsenopyrite and stibnite. The stibnite occurs in fibrous and columnar twinned crystals and as fine-grained massive aggregates (Robinson and Bundtzen, 1982). In 1916, an assay of mineralized rock showed an average grade of $4 in gold (about 0.19 ounce of gold per ton) and 8 ounces of silver per ton (Brooks, 1916 [B 649, p. 29]). Most of the antimony ore that was produced had grades of 56 to 60 percent antimony; ore mined in 1970 and 1971 had a lower grade of 12 to 16 percent antimony (Robinson and Bundtzen, 1982, p. 3).

In 1982, Robinson and Bundtzen (1982) spent three days mapping and sampling several trenches on the Scrafford property and the following is a summary of their findings. Rocks in the trenches include quartz-mica schist, micaceous quartz schist, calc-schist, feldspathic schist, felsic tuff, and graphitic schist. Several felsic dikes are also present. The center of antimony-gold mineralization occurs along an east-west-trending shear zone that separates a barren hanging-wall sequence of quartz-muscovite schist, micaceous quartzite, and quartz-feldspar schist from a mineralized footwall sequence of feldspathic, micaceous quartzite and minor quartz-mica schist. The footwall rocks are highly oxidized, sheared, and cut by anastomosing quartz-sulfide veinlets. The shear zone in the main open cut is exposed for at least 320 feet; it strikes N. 80-85 E and dips 55-60 S. The stibnite-bearing vein in the shear pinches and swells from a width of 4 to 19 feet and is confined to the footwall side of the shear zone. The shear zone ranges from 6 to 38 feet wide. The hanging wall of the shear zone is dominated by incompetent quartz-mica schist, and the footwall is locally mineralized feldspathic quartzite (metatuff). The footwall quartzite is competent and highly fractured; the result is a favorable site for ore deposition.

In 1991-93, American Copper and Nickel Company drilled three reverse-circulation holes to investigate gold mineralization within the shear zone and in the silicified footwall schist (Dashevsky, 1993). The 1992 core hole was 330 feet deep. Nineteen feet assayed 0.107 ounce of gold per ton; five feet in the Scrafford shear zone assayed 0.026 ounce of gold per ton; and 14 feet in the silicified footwall assayed 0.136 ounce of

gold per ton. The drilling program indicated that the footwall mineralization is confined within a narrow, sub-parallel zone beneath the Scrafford shear, and was probably not a viable bulk-minable target (Dashevsky, 1993).

Alteration:

The footwall rocks of the deposit are highly oxidized and contain stibiconite and scorodite (Robinson and Bundtzen, 1982, p. 5). The main shear is filled with black graphitic gouge, bright-orange iron-stained clay, and white clay that supports clasts of schist, stibnite, and stibnite oxidation products (Dashevsky, 1993). Strong clay and sericite alteration is confined to gouge zones within the shear. The schist footwall is silicified and quartz veined (Dashevsky, 1993).

Workings/exploration:

Mining from open cuts took place from 1915 to 1916, in 1926, and from 1968 to 1970 (Cobb, 1976 [OFR 76-662, p. 169-170]). The shear-zone system in the main opencut is exposed for at least 320 feet (Robinson and Bundtzen, 1982). In 1982, Robinson and Bundtzen (1982) spent 3 days mapping and sampling several trenches on the Scrafford property. In 1991-93, American Copper and Nickel Company conducted soil sampling and drilled three reverse-circulation holes, totalling 1295 feet, to pursue the gold potential that was reported by Robinson and Bundtzen (Dashevsky, 1993).

In 2016, the Treasure Creek Partnership consolidated three, separately owned properties, including numerous prospects and occurrences (LG038; LG039; FB074; FB075; FB076; FB077; FB078; FB079; FB080; FB081) in the Treasure and Any Creek watersheds that potentially host plutonic-related, lode-gold mineralization contained in shear zones north of Fairbanks. Exploration activity in 2016 included conducting field work and reviewing and updating 1990s-era exploration information (Athey and Werdon, 2017).

Production notes:

Mining from open cuts took place from 1915 to 1916, in 1926, and from 1968 to 1970 (Cobb, 1976 [OFR 76-662, p. 169-170]). Production has been estimated at over 2,700 tons of ore, much of it from ore that ran 50 to 60 percent antimony (Robinson and Bundtzen, 1982).

Reserves:

None.

Geologic description:

The following geologic description is summarized from a report by Sam Dashevsky (1993) on work done by American Copper and Nickel Company on the Eagle Creek property in the early 1990s. In the shallow subsurface at this prospect, a 30-foot-thick, medium-grained, equigranular granite and quartz porphyry sill intrudes quarz-mica schist and micaceous quartzite. The intrusion is truncated by a major fault, believed to be the eastern extension of the Scrafford shear zone (see FB077). The Scrafford shear trends N80-85E and dips 55-60 S. (Robinson and Bundtzen,1982). The upper intrusive contact is irregular and sub-horizontal and lies under 10 feet of schist and 4 feet of loess. At the surface, chip samples across the 30-foot exposure of the intrusion, are enriched in gold and arsenic; the samples average 0.024 ounce of gold per ton and 2,060 to 6,490 ppm arsenic. No significant antimony values are reported. Schist in the wallrock is weakly to unmineralized. The Scrafford shear contains as much as 350 ppb gold, 2,480 ppm arsenic, and 102 ppm antimony. Drilling indicated that the quartz porphyry sill does not exceed 210 ppb gold. The deeper intersection of the sill and the shear, which is composed largely of intrusive and quartz clasts in gouge, averages 0.029 ounce of gold per ton over 35 feet and 0.1 to 1.0 percent arsenic. The intrusive at the surface is moderately to strongly silicified, locally bleached, and iron stained. The schist country rock is strongly silicified at the intrusive contact. Downhole, the sill is cut by sparse, hairine quartz veinlets. In the shear zone, intrusive fragments are highly silicified and locally altered to clay.

Alteration:

Geologic description:

The following geologic description is summarized from a report by Sam Dashevsky (1993) on work done by American Copper and Nickel Company on the Eagle Creek property in the early 1990s. In 1964, a high-grade antimony shear zone, the No. 2 vein, was discovered by Silver Ridge Mining Co. The shear was explored by minor trenching and a 35-foot shaft. In 1976, high gold values were recognized at the prospect. The prospect is within sub-horizontal, quartz-mica and graphitic phyllitic schists that are cut by a 4.5-foot-wide zone filled with gouge. The fault zone is exposed in one of several sloughed trenches that trend east-northeast across the ridge along Old Murphy Dome road. The fault zone is exposed for 160 feet along strike in trenches; it is 3.5 to 9.5 feet thick and extends beyond the trenches for an unknown distance. Twenty-five feet of schist in the footwall contains 220 to 750 ppb gold and averages 0.01 ounces of gold per ton. A 4.5-foot-wide fault zone at the southeast end of the trench averages 11,300 ppb gold (0.33 ounce of gold per ton) and 1 to 3 percent antimony. A reverse circulation drill hole intercepted a weakly mineralized zone, 5 feet long of quartz, limonitic schists, and abundant gouge that contained 130 ppb gold, 722 ppm arsenic, and 1,334 ppm anitmony. Limonitic footwall schist persists for 85 feet,and is truncated by a shear zone that runs 0.06 ounces of gold per ton over 5 feet.

Alteration:

Pervasive iron-staining is found in the footwall schist. Clay-sericite alteration and fault gouge are developed in the shear zone (Dashevsky, 1993).

Age of mineralization:

Generic deposit model:

Deposit model:

Gold-antimony shear zone in quartz-mica and graphitic, phyllitic schists.

Geologic description:

The following geologic description is summarized from a report by Sam Dashevsky (1993) on work done by American Copper and Nickel Company (ACNC) on the Eagle Creek property in the early 1990s. Local zones of anomalous arsenic in soils were first identified on the property in the 1970s by Cantu Minerals Association. In the 1980s, Silverado Gold Mines, Ltd. and Tri-Con Mining delineated a gold anomaly; trenching resulted in the discovery of a narrow, high-grade quartz breccia vein near mile 3 of Old Murphy Dome road. In 1991 and 1992, ACNC conducted a soil sampling program and drilled four reverse circulation holes. Soil sampling identified an irregularly shaped multi-element soil anomaly measuring 5,000 feet long by 500 to 2,500 feet wide that was marked by anomalous arsenic, lead, and bismuth. Three nodes of anomalous gold, antimony, and lead also occur in the area. Silt samples from Independence Creek at the 1,000-, 1,100- and 1,200-foot elevations show anomalous gold. On Wildcat Creek, stream sediment samples contained anomalous gold at the 850-, 900-, 1,000- and 1,150-foot elevations. Drilling and distribution of rock fragments in soil sample pits indicate that the area is predominantly underlain by quartz-mica schist and micaceous quartzite, with subordinate graphitic phyllite and chloritic-biotite schists at depth. Soil samples from the east flank of upper Independence Creek, and several other nearby sites have abundant felsic intrusive rocks mixed with schist chips and regolith. Rock fragments are commonly altered and limonitic, and vein quartz fragments are broadly distributed throughout the zone. Drilling intersected sporadic pegmatite veinlets. Directly east of the gate to the East Scrafford prospect, limonite-stained finely fractured schist without quartz veining contains 5,000-6,000 ppb gold (0.14-0.18 ounce of gold per ton). Five hundred feet farther east, pieces of quartz-sulfide float as much as 18 inches thick contain 11,000 to 19,000 ppb gold (0.32 to 0.55 ounce of gold per ton). Isolated fragments of silicified felsic intrusive breccia contain 6,850 ppb gold. Four drill holes indicate broad zones of weakly mineralized schist in sparsely veined, weakly pyritic, silicified zones that are at depths exceeding 400 feet. The high-grade veins at the surface were intercepted in the drilling program; one 110-foot intercept ran 0.026 ounce of gold per ton, and one 5-foot interval ran 0.068 ounce of gold per ton. Rock fragments in soils show much evidence of silicification, clay alteration, and limonite. Drilling identified broad zones of pyritic silicification at a depth of more than 400 feet; argillation, patchy silicification, and chloritic alteration were confined to sheared zones at higher levels.

Alteration:

Rock fragments in soils show much evidence of silicification, clay alteration, and limonite. Drilling identified broad zones of pyritic silicification at depths of more than 400 feet; argillation, patchy silicification, and chloritic alteration occurred in shallower rocks (Dashevsky, 1993).

Site name(s): Fox Creek

Site type: Mine

ARDF no.: FB086

Latitude: **Quadrangle:**

Longitude:

Location description and accuracy:

At least two miles of Fox Creek has been mined; part is in the Fairbanks quadrangle, part is in the Livengood quadrangle. Most of the mining or at least the mining since WWII, has been in the Livengood quadrangle. But much of the information of record about placer mining on Fox creek cannot be assigned to one of the quadrangles. For convenience, all of the information on Fox Creek has been consolidated into a single Livengood-quadrangle record (LG081).

Site name(s): Fort Knox

Site type: Mine

ARDF no.: FB115

Latitude: 64.992 **Quadrangle:** FB D-1

Longitude: 147.3614

Location description and accuracy:

As of the end of 2011, the Fort Knox Mine was a large operating open pit nearly a mile in diameter that covers much of the area between Melba Creek and Monte Cristo Creeks at the head of Fish Creek. The coordinates are at about the center of the pit. The mine occupies much of the northwest quarter of section 21 and the southwest quarter of section 16, T. 2 N., R. 2 E. The location is accurate.

Commodities:

Main: Au

Other: As, Bi, Mo, Te, W

Ore minerals: Arsenopyrite, bismite, bismuth, bismuthinite, eulytite, gold, maldonite, molybdenite, scheelite, tellurobismuthite, tetradymite

Gangue minerals: Quartz

Geologic description:

In 1913, a bismuth-bearing, gold-quartz vein was prospected on the ridge between Melba and Monte Cristo Creeks by Edward Voght (see FB116) (Chapin, 1914). When visited in July of 1949, the workings were completely caved, and all that remained was almost completely disintegrated rock on dumps around an old caved shaft and the ruins of a small mill (Wedow and White, 1954).

In 1987, geologist Rodney A. Blakestad, graduate of the University of Alaska, Geology, 1973, was sampling and mapping a trench that was dug the previous day. It became apparent that close inspection of the two- to four-millimeter thick, sheeted quartz veins cutting through the granite contained specks of free gold approximately 0.5 mm in diameter. It took only an hour of observing the multitude of veinlets exposed over the entire length of the 200 foot long trench to decide that another trench might be instructive as to the magnitude of the 'discovery'.

The bulldozer was owned by Mr. Blakestad, so he fired it up and drove 200 feet up hill and dug a second trench parallel to the first. Similar quartz veinlets with similar free gold were encountered in the second trench. Without taking a sample, Blakestad drove back to Fairbanks and reported the news to the funding group and a second geologist, Dr. Benjamin I. Collins, was dispatched to verify the discovery (Rodney A. Blakestad, personal communication, 2015).

This discovery was followed by an extensive exploration program. By 1989, Fairbanks Gold Ltd. and its joint venture partners had spent $4.5 million on exploration at the Fort Knox deposit. More than 72,000 feet of drilling and 5 miles of trenching outlined an area predicted to contain 4 million ounces of gold. In 1990, five drill rigs were operating 24 hours a day, drilling almost 60,000 feet in 104 drill holes, and a 170,000-ton bulk sample was taken. In 1990, the Fort Knox property was the largest exploration project outside of southeast Alaska (Swainbank and others, 1991). Exploration consisted of 46,300 feet of diamond drilling and 62,600 feet of reverse circulation drilling. The 170,000-ton bulk sample was reduced to 45 tons; seven tons of this sample was split for metallurgical testing. In 1991, another 32,600 feet of reverse circulation drilling was completed (Bundtzen and others, 1991). Geotechnical work consisted mainly of condemnation drilling to determine where to put the mill, tailings pond, and other mine support facilities (Bundtzen and others, 1991). Late in 1991, Amax Gold Inc. announced its intention to purchase all assets of Fairbanks

Gold Ltd. (Bundtzen and others, 1991). By 1996, as many as 800 workers had completed a power line to the site, the freshwater dam and tailings dam, the primary crusher, a coarse-ore conveyor, apron feeders, and all components of the mill (Swainbank and others, 1997). In November, 1996, the first gold was produced from the mine and it has been in continual operation to the present (Feb. 2011) as a large open pit. In 1998, Kinross Gold Corp. acquired a 100 percent interest in the mine and operated it continuous to early 2012. As of early 2012, they have resources that they predict will allow operation until 2018 (Kinross Gold Corp., 2011).

The Fort Knox gold deposit is in a granite body, now commonly referred to as the Fort Knox pluton, which has been dated at 92 Ma by the U/Pb method (Bakke, 1992, 1994). Gold occurs along margins of stockwork quartz veins and veinlets, along quartz-filled shear zones, and along fractures within the granite. In the ore zones, the sulfide content is low, less than 0.5 percent. There are only minor amounts of arsenopyrite (McCoy and others, 1997) and the dominant sulfide is bismuthinite. There is strong geochemical association of the gold with bismuth and tellurium. The following bismuth and tellurium minerals have been identified in small amounts: native bismuth, maldonite, tellurobismuthite, bismite, tetradymite, and eulytite. Trace to minor molybdenite and scheelite also occur. The pluton has been subdivided into three phases, primarily on on the basis of texture: (1) fine-grained, biotite- and hornblende-rich granite, (2) medium- to coarse-grained, seriate, porphyritic granite (the youngest phase), and (3) a hybrid, biotite- and hornblende-rich rock with relict texture similar to the porphyritic granite, and formed by local contact metamorphism of impermeable country rocks (Bakke, 1992; J. Odden, written communication, 2000). The most significant gold mineralization is in milky-white, quartz-stockworks veins and along shear zones (Bakke, 1992). The stockwork veins mostly strike east and have no consistent dip. The gold distribution in the stockwork veins is erratic; some ore contains as high as 7.0 ounces of gold per ton; the gold occurs in grains that vary in size from less than 0.1 to 2 mm. In contrast, the quartz-filled shear zones contain evenly distributed, micron-size gold. White mica from the stockworks has been dated by the 40Ar/39Ar method at 86.2 to 89.3 Ma (McCoy and others, 1997). Alteration consists of vein-controlled phyllic, potassic, albitic, and argillic alteration (Bakke, 1992). A late, low-temperature, thermal alteration event has produced an assemblage of calcite, zeolite (stilbite), chalcedony, and clay in breccia zones, on joint surfaces, and in fractures within the granite (Bakke, 1992).

From 1996 to December 31, 2011, the Fort Knox Mine produced 5,246,631 ounces of gold (Quant, 29008; Szumigala and others, 2011, Kinross Gold, Corp., 2012). This included 289,794 ounces of gold that was produced in 2011. Most of this was processed through a carbon-in-pulp mill with a capacity of about 33 to 45 thousand tonnes per day. A large heap leach facility was constructed in 2009 that began processing a large stockpile of low grade ore; the company anticipates adding low-grade material to the heap leach pile from the pit, material that would not be economical to process through the mill. This heap-leach facility will extend the life of the mine to 2018 and and should increase gold production to an average 370,000 ounces of gold per year.

As of December 31, 2011, the Fort Knox Mine has proven and probable reserves of 314.669 million tonnes with an average grade of 0.43 grams of gold per tonne (or 4.303 million ounces of gold) (Kinross Gold Corp., 2012). There is an addition measured and indicated resource of 112.098 million tonnes with an average grade of 0.40 grams of gold per tonne (or 1.426 million ounces of gold).

Alteration:

The deposit features vein-controlled phyllic, potassic, albitic, and argillic alteration (Bakke, 1992). A late, low-temperature, thermal alteration event has resulted in an assemblage of calcite, zeolite (stilbite), chalcedony and clay in breccia zones, on joint surfaces, and in fractures in the granite (Bakke, 1992).

Age of mineralization:

Stockwork white mica which is probably contemporaneous with the mineralization has been dated by the 40Ar/39Ar method at 86.2 to 89.3 Ma (McCoy and others, 1997).

Generic deposit model:

Deposit model:

Intrusion related gold.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; large

Site Status: Active

Workings/exploration:

In 1913, a bismuth-bearing, gold-quartz vein was prospected on the ridge between Melba and Monte Cristo Creeks by Edward Voght (see FB116) (Chapin, 1914). When visited in July of 1949, the workings were completely caved, and all that remained was almost completely disintegrated rock on dumps around an old filled shaft and the ruins of a small mill (Wedow and White, 1954). In 1987, a geologist walking behind a bulldozer on the Fort Knox claims picked up a piece of granite containing visible gold; this discovery was followed by an extensive exploration program. By 1989, Fairbanks Gold Ltd. and its joint venture partners had spent $4.5 million on exploration at the Fort Knox deposit. More than 72,000 feet of drilling and 5 miles of trenching outlined an area predicted to contain 4 million ounces of gold. In 1990, five drill rigs were operating 24 hours a day, drilling almost 60,000 feet in 104 drill holes, and a 170,000-ton bulk sample was taken. In 1990, the Fort Knox property was the largest exploration project outside of southeast Alaska (Swainbank and others, 1991). Exploration consisted of 46,300 feet of diamond drilling and 62,600 feet of reverse circulation drilling. The 170,000-ton bulk sample was reduced to 45 tons; seven tons of this sample was split for metallurgical testing. In 1991, another 32,600 feet of reverse circulation drilling was completed (Bundtzen and others, 1991). Geotechnical work consisted mainly of condemnation drilling to determine where to put the mill, tailings pond, and other mine support facilities (Bundtzen and others, 1991). Late in 1991, Amax Gold Inc. announced its intention to purchase all assets of Fairbanks Gold Ltd. (Bundtzen and others, 1991). By 1996, as many as 800 workers had completed a power line to the site, the freshwater dam and tailings dam, the primary crusher, a coarse-ore conveyor, apron feeders, and all components of the mill (Swainbank and others, 1997). In November, 1996, the first gold was produced from the mine and it has been in continual operation to February of 2011 as a large open pit. In 1998, Kinross Gold Corp. acquired a 100 percent interest in the mine and operated it continuous to early 2012. As of early 2012, they have resources that they predict will allow operation until 2018 (Kinross Gold Corp., 2011).

In 2016, Kinross Gold Corporation conducted exploration at Fort Knox mine and surrounding brownfield properties. Exploration drilling of the east and south walls of the existing open pit returned positive results. A total of 2,300 meters were drilled, and the 15-hole program tested the existing geologic-resource model for a potential mineral-resource addition, and refined the granite-schist contact. Positive intercepts were intersected in every hole drilled; highlights include 29 meters of 0.029 ounce of gold per ton, 13.7 meters of 0.054 ounce of gold per ton, 36.6 meters of 0.019 ounce of gold per ton, 35 meters of 0.029 ounce of gold per ton, and 24.4 meters of 0.058 ounce of gold per ton (Athey and Werdon, 2017).

Production notes:

From 1996 to December 31, 2011, the Fort Knox Mine produced 5,246,631 ounces of gold (Quant, 2008; Szumigala and others, 2011, Kinross Gold, Corp., 2012). This included 289,794 ounces of gold that was produced in 2011. Most of this was processed through a carbon-in-pulp mill with a capacity of about 33 to 45 thousand tonnes per day. A large heap leach facility was constructed in 2009 that began processing a large stockpile of low grade ore; the company anticipates adding low-grade material to the heap leach pile from the pit, material that would not be economical to process through the mill. This heap-leach facility will extend the life of the mine to 2018 and and should increase gold production to an average 370,000 ounces of gold per year.

Fort Knox mine celebrated its 20th anniversary of operation and poured its 7-millionth ounce of gold in 2016; gold production totaled 409,844 ounces. Production increased slightly compared with 2015, mainly as a result of record production from the heap leach, but was partially offset by lower mill grades. Fort Knox mined 34,998,000 tons of material, processed 14,570,000 tons of ore through the mill, and processed 32,124,000 tons of ore on the heap leach pad. Mill grade averaged 0.022 ounce of gold per ton with an 83 percent recovery rate, and the heap-leach grade averaged 0.009 ounce of gold per ton. As of 2016, termination of open pit mining is scheduled for 2019. In May 2016, the U.S. Bureau of Land Management announced it is considering a proposal to relinquish 709 acres of National Oceanic and Atmospheric

Administration land immediately west of the phase-8 expansion of Fort Knox mine to the State of Alaska, as this land is no longer needed to fulfill its mission. Access to this land could add to the mine's life (Athey and Werdon, 2017).

Reserves:

As of December 31, 2011, the Fort Knox Mine has proven and probable reserves of 314.669 million tonnes with an average grade of 0.43 grams of gold per tonne (or 4.303 million ounces of gold) (Kinross Gold Corp., 2012). There is an addition measured and indicated resource of 112.098 million tonnes with an average grade of 0.40 grams of gold per tonne (or 1.426 million ounces of gold).

As of December 31, 2016, Fort Knox contains proven and probable reserves of 115,399,732 short tons grading 0.014 ounce of gold per ton, for a contained metal content of 1,506,000 ounces of gold. Measured and indicated resources include 104,745,905 tons grading 0.016 ounce of gold per ton, for a contained metal content of 1,440,000 ounces of gold, and inferred resources include 14,369,713 tons grading 0.016 ounce of gold per ton, for a contained metal content of 193,000 ounces of gold (Kinross Gold Corporation, 2016).

Site name(s): Liberty Bell

Site type: Mine

ARDF no.: FB132

Latitude: 64.052 **Quadrangle:** FB A-4

Longitude: 148.845

Location description and accuracy:

The Liberty Bell mine is located approximately 5.6 miles south-southeast of Rex Dome in the NW1/4 sec. 13, T. 10 S., R. 7 W., of the Fairbanks Meridian. This mine is marked on the Fairbanks A-4 topographic map, and the buildings and workings are prominent in the field. As of 1998, the Liberty Bell property was owned by Columbia Yukon Exploration Inc., and it consisted of five targets over a 10,500-acre claim block (Columbia Yukon Exploration Inc., news release no. 83, June 9, 1998). The mine is locality 40 of Cobb (1972 [MF 410]). This location is probably accurate to within 1000 feet.

Commodities:

Main: Ag, Au, Bi, Cu

Other: Pb, Zn

Ore minerals: Arsenopyrite, bismuthinite, bornite, chalcopyrite, covellite, enargite, galena, gold, kobellite, loellingite, malachite, pyrite, pyrrhotite, sphalerite, tennantite, ullmannite

Gangue minerals: Actinolite, allanite, biotite, carbonate, feldspar, quartz, sericite

Geologic description:

The following geologic summary is taken from Yesilyurt, 1996. The geology of the Liberty Bell gold mine area is dominated by weakly metamorphosed volcaniclastic-sedimentary rocks of the California Creek Member of the Totatlanika Schist, which is of Devonian-Mississippian(?) age. Metamorphosed Mesozoic(?) mafic dikes and unmetamorphosed Late Cretaceous felsic porphyry dikes and plugs are scattered throughout the area. Continental clastic rocks of the Tertiary Nenana Gravel overlie these rocks in angular unconformity. Gold mineralization is associated with sulfide- and sulfosalt-rich lenses, veins, and low-angle shear zones in the Paleozoic phyllitic rocks adjacent to a porphyry intrusion.

Six types of hydrothermal alteration have been differentiated. Carbonate-quartz alteration occurs in a peripheral zone of the metasomatic mineralization at the mine area. An actinolite-pyrrhotite assemblage occurs adjacent to the gold mineralization. Potassium silicate alteration occurs adjacent to the porphyry intrusions; it consists mainly of alkali feldspar, biotite, tourmaline, allanite, and quartz. A chlorite-sericite-carbonate alteration assemblage occurs sporadically in the area. The most widespread type of alteration at Liberty Bell is a quartz-sericite-clay assemblage. Supergene alteration and weathering overprint all of the hydrothermal assemblages. The age of hydrothermal alteration is about 92 Ma, based on two K-Ar radiometric determinations on hydrothermal biotite and sericite.

The principal ore minerals at Liberty Bell are arsenopyrite, pyrite, and pyrrhotite. Also present are chalcopyrite, kobellite, ullmannite, bismuthinite, tennantite, and loellingite, and trace amounts of enargite, covellite, bornite, sphalerite, galena, malachite, and native gold. The ore minerals occur mostly as tabular and stringer replacement bodies, disseminations, cross-cutting veins, and as open space fillings.

The initial discovery was float samples that contained arsenopyrite, bismuth, and bismuthinite. Several shafts and tunnels were driven in 1915 and 1916. By 1930, development included more than 1,000 feet of adits, and several shafts and raises (Moffit, 1933). In 1931 a mill was installed; mining in 1932-33 produced a total of 8,400 ounces of gold from 17,500 tons of ore (Smith, 1933 [B 844-A, p. 19]; Smith, 1937; Toupe and others, 1986). In midsummer of 1936, all work was discontinued and work on the property did not

resume until the 1970s (Smith, 1938, p. 35-36). Since 1973, more than 16,000 feet of core has been produced by diamond drilling, and there has been considerable trenching, geologic mapping, geophysical surveys, and several thousand feet of reverse-circulation drilling (see Workings and Exploration field). Recently, five targets have been identified on the 10,500-acre property. The Mine Zone has mineable resources of 1,240,000 tons with an average grade of 0.1 ounce of gold per ton. Drilling has indicated that there is the potential for 250,000 ounces of gold in the Mine Zone and the Northwest Copper Zone (Columbia Yukon Explorations Inc., web site describing 1998 exploration activity).

Results from a detailed state airborne geophysical survey completed in 2002 by Alaska Division of Geological and Geophysical Surveys (DGGS) in the Bonnifield Mining District reveal a positive aeromagnetic anomaly at Liberty Bell which suggests an underlying large pluton. This idea is supported by follow-up ground truthing by DGGS in 2005 that noted extensive hornfels and hydrothermal alteration, in addition to granite and granodiorite dikes. The authors suggested from this work that viable exploration targets in the area include replacement/skarn and structurally controlled mineralization, which are both documented at Liberty Bell (Athey and others, 2006).

Alteration:

Six types of hydrothermal alteration have been differentiated (Yesilyurt, 1996). Carbonate-quartz alteration occurs in a peripheral zone of the metasomatic minerlization at the mine. An actinolite-pyrrhotite assemblage occurs adjacent to the gold mineralization. Potassium silicate alteration occurs adjacent to the porphyry intrusions and consists mainly of alkali feldspar, biotite, tourmaline, allanite, and quartz. A chlorite-sericite-carbonate alteration assemblage occurs sporadically in the area. The most widespread type of alteration at Liberty Bell is a quartz-sericite-clay assemblage. Supergene alteration and weathering overprint all of the hydrothermal assemblages (Yesilyurt, 1996).

Age of mineralization:

The age of mineralization has been a source of controversy; the suggestions range from Mesozoic to late Tertiary (Yesilyurt, 1996, p. 1282). Yesilyurt (1996) gives the age of hydrothermal alteration associated with the ore as about 92 Ma, on the basis of two K-Ar radiometric determinations on hydrothermal biotite and sericite that was probably formed contemporaneously with the mineralization.

Generic deposit model:

Deposit model:

Many investigators of the property have suggested various types of syngenetic massive sulfide models. Others favor an epigenetic origin, for instance, Yesilyurt (1996, p. 1282), who has done the most thorough modern work on the deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

By 1918, a tunnel 35 feet long and a shaft 15 feet deep were opened in loose rock (Overbeck, 1918, p. 360). Development work was reported in 1922, 1923, and 1924 (Brooks and Capps, 1924, p. 40; Brooks, 1925, p. 31; Smith, 1926, p. 26). By 1930, developments included more than 1,000 feet of adits and several shafts and raises (Moffit, 1933). In 1931, a mill was constructed by the Fairbanks-based Eva Creek Mining Company (Smith, 1933 [B 844-A, p. 19]). Due to the intense shearing and the degree of decomposition of the schist, much timbering was required to prevent caving (Moffit, 1933). In 1934, very little work was done, and mining was reported to be expensive due to the caving (Smith, 1936, p. 24). In the mid-summer of 1936, all work was discontinued (Smith, 1938, p. 35-36). Interest in the property resumed in the 1970s. In 1973, Alaska Petroleum and Mining and its joint partner Gulf Mineral Company drilled 20 diamond-drill

holes totaling 5,839 feet (Yesilyurt, 1996, p. 1282). In 1977, Resource Associates of Alaska (RAA) drilled six diamond-drill holes totaling 4,289 feet (Yesilyurt, 1996, p. 1282). In 1978, the claims were optioned to Cominco Limited, and in 1984 Cominco drilled seven diamond-drill holes totaling 1,578 feet. After the 1984 drilling, RAA acquired the claims under a joint-venture agreement with Cyprus Gold Corporation. A preliminary field study was conducted in 1986, and advanced exploration work began in 1987; it included thirty reverse-circulation drill holes, trenching, and detailed geologic mapping and sampling. In 1989, Nerco Minerals conducted exploration and detailed metallurgical studies at the property (Bundtzen and others, 1990, p. 12). In 1991, some exploration was reported by Amax Gold Inc. (Bundtzen and others, 1991, p. 10). In 1992, Amax Gold completed 5,845 feet of reverse-circulation drilling at the (Nerco-owned) property (Swainbank and others, 1993, p. 9). In 1993, operating on an option from the Liberty Bell Mining Company, Noranda Exploration Inc., funded by Hemlo Gold, mapped and sampled several mineralized zones (Bundtzen and others, 1994, p. 10). In 1994, Noranda Exploration trenched several anomalies that were discovered through geochemistry and geophysics (Swainbank and other, 1995, p. 10). In 1996, lessees of Pacific Northwest Resources Co. conducted a small drilling program (Swainbank and others, 1997, p. 8). In 1997, Liberty Bell Mining conducted a 5,000-foot core-drill program (Swainbank and others, 1998, p. 9).

During 2008, New Gold Inc. completed an exploration program at Liberty Bell consisting of a property-wide geophysical IP-Resistivity survey in combination with surface mapping and geochemical sampling. This work, combined with the results of work completed in 2007, has resulted in the delineation of five separate areas of prospective gold mineralization (New Gold Inc., 2008).

New Gold’s 2009 field program included more geologic mapping, geochemical sampling, and a core drilling program, although no results were announced (Szumigala and others, 2010).

Field work during 2010 by New Gold included geologic mapping, geochemical sampling, and a 9,967-foot core drilling program. Geochemical sampling included whole-rock analysis, U–Pb SHRIMP geochronology, and petrographic analysis. No results were announced. New Gold dropped its option on the Liberty Bell property at year’s end (Szumigala and others, 2011).

In 2002, Alaska Department of Natural Resources-Division of Geological and Geophysical Surveys completed a detailed state airborne geophysical survey covering 276 square miles in the Western Bonnifield Mining district, in which lies Liberty Bell. Follow-up geologic ground-truth mapping took place in 2005 and covered 131 square miles. The purpose of the Liberty Bell project was to produce a 1:50,000-scale geologic map to foster a better understanding of the geology and mineral potential of the area (Athey, 2006). This map was published in 2006 (Athey and others, 2006).

Production notes:

Mining in 1932 and 1933 produced a total of 8,400 ounces of gold from 17,500 tons of ore (Smith, 1937; Toupe and others, 1986).

Reserves:

In 1933, the reserves were estimated at 37,000 tons of ore that had an average assay of $22 in gold per ton (1.06 ounces of gold per ton) (Moffit, 1933). More recent drilling on the Northwest Copper Zone, approximately 2,000 feet from the Mine Zone, indicated an aggregated resource of 2,000,000 tons with a grade of 0.05 ounce of gold per ton (Columbia Yukon Explorations Inc., news release no. 83, June 9, 1998). The Mine Zone has mineable resources of 1,240,000 tons with an average grade of 0.1 ounce of gold per ton. Drilling has indicated that there is the potential for 250,000 ounces of gold in the Mine Zone and the Northwest Copper Zone (Columbia Yukon Explorations Inc., web site describing the 1998 exploration).

Additional comments:

Other names associated with Liberty Bell include 'Bearpaw', 'Eva Mining Co.', 'Eva Quartz Mining Co.', 'Irene', 'Johnson, Norberg and Erickson', 'Swanson and Mountaine', 'Short', 'Rose', and 'Wild Goose' (Cobb, 1976 [OFR 76-662 p. 162-167]).

Last report date: 2016-02-25

Site name(s): Unnamed (near Ester Dome)

Site type: Prospect

ARDF no.: FB156

Latitude: 64.8897 **Quadrangle:** FB D-3

Longitude: 148.0675

Location description and accuracy:

Although several other older, small prospects (FB005 to FB011) are peripheral to or within the large block of claims of this prospect, it covers an area trending north-northwest about 5,900 feet long by 590 to 1,640 feet wide that was drilled in 2011. The coordinates are near the center of the area about a mile north-northwest of the top of Ester Dome in the north half of section 25, T. 1 N., R. 3 W. The location is accurate.

Commodities:

Main: Au

Other: As, Sb

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Quartz

Geologic description:

Since the early 1900s , the Ester Dome area has been known for scattered gold-quartz veins with stibnite and arsenopyrite, some of which have been mined. Much of the area has been claimed and reclaimed several times, including the area surrounding this prospect on the north side of Ester Dome. In 2009, Miranda Gold Corporation (2009) leased a large block of claims from Range Minerals Inc. on the north side of Ester Dome and began exploration. The block included several older, small prospects (FB005-FB011), mostly gold-quartz veins, but Miranda's work was m mainly to test the area for large, bulk-minable, intrusion-related gold deposits. By 2011, Miranda had defined a north-northwest-trending area, geochemically anomalous in gold, about 5,900 feet long ft long by 590 to 1,640 feet wide. Miranda and their partner Agnico-Eagle (USA) drilled 6 holes on the anomaly in 2011 (Miranda Gold Corporation, 2012); four of the holes cut mineralization with more than 0.01 ounce of gold per ton. The four mineralized holes had 17 intercepts 0.9 to 6.1 meters wide with more than 0.5 gram of gold per tonne. Notable intercepts were 0.9 meters with 0.922 gram of gold per tonne, 2.3 meters with 0.723 gram of gold per tonne, 2.6 meters with 0.831 gram of gold per tonne, and 6.1 meters with 0.603 gram of gold per tonne, and 1.5 meters with 1.005 gram of gold per tonne. The mineralization is related to quartz sulfide veinlets and intense fracturing accompanied by iron oxides and selvages with quartz-sericite-pyrite alteration. In 1998, Placer Dome drilled similar mineralization (FB011) near the southern border of Miranda's geochemical anomaly.

The rocks in the area are part of the Fairbanks Schist composed of quartz-muscovite schist, quartzite, and chlorite-quartz schist that are cut by thrust faults (Newberry and others, 1996). The geochemical anomaly defined and drilled by Miranda is associated with a cluster of granitic bodies that intrude the metamorphic rocks (Miranda Gold Corp., 2011).

Alteration:

The mineralization is related to quartz sulfide veinlets and to intense fracturing accompanied by iron oxides and selvages with quartz-sericite-pyrite alteration.

Age of mineralization:

Probably about 90 Ma based on similarities to many gold deposits in the Fairbanks District.

Generic deposit model:

Deposit model:

Gold-quartz veins; intrusion-related, bulk-tonnage gold deposit (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

In 2009. Miranda Gold Corporation (2009) leased a large block of claims from Range Minerals Inc. on the north side of Ester Dome 11, and began exploration. By 2011, Miranda had defined a north-northwest-trending area, geochemically anomalous in gold, about 5,900 feet long by 590 to 1,640 feet wide, within their block of claims. Miranda and their partner Agnico-Eagle (USA) drilled 6 holes on the anomaly in 2011 (Miranda Gold Corporation, 2012).

Production notes:

None.

Reserves:

None.

Last report date: 2012-04-01

Site name(s): Wattamuse Creek

Site type: Mine

ARDF no.: GO021

Latitude: 59.3278 **Quadrangle:** GO B-6

Longitude: 161.2391

Location description and accuracy:

Wattamuse Creek is a northwest tributary to Slate Creek (GO020), a north tributary to Goodnews River. It has been placer mined from its junction with Slate Creek for a distance of about 2 miles. The coordinates are at the approximate midpoint of the workings, in the NE1/4 of section 9, T. 10 S., R. 71 W., of the Seward Meridian.

There are conflicting opinions about the extent of Wattamuse Creek. Some hold that it extends down to Slate Creek; some that it continues to the mouth of Cascade Creek (GO022) and Cascade Creek continues to Slate Creek. For this record, Wattamuse Creek continues to Slate Creek following local usage.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Wattamuse Creek is the principal gold producer in the Goodnews River drainage. Gold was discovered in 1917 by a native reindeer herder (Harrington, 1921), and the first mining took place in the fall of 1917, when about 500 ounces were produced. There has been extensive mining along Wattamuse Creek for at least two miles above the mouth of Slate Creek (Fechner, 1988; Calista Corp., 2008). Much of the mining until the early 30s was by various hand and small-scale mechanized mining when the New York-Alaska Company drilled the property. It was subsequently leased and a 2 1/2- foot dredge was built in 1938. The dredge operated until 1941 and mined from near the mouth of Cascade Creek downstream for about 1.4 miles to Slate Creek. In 1946 and 1947, Bristol Bay Mining Company used a dragline to mine in the narrow canyon above the mouth of Cascade Creek on claims 2 Above and 5-8 Above.

The pay streak on Wattamuse Creek was 20 to 30 feet wide in upper parts of the creek to over 100 feet wide on lower parts. The pay, 1 to 2 feet of gravel and about 6 inches of bedrock, ranged in grade from 0.015 to 0.15 ounce of gold per cubic yard. The overburden was 2 to 5 feet of soil and gravel (Harrington, 1921). The gravel became coarser upstream, where boulders up to a few feet across became more abundant. The gold recovery in the dredge was about four times that indicated by the drilling due to the large boulders in the creek.

Fechner (1988) collected eight 0.1 cubic yard placer samples in the Wattamuse Creek drainage, including one from lower Wattamuse below the mouth of Cascade Creek. These samples, from along the active drainage and from benches, contained 0.0013 to 0.7583 ounce of gold per cubic yard. Fechner (1988) indicates that the tailings along the creek could be reworked and that local unmined areas are also present. One unmined area is estimated to contain 60,000 cubic yards with an average grade of 0.015 to 0.018 ounce of gold per cubic yard. The lower dredged part of the creek (included with Cascade Creek by Fechner, 1988) is estimated to have had about 800,000 cubic yards of tailings. In as much as the dredge is reported to have recovered about 0.025 ounce of gold per cubic yard (Fechner, 1988), about 20,000 ounces of gold production are indicated for this part of the creek. However, the recorded production for this creek segment

is 9,300 ounces of gold (Fechner, 1988). The upper part of the creek has recorded and estimated production of 18,300 ounces of gold (Fechner, 1988), possibly making total production from the creek as much as 38,000 ounces.

Wattamuse Creek is a glaciated drainage. Bedrock in the area includes Paleozoic and Mesozoic sedimentary and volcanic rocks intruded by an Upper Cretaceous granitic stock in the headwaters of the creek (Hoare and Coonrad, 1978).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; medium

Site Status: Probably inactive

Workings/exploration:

Gold was discovered in 1917 by a native reindeer herder (Harrington, 1921), and the first mining took place in the fall of 1917, when about 500 ounces were produced. There has been extensive mining along Wattamuse Creek for at least two miles above the mouth of Slate Creek (Fechner, 1988; Calista Corp, 2008). Site name(s): Cascade Creek

Site type: Prospect

ARDF no.: GO022

Latitude: 59.3311 **Quadrangle:** GO B-6

Longitude: 161.2407

Location description and accuracy:

Cascade Creek is a north tributary to Wattamuse Creek (GO021). The mouth of Cascade Creek is about 1 mile upstream from the mouth of Wattamuse Creek on Slate Creek. The lower potentially auriferous portion flows through the upper part of section 9 and the center of section 4, T. 10 S., R. 71 W.

There are conflicting opinions about the extent of Wattamuse Creek. Some hold that it extends down to Slate Creek; some that it continues to the mouth of Cascade Creek (GO022) and Cascade Creek continues to Slate Creek. For this record, Wattamuse Creek continues to Slate Creek following local usage.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Cascade Creek has been explored, and drilled but apparently the only mining was near its mouth where a dredge began to work down Wattamuse Creek (GO021) (Calista Corp., 2008). The gravels are somewhat finer than on Wattamuse Creek and 8 to 10 feet deep. The drilling on Cascade Creek produced poor results.

Six, 0.1 cubic yard placer samples from along about 4 miles of Cascade Creek contained a trace to 0.0017 ounce of gold per cubic yard (Fechner, 1988). Bedrock in the area includes Paleozoic and Mesozoic sedimentary and volcanic rocks, locally intruded by Upper Cretaceous to Lower Tertiary granitic rocks and Jurassic mafic/ultramafic plutonic rocks (Hoare and Coonrad, 1978).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au-PGE (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

Exploration including drilling has taken place, especially along lower Cascade Creek near its confluence with Wattamuse Creek (GO021).

Production notes:

None.

Site name(s): Wattamuse

Site type: Prospect

ARDF no.: GO023

Latitude: 59.3448 **Quadrangle:** GO B-7

Longitude: 161.3346

Location description and accuracy:

This lode prospect is on the ridge crest that makes up the divide between the headwaters of Wattamuse Creek (GO021), Granite Creek, and South Fork Arolik River. It is on the saddle about 1,000 feet east of a 1,813-foot summit, and 0.6 mile due north of Granite Creek. It is accurately located.

Commodities:

Main: Au

Other: Ag, Hg, Sb, W

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, pyrrhotite, stibnite

Gangue minerals: Quartz

Geologic description:

An Upper Cretaceous granodiorite-diorite stock underlies the head of Granite and Wattamuse Creeks (Hoare and Coonrad, 1978). This stock hosts 1 inch- to 1-foot-thick quartz veins containing arsenopyrite, stibnite, pyrite, and some chalcopyrite (Calista Corp. 2008). A soil-geochemical grid over about a 1/4- by 1/2-mile area straddling the ridge crest showed large areas of soil containing more than 100 parts per billion (ppb) gold, and several areas containing more than 1,000 ppb gold. Individual grab samples collected for Calista Corporation contain up to 9.5 parts per million (ppm) gold, 14.9 ppm silver, 17 percent arsenic, 22 percent antimony, and 1,500 ppm mercury (Fechner, 1988, p. 58). The U. S. Bureau of Mines collected 19 grab samples of rocks in the headwaters of Wattamuse Creek. One of these, a composite grab sample collected in this prospect area, assayed 2.18 ounces of gold per ton, 6.6 ppm silver, 2,850 ppm arsenic, 400 ppm bismuth, 40 ppm antimony, and 184 ppm tungsten (Fechner, 1988). Grab samples of quartz veins contained 1.25 to 5.3 ppm Au. The country rocks around the granitic stock locally include mafic rocks; a sample of mafic rock containing arsenopyrite, pyrrhotite, and chalcopyrite assayed 17.4 ppm silver, 3.3 ppm gold, 0.13 percent arsenic, 30 ppm bismuth, and 0.19 percent copper (Fechner, 1988, p. 58).

Alteration:

Silicification.

Age of mineralization:

Late Cretaceous or younger. A K/Ar age of biotite from the host granitic stock is 71.3 +/- 2.1 Ma on biotite (Hoare and Coonrad, 1978).

Generic deposit model:

Deposit model:

Granitic rock-hosted epithermal gold/silver.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

A soil geochemistry grid, selected rock sampling, and probably surface mapping have been completed on the prospect (Calista Corp., 2008).

Production notes:

None.

Reserves:

None.

Site name(s): Grubstake

Site type: Prospect

ARDF no.: GU019

Latitude: 62.7888 **Quadrangle:** GU D-1

Longitude: 144.0327

Location description and accuracy:

The center of the Grubstake prospect is about 6.2 miles north-northwest of the community of Slana and about 0.5 mile west-northwest of peak 5509. It is about 0.6 mile east-southeast of the center of section 25, T. 12 N., R. 7 E., of the Copper River Meridian. The location is accurate within 1/4 mile.

Commodities:

Main: Au, Cu

Other: Fe, Pb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, galena, magnetite, malachite, sphalerite

Gangue minerals: Barite, carbonate, quartz

Geologic description:

The upper Grubstake Creek area is underlain by highly altered, border-phase rocks of the Pennsylvanian to Permian, Ahtell Creek quartz monzonite pluton. The pluton intrudes the Pennsylvanian to Permian, Tetelna Formation, which is mainly volcanic rocks. Both the Ahtell pluton and the Tetelna Formation are cut by dikes and irregular bodies of a mid-Jurassic complex that varies from diorite to quartz diorite (Richter and Matson, 1968; Bull, Schneider, and Freeman, 1997; Bull, Freeman, and Schneider, 1999; Taylor 2010). Where the Tetelna rocks have been intruded by the diorite complex they have been converted to multicolored, biotite and hornblende hornfels.

Porphyry mineralization occurs mainly in the diorite complex and adjacent hornfels (Taylor, 2010). Various subtypes occur: 1) propylitic altered zones with as much as 10 percent pyrite are cut by quartz-carbonate veins that contain pyrite, chalcopyrite, and galena; 2) potassic altered zones containing secondary biotite and K-feldspar are cut by quartz-K feldspar veins, veinlets, and sporadic concentrations of as much as 15 percent pyrite, chalcopyrite, arsenopyrite, and magnetite; and 3) sericite/phyllic altered zones locally stained with malachite contain 5-30 percent sulfides. There are widespread localized zones of argillic and iron-carbonate alteration. The hornfelsed Tetelna Formation within about 100 feet of diorite also has several subtypes of porphyry mineralization including: 1) silicified zones containing as much as 15 percent pyrite; 2) quartz-carbonate veins with pyrite, chalcopyrite, arsenopyrite, and galena; and 3) chloritic-magnetite or chloritic-pyrite breccia cut by quartz-pyrite-chalcopyrite veinlets. The hornfels adjacent to chloritic zones typically is bleached. Reconnaissance mapping by Homestake Mining Company geologists (Bull, Scheider, and Freeman, 1997; Bull, Freeman, and Schneider, 1999; Taylor, 2010) indicates that the porphyry alteration and mineralization is crudely zoned, with potassic alteration at lower elevations and in upper Grubstake Creek. Discrete veins in the Grubstake area, such as the J. D. Lyons prospect (GU018), appear to be related to the hornfels phase of this porphyry deposit. As visualized by Taylor (2010), potassic alteration with potassium feldspar, biotite, and magnetite is nearest the mineralization. Outward, there is a shell of sodium-calcium alteration with albite, actinolite, and magnetite, followed by an outermost shell of propylitic alteration with pyrite, chlorite, epidote, and magnetite.

International Tower Hill Inc. staked a large block of claims in the area in 2006, carried out extensive geologic mapping, sampling, and geochemical surveys, and flew an aerial geophysical survey over the area. Corvus Gold Inc. (a spinoff of International Tower Hill) drilled 3 holes in 2010 that intersected extensive

altered and veined rock (Corvus Gold, 2010). Notable intercepts in two of the holes were 199.3 meters with 0.08 percent copper and 0.06 grams of gold per tonne and 129.9 meters with 0.19 percent copper and 0.15 grams of gold per tonne. Taylor (2010) suggests that the mineralization is Cretaceous.

In 2010, Corvus (2011) discovered a series of en-echelon quartz-dolomite-barite veins 20 centimeters to 2 meters thick at Grubstake. This swarm of veins strikes north-northeast to northeast for a strike length of more than 600 feet. Nineteen rock samples averaged 7.38 grams of gold per tonne, 8.82 grams of silver per tonne, 0.91 percent lead, and 0.16 percent zinc; the best had 46.5 grams of gold per tonne, 29.8 grams of silver per tonne, 4.22 percent lead, and 1.22 percent zinc.

Alteration:

Potassic alteration with potassium feldspar, biotite, and magnetite is nearest the mineralization. Succeeded by a shell of sodium-calcium alteration with albite, actinolite, and magnetite, followed by an outermost shell of propylitic alteration with pyrite, chlorite, epidote, and magnetite. Much hornfels locally (Taylor, 2010).

Age of mineralization:

Possibly related to the nearby Pennsylvanian to Permian Ahtell pluton or to other plutons, variously considered to be Jurassic or Cretaceous (Taylor, 2010).

Generic deposit model:

Deposit model:

Porphyry Cu-Au (Cox and Singer, 1986; model 20c) and polymetallic barite veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

Grubstake Creek has been explored extensively since the discovery of placer deposits in the area in 1934 (GU017). Work by Richter and his associates appears to have triggered exploration in the 1960s and 1970s (Richter, 1964,1966; Richter and Matson, 1968). Kirk Stanley was active at that time. More recently, the area has been studied by Cominco Exploration (St. George, 1992), and Homestake Mining Company (Bull, Schneider and Freeman, 1997; and Bull, Freeman, and Schneider, 1999). International Tower Hill Mines Inc. staked a large block of claims in the area in 2006, carried out extensive geologic mapping, sampling, and geochemical surveys, and flew an aerial geophysical survey over the area.

In 2007, based on favorable results in the southeast end of the belt, a helicopter magnetic survey was flown over the Grubstake target. In addition, an analysis of satellite imagery was undertaken in 2007 which produced an iron oxide and clay alteration map of the region outlining a number of new target areas which have yet to be explored.

In 2008 and 2009, ITH covered the bulk of the claim blocks with a stream sediment survey which identified multiple targets in the SE extension of the main Chisna claim block. In addition, a number of magnetic anomalies were investigated in the area southwest of the main claim blocks which returned copper mineralization from follow up prospecting and additional claims were staked.

Corvus took over the project from ITH in 2010 and will be managing the joint venture with Ocean Park (OCP). The Corvus-OCP joint venture is focused on testing the porphyry and precious metal potential of the Chisna belt using detailed airborne and ground geophysics to define drill targets which will be aggressively tested. A 2010 summer exploration program was carried out and included 2,926 meters (9600 feet) of diamond drilling, soil and rock sampling, airborne ZTEM surveying, and ground-based magnetotelluric (MT) with three-dimensional induced polarization chargeability-resistivity surveying and inversion modeling over selected target areas. Three of the holes drilled intersected extensive altered and mineralized rock (Corvus Gold, 2010).

In the summer 2012 exploration season, Corvus continued with surface prospecting and mapping. High-grade structurally controlled copper mineralization was found (Corvus Gold, 2014).

Production notes:

None.

Reserves:

None.

Last report date: 2014-05-30

Site name(s): Notch; Golden Range

Site type: Prospect

ARDF no.: GU045

Latitude: 62.8914 **Quadrangle:** GU D-1

Longitude: 143.9986

Location description and accuracy:

The Notch prospect is about 13.0 miles north of Slana. It is 3.1 mile northwest of VABM 6677 'Ahtell', near the center of section 24, T. 3 S., R. 7 E. The location is accurate.

Commodities:

Main: Ag, As, Au

Other:

Ore minerals: Arsenopyrite, gold

Gangue minerals: Carbonate minerals, quartz

Geologic description:

The rocks in the area of the Notch prospect are diorite and quartz diorite of the Permian to Pennsylvania Ahtell pluton (Richter, 1966; Richter and others, 1975; Wilson and others, 1998; Corvus Gold Inc., 2012). The rocks are cut by extensive dike swarms and faults. The mineralization is on the northeast side of a regional-scale northwest-striking fault.

The Notch prospect may have been sampled in 1980 when WGM Inc. on behalf of the Ahtna Native Corporation searched for the source of geochemical anomalies in gold that outlined a northwest-trending area several miles long that WGM had identified in 1979 (WGM Inc., 1979, 1980). In 1980, they collected several rock samples at scattered locations along the trend that contained up to 3,260 parts per billion (ppb) gold.

In 2010, Corvus Gold Inc. revisited the area, outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range target. They collected more than 300 rock and soil samples in the area. The 151 rock samples averaged 0.6 gram of gold per tonne; 29 of the 151 had more than 0.10 gram of gold per tonne, and the best had 50.4 grams of gold per tonne.

By 2011, Corvus had identified at least 5 prospects in the Golden Range target area that they had sampled and drilled (Corvus Gold, Inc., 2012). One is the Notch prospect where they drilled 7 holes totaling 1,674 meters and dug 4 trenches that totaled 104 meters.

The Notch drilling defined a mineralized, east-west striking shear zone that can be traced for more than a kilometer; it is 40-60 meters thick and dips south. The shear zone is highly altered. The alteration consists of pre- to syn-mineralization sericitic alteration followed by syn- and postmineral carbonate and iron-carbonate alteration. The shear zone hosts arsenopyrite-quartz veins which commonly are folded and disarticulated. The hanging wall of the zone is quartz diorite; the footwall is diorite. The mineralized shear zone is offset by a steep north-dipping fault that offsets the zone for about 40 meters. The drilling indicates that the mineralization continues down dip for at least 250 meters. Some notable intercepts are: 1)15.8 meters with 23.19 grams of gold per tonne and 1.93 grams of silver per tonne; 2) 12.3 meters with 1.60 grams of gold per tonne and 1.93 grams of silver per tonne; 3) 44.9 meters with 0.34 grams of gold per tonne and 0.68 grams of silver per tonne; 4) 16.9 meters with 1.99 grams of gold per tonne, and 5) 5.1 meters with 4.57 grams of gold per tonne.

Alteration:

Pre- to syn-mineralization sericitic alteration followed by syn- and postmineral carbonate and iron-carbonate alteration.

Age of mineralization:

Younger than the Permian to Pennsylvanian host rocks.

Generic deposit model:

Deposit model:

Mineralized zone with arsenopyrite-quartz veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Site name(s): Matador

Site type: Prospect

ARDF no.: GU047

Latitude: 62.9121 **Quadrangle:** GU D-1

Longitude: 144.0404

Location description and accuracy:

The Matador prospect is about 14.0 miles north of Slana. It is about 3.9 miles northwest of VABM 6677 'Ahtell' in the northwest quarter of section 14, T. 3 S., R. 7 E., of the Copper River Meridian. The location is accurate within 1/4 mile.

Commodities:

Main: Ag, Au

Other:

Ore minerals:

Gangue minerals: Carbonate minerals, quartz

Geologic description:

The rocks in the area of the Matador prospect are diorite and quartz diorite of the Permian to Pennsylvania, Ahtell pluton (Richter, 1966; Richter and others, 1975; Wilson and others, 1998; Myers and others, 2011; Corvus Gold Inc., 2012a). The rocks are cut by extensive dike swarms and faults. The mineralization is on the northeast side of a regional-scale northwest-striking fault.

The Matador prospect may have been sampled in 1980 when WGM Inc. on behalf of the Ahtna Native Corporation searched for the source of geochemical anomalies in gold that outlined a northwest-trending area several miles long WGM Inc. identified in 1979 (WGM Inc., 1979, 1980). In 1980, they collected several rock samples at scattered locations along the trend that contained up to 3,260 parts per billion (ppb) gold.

In 2010, Corvus Gold Inc. revisited the area, outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range target. They collected more than 300 rock and soil samples. The 151 rock samples averaged 0.6 gram of gold per tonne; 29 of the 151 had more than 0.10 gram of gold per tonne, and the best had 50.4 grams of gold per tonne (Corvus Gold Inc., 2011).

By 2011, Corvus had identified at least 5 specific prospects in the Golden Range target area that they had soil sampled, rock chip sampled, and drilled (Corvus Gold, Inc., 2012a). One is the Matador prospect where they drilled 2 holes. A notable intercept was 2.7 meters that averaged 0.02 gram of gold per tonne and 681.23 grams of silver per tonne.

The rock sample geochemistry has a signature of 5.3 to 1 ratio of silver to gold, 419 to 1 ratio of arsenic to antimony, 42 to 1 ratio of bismuth to tellurium, and 28 to 1 ratio of arsenic to copper (Brown and others, 2012).

No further details on the mineralization are available but it is probably similar to that at the nearby Notch prospect (GU045), where arsenopyrite-quartz veins are in a thick mineralized zone marked by sericitic and quartz-carbonate alteration (Myers and others, 2011).

Alteration:

Extensive silica-carbonate alteration of diorite and quartz diorite? (Corvus Gold Inc., 2012a).

Age of mineralization:

Younger than the Permian to Pennsylvanian host rocks (Corvus Gold Inc., 2012a).

Generic deposit model:

Deposit model:

Mineralized zone with arsenopyrite-quartz veins - polymetallic veins? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

In 2010, Corvus Gold Inc. revisited the area, outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range target. They collected more than 300 rock and soil samples in the area. The 151 rock samples averaged 0.6 gram of gold per tonne; 29 of the rock samples had more than 0.10 gram of gold per tonne, and the best had 50.4 grams of gold per tonne.

By 2011, Corvus had identified at least 5 specific prospects in the Golden Range target area that they had sampled and drilled (Corvus Gold, Inc., 2012a). One is the Jolly Green prospect where they only collected rock samples; 10 of which they considered significant. Those samples contained 3.0 to 126.5 grams of gold per tonne, 25.7 to 198.0 grams of silver per tonne, and 0.4 to 17.7 percent copper. Little information is available about the mineralization other than they note it has base metals and may reflect a copper-gold porphyry at depth.

The Jolly Green mineralization may be related to that at the unnamed prospect about 1.3 miles to the southeast (GU037), where chalcopyrite and molybdenite commonly occur along joint surfaces in silica-carbonate rock, which is widely developed near the western contact of a pluton.

In 2011, Corvus performed a soil x-ray fluorescence (XRF) survey, which indicated high grade mineralization hosted in north-northwest trending shear zones/quartz vein-breccias. Pervasive fracture-controlled copper oxide coating in quartz-diorite forms supergene halos around shears. High-grade gold is constrained to Jolly Green shear zone. The Jolly Green shear zone hosts over 1 percent copper on 700 meters of strike (Brown and others, 2012).

Alteration:

Copper-oxide in supergene halos around shears. High grade copper + gold + silver + molybdenum in shear/quartz-vein breccia zones (Brown and others, 2012).

Age of mineralization:

Younger than the Permian to Pennsylvanian host rocks (Wilson and others, 1998).

Generic deposit model:

Deposit model:

Porphyry Cu-Au? (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c?

Production Status: None

Site Status: Active

Workings/exploration:

The Jolly Green prospect may have been sampled in 1980 when WGM Inc. on behalf of the Ahtna Native Corporation searched for the source of geochemical anomalies in gold that outlined a northwest-trending area several miles long that WGM. had identified in 1979 (WGM Inc., 1979, 1980). In 1980, they collected several rock samples at scattered locations along the trend.

In 2010, Corvus Gold Inc. revisited the area, outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range target. They collected more than 300 rock and soil samples in the area. By 2011, Corvus had identified at least 5 specific prospects in the Golden Range target area that they had sampled and drilled (Corvus Gold, Inc., 2012a). One is the Jolly Green prospect where they only collected rock samples.

In 2010 and 2011, Corvus performed a soil survey at Jolly Green of over 12 km in length and average over 10 grams of gold per ton over 12 kilometers with over 50 grams of gold per ton widespread. In 2011, Corvus performed a soil x-ray fluorescence (XRF) survey, which indicated high grade mineralization hosted in north-northwest trending shear zones/quartz vein-breccias. Pervasive fracture-controlled copper oxide coating in quartz-diorite forms supergene halos around shears. High-grade gold is constrained to Jolly Green shear zone. The Jolly Green shear zone hosts over 1 percent copper on 700 meters of strike (Brown and others, 2012). 2011 drilling highlights are 126.5 grams of gold per ton, 198 grams of silver per ton and 17.7 percent copper (Corvus Gold Inc., 2012b).

Production notes:

None.

Reserves:

None.

Last report date: 2014-12-08

Site name(s): NOM; Golden Range

Site type: Prospect

ARDF no.: GU049

Latitude: 62.89 **Quadrangle:** GU D-1

Longitude: 144.0392

Location description and accuracy:

The NOM target is about 12.7 miles north-northwest of Slana. It is about 3.4 miles northwest of VABM 6677 'Ahtell' and about 0.2 mile southwest of the center of section 23, T. 13 N., R. 7 E., of the Copper River Meridian. The location is accurate within 1/4 mile.

Commodities:

Main: Ag, Au, Cu

Other: Bi, Te, Sb

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Carbonate minerals, quartz

Geologic description:

The rocks in the area of the NOM prospect are diorite and quartz diorite of the Permian to Pennsylvania Ahtell pluton (Richter, 1966; Richter and others, 1975; Wilson and others, 1998; Corvus Gold Inc., 2012). The rocks are cut by extensive dike swarms and faults. The mineralization is on the northeast side of a regional-scale northwest-striking fault.

The NOM prospect may have been sampled in 1980 when WGM Inc. on behalf of the Ahtna Native Corporation searched for the source of geochemical anomalies in gold that outlined a northwest-trending area several miles long that WGM had identified in 1979 (WGM Inc., 1979, 1980). In 1980, they collected several rock samples at scattered locations along the trend that contained up to 3,260 parts per billion (ppb) gold.

In 2010, Corvus Gold Inc. revisited the area, outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range prospect area. They collected more than 300 rock and soil samples in the area. The 151 rock samples averaged 0.6 gram of gold per tonne; 29 of the 151 had more than 0.10 gram of gold per tonne, and the best had 50.4 grams of gold per tonne (Corvus Gold Inc., 2011).

By 2011, Corvus had identified at least 5 specific prospects in the Golden Range target area that they had sampled and drilled (Corvus Gold, Inc., 2012). One is the NOM prospect where they drilled 4 holes and dug 3 trenches. Notable intercepts in the drill holes were: 1) 8.0 meters that averaged 0.48 gram of gold per tonne and 1.57 grams of silver per tonne; 2) 5.1 meters that averaged 0.90 grams of gold per tonne and 0.76 gram of silver per tonne; 3) 6.5 meters that averaged 0.60 gram of gold per tonne and 1.27 grams of silver per tonne, and 4) 3.1 meters that averaged 0.90 gram of gold per tonne and 0.96 gram of silver per tonne. The best sample in a trench was 7.50 meters that averaged 3.26 grams of gold per tonne and 4.74 grams of silver; this included 2.0 meters that averaged 10.40 grams of gold per tonne and 10.91 grams of silver per tonne.

No details on the mineralization are available but it is probably similar to that at the nearby Notch prospect (GU045) arsenopyrite-quartz veins are in a thick mineralized zone marked by sericitic and quartz-carbonate alteration (Myers and others, 2011).

Brown and others (2012) have defined rock geochemical signatures at NOM as follows: 3.1 to 1 ratio of silver to gold, 280 to 1 ratio of arsenic to antimony, 3 to 1 ratio of bismuth to tellurium, and 69 to 1 ratio of arsenic to copper.

Alteration:

Extensive silica-carbonate alteration of diorite and quartz diorite? (Corvus Gold Inc., 2012).

Age of mineralization:

Younger than the Permian to Pennsylvanian host rocks (Corvus Gold Inc., 2012).

Generic deposit model:

Deposit model:

Mineralized zone with arsenopyrite-quartz veins - polymetallic veins? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

The NOM prospect may have been sampled in 1980 when WGM Inc. on behalf of the Ahtna Native Corporation searched for the source of geochemical anomalies in gold that outlined a northwest-trending area several miles long that WGM had identified in 1979 (WGM Inc., 1979, 1980). In 1980, they collected several rock samples at scattered locations along the trend. Site name(s): West Green

Site type: Prospect

ARDF no.: GU051

Latitude: 62.9248

Quadrangle: GU D-1

Longitude: 144.1185

Location description and accuracy:

The West Green prospect is located about 15.8 miles north-northwest of Slana. It is about 6.6 miles northwest of VABM 6677 'Ahtell' and about 0.4 mile northeast from the center of section 8, T. 13 N., R. 7 E., of the Copper River Meridian. The location is accurate within 1/4 mile.

Commodities:

Main: Ag, Au, Cu

Other: Fe

Ore minerals: Chalcopyrite, gold, molybdenite

Gangue minerals: Calcite, quartz

Geologic description:

The rocks in the area of the West Green prospect are diorite and quartz diorite of the Permian to Pennsylvania Ahtell pluton (Wilson and others, 1999). The rocks are cut by extensive dike swarms and faults. Mineralization is on the northeast side of a regional-scale northwest-striking fault (Corvus Gold Inc., 2012).

In 2011, Corvus identified the West Green prospect, where mineralization is in a typical copper porphyry style with high grade gold, through sampling and drilling (Corvus Gold Inc. 2012). Mineralization is centered on second order conjugate structures (Brown and others, 2012).

Over 0.5 percent copper grade follows potassic-propylitic alteration front with disseminated and veinlet chalcopyrite. Alteration is characterized as porphyry zoned alteration of potassic core with propylitic shell. Extensive quartz-calcite-chalcopyrite sheeted veins, stockwork veins, and vein breccias are present. Grab samples resulted in assay values of up to 10 parts per million (ppm) silver, 1 ppm molybdenum, and 0.6 percent copper (Brown and others, 2012).

Alteration:

Porphyry zoned alteration of potassic core with propylitic shell. Over 0.5 percent copper grade follows potassic-propylitic alteration front with disseminated and veinlet chalcopyrite. Extensive quartz-calcite-chalcopyrite sheeted veins, stockwork veins, and vein breccias (Brown and others, 2012).

Last report date: 2014-05-30

Site name(s): Southwest Grubstake

Site type: Occurrence

ARDF no.: GU052

Latitude: 62.892 **Quadrangle:** GU D-1

Longitude: 144.038

Location description and accuracy:

The Southwest Grubstake target is about 12.7 miles north-northwest of Slana. It is about 3.4 miles northwest of VABM 6677 'Ahtell' and about 0.2 mile southwest of the center of section 23, T. 13 N., R. 7 E., of the Copper River Meridian. The location is accurate within 1/4 mile.

Commodities:

Main: Ag, Au, Pb, Zn

Other: Ba

Ore minerals: Barite, galena, gold, magnetite

Gangue minerals: Biotite, dolomite, quartz

Geologic description:

This occurrence is part of the Chisna Project; operated as of 2014 by Corvus Gold Inc. Stream sediment surveying and geological mapping in the greater area identified several areas with alteration and mineralization styles that are typical of high level porphyry-type alteration including potassic alteration with biotite and magnetite veining. Mineralization is generally hosted in Permian-Triassic volcanic rocks which have been intruded by Jurassic and Cretaceous mafic and felsic intrusions (Corvus Gold Inc., 2014).

Southwest Grubstake is a mineral occurrence that presents as a series of en-echelon quartz-dolomite-barite veins up to 2 meters wide defined over a 600-meter-long trend. These polymetallic quartz veins have returned high gold values along with significant silver, lead and zinc values from veins ranging in width from 20 cm up to 2 meters. This vein swarm, which strikes NNE to NE within a NW to SW mineralized trend, has been delineated over a strike length in excess of 600 meters. A total of 19 rock samples derived from in-place quartz-dolomite-barite boulder trains and outcrops returned an average of 7.38 grams per tonne gold, 8.82 grams per tonne silver, 0.91 percent lead and 0.16 percent zinc, with highs of 46.5 grams per tonne gold, 29.8 grams per tonne silver, 4.22 percent lead and 1.22 percent zinc (Corvus Gold Inc., 2014).

Mapping of vein lengths and density, and determination of the relationship between this veined mineralization and the adjacent Grubstake copper-gold porphyry system, was the primary focus of 2011 exploration in advance of drilling (Corvus Gold Inc., 2014).

Alteration:

Potassic alteration with biotite and magnetite veining (Corvus Gold, 2014).

Age of mineralization:

Younger than the Permian - Triassic host rocks (Corvus Gold, 2014).

Generic deposit model:

Deposit model:

Porphyry Cu-Au (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
20c

Production Status: None

Site Status: Active

Workings/exploration:
Corvus Gold Inc., in a joint venture with Ocean Park, discovered the Southwest Grubstake target from the results of surface exploration in summer 2010 (Corvus Gold Inc., 2011).
In summer 2011, Corvus conducted an exploration program that included mapping of vein lengths and density, and determination of the relationship between this veined mineralization and the adjacent Grubstake copper-gold porphyry system. Corvus reported that rock samples from networks of quartz-galena-barite veins at the Southwest Grubstake prospect have produced a large number of high grades samples with gold values of over 5 parts per million (Corvus Gold Inc., 2011).

Production notes:
None.

Reserves:
None.

Last report date: 2014-05-30

Site name(s): Corazon; El Corazon

Site type: Occurrence

ARDF no.: GU053

Latitude: 62.8877 **Quadrangle:** GU D-1

Longitude: 144.0404

Location description and accuracy:

The Corazon target is about 12.7 miles north-northwest of Slana. It is about 4.4 miles west-northwest of VABM 6677 'Ahtell' and about 0.5 mile southwest of the center of section 23, T. 13 N., R. 7 E., of the Copper River Meridian. The location is accurate within 1/4 mile. The previous record listed Corazon as the same as NOM; however current workers distinguish the two based on location and geochemistry.

Commodities:

Main: Ag, Au

Other:

Ore minerals: Arsenopyrite, gold

Gangue minerals: Carbonate minerals, quartz

Geologic description:

The rocks in the area of the Corazon prospect are diorite and quartz diorite of the Permian to Pennsylvania Ahtell pluton (Wilson and others, 1998; Corvus Gold Inc., 2012). The rocks are cut by extensive dike swarms and faults. The mineralization is on the northeast side of a regional-scale northwest-striking fault (Corvus Gold Inc., 2012).

In 2010, Corvus Gold Inc. outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range prospect area. Through exploration in the general area, Corvus identified Corazon prospect in 2011. They drilled two holes and dug two trenches. Drilling highlights include 5.1 meters of 0.9 gram per ton of gold and 0.76 grams per ton of silver from GR-11-04. The best sample in a trench was 7.5 meters that averaged 3.3 g/t gold and 4.6 g/t silver (Corvus Gold Inc., 2012). The mineralization is associated with a shear zone. The rock sample geochemistry has a signature of 1.6 to 1 ratio of silver to gold, 302 to 1 ratio of arsenic to antimony, 12 to 1 ratio of bismuth to tellurium, and 32 to 1 ratio of arsenic to copper (Brown and others, 2012).

Alteration:

Extensive silica-carbonate alteration of diorite and quartz diorite? (Corvus Gold Inc., 2012).

Age of mineralization:

Younger than the Permian to Pennsylvanian host rocks (Corvus Gold Inc., 2012).

Generic deposit model:

Deposit model:

Mineralized zone with arsenopyrite-quartz veins - polymetallic veins? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

The Corazon prospect may have been sampled in 1980 when WGM Inc. on behalf of the Ahtna Native Corporation searched for the source of geochemical anomalies in gold that outlined a northwest-trending area several miles long that WGM had identified in 1979 (WGM Inc., 1979, 1980). In 1980, they collected several rock samples at scattered locations along the trend.

In 2010, Corvus Gold Inc. outlined an area of mineralization 2 by 9 kilometers in size, and called it the Golden Range target. They collected more than 300 rock and soil samples in the area. By 2011, Corvus had identified at least 5 prospects in the Golden Range target area that they had sampled and drilled (Corvus Gold, Inc., 2012). One is the Corazon prospect where they completed a soil and rock sampling program in 2011 and followed up with two drill holes and two trenches in 2012 (Corvus Gold, Inc., 2012).

Production notes:

None.

Reserves:

None.

Additional comments:

In 2014, 'Corazon' was removed from GU049 'NOM' to create a unique site record for Corazon since both prospects are geologically distinct and results are reported separately for each record (Myers and others, 2011; Brown and others, 2012).

Last report date: 2014-05-30

Site name(s): McCall

Site type: Prospect

ARDF no.: HE001

Latitude: 63.69 **Quadrangle:** HE C-6

Longitude: 149.74

Location description and accuracy:

The McCall prospect is at an elevation of about 2,400 feet on a northeast-trending spur above the headwaters of the Sushana River. It is in the northwest corner of sec. 19, T. 14 S., R. 11 W., of the Fairbanks Meridian. The location is accurate to within 1 mile. This is location 1 of Clark and Cobb (1972).

Commodities:

Main: Ag, Pb

Other:

Ore minerals: Galena

Gangue minerals: Calcite, quartz, siderite

Geologic description:

Little information about this prospect has been made public. Apparently, it consists of galena-bearing quartz-carbonate veins that cut Devonian metavolcanic schist and phyllite. Samples contain up to 55 percent lead and 6 ounces of silver per ton (Berg and Cobb, 1967).

Alteration:

Age of mineralization:

The veins are Devonian or younger.

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Inactive

Workings/exploration:

Minor surface workings. Samples contain up to 55 percent lead and 6 ounces of silver per ton (Berg and Cobb, 1967).

Production notes:

None.

Reserves:

None.

Additional comments:

This site is in Denali National Park.

Site name(s): Silver King

Site type: Prospect

ARDF no.: HE026

Latitude: 63.26 **Quadrangle:** HE B-6

Longitude: 149.55

Location description and accuracy:

The Silver King prospect is located on the eastern side of Colorado Creek in the northern half of sections 19 and 24, T. 19 S., R. 10 W., of the Fairbanks Meridian. The location is accurate to within 0.5 mile. The Silver King prospect is not the same as the Silver King mine shown on the Healy A-6 1:63,360-scale topographic sheet.

Commodities:

Main: Ag, Au, Cu

Other: Bi, Co, Sb

Ore minerals: Arsenopyrite, chalcopyrite, pyrite, pyrrhotite, stibnite

Gangue minerals: Calcite, quartz

Geologic description:

Thick Quaternary glacial deposits and Upper Tertiary sedimentary strata cover the bedrock in this area. The country rocks in the area of the Silver King prospect consist of Upper Jurassic to Upper Triassic(?) crystal tuff, argillite, chert, graywacke, and limestone that are intruded by Upper Cretaceous quartz diorite porphyry stocks and dikes (Wilson and others, 1998). Intrusion of the dikes and quartz-sulfide mineralization are localized along the nearby Chulitna fault. The Silver King deposit includes: tactite (skarn) replacement bodies; auriferous arsenopyrite-chalcopyrite quartz veins; stibnite-gold-silver veins; silver-lead-zinc veins; and as breccia pipes associated with porphyry stock and dikes. Sporadic mineralization is present over a 2,000 feet by 800 feet area. (Hawley and Clark, 1974).

Hawley and Clark (1974) reported the following sample analyses. A massive sulfide pod in skarn contained 8.3 ounces of gold per ton. An arsenopyrite-rich vein contained 50 ppm silver, 200 ppm gold, 700 ppm cobalt, 1,500 ppm copper, 200 ppm lead, 500 ppm antimony, 200 ppm zinc, more than 1,000 ppm bismuth and more than 10,000 ppm arsenic. A stibnite-rich vein contained 10 ppm silver, 23 ppm gold, 200 ppm copper, 300 ppm lead, 1,500 ppm zinc, 7,000 ppm arsenic and more than 10,000 ppm antimony. Salisbury and Dietz (1984) reported the following: arsenopyrite veins returned assay values of 0.85 ounces of silver per ton, 0.87 ounces of gold per ton and 0.44% cobalt; and stibnite-bearing veins contained 0.12 ounces of silver per ton and 0.29 ounces of gold per ton. The Silver King deposit is part of a northeast trending mineralized zone that includes the Liberty (HE028), Lucrata (HE029) and Eagle (HE030) prospects.

Alteration:

Skarn formation widespread; porphyry-type alteration is also reported.

Age of mineralization:

Similar sulfide-bearing intrusive rocks and veins in the district have been dated as Late Cretaceous (Swainbank and others, 1977), but Au-Ag-stibnite and Ag-Pb-Zn veins could be younger (Early Tertiary?).

Generic deposit model:

Deposit model:

Polymetallic vein, Cu-Au porphyry, Cu skarn, and Simple Sb veins (Cox and Singer, 1986; models 22c, 20c, 18b, and 27d)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c, 20c, 18b, 27d

Production Status: Undetermined

Site Status: Active

Workings/exploration:

Surface workings, mostly trenches and pits. Site-specific geophysical surveys noted in literature and probably drill testing, but specific data are not available.

Hawley and Clark (1974) reported the following sample analyses. A massive sulfide pod in skarn contained 8.3 ounces of gold per ton. An arsenopyrite-rich vein contained 50 ppm silver, 200 ppm gold, 700 ppm cobalt, 1,500 ppm copper, 200 ppm lead, 500 ppm antimony, 200 ppm zinc, more than 1,000 ppm bismuth and more than 10,000 ppm arsenic. A stibnite-rich vein contained 10 ppm silver, 23 ppm gold, 200 ppm copper, 300 ppm lead, 1,500 ppm zinc, 7,000 ppm arsenic and more than 10,000 ppm antimony.
