This mineralization was discovered by Still and others (2002). The rocks in this borrow pit consist mainly of fine- to medium-grained gray to dark green diorite. Intrusive rocks were previously unknown at this site although intermediate intrusive rocks of Cretaceous age have been mapped to the north and south of the pit (Brew and others, 1984). Pyrrhotite makes up 1-2 percent of the diorite and fine-grained chalcopyrite is common in the pit. The sulfides occurs as thin coatings along fractures. Rare molybdenite was also identified. The intrusive in the pit is cut by several faults and the sulfides are commonly localized along them. One of the faults contains bands of sulfides, mainly pyrrhotite with chalcopyrite, sphalerite, galena, arsenopyrite, and pyrite. Hornfels, probably metamorphosed from Cretaceous phyllite, is exposed north of the pit (Brew and others, 1984).

Still and others (2002) collected 12 samples from 8 to 20 feet long in the pit. They averaged 163 parts per million (ppm) copper. A select sample of sulfide-rich material contained 3,271 parts per billion (ppb) gold, 12.9 ppm silver, 3.025 ppm copper, 4,708 ppm lead, 1.4 percent zinc, and 9,762 ppm arsenic. Other samples contained up to 855 ppm molybdenum and 1,365 ppm nickel.

Alteration:

Age of mineralization:

Cretaceous(?) or younger based on the age of nearby intrusive rocks.

Generic deposit model:

Deposit model:

Porphyry copper?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Sampling by Bureau of Land Management geologist in borrow pit.

Production notes:

None.

Reserves:

None.

Reporter(s): Donald Grybeck ((Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Portage Mountain Group

Site type: Prospect

ARDF no.: PE080

Latitude: 56.875 **Quadrangle:** PE D-4

Longitude: 133.2439

Location description and accuracy:

There is some confusion in the old literature about the location and geology of two prospects in the area between Portage Mountain and the North Arm of Duncan Canal. Still and others (2002) spent considerable time in the field and library trying to decipher their location and descriptions. They concluded that the Portage Mountain Group consisted of 4 quartz-calcite veins that are at an elevation of between 2,000 and 3,000 feet on the west side of Portage Mountain. They could not find the old workings that they think are in the NE 1/4, NW 1/4, section 2, T. 58 S., R. 77 E. The coordinates above reflect their preferred location (The other prospect is the Silver Star prospect which consists of hornblendite with sulfides is at an elevation of about 400 feet, about 1.6 mile west-southwest of Duncan Peak; it is ARDF PE009.)

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Bornite, chalcopyrite, pyrite, pyrrhotite tetrahedrite

Gangue minerals: Calcite, quartz

Geologic description:

As described by Wright and Wright (1905, 1908) and Roehm (1945), the deposit consists of four, thin northeast-striking quartz-calcite veins with pyrite, pyrrhotite, chalcopyrite, bornite, and tetrahedrite. Samples of the veins contained up to 0.4 ounce of gold per ton and 2 ounces of silver per ton. The rocks have been variously mapped as metasedimentary rocks of the Jurassic to Cretaceous Seymour Canal Group by Karl and others (1999) or Cretaceous Stephens Passage Group by Brew (1997) that have been intruded by Cretaceous diorite. Roehm (1945) noted that the workings included a 130-foot adit and open cuts. However, Still and others (2002) could not locate the prospect in spite of a diligent search.

Alteration:

Age of mineralization:

Too little evidence to determine.

Generic deposit model:

Deposit model:

Polymetallic quartz-calcite veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Roehm (1945) noted that the workings included a 130-foot adit and open cuts. However, Still and others (2002) could not locate the prospect in spite of a diligent search.

Production notes:

None.

Reserves:

None.

Additional comments:

This prospect is now in the Petersburg Creek-Duncan Salt Chuck Wilderness which is closed to mineral exploration and mining.

Some recent U.S. Geological Survey publications including Cobb (1978) Cobb (1972), Berg and Cobb (1967), and an earlier generation of ARDF probably combine two different prospects on the west side of Portage Mountain that are described separately in ARDF as this prospect and PE 009.

Location description and accuracy:

This prospect is on Towers Creek at an elevation of about 170 feet, about about 1.5 miles from the head of Towers Arm. It is near the center of section 11, T. 58 S., R. 76 E.

Commodities:

Main: Cu

Other:

Ore minerals: Chalcopyrite, pyrite

Gangue minerals:

Geologic description:

Still and others (2002) sampled this prospect which consists of an outcrop/boulder in Towers Creek of iron-stained, calcareous, silicified schist with disseminated and narrow bands of pyrite with sparse chalcopyrite. The country rock is Devonian schist near the contact with Triassic argillite of the Hyd Group (Karl and others, 1999). Six samples across the schist and the sulfide bands contained 175 to 713 ppm copper. This prospect was one of the discoveries by Amoco Minerals in 1978 and 1979. This work included airborne and ground geophysics, geologic mapping, soil and stream geochemical samples, and core drilling on a large block of claims covering the Tower Creek prospect.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

This prospect was one of the discoveries by Amoco Minerals in 1978 and 1979. This work included airborne and ground geophysics, geologic mapping, soil and stream geochemical samples, and core drilling on a large block of claims covering the Tower Creek prospect.

Site name(s): Salt Chuck

Site type: Prospect

ARDF no.: PE082

Latitude: 56.8408 **Quadrangle:** PE D-4

Longitude: 133.3226

Location description and accuracy:

This prospect is near the center of the peninsula that separates North Arm from Towers Arm at the head of Duncan Canal. It is near the center of section 17, T. 58 S., R 77 E. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

The Salt Chuck prospect was found in late 1978 when Amoco Minerals Co. carried out a major exploration program at the head of Duncan Canal that included aerial and ground geophysics, geologic mapping, soil and stream sediment geochemistry, and diamond core drilling over many hundreds of claims (AMOCO Mineral Company, 1979; Zelinska, 1979).

At Salt Chuck, airborne electromagnetic anomalies followed ground electromagnetic and soil geochemistry surveys. The prospect is tied to an 8,000-foot-long anomaly defined by airborne and ground geophysics and by five diamond drill holes that were drilled to test this anomaly. The holes were drilled to a depth of 600 to 1,000 feet along about 5,000 feet of the anomaly. Several massive-sulfide bands were cut in the drilling but they were thin, discontinuous and generally low grade. The best intersections were one that was 1.7 feet long and averaged 1.86 percent copper and another that was 10 feet long and averaged 0.877 percent copper.

The rocks in the vicinity of the Salt Chuck prospect are Devonian phyllite, schist, and greenstone (Karl and others, 1999).

Amoco geologists also located several outcrops of mineralization in this area (AMOCO Mineral Company, 1979; Zelinska, 1979). The westernmost is about 3 miles north of the tip of the peninsula between Towers Arm and North Arm and 0.6 mile inland from North Arm. The mineralization there is an outcrop 10 feet long by 5 feet wide that consists of a band of chalcopyrite-rich massive sulfides in rhyolite. Samples averaged 6.3 percent copper, 0.02 percent zinc, and 0.32 ounce of silver per ton. Another mineralized zone is about 2,000 feet to the east where three sulfide bands, each less than 6 inches thick, are exposed along the beach. The bands consist of chalcopyrite, sphalerite, and galena, in rhyolite. Samples contain 0.01 to 0.13 percent copper, 0.10 to 25.3 percent lead, 0.15 to 7.8 percent zinc, and 0.2 to 13.62 ounces of silver per ton. These outcrops of mineralization were examined and sampled by Still and others (2002); their analyses were generally similar to those done by Amoco. They also suggested that the prospects were likely to be replacement deposits rather than volcanogenic massive sulfide deposits.

Alteration:

Age of mineralization:

Devonian or later based on the age of the host rocks.

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit? Replacement deposits?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Site type: Occurrences

ARDF no.: PE083

Latitude: 56.8384 **Quadrangle:** PE D-5

Longitude: 133.5709

Location description and accuracy:

This record covers a scattering of several occurrences in an area about 5 miles by 2 1/2 mile in size with the long dimension oriented north. The center of the area is east of the head of Big John Creek near hill 1908 which is southwest of Towers Lake and about 0.3 mile southwest of the center of section 14, T. 58 S., R. 74 E.

Commodities:

Main: Au, Ba, Co, Zn

Other: As,Cu, Hg, Ni, Pb, Sb

Ore minerals: Pyrite

Gangue minerals: Quartz

Geologic description:

This site was originally of interest because of widespread geochemical anomalies in a large suite of elements, zinc in particular. The samples commonly contain anomalous copper, molybdenum, and nickel, and various samples were anomalous in silver, lead, cadmium, manganese, mercury, arsenic, and antimony (Bittenbender and others, 2001). Still and others (2002) indicate that the suite suggests the presence of volcanogenic massive sulfide deposits. In following up these anomalies, they found several occurrences of mineralization in scattered borrow bits and road cuts. None seemed to explain the magnitude of the widespread geochemical anomalies but they do lend support to the concept of massive sulfide mineralization in the area.

The rocks in the area are part of the Cannery Formation of Permian and Mississippian age (Karl and others, 1999); they are a heterogeneous unit of chert, cherty argillite, silicified limestone, siltstone, and graywacke, with minor conglomerate, tuff, and volcanic rocks. In the three most notable areas of outcrop where the mineralization was found, it consists of: 1) pyrite in seams and layers in a 20-foot-thick unit of silicified schist, chert, and graphitic schist, 2) seams and patches of fine-grained to crystalline pyrite in quartz veins and silicified schist and slate, and 3) layers of pyrite up to 2 inches thick in a layer of silicified schist at least 10 feet thick in a unit of argillite. Numerous samples were collected and analyzed. None had high values in any of the common ore elements but many had values above background. The highest values were 136 parts per billion gold, 1,762 parts per million (ppm) zinc, 0.9 ppm silver, 166 ppm copper, 920 ppm lead, 727 ppm arsenic, 486 ppm nickel, and 9,176 ppm barium.

Alteration:

The schists is commonly silicified.

Age of mineralization:

Probably contemporaneous with the Permian and Mississippian host rocks.

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

The only work was sampling by the Bureau of Land Management during a regional mineral assessment.

Production notes:

None.

Reserves:

None.

Location description and accuracy:

This prospect which was first located in 1997, is south of the middle part of Taylor Creek and about 0.6 mile north of hill 1606. It is about 0.4 mile west-southwest of the center of section 36, T. 59 S., R. 76 E. The location is accurate.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals:

Gangue minerals:

Geologic description:

This prospect was first staked by Kennecott Exploration Company in 1997 based on geophysical and geophysical anomalies and they drilled five holes in 2000. Still and others (2002) examined the property and collected several samples. The rocks in the area consist of calcareous chlorite schist interbedded with calcareous graphitic slate; they are part of the Triassic Hyd Group as mapped by Karl and others (1999). At the surface, the mineralization consists of massive to semi-massive layers of pyrite parallel to the foliation of the host rocks and most of the layers are about an inch thick. Four samples were collected by Still and others (2002). One sample across a 3.0-foot layer of semi-massive pyrite contained 197 parts per billion (ppb) gold, 19.2 parts per million (ppm) silver, 335 ppm lead, and 479 ppm zinc. Another sample across a 0.6-foot layer of semi-massive pyrite in slate contained 453 ppm lead and 2,518 ppm zinc. They considered the deposit to be a volcanogenic massive sulfide deposit similar to others in the area.

Alteration:

Age of mineralization:

Contemporaneous with the Triassic host rock.

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Staked in 1997 and 5 holes were drilled by Kennecott in 2000. Sampled by the Bureau of Land Management in the late 1990s.

Production notes:

None.

Reserves:

None.

Site name(s): Spruce Creek

Site type: Prospect

ARDF no.: PE086

Latitude: 56.6647

Quadrangle: PE C-4

Longitude: 133.0303

Location description and accuracy:

The Spruce Creek prospect is about 1.1 mile east of hill 2030 and about 1.1 mile north-northeast of hill 2605, both high points on the ridge that borders the east side of Duncan Canal opposite the Castle Islands. The prospect has three areas of mineralization and the coordinates are at the center of them near the middle of the south boundary of section 18, T. 60 S., R. 79 E.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

As described by Still and others (2002), The Spruce Creek prospects were discovered and staked in 1983. The claims were optioned to Westmin Resources, Ltd. in 1992 and they carried out geophysical surveys and soil geochemistry and mapped the mineralization before dropping the prospect in 1993. Paul Pieper who discovered the prospect drilled several shallow holes on the mineralization and held 10 claims as of 2002.

As mapped by Karl and others (1999), the rocks in the area are part of the Permian and Mississippian Cannery Formation that are in fault contact with volcanic and sedimentary rocks of the Triassic Hyd Group.

Still and others (2002) found three areas of mineralization. One in greenstone schist near a borrow pit consists of a 0.3-foot-thick quartz vein with pyrite, galena, and sphalerite. A sample across the vein contained 213 parts per billion (ppb) gold, 1,690 parts per million (ppm) lead, and 4,163 ppm zinc. Paul Pieper, the claim owner drilled a 19-foot hole there in 1996. Another occurrence of mineralization near a waterfall consists of gray bands of fine-grained sulfides in limestone. A 1.4-foot sample across the sulfide bands contained 416 ppb gold, 14.9 ppm silver, 820 ppm lead, and 5,221 ppm zinc. The third location is in a clearcut and consists of a 4-foot-thick bed of marble in greenstone. A sample taken in the marble of a 0.4-foot-thick band with galena and sphalerite contained 779 ppb gold, 59.1 ppm silver, 5.6 percent lead, and 2.1 percent zinc.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Thin quartz veins with sulfides and bands of mineralization in marble.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Claims have been held on the property since 1983. Westmin Resources Ltd. had an option on the prospect from 1992 to 1993 and did considerable mapping, geochemistry, and ground geophysics. The owner has drilled several shallow holes on the mineralization prior to 2002.

Production notes:

None.

Reserves:

None.

Site name(s): Rubble; East Duncan Pyrite

Site type: Occurrences

ARDF no.: PE087

Latitude: 56.655 **Quadrangle:** PE C-4

Longitude: 133.0863

Location description and accuracy:

These occurrences are on large block of claims on the east side of Duncan Canal, east of the Castle Islands. The claim block extends for about 2 miles along the shoreline and inland for about 1.2 miles to the crest of the ridge that parallels Duncan Canal. The coordinates are on the shoreline at about the middle of the west side of the claim block along Duncan Canal. The occurrences are spread along the shoreline in section 23, T. 59 S., R. 78 E., and probably extend some distance into the sections to the northwest and southeast.

This record also includes the 'East Duncan Pyrite' occurrence listed in Still and others (2002) as a separate site. It appears similar to other occurrences described in this record and they note that it is within the claim block that defines this record. It is on a logging road just above the east shoreline of Duncan Canal opposite Big Castle Island.

Commodities:

Main: Ba, Cu, Pb, Zn

Other:

Ore minerals: Barite, chalcopyrite, galena, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

After Amoco Minerals Co looked at this area and defined several geophysical and geochemical anomalies, in 1985, Atna Resources Ltd. staked 70 claims here and termed the property the 'Rubble'. They abandoned the claims in 1988. Much of the area is covered by heavy vegetation but Still and others (2002) examined the outcrops along the shoreline for several miles and collected numerous rock and stream sediment samples.

Most of the shoreline exposures are part of the Triassic Hyd Group that is the host rock for many volcanogenic massive sulfides deposits in Duncan Canal and beyond (Karl and others, 1999). The claim block is underlain by alternating bands of Hyd Group rocks and the Permian and Mississippian Cannery Formation; the Hyd and Cannery rocks are separated by east-dipping thrust faults. The rocks along the shoreline that Still and others (2002) examined are mainly slate with interbeds of quartz-sericite schist, calcite-chlorite schist, and chert. The schist commonly contains bands and disseminations of pyrite and analyses commonly show 1 to 2 percent barite. Usually the pyrite bands are thin but locally they may be up to a foot thick and consist of to 80 percent pyrite. Samples from most of the pyrite bands are devoid of other metals in notable quantity. However, in one area marked by a conductive geophysical anomaly defined in a 1997 airborne geophysical survey (Alaska Division of Geological and Geophysical Surveys, 1997). Still and others (2002) examined the ground under the anomaly and found a 0.5-inch-thick quartz vein with sphalerite, galena, and chalcopyrite; boulders with 30-50 percent barite; and sulfide bands that include pyrrhotite in addition to pyrite. The geophysical anomaly was also marked by geochemical anomalies in copper, zinc, barium, and molybdenum (Bittenbender and others, 2001).

This record also includes the 'East Duncan Pyrite' occurrence listed by Still and others (2002). It is within the claim block that defines this site. At the occurrence, a pyrite-rich band occurs in a medium to dark gray

slate. Karl and others (1999) map the rocks in this area as part of the Triassic Hyd Group. Still and others (2002) collected three samples; the highest values in them were 9 parts per billion gold, 998 parts per million (ppm) copper, 244 ppm zinc, and all of the samples had about 0.5 percent barium.

Alteration:

Age of mineralization:

Triassic based on the age of the host rocks.

Generic deposit model:

Deposit model:

Barite facies of a Kuroko massive-sulfide model (Cox and Singer, 1986; model 28a); alternatively a barite facies of a Sierran Kuroko model (Bliss, 1992; model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Undetermined

Workings/exploration:

No workings are described but a large claim block was staked over the occurrences in 1985 and there probably was at least some ground exploration. Sampled by government geologists in the late 1990s.

Production notes:

None.

Reserves:

None.

Site name(s): Nicirque

Site type: Prospect

ARDF no.: PE088

Latitude: 56.647 **Quadrangle:** PE C-4

Longitude: 133.0281

Location description and accuracy:

The Nicirque prospect is about 2.5 miles northeast of Grief Island in Duncan Canal at an elevation of about 2,300 feet. It is about 0.4 mile north-northeast of the center of section 30, T. 60 S., R. 59 E. The location is accurate to within one-quarter mile.

Commodities:

Main: Ag, Au, Zn

Other:

Ore minerals: Pyrite

Gangue minerals:

Geologic description:

The Nicirque prospect was staked in 1993 and was active at least as recently as 1998 (Still and others, 2002). It is near the fault contact of the Permian and Mississippian Cannery Formation with volcanic and sedimentary rocks of the Triassic Hyd Group (Karl and others, 1999). A fossil find at the prospect indicates that it may be in slate of Hyd Group. The mineralization is reportedly a massive pyrite vein in a breccia zone. Still and others (2002) collected a sample across three feet of slate with pyrite bands. The sample contained 56 parts per billion gold, 2.6 parts per million (ppm) silver, and 333 ppm zinc.

Alteration:

Age of mineralization:

Possibly Triassic based on the age of the host rock.

Generic deposit model:

Deposit model:

Pyrite bands in slate.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

There is no record of work at this prospect other than that it was first staked in 1983 and that the Bureau of Land Management examined the it and collected a sample.

Production notes:

None.

Reserves:

None.

Site name(s): Scott Gold

Site type: Prospect

ARDF no.: PE090

Latitude: 56.5748 **Quadrangle:** PE C-4

Longitude: 133.0039

Location description and accuracy:

The Scott Gold prospect is about 1.6 miles northeast of the east end of Harvey Lake and about 0.5 mile northeast of the center of section 24, T. 61 S, R. 79 E. 9., of the Copper River Meridian. It is in a steep, heavily vegetated area along a gully at an elevation of about 580 feet. The location is accurate.

Commodities:

Main: Au, Pb, Zn

Other: Ba

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

At various times from the 1970s, much of central Woewodski Island has been staked by a succession of companies; these include Resource Associates of Alaska, Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, Houston Oil and Minerals, Westmin Resources, and the Olympic Resources Group. During several episodes in the late 1980s and early 1990s, there was considerable soil sampling in the area including on the nearby Scott prospect (PE091) where three three holes were drilled (Still and others, 2002). The Scott Gold prospect shares a similar exploration history although only mineralized rubble is exposed along a shallow, west-trending gulch in heavy vegetation. Claims are still active on the Scott Show prospect in 2008.

The country rocks at the Scott Gold prospect are mainly semischist and phyllite, part of the Triassic Hyd Group (Karl and others, 1999, Brew, 1997). Silicified quartz-rich greenstone contain bands of disseminated pyrite, galena, and sphalerite. Samples collected by Still and others (2002) continued 834 to 1,793 parts per billion gold, 826 to 2,559 parts per million (ppm) lead, and 9,428 ppm to 2.52 percent zinc. One sample contained 13.76 percent barium.

Alteration:

The semischist and phyllite host rocks are notably silicified.

Age of mineralization:

Probably upper Triassic or younger based on the age of the host rocks and similarities to the Duncan-Zarembo belt of massive sulfide mineralization.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active

It is in a steep gully at an elevation of about 770 feet. The location is accurate. Figure 20 in Still and others (2002) is a detailed map of the Scott prospect.

Commodities:

Main: Ag, Au, Ba, Pb, Zn

Other:

Ore minerals:

Gangue minerals: Barite

Geologic description:

At various times from the 1970s, much of central Woewodski Island has been staked by a succession of companies; these include Resource Associates of Alaska, Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, Houston Oil and Minerals, Westmin Resources, and the Olympic Resources Group. During several of these episodes in the 1980s and early 1990s, there was soil sampling on the Scott prospect and three holes were drilled there (Still and others, 2002). It has been examined several times since and claims are still active on it in 2008. The nearby Scott Gold prospect (PE090) shares a similar history.

The Scott deposit can be traced for 300 feet in a series of discontinuous exposures along a steep gully. The mineralization consists of bands and lenses of barite, pyrite, and galena, 0.1 to 2.0 feet thick, that parallel the layering in the host rock. The host rocks at the prospect are semischist and phyllite that are correlative with the Triassic Hyd Group (Karl and others, 1999, Brew, 1997). Individual lenses of mineralization can be traced for to up to 30 feet. Still and others (2002) collected 22 samples that contained up to 1,122 parts per billion (ppb) gold, 47.3 parts per million (ppm) silver, 2.63 percent lead, and 40.9 percent zinc. Lower metal values persist out into the wall rock as disseminated ore minerals and a sample of quartz and greenstone float found near the sulfide lenses contained up to 8,157 ppb gold. (There is no information available on the drill holes.)

Alteration:

None specifically noted.

Age of mineralization:

Triassic or younger based on age of the host rock.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
28a

Location description and accuracy:

This prospect is near the middle of the south side of the small lake, locally called 'Lost Lake', that is about 0.7 mile north of the west end of Harvey Lake It is in the NE1/4, section 22, T. 61 S., R. 79 E.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals: Quartz

Geologic description:

Guided by an unpublished map dated 1933, Still and others (2002) located a 45-foot-long trench on four claims staked in the 1930s under the name 'Hope'. The trench exposes 12 feet of quartz rubble and 19 feet of a quartz vein in schist. The vein strikes N30W, and dips 45SW. A chip sample across 8.7 feet of the middle of the quartz vein averaged 4,400 parts per billion gold. Another trench is caved. The rocks in the area consist of felsic and intermediate volcanic flows and breccias, limestone, and argillite of the Hyd Group of Triassic age (Karl and others, 1999). In recent years, the prospect had often been covered by the claims of the 'Lost Show' prospect (PE029) on the north side of Lost Lake.

Alteration:

None noted.

Age of mineralization:

Triassic or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Low-sulfide gold quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active?

Workings/exploration:

Two trenches were dug on this prospect in the 1930s. One is now caved but the other was sampled by Still and others (2002).

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (adjacent to Helen S Mine)

Site type: Prospect

ARDF no.: PE093

Latitude: 56.5693 **Quadrangle:** PE C-4

Longitude: 133.0683

Location description and accuracy:

This deposit adjoins or overlaps the veins at the Helen S Mine (PE028). At this prospect, volcanogenic massive sulfides are exposed in several pits and occur in float for about 700 feet along a small south-flowing creek whose mouth is about 50 yards north of the mouth of the creek that drains Harvey Lake on Woewodski Island. The coordinates are at a pit with the best exposed mineralization; it is about 400 feet north of the high-tide line in southwest corner of section 22, T. 61 S., R 79 E. Figure 15 of Still and others is a detailed map of this mineralization and the Helen S Mine.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Ba

Ore minerals: Arsenopyrite, chalcopyrite, galena, pyrrhotite, sphalerite

Gangue minerals: Barite, quartz

Geologic description:

This volcanogenic massive-sulfide deposit is within the old claim of the Helen S Mine (PE028). The massive sulfides are present in several pits that may date back to the early 1900s. However, the massive sulfides were not recognized until 1980 (Berg and Grybeck,1980). Subsequently, the deposit has been examined by numerous geologists and it was examined and sampled by Still and others (2002) as part of a regional mineral assessment for the Bureau of Land Management.

The rocks in the area are mainly metamorphosed felsic and intermediate flows and breccia and argillite of the Triassic Hyd Group that have been intruded by Mesozoic hornblende gabbro exposed just a few hundred feet to the west and Cretaceous diorite a mile to the south (Brew, 1997; Karl and others, 1999).

The best exposure of the massive sulfide mineralization is in an old pit about 400 feet north of the site of the old Helen S mill. The massive sulfides consist of crudely banded pyrite, pyrrhotite(?), arsenopyrite, sphalerite, and galena with barite in greenstone and greenschist. Similar mineralization occurs in several small pits and in float for about 400 feet north along a small creek. Still and others (2002) collected several samples in the southern pit; selected samples contained up to 113.5 parts per million (ppm) silver, up to 2.5 percent lead, and 3.0 percent zinc. Samples from the northern pits contained up to 2.13 ounces of silver per ton, 1.74 percent lead, and 8.5 percent zinc. The massive sulfide deposits do not contain detectable gold as distinct from the gold-quartz veins of the adjacent Helen S Mine. Berg and Grybeck (1980) interpreted the massive sulfides as part of the Duncan-Zarembo belt of dismembered, Upper Triassic volcanogenic massive sulfide deposits.

Alteration:

Age of mineralization:

The volcanogenic massive sulfides in the Duncan-Zarembo belt are Upper Triassic (Berg and Grybeck, 1980).

Generic deposit model:

Deposit model:

Barite facies of a Kuroko massive-sulfide model (Cox and Singer, 1986; model 28a); or alternatively a barite facies of a Sierran Kuroko model (Bliss, 1992; model 28a.1).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 28a.1

Production Status: None

Site Status: Active

Workings/exploration:

This volcanogenic massive-sulfide deposit is within the old claim of the Helen S Mine (PE028). The massive sulfides are present in several pits that may date back to the early 1900s. However, the massive sulfides were not recognized until 1980 (Berg and Grybeck, 1980). Subsequently, the deposit has been examined by numerous geologists and it was examined and sampled by Still and others (2002) as part of a regional mineral assessment for the Bureau of Land Management.

Production notes:

None.

Reserves:

None.

Additional comments:

All the workings are on a patented claim.

Site name(s): Unnamed (on south Fork Andrew Creek)

Site type: Occurrences

ARDF no.: PE094

Latitude: 56.5686

Quadrangle: PE C-1

Longitude: 132.1044

Location description and accuracy:

These occurrences are on the South Fork of Andrew Creek at an elevation of about 1000 feet. They are about 12.6 miles east-northeast of Wrangell near the center of section 23, T. 61 S., R. 85 E.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

During a reconnaissance examination of Andrew Creek, Still and others (2002) found a piece of quartz float with visible gold in the South Fork of Andrew Creek at an elevation of about 1,000 feet. They could not locate the lode source but several other samples of quartz float in the creek contained 137 to 1,992 parts per billion (ppb) gold. They also collected 21 stream-sediment sample and a panned concentrate. The stream sediment samples contained up to 493 ppb gold and the panned concentrate sample contained 1,058 ppb gold. Andrew Creek largely flows on Mesozoic and Paleozoic schist and gneiss that is intruded by Cretaceous tonalite plutons (Brew, 1997; Karl and others, 1999) . These make up the western border zone of the Coast Plutonic Complex. East of Andrew Creek the complex consists largely of Tertiary tonalite and migmatite. (Brew, 1997; Karl and others, 1999).

Alteration:

Age of mineralization:

Uncertain because the mineralization was not found in place.

Generic deposit model:

Deposit model:

Visible gold in quartz float.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only sampling by government engineers and geologists.

Production notes:

None.

Reserves:

None.

Additional comments:

The area is now within the Stikine-LeConte Wilderness which is closed to mineral exploration and mining.

Longitude: 132.9855

Location description and accuracy:

Wright and Wright (1908) showed 14 prospects on the heavily vegetated northeast portion of Woewodski Island; little more has been published about them since. The prospects are scattered along a belt about two miles long that extends north-northwest from near Point Lockwood on Wrangell Narrows. The coordinates are at about the center of the belt. The location of any one of the prospects is uncertain owing to the small scale and lack of detail on Wrights' map.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Although much of Woewodski Island has been staked by a succession of companies since the 1980s, there appears to be little if any work concentrated on the northeast of the island along Wrangell Narrows. The only indication of mineralization at this site is on an old, small-scale map by Wright and Wright (1908); they show 14 'X' marks scattered along a belt about two miles long with the notation 'Finzen's Prospects'. Since the main commodity of interest then was gold, it is assumed that the prospect were for gold. There is no more recent information on these prospects although Still and others (2002) collected several several stream sediment samples and rock in the vicinity for geochemical analysis. None showed significant metal values. The rocks in the vicinity are part of the Triassic Hyd Group that consists mainly of volcanic flows and breccias, argillite, and some limestone (Brew, 1997; Karl and others, 1999).

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active?

Workings/exploration:

Although much of Woewodski Island has been staked by a succession of companies since the 1980s, there appears to be little if any work concentrated on the northeast of the island along Wrangell Narrows. The only indication of mineralization at this site is on an old, small-scale map by Wright and Wright (1908); they show 14 'X' marks scattered along a belt about two miles long with the notation 'Finzen's Prospects.' Site name(s): Unnamed (on west side of lower Duncan Canal)

Site type: Occurrence

ARDF no.: PE096

Latitude: 56.565 **Quadrangle:** PE C-4

Longitude: 133.1014

Location description and accuracy:

This occurrence is in a borrow pit near sea level on the west side of Duncan Canal opposite the mouth of the creek that drains Harvey Lake on Woewodski Island. It is near the southwest corner of section 21, T. 61 S., R. 79 E. The location is accurate.

Commodities:

Main: As, Au, Cu

Other:

Ore minerals: Chalcopyrite, pyrite

Gangue minerals:

Geologic description:

This occurrence was found during the exploration of the Duncan Canal area by Amoco Minerals Co. in the late 1970s. Still and others (2002) visited the site and collected several samples of greenstone that contained disseminated pyrite and chalcopyrite. The samples contained 15 to 821 parts per billion gold, 954 to 1,189 parts per million (ppm) copper, and 21 to 1,906 ppm arsenic. The rocks in the area are part of the Triassic Hyd Group which are known to be favorable for volcanogenic massive sulfide deposits in the Duncan Canal area (Karl and others, 1999).

Alteration:

Age of mineralization:

Triassic based on the age of the host rocks.

Generic deposit model:

Deposit model:

Volcanogenic massive sulfide deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

First located in the late 1970s; only limited surface sampling by government and industry.

Production notes:

None.

Reserves:

None.

Site name(s): Maid of Texas

Site type: Prospect

ARDF no.: PE097

Latitude: 56.5648 **Quadrangle:** PE C-4

Longitude: 133.0289

Location description and accuracy:

The Maid of Texas prospect is often described with the adjacent Maid of Mexico Mine. It t is separate vein, however, and at least at some time in the past on separate claim(s). The Maid of Texas vein is parallel to the Maid of Mexico and about 200 feet to the southeast. It is about 0.4 mile south-southeast of the center of section 23, T 61 S, R. 79E. In 1996, a trail was still passable from the center of the north shore of Harvey Lake, north to the nearby Maid of Mexico Mine, but in later years it was difficult to follow in the heavy timber and vegetation. The location of the Maid of Texas is shown on Figure 17 of Still and others (2002). The location is accurate.

Commodities:

Main: Au

Other: Zn

Ore minerals: Native gold?

Gangue minerals: Quartz

Geologic description:

The Maid of Texas vein as located by Still and others (2002) is parallel to and about 200 feet southeast of the Maid of Mexico Mine. It was discovered before 1933 but there has been little work on it and no production from it. There is a small cut on the Maid of Texas vein that now can can be traced as a line of scattered quartz float that trends northeast. in gullies. Still and others (2002) collected three samples that contained up to 8 parts per billion (ppb) and 419 parts per million zinc. Two samples of iron-stained, pyrite-rich schist contained 51 and 61 ppb gold. The vein is at the contact of semischist and phyllite of the Triassic Hyd Group (Brew, 1997).

Alteration:

None specifically noted.

Age of mineralization:

Triassic or younger based on age of the host rock.

Generic deposit model:

Deposit model:

Gold quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only a cut opened before 1933.

Production notes:

None.

Reserves:

None.

Site name(s): Independence

Site type: Prospect

ARDF no.: PE099

Latitude: 56.5476 **Quadrangle:** PE C-4

Longitude: 133.0423

Location description and accuracy:

The Independence prospect consists of a shaft and 12 cuts that extend for about 1,800 feet along a quartz vein. The coordinates are at the shaft which is at an elevation of about 500 feet, about 0.3 mile north-northwest of the north end of Harrys Lake on Woewodski Island. It is about 0.5 mile north of the center of section 35, T. 61 S., R. 79 E.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

The Independence prospect was found sometime before 1931 (Nelson, 1931) and by 1933 consisted of 12 cuts and a shaft 10 to 20 feet deep along a vein that extended for about 2,000 feet (Still and others, 2002). Apparently there has been no later work specifically on this prospect although much of the center of Woewodski Island has been covered by claims since the 1970s and this prospect probably still is.

The rocks in the vicinity are mainly felsic volcanic rocks of the Triassic Hyd Group (Brew, 1997, Karl and others, 1999). At the south end of the prospect, the volcanics are cut by Cretaceous hornblende diorite. The mineralization consist of a quartz vein up to 10 feet thick that strikes north and has been traced on the surface for about 2,000 feet. Still and others (2002) collected 8 samples from the pits along the vein and from the shaft dump. Six contained less than 5 parts per billion (ppb) gold, one contained 74 ppb gold, and one contained 94 ppb gold.

Alteration:

None specifically noted.

Age of mineralization:

Cretaceous or younger based on the age of the diorite host rock to the vein.

Generic deposit model:

Deposit model:

Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Site name(s): Mad Dog 2

Site type: Prospect

ARDF no.: PE100

Latitude: 56.5472 **Quadrangle:** PE C-4

Longitude: 133.0254

Location description and accuracy:

The Mad Dog 2 prospect is about 0.9 mile south-southeast of the east end of Harvey Lake at an elevation of about 400 feet. It is near the northwest corner of section 36, T. 61 S., R. 79 E.

Commodities:

Main: Ag, Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals:

Geologic description:

Since the 1970s much of Woewodski Island has been covered by claims held by a succession of companies: Resource Associates of Alaska, Cominco Exploration, Colony Pacific, Amselco, Kennecott Exploration, Westmin Resources, and currently (2008) the Bravo Venture Group. This prospect probably was within those claims several times and it is under claim in 2008. In 1998, two holes were drilled on the Mad Dog 2 prospect by P. Beardslee (Still and others, 2002).

Most of the area is heavily vegetated. The sparse outcrop consists of metamorphosed intermediate to felsic volcanic rocks of the Triassic Hyd Formation (Brew, 1997; Karl and others, 1999). Near the 1998 drill site, Still and others (2002) located an outcrop of schist with a band of pyrite, chalcopyrite, and sphalerite 0.3 to 0.8 feet thick. Six samples contained 67 to 2,867 parts per billion gold, 2.4 to 27.1 parts per million (ppm) silver, 240 to 1,512 ppm copper, and 732 ppm to 2.9 percent zinc. The drill holes were said to miss any significant mineralization.

Alteration:

Age of mineralization:

Late Triassic based on the age of the host rock and similarities to massive sulfide deposits in the Duncan-Zarembo belt of mineralization.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active?

ARDF no.: PE101

Latitude: 56.5218 **Quadrangle:** PE C-3

Longitude: 132.9966

Location description and accuracy:

This prospect covers an area of about 1,500 feet by 5,000 feet , centered about 0.6 mile north of the southern tip of Woewodski Island. The center of the area is about 0.6 mile south-southeast of the northwest corner of section 5, T. 62 S., R. 80 E.

Commodities:

Main: Au

Other: As

Ore minerals:

Gangue minerals:

Geologic description:

In the late 1990s, Olympic Resources collected hundreds of soil samples on a grid and outlined an area about 1,500 feet by 5,000 feet in size with anomalous gold values. However, when the Bureau of Land Management (Still and others, 2002) recollected some samples in the area, on analysis they could not verify the original results. The discrepancy cannot be explained. In 2000, Olympic Resources drilled seven holes in the area; the results have not been published but were said to be 'not favorable' by Still and others (2002).

The rocks in the area are volcanics of the Triassic Hyd Group that have been intruded by a Upper Cretaceous hornblende diorite (Brew, 1997; Karl and others, 1999). While the persistent high gold values of the original soil sampling could not be confirmed by Still and others (2002), several of their soil samples contained anomalous gold and arsenic. Two samples contained 67 and 75 parts per billion (ppb) gold and 122 and 124 parts per million (ppm) arsenic. They also collected two samples of silicified greenstone with disseminated pyrite that contained 94 to 730 ppb gold and 1,374 to more than 10,000 ppm arsenic.

Alteration:

Volcanic rocks are silicified near one mineralized outcrop.

Age of mineralization:

Probably Triassic of younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Site name(s): AMAX Molybdenum

Site type: Prospect

ARDF no.: PE102

Latitude: 56.5164 **Quadrangle:** PE C-1

Longitude: 132.0607

Location description and accuracy:

The AMAX Molybdenum prospect consists of 4 deep holes drilled between 1976 and 1981 by Amax Exploration Inc. The holes extend along a line about 5,000 feet long trending about N 40 W. The location is at about the center of this line of holes, near the site of one of the holes. Still and others (2002) locate the holes precisely on their Plate 3. The center of the line of holes is at an elevation of about 3,000 feet about 1.3 miles southwest of Mount Waters and about 0.6 mile south-southwest of the center of section 6, T. 62 S., R. 85 E., in Groundhog Basin. The location is accurate.

Commodities:

Main: Mo

Other: W

Ore minerals: Molybdenite, scheelite

Gangue minerals: Fluorite, quartz

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin adjacent to the lines of drill holes that define this prospect, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton about 1,000 by 2,0000 feet in size. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

From 1976 to 1981, AMAX Exploration Inc. drilled four holes, 506 to 2,727 feet deep, to test the molybdenum potential of the small biotite granite exposed on the ridge northeast of the drill holes. During surface mapping in the area, AMAX collected samples that contained up to 5,000 parts per million (ppm) molybdenum in the biotite granite stock and gneiss (AMAX Exploration Inc., 1981a, 1981b). The mineralization consists of thin fractures with molybdenite in the granite and gneiss. The molybdenite is associated with quartz and fluorite in stringers and vugs, sericite-chlorite alteration, and some tungsten in the assays. The four holes that AMAX drilled were oriented to penetrate the granite at depth and three of the holes did so. Mineralization was cut in several of the holes but the best interval contained only 69 parts per million molybdenum. Still and others (2002) examined the area as part of a Bureau of Land Management mineral assessment of the area but their work was confined to a few surface samples.

Alteration:

The molybdenite is associated with quartz and fluorite in stringers and vugs and sericite-chlorite alteration.

Age of mineralization:

Associated with a 16.3 Ma granite.

Generic deposit model:

Deposit model:

Porphyry molybdenum.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

From 1976 to 1981, AMAX Exploration Inc. drilled four holes, 506 to 2,727 feet deep, to test the molybdenum potential of the small biotite granite pluton exposed on the ridge northeast of the drill holes. They also did considerable surface mapping in the area. A few surface samples collected by Still and others (2002).

Production notes:

None.

Reserves:

Site name(s): Northeast Cliffs

Site type: Prospect

ARDF no.: PE103

Latitude: 56.5164 **Quadrangle:** PE C-1

Longitude: 132.0607

Location description and accuracy:

This prospect represents sampling by an unknown company and by Still and others (2002) on the steep north-trending cliff face east of the middle section of Groundhog Basin. The coordinates are at about the center of the work at an elevation of about 3,400 feet; it is about 0.5 mile south of the center of section 6, T. 62 S., R. 86 E. The general location is accurate but the location of the specific sampling by industry is uncertain.

Commodities:

Main: Cu, Pb, Sn, Zn

Other:

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals:

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin just west of the cliff faces, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton about 1,000 by 2,0000 feet in size. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

Still and others (2002) found fixed climbing ropes at several places along about 0.5 mile on the cliff faces east of Groundhog Basin that probably represent sampling and mapping by AMAX Exploration Inc. between 1976 and 1981. Still and others (2002) collected several samples at the north and south ends of the cliffs. The rocks along the cliffs are mainly silicified gneiss and rhyolite. The mineralization consists of disseminated chalcopyrite, galena, and sphalerite (probably similar in origin to the mineralization at the Groundhog Basin prospect in the valley below (PE040)). Four samples collected by Still and others (2002) contained 112 to 980 parts per million (ppm) copper, 1,569 to 9,559 ppm zinc, and 58 to 1,941 ppm tin.

Alteration:

None specifically noted.

Age of mineralization:

16.3 Ma based on a probable genetic tie to a nearby, zinnwaldite 'tin' granite (Newberry and Brew, 1989).

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Still and others (2002) found fixed climbing ropes at several places along about 0.5 mile on the cliff faces east of Groundhog Basin that probably represent sampling and mapping by AMAX Exploration Inc. between 1976 and 1981. Still and others (2002) collected several samples at the north and south ends of the cliffs.

Production notes:

None.

Reserves:

None.

Last report date: 2008-03-04

Site name(s): North Silver West

Site type: Prospect

ARDF no.: PE104

Latitude: 56.515 **Quadrangle:** PE C-1

Longitude: 132.0484

Location description and accuracy:

This prospect is about 1.0 mile southwest of Mount Waters at an elevation of about 4,220 feet; it is about 0.5 north-northeast of the center of section 7, T. 62 S., R. 85 E. The location is accurate and it is Map No. 94 of Still and others (2002).

Commodities:

Main: Ag, Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin about a mile southwest of this prospect, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

In the late 1950s, Moneta Porcupine Company staked claims in the area but subsequently dropped them. William Huff and James Fucas continued prospecting in the area and Huff discovered the North Silver West prospect in 1963. Their claims were optioned by the Bunker Hill Mining Company in 1965 and they dug several pits on the mineralization. They dropped the claims at the end of the field season and the property was optioned by a succession of companies, Humble Oil and Refining Company, El Paso Natural Gas Company and AMAX Exploration Inc., through 1981. An adit driven early in the history of the prospect extended only a few feet into the rock. Still and others (2002) sampled the prospect during a Bureau of Land Management mineral assessment of the area.

The North Silver West prospect is associated with a fault zone up to 10 feet thick that strikes N20-40E and dips 50-89 degrees southeast. The footwall of the fault schist with 0.5-to-4-foot-thick, irregular lenses and pods of quartz with massive and disseminated pyrite, galena, and sphalerite. The fault zone, as now exposed extends for about 185 feet. Samples collected by Still and others (2002) across 0.5 to 4.9 feet of the mineralization contained 31.3 to 79.46 parts per million (ppm) silver, 1,795 ppm to 33.47 percent lead, and from 2,734 ppm to 9.8 percent zinc.

Alteration:

Age of mineralization:

Probably related to a nearby 16.3 Ma biotite granite pluton.

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Site name(s): North Silver Whistlepig Adit

Site type: Prospect

ARDF no.: PE105

Latitude: 56.5116 **Quadrangle:** PE C-1

Longitude: 132.0435

Location description and accuracy:

The North Silver Whistlepig Adit is about 1.0 mile south-southwest of Mount Waters on a steep slope at the head of a cirque. It is at an elevation of about 4,050 feet about 0.5 mile northeast of the center of section 7, T. 62 S., R. 85 E. The location is accurate and is is Map No. 95 of Still and others (2002).

Commodities:

Main: Ag, Au, Pb, Sn, Zn

Other:

Ore minerals: Galena, sphalerite

Gangue minerals: Fluorite, quartz

Geologic description:

In the late 1950s, Moneta Porcupine Company staked claims in the area but subsequently dropped them. William Huff and James Fucas continued prospecting in the area and staked several claims. Their claims were optioned by the Bunker Hill Mining Company in 1965. They dropped the claims at the end of the field season and the property was optioned by a succession of companies through 1981: Humble Oil and Refining Company, El Paso Natural Gas Company, and AMAX Exploration Inc. Sometime in the 1970s, a mine car and track were taken by helicopter to the prospect and an adit was started to intersect a silver vein. However, the adit extended only a few feet into the rock. About 20 feet of trenching was also done at that time. Still and others (2002) sampled the prospect during a Bureau of Land Management mineral assessment of the area.

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin about a mile northwest of this prospect, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

The mineralization at the North Silver Whistlepig Adit prospect consists of narrow, argentiferous, galena-bearing quartz veins (Still and others, 2002). The veins are from 0.2 to 1.0 foot thick, pinch and swell, and are exposed for about 50 feet in the steep rock face above a short adit that only extends a few feet into rock and does not intersect the veins. Several samples of the vein material collected by Still and others (2002) contained from less that 5 to 4,345 parts per billion gold, 11.5 parts per million (ppm) to 517.62 ounces of silver per ton, 778 ppm to 39.75 percent lead, 377 ppm to 11.0 percent zinc, and 17 to 1,497 ppm tin. Gneiss at the adit contains small vugs of quartz and fluorite; a sample across 3.6 feet of the gneiss contained 954 ppm lead, 399 ppm zinc, and 11.9 ppm silver.

Alteration:

Age of mineralization:

Probably related to a nearby 16.3 Ma biotite granite.

Generic deposit model:

Deposit model:

Argentiferous, galena-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to Tertiary or Cretaceous schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton about 1,000 by 2,0000 feet in size. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

El Paso Natural Gas Company worked in the area from 1971 to 1976 (George and Wyckoff, 1973). They collected more than 200 surface samples along a line about 1,900 feet long that extended south-southwest from Peak 4326. They also drilled a hole 149 feet deep about 0.1 mile southwest of Peak 4326. Still and others (2002) identified the mineralization as quartz veins and stringers up to 10 feet thick that follows the layering in the gneiss hostrock. Four samples contained up to 63.9 parts per million (ppm) silver, 1,417 ppm lead, and 1,089 ppm tin. In the samples El Paso Natural Gas Company collected, the 6 best surface samples contained 840 to 1,655 ppm zinc, and 320 to 2,720 ppm lead. A 32-foot intercept in the El Paso drill hole consisted of rhyolite and gneiss cut by quartz stringers with sphalerite and galena; the intercept averaged 0.7 percent zinc, 1.0 percent lead, and 0.3 ounce of silver per ton. The mineralization is almost certainly of the same origin and age as that at the nearby Groundhog Basin prospect (PE040).

Alteration:

Age of mineralization:

16.3 Ma based on a genetic tie to a nearby, zinnwaldite 'tin' granite (Newberry and Brew, 1989).

Site name(s): Copper Zone

Site type: Prospect

ARDF no.: PE107

Latitude: 56.5052 **Quadrangle:** PE C-1

Longitude: 132.0504

Location description and accuracy:

The Copper Zone prospect is high on the cirque wall at the head of Groundhog Basin; it is at an elevation of about 3,500 feet, about 0.5 mile west-southwest of the prominent peak 4326. The prospect is about 0.3 mile south-southeast of the center of section 7, T. 62 S., R. 86 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Sn, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrrhotite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to Tertiary or Cretaceous schist and gneiss The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton about 1,000 by 2,0000 feet in size. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

The earliest work reported on this prospect was done by El Paso Natural Gas Company in 1972; they collected 1,044 rock samples and drilled nine holes (George and Wyckoff, 1973; Still and others, 2002) . They defined a mineralized area about 125 feet by 160 feet in size. Still and others (2002) report that the area is notable for rhyolite sills up to 60 feet thick that generally follow the layering in gneiss and schist. Disseminated chalcopyrite occurs along fractures that parallel and crosscut the foliation of the metamorphic rocks. Some lenses and bands of massive chalcopyrite and pyrrhotite up to 0.4 feet thick also occur along the fractures. Chip samples up to 0.7 feet long across the fractures contained up to 4,580 parts per billion gold, 19.65 ounces of silver per ton, 8.1 percent copper, 1.71 percent lead, 2.65 percent zinc, and 1,728 parts per million tin. Only one of the nine holes drilled by El Paso Natural Gas Company intersected mineralization; the best intercept was 70 feet that averaged 0.11 percent copper. The deposit is similar to the mineralization at the nearby Groundhog Basin prospect (PE040) and may be a continuation of it.

Alteration:

None noted specifically.

Age of mineralization:

16.3 Ma based on a probable genetic tie to a nearby, zinnwaldite 'tin' granite (Newberry and Brew, 1989).

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

The earliest work reported on this prospect was by El Paso Natural Gas Company in 1972; they collected 1,044 rock samples and drilled nine holes. The prospect was later sampled by Still and others (2002) as part of a BLM mineral assessment.

Site name(s): Lake Cirque

Site type: Prospect

ARDF no.: PE109

Latitude: 56.4992 **Quadrangle:** PE B-1

Longitude: 132.052

Location description and accuracy:

The Lake Cirque prospect consists of three areas of mineralization that crop out through patches of ice and snow along a generally north-south trend about 2,000 feet long. The coordinates are at about the center of the mineralization; it is about 0.9 mile north-northwest of Marsha Peak and about 0.4 mile north of the center of section 18, T. 62 S., R. 86 E. The location is accurate. A map of the mineralization is Plate 29 of Still and others (2002).

Commodities:

Main: Ag, Cu, Pb, Sn, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to Tertiary or Cretaceous schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin,. about a mile to the north-northeast of this prospect, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton about 1,000 by 2,0000 feet in size. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

The mineralization at this prospect and in the surrounding area was described in detail by Gault and others (1953). The prospect area was included in various claims blocks staked in the 50s and 60s but for most of that time, the area was covered by permanent snow and ice. In 1976, Bunker Hill Mining Company was able to trace the ore beds in Groundhog Basin (PE040) into the cirque around this prospect and drilled two holes in the mineralization. Still and others (2002) better defined the and sampled the mineralization in a year when much of the snow had melted off.

The mineralization at the Lake Cirque prospect is a continuation of the ore beds at the better known Groundhog Basin prospect (PE040) to the north. Still and others (2002) identified three zones of mineralization among the snow banks. The mineralization is similar in all three. It consists of layers of gneiss and/or calc-silicate gneiss that contain tabular to layered masses of chalcopyrite, galena, sphalerite, pyrite, and pyrrhotite. In the eastern zone, five samples taken in a tabular body several feet thick averaged 8.2 parts per million (ppm) silver, 752 ppm copper, 8,374 ppm lead, 5.13 percent zinc and 842 ppm tin. The west zone is about 80 feet long and 3 feet wide; samples averaged 36.9 ppm silver, 2.318 ppm copper, 9,223 ppm zinc, and 3,267 ppm tin. The mineralization at the south zone is in sheared gneiss with vuggy quartz veinlets. Samples across 9 feet of this zone's best mineralization averaged 3 ppm silver, 446 ppm copper, 1.68 percent zinc, and 567 ppm tin. Another area of mineralization originally located by Gault and others (1953) is on the south side of the cirque and consists of irregular bands and lenses of massive and disseminated pyrrhotite, galena, and sphalerite in calc-silicate gneiss and along fractures. The best sample

collected in this zone by Still and others (2002) contained 130 ppm silver, 1,057 ppm copper, 1.06 percent led, 2.8 percent zinc, and 757 ppm tin.

Alteration:

None specifically noted.

Age of mineralization:

Probably 16.3 Ma based on a genetic tie to a nearby, zinnwaldite 'tin' granite (Newberry and Brew, 1989).

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

The mineralization in this area was first described by Gault and others (1953). The prospect area was included in various claims blocks staked in the 50s and 60s, but for most of that time the area was covered by snow and ice. In 1976, Bunker Hill Mining Company was able to trace the ore beds in Groundhog Basin (PE040) in to the cirque around this prospect and drilled two holes. Still and others (2002) were able to better define and sample the mineralization in a year when much of the snow had melted and the rocks were better exposed.

Production notes:

None.

Reserves:

None.

Site name(s): North Marsha Peak

Site type: Prospect

ARDF no.: PE110

Latitude: 56.4934 **Quadrangle:** PE B-1

Longitude: 132.0438

Location description and accuracy:

The North Marsha Peak prospect is about 0.5 mile north of Marsha Peak and about 0.4 mile east of the center of section 18, T. 62 S., R. 86 E. The location is accurate. A map of the prospect is Figure 30 of Still and others (2002).

Commodities:

Main: Ag, Pb, Sn, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to Tertiary or Cretaceous schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin, about 2 miles northwest of this prospect, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton about 1,000 by 2,0000 feet in size. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

The mineralization at this prospect was described by Gault and others (1953) but little was done on it by industry until the property was optioned by the Bunker Mill Mining Company in 1965. From 1968 to 1970, Humble Oil and Refining Company optioned the property and drilled two holes on it through the Nelson Glacier. El Paso Natural Gas Company optioned the property from 1971 to 1973, collected numerous surface samples, and drilled three holes on it, 116 to 230 feet long (George and Wyckoff, 1973). Still and others (2002) re-examined the property during a mineral assessment of the area by the BLM.

The mineralization here is generally similar to that in Groundhog Basin (PR040) several miles to the north and probably shares the same origin. Here the mineralization is associated with two sheared zones that parallel the foliation of the gneiss and the rhyolite sills in the gneiss; the fault zones strike north and are about 750 feet apart. As reported by Still and others (2002) the western shear zone is 4 to 12 feet thick and about 1,100 feet long. Samples averaged 1.5 ounces of silver per ton, 0.3 percent copper, 0.22 percent lead, and 0.58 percent zinc. The eastern shear zone is about 4 feet thick and can be traced for about 600 feet to where it disappears under the Nelson Glacier. Select samples of thin veinlets along the shear zone contained up to 20.7 ounces of silver per ton, 70 percent lead, and 22 percent zinc. One hole by El Paso Natural Gas Company in the western zone was probably drilled parallel to the mineralized shear zone; it averaged 1.1 percent zinc and 0.25 percent lead over its entire 116 foot length. Another drill hole in the eastern shear zone had a 13-foot interval that averaged 0.87 ounce of silver per ton, 0.08 percent copper, 0.6 percent lead, and 4.3 percent zinc.

Alteration:

Age of mineralization:

Probably 16.3 Ma based on a genetic tie to a nearby, zinnwaldite 'tin' granite (Newberry and Brew, 1989).

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Site name(s): Unnamed (on Nelson Glacier)

Site type: Occurrences

ARDF no.: PE111

Latitude: 56.4913 **Quadrangle:** PE B-1

Longitude: 132.015

Location description and accuracy:

These occurrences are in an area that covers most of the center and upper portions of the Nelson Glacier. Much of the glacier was covered by claims from 1964 to 1981, when there was considerable exploration to the west from Marsha Peak to Groundhog Basin. At least one occurrence is on a small nunatak on the glacier, and there is a deep hole in the upper basin of the glacier that went through 621 feet of ice before it struck rock and cut a thin intercept of mineralization (see the Geologic Description for details) This area is essentially Map no. 105 of Still and others (2002) and the coordinates are at about its center.

Commodities:

Main: Ag, Cu, Pb, Sn, Zn

Other:

Ore minerals:

Gangue minerals:

Geologic description:

From about 1964 to 1981 when there was considerable exploration across a wide swatch from from Glacier Basin to Groundhog Basin, a succession of companies considered the potential of the ground under Nelson Glacier. Much if not all of the Glacier were first staked in 1964 and first optioned to Bunker Hill Mining Company. The claims were subsequently optioned to Humble Oil and Refining Company from 1968 to 1970 and they drilled two holes through the ice in the upper part of the glacier. El Paso optioned the claims from 1971 to 1973 and AMAX Exploration Inc. optioned the claims from 1976 to 1981. Still and others (2002) did some limited sampling on or adjacent to the glacier. In 2002. there were no active claims on the glacier.

The rocks west of and under the center of the Nelson Glacier and from Glacier Basin, through Marsha Peak, and along Groundhog Basin consists mainly of Tertiary biotite and hornblende schist and gneiss with local marble interbeds, an assemblage that has been metamorphosed from Mesozoic and/or Paleozoic sedimentary and volcanic protoliths (Gault and others, 1952; George and Wyckoff, 1973; Gehrels and Berg, 1992, Brew, 1997) . The metamorphic rocks are intruded by a small 16.3 Ma stock of tin granite just north of Groundhog Basin that probably is the source of numerous rhyolite dikes and sills that cut the metamorphic rocks around Nelson Glacier as well as the source for the mineralization in the Groundhog Basin area. West of Groundhog Basin, the metamorphic rocks are intruded by several large plutons of Cretaceous tonalite, quartz diorite, and granodiorite. At the east side of the Nelson Glacier, the rocks are dominated by a thick 70-90 Ma Tertiary tonalite sill that forms the west boundary of the Coast Range igneous-metamorphic complex that extends the length of southeastern Alaska. The Tertiary metamorphic rocks and rhyolite in particular probably underlie most of the Nelson Glacier.

Many of the other prospects and occurrences along the ridges between Glacier Basin and Groundhog Basin either border Nelson Glacier or may extend beneath it ; there has been considerable speculation about mineralization under Nelson Glacier and some effort to locate it. Humble drilled two 1,700-foot, vertical holes through the ice (Humble Oil and Refining Company, 1970a and 1970b). One (H1), about 0.6 mile north-northeast of Marsha Peak, went through 491 feet of ice into gneiss but did not intersect

mineralization. The other (H2), went through 621 feet of ice into gneiss; the best intercept in it was 10 feet that averaged 0.5 ounce of silver per ton, 0.4 percent lead, and 1.7 percent zinc. El Paso National Gas (Quigley, 1973) flew an aerial magnetometer survey over the area and traced several faults zones under the glacier. Still and others (2002) found float at several areas on the glacier, most notably on a nunatak about 1.1 mile east-southeast of Marsha Peak. Samples contained up to 8.43 ounces of silver per ton, 1.5 percent copper, 8.21 percent lead, 25.95 percent zinc, and 904 parts per million tin.

Alteration:

Age of mineralization:

Probably related to a 16.9 Ma tin granite pluton near Groundhog Basin and the numerous rhyolite dikes and sills that intrude the metamorphic rocks in the area.

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-03-04

Site name(s): East Marsha Peak

Site type: Prospect

ARDF no.: PE112

Latitude: 56.491 **Quadrangle:** PE B-1

Longitude: 132.0315

Location description and accuracy:

The East Marsha Peak prospect is about 0.5 mile northeast of Marsha Peak near the edge of the Nelson Glacier. It about 0.3 mile south of the center of section 17, T. 62 S., R. 86 E. The location is accurate. A map of the prospect is Figure 30 of Still and others (2002).

Commodities:

Main: Ag, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Fluorite, quartz

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to Tertiary or Cretaceous schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). On the north side of Groundhog Basin, about 2 miles northwest of this prospect, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton about 1,000 by 2,0000 feet in size. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

The East Marsh Peak prospect was mapped and sampled by El Paso Natural Gas Company in the early 1970s; they dug three, 20- to 60-foot, samples on the property. Several other companies have looked at the property and Still and others (2002) mapped and sampled the prospect as part of a regional mineral assessment for the BLM.

The mineralization here is similar in origin to that at the he well known mineralization at the Groundhog Basin deposit (PE040) to the north and the numerous other base-metal prospect sin the area. The East Marsha Peak prospect is associated with a fault zone that strikes about N 25 E and crosscuts the northwest-trending layering in the gneiss and the rhyolite sills in the gneiss The shear zone is 30 to 40 feet wide and extends for about 2,000 feet. The hanging wall is highly silicified with vugs of quartz and fluorite. Sphalerite, galena, chalcopyrite, and pyrrhotite occur in masses and disseminations in brecciated gneiss along the shear zone and in gouge. The ore minerals also occur in a network of fractures that extend out into the gneiss wallrock for up to 40 feet. El Paso Natural Gas Company (George and Wyckoff, 1973) and Still and others (2002) collected numerous samples in the trenches and in surface outcrops. In one trench at an elevation of about 4,075 feet, El Paso sampled a zone up up 30 feet thick that averaged 3.19 percent zinc, 1.67 percent lead, and 1.99 ounces of silver per ton. Their trench at an elevation of about 4,100 feet exposed a zone 13 feet thick that averaged 1.45 percent zinc, 2.75 percent lead, and 1.23 ounce of silver per ton; an additional 18 feet across the mineralization averaged 1.79 percent zinc with little lead and silver. Other samples gave similar values.

Alteration:

Silicification along a sheared zone.

Age of mineralization:

Probably 16.3 Ma based on a genetic tie to a nearby, zinnwaldite 'tin' granite (Newberry and Brew, 1989).

Generic deposit model:

Deposit model:

Banded Ag-Cu-Sn-Pb-Zn tabular replacement bodies, veins, and stringers.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

The East Marsh Peak prospect was mapped and sampled by El Paso Natural Gas Company in the early 1970s. They dug 3, 20 to 60 foot, samples on the property. Several other companies have looked at the property and Still and others (2002) mapped and sampled the prospect as part of a regional mineral assessment for the BLM.

Latitude: 56.424 **Quadrangle:** PE B-3

Longitude: 132.9841

Location description and accuracy:

The occurrence is in fill on Forest Service Road 52009. It is about 0.8 mile southwest of Zarembo Springs at the head of St. Johns Harbor and about 0.2 mile northeast of the center of section 7, T. 63 S., R. 80 E.

Commodities:

Main: As, Au, F

Other:

Ore minerals: Fluorite

Gangue minerals:

Geologic description:

Still and others (2002) found road fill on a logging road southwest of St. Johns Harbor that contained vuggy quartz, purple fluorite, and (unidentified) sulfides. A grab sample of the more sulfide-rich quartz and fluorite in the road fill contained 546 parts per billion gold and 826 parts per million arsenic. They could not locate the source of the fill; it may have come from a fluorite occurrence about 10 miles to the south (PE060) but they felt the source was nearby and it seems unlikely that anyone would truck fill in from the occurrence to the south when there are so many borrow pits nearby. They did not discuss the petrology of the road fill. As mapped by Karl and others (1999), the rocks in the immediate area are sedimentary and volcanic rocks of the Triassic Hyd Group . But there are large areas of Quaternary and Tertiary rhyolite just to the south and there is a borrow pit about a half mile to the west that may be in this rhyolite.

Alteration:

Age of mineralization:

Probably Tertiary based on the age of rhyolite of that age nearby.

Primary Reference:

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Unnamed (on Shrubby Island)

Site type: Occurrence

ARDF no.: PE116

Latitude: 56.2385 **Quadrangle:** PE A-3

Longitude: 132.986

Location description and accuracy:

This occurrence is in a borrow pit about 0.8 mile east-southeast of the northwest tip of Shrubby Island; the pit is shown on the 1:63,360-scale topographic map. It is in the NE1/4, section 14, T. 65 S., R. 80 E.

Commodities:

Main: Pb, Zn

Other: Ag, Au

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Calcite

Geologic description:

Still and others (2002) visited the borrow pits on Shubby Island and examined the road cuts on the logging roads of the island to try to discover the source of the strongly anomalous stream sediment samples that were reported earlier by the U.S. Geological Survey. They discovered mineralization in a borrow pit on the northwest end of the island. The mineralization consists of pods of sulfides in blocky, dark gray to white limestone of the Heceta Limestone (Karl and others, 1999). The pods are up to 2 feet long, 1 foot thick, and are mainly of fine grained pyrite with sphalerite and minor galena. The sulfides also occur in a network of thin veinlets that cut the limestone in an area about 10 feet in diameter. A 0.5-foot sample across one of the pods contained 8.1 percent zinc, and 3,646 parts per million (ppm) lead. A sample across 2.1 feet of the sulfide veinlets in the limestone contained 1.3 percent zinc and 476 ppm lead. The highest gold value in the samples Still and others (2002) collected was 19 parts per billion; the highest silver value was 2.6 ppm.

Alteration:

Age of mineralization:

Silurian or younger based on the age of the Heceta Limestone that hosts the mineralization.

Generic deposit model:

Deposit model:

Pb-Zn sulfide pods in limestone.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only sampling by government engineers and geologists.

Production notes:

None.

Reserves:

None.

Reporter(s): D. J. Grybeck (Port Ludlow, WA)

Last report date: 2007-04-08

Site name(s): Unnamed (at head of Mosman Inlet)

Site type:

ARDF no.: PE117

Latitude: 56.1453

Quadrangle: PE A-2

Longitude: 132.5823

Location description and accuracy:

This occurrence is at the head of Mosman Inlet about 0.5 mile southeast of triangulation station 'Moss. It is near the center of section 16, T. 66 S., R. 83 E.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, magnetite, pyrite, sphalerite

Gangue minerals: Calcite, garnet

Geologic description:

This occurrence was first reported by Pittman (1962) as a 3-feet-wide calcite vein exposed for about 10 feet on the beach and below the high-tide line. The vein has abundant garnet, chalcopyrite, pyrite, and light colored sphalerite. A sample across the vein contained 9.5 percent zinc, 0.13 percent copper, 0.41 ounce of silver per ton, and traces of gold and lead. Still and others (2002) examined the area but did not find Pittman's vein. They did find a zone of tactite with calcite, garnet, magnetite, calc-silicate minerals, and chalcopyrite. The tactite is 0.1 to 0.7 foot thick and 3 feet long in a cliff near tidewater. Samples across the tactite contained up to 1,482 parts per billion gold, 35.4 parts per million (ppm) silver, 3,635 ppm copper, and 585 ppm zinc. The area is at or near the contact of Tertiary granite with Triassic and Cretaceous greenstone and Mesozoic or Paleozoic metasedimentary and metavolcanic rocks (Karl and others, 1999).

Alteration:

Occurrence at least in part is a contact metamorphic assemblage with sulfides.

Age of mineralization:

Generic deposit model:

Deposit model:

A calcite vein and/or tactite with silver, gold copper, and zinc minerals.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Apparently only sampling by government engineers and geologists.

Production notes:

None.

Reserves:

None.

Last report date: 2007-04-08

Site name(s): North Silver North

Site type: Prospect

ARDF no.: PE118

Latitude: 56.5239 **Quadrangle:** PE C-1

Longitude: 132.0436

Location description and accuracy:

The North Silver North prospect is about 0.6 mile west of Mount Waters and about 0.4 mile east of the center of section 6, T. 62 S., R. 85 E. The workings are in an area about 400 feet wide and 1,000 feet in length; the location is at about the center of the main exposures of the mineralization. The location is accurate and a map of the workings is Figure 27 of Still and others (2002).

Commodities:

Main: Ag, Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the prospect area are part of a belt of Mesozoic or Paleozoic sedimentary and volcanic rocks that have been metamorphosed to schist and gneiss. The belt is about 1 1/2 mile wide and strikes northwest (Brew, 1997; George and Wyckoff, 1973). The metamorphic rocks are bounded on the east by a thick, regionally extensive, 60 to 70 Ma tonalite sill and on the west by a 90 Ma granodiorite pluton (Brew, 1997 Still and others, 2002). The metamorphic rocks at the prospect include several prominent thin marble layers and a quartzite layer. On the north side of Groundhog Basin about two miles to the southwest, the metamorphic rocks are intruded by a 16.3 Ma biotite 'tin' granite pluton. The granite is probably the source of the numerous rhyolite dikes and sills that extend from it and the mineralization in the area (Newberry and Brew, 1989).

In the late 1950s, Moneta Porcupine Company staked claims in the area but subsequently dropped them William Huff and James Fucas continued work in the area and Huff discovered the North Silver North prospect in 1963. Their claims were optioned by the Bunker Hill Mining Company in 1965 and they drilled 7 holes, 85 to 224 feet deep, and blasted several pits. Bunker Hill dropped the claims at the end of the field season and the property was optioned by a succession of companies, Humble Oil and Refining Company, El Paso Natural Gas Company and AMAX Exploration Inc., through 1981. Still and others (2002) sampled the prospect during a Bureau of Land Management mineral assessment of the area.

The North Silver North prospect is associated with crosscutting, northeast trending, steeply dipping fault zones that are associated with irregular sulfide-bearing veins and lenses of quartz with sulfides. The quartz veins and lenses make up less than 10 percent of the faults (Still and others, 2002). To the east, the veins extend into limestone beds up to 30 feet thick that contain replacement deposits.

The two most prominent veins are along the Bear and Camp faults which approach to within 80 feet of each other (Still and others, 2002). The Black Bear vein can be traced for about 1,000 feet and consists of scattered lenses of quartz with pyrite, sphalerite, and galena. The best mineralization exposed on the surface of the Black Bear vein was about 4 feet thick and a sample contained 39.1 parts per million (ppm) silver, 3.3 percent lead, and 2.39 percent zinc. A 1-foot sample collected nearby contained 92 ppm silver, 9.9 percent lead, and 4.1 percent zinc. Several drill holes on the vein cut mineralization with lesser values at depth. The Camp vein is about 0.2 to 4 feet thick and can be traced for about 350 feet. It consists of

scattered quartz lenses with pyrite, sphalerite, and galena. The best mineralization exposed at the surface is about 0.4 feet thick and a sample across it contained 119.32 ppm silver. 48.61 percent lead, and 3.6 percent zinc. Two marble beds 4 to 50 feet thick can be traced for several thousand feet. Irregular bands and lenses of disseminated to massive pyrite, sphalerite, and galena are scattered along the marble for about 600 feet. The individual bands and lenses are 0.5 to 9 feet thick and extend from 3 to 100 feet. The best mineralization was a 6-foot-thick layer that contained 58 ppm silver, 5,114 ppm lead, and 12,758 ppm zinc.

Alteration:

None specifically noted.

Age of mineralization:

Probably related to a nearby 16.3 Ma biotite granite pluton.

Generic deposit model:

Deposit model:

Scattered Ag-Pb-Zn quartz veins and lenses along fault zones and Ag-Pb-Zn replacement deposits in marble.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

In the late 1950s, Moneta Porcupine Company staked claims in the area but subsequently dropped them. William Huff and James Fucas continued work in the area and Huff discovered the North Silver North prospect in 1963. Their claims were optioned by the Bunker Hill Mining Company in 1965 and they drilled 7 holes, 85 to 224 feet deep, and blasted several pits. Bunker Hill dropped the claims at the end of the field season and the property was optioned by a succession of companies through 1981: Humble Oil and Refining Company, El Paso Natural Gas Company, and AMAX Exploration Inc. Still and others (2002) sampled the prospect during a Bureau of Land Management mineral assessment of the area.

Production notes:

None.

Reserves:

None.

Site name(s): Blue Quartz

Site type: Prospect

ARDF no.: PE119

Latitude: 56.5366 **Quadrangle:** PE C-4

Longitude: 133.054

Location description and accuracy:

The Blue Quartz prospect extends for about 500 yards a short distance inland from the shoreline of Woewodski Island, from opposite the southeast end of Butterworth Island to about the middle of the east side of Krauses Hole. It is near the east boundary of the SE1/4, section 34, T. 61 S., R. 79 E. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

This prospect was discovered about 2004 and was extensively explored in 2006 and 2007 by Bravo Venture Group (2007, 2008). Quartz veins with a distinctive bluish color occurs in widely spaced, east-northeast-trending, sub-parallel zones up to 10 meters wide that extend for at least 500 meters. The veins cut Triassic metamorphic rocks and a Cretaceous diorite stock. The mineralization was hand trenched and sampled in 2006. One grab sample contained 542 grams of gold per tonne and several grab or float samples contained more than 3.0 grams of gold per ton. A channel sample contained 3.0 grams of gold per tonne across 2.0 meters. In 2007, 33 short core holes were drilled that totaled 2,541 meters. Blue quartz veins were intersected in many of these holes; the best intervals were 1.13 meters with a grade of 4.0 grams of gold per tonne and 0.73 meters with a grade of 7.2 grams of gold per tonne.

As mapped by Karl and others (1999), the rocks in the area are part of the Triassic Hyd Group, which consists of greenstone, pillow breccia, and volcanic breccia, with tuff, limestone, chert, conglomerate, sandstone, and argillite, that have been intruded by a Cretaceous diorite stock.

Alteration:

Age of mineralization:

Cretaceous or younger based on the age of the diorite that the veins cut.

Generic deposit model:

Deposit model:

Gold-quartz vein (no sulfide).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Site name(s): Red Quartz

Site type: Prospect

ARDF no.: PE120

Latitude: 56.5263 **Quadrangle:** PE C-4

Longitude: 133.0174

Location description and accuracy:

The Red Quartz prospect is centered about 1.3 mile northwest of the south tip of Woewodski Island at an elevation of about 500 feet. It is about 0.2 mile northwest of the center of section 1, T. 62 S., R. 29 E. The location is accurate.

Commodities:

Main: Ag, As, Au, Sb

Other:

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The Red Quartz prospect was discovered in 2005 and was explored in 2006 by Bravo Ventures Group (2207). Distinctly reddish quartz veins occur in float, rubble, and outcrop for about 300 meters in heavy vegetation. Thirteen of the 30 samples that were collected contain more than 1 gram of gold per ton; the best contained 3.8 grams of gold per ton. Eight of the 30 contained 7.8 to 91.3 grams of silver per ton with notable arsenic and antimony values. The mineralization is distinctly different from the massive sulfide mineralization in Brushy Creek just to the south (PE033) and suggests epithermal gold-silver mineralization of a type that has not previously been found on Woewodski Island.

As mapped by Karl and others (1999), the rocks in the area are part of the Triassic Hyd Group which consists of greenstone, pillow breccia, and volcanic breccia, with tuff, limestone, chert, conglomerate, sandstone, and argillite. A Cretaceous diorite stock is nearby.

Alteration:

None specifically mentioned.

Age of mineralization:

Triassic or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Silver-gold quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Numerous samples of float and rubble and from outcrop were collected in 2006.

Production notes:

None.

Reserves:

None.

Site name(s): Raven Zone

Site type: Prospect

ARDF no.: PE121

Latitude: 54.9463 **Quadrangle:** PE D-5

Longitude: 131.4321

Location description and accuracy:

The Raven Zone prospect is on northwest Duke Island about 1.5 mile south-southwest of Form Point and about 2.7 miles east-northeast of Point White. It is in the center of section 8, T. 80 S., R. 93 E. at an elevation of about 450 feet. The location is accurate.

Commodities:

Main: Co, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, pentlandite, platinum-group minerals, pyrrhotite

Gangue minerals:

Geologic description:

The Raven Zone prospect is on northwestern Duke Island, well known as the type locality of the Alaska-type, Cretaceous zoned ultramafic complex (Irvine, 1974). The ultramafic complex is concentrically zoned outward from a core of dunite and peridotite, succeeded by shells of olivine pyroxenite and hornblende pyroxenite. The complex is distinguished by locally conspicuous graded layering and other cumulate features, especially in the dunite, peridotite, and olivine pyroxenite. It has long been known (Berg and Cobb, 1967) that the dunite contains small lenses and disseminated chromite; the hornblende pyroxenite contains segregations of titaniferous magnetite that have been drilled; and rare specks of pyrrhotite, pyrite, pentlandite, and chalcopyrite occur widely (PR001). However, until recently no deposit of substantial size had been identified on Duke Island.

In 2001 and 2005, Quaterra Resources (2008a) drilled 11 holes totaling 5,971 feet in two area: 8 holes in the the Maquis Zone (PR New C110) and 3 in the Raven Zone, on mineralization they consider unlike anything that had previously been identified on Duke Island. They interpret the mineralization as possibly related to a layered mafic complex.

The Raven Zone is in a plug of gabbro and pyroxenite about a half mile in diameter surrounded by quartz diorite, granodiorite , and quartz monzonite (Quaterra Resources Inc., 2008b). The best intercept in the three holes drilled in 2005 was 387 feet that contained 2,035 parts per million ppm copper, 56 parts per billion (ppb) platinum, and 59 ppb palladium. The mineralization consists of disseminated and net-textured chalcopyrite and pyrrhotite in coarse-grained pyroxenite. The ore textures suggest sulfide-silicate immiscibility during sulfide deposition.

No drilling was done in 2007. However, the data were reviewed and several other areas of interest were identified. In February, 2008, Quaterra had a 388-line-mile airborne geophysical survey flown over the area. Quaterra's work suggest that the mineralization extends for 14.5 kilometers along strike and is 3.8 kilometers wide.

Alteration:

Age of mineralization:

The Duke Island complex is about 110 Ma; this mineralization is probably genetically related to it.

Generic deposit model:

Deposit model:

Disseminated copper and platinum-group elements in a layered mafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 2005, Quaterra Resources Ltd., drilled 3 holes on the Raven Zone. No drilling was done in 2007. However, the data was reviewed and several others areas of interest were identified. In February, 2008, Quaterra had a 388-line-mile airborne geophysical survey flown over the area.

Production notes:

None.

Reserves:

None.

Last report date: 2008-06-05

Site name(s): Unnamed (on Stikine River)

Site type: Mines(?)

ARDF no.: PE122

Latitude: 56.7051 **Quadrangle:** PE C-1

Longitude: 132.1682

Location description and accuracy:

Fine placer gold was mined on bars of the Stikine River in the 1860's but it is unclear if any gold was produced along the Alaskan portion of the Stikine and if so, there are several opinions where in Alaska that might have taken place. Roppel (2005) concluded that most if not all of this early mining on the Stikine took place across the border in Canada. The only reference she could find to gold mining along the Alaskan portion of the Stikine River in the 1860's was to passing interest in fine flour gold near the mouth of what is now called 'Dry Wash' below the Popof Glacier. ('Dry Wash' is identified on the USGS 1:250,000-scale topographic map but not on the more detailed 1:63,360-scale topographic map.) Roppel's location in about the middle of the north side of section 3, T. 60 S., R.85 E. is considered the most likely site of this early mining in Alaska, even if it is uncertain. (But see the Geologic Description for addition information.)

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Fine placer gold was found on bars of the Stikine River in the 1860s when Russia still owned Alaska. However, the boundary between Russian America and Canada was not delineated then and the location of this placer mining is uncertain (Blake, 1868; Spurr, 1898). Still and others (2002) conclude that this early placer mining was at 'Buck Bar' and place it between Shakes Slough and the mouth of the Ketili River in about the middle of section 31, T. 59 S., R.85 E. Roppel (2005), however, in her considerable research into early gold mining in southeastern Alaska found little evidence that Bucks Bar and the other auriferous bars being mining on the Stikine River or its tributaries were in Alaska but instead were probably across the border in Canada. The only reference she could find to gold mining on the Alaskan portion of Stikine River in the 1860s was to passing interest in fine flour gold near the mouth of what is now called 'Dry Wash' below the Popof Glacier. ('Dry Wash' is labeled on the USGS 1:250,000-scale topographic map but not on the more detailed 1:63,360-scale topographic map.) Roppel's location is used here. In any event, the amount of gold that was mined along the Stikine in Alaska was probably small at best. Brooks (1923) noted that this may have been the first gold mined in Alaska.

Alteration:

Age of mineralization:

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer gold (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Fine placer gold was found on bars of the Stikine River in the 1860s during early exploration for gold; some of it may have been mined in Alaska, although most was probably mined in Canada.

Production notes:

Probably trivial.

Reserves:

None.

Additional comments:

In view of the many generations of prospectors and others who for more than 140 years have passed along the natural corridor of the Stikine River into the interior of Canada without any further mention of placer gold on the Stikine River in Alaska, this site should now be considered to be little more than a historic point of interest.

Primary Reference: Roppel, 2005

Reporter(s): D.J. Grybeck (Port Ludlow, WA)

Last report date: 2008-03-04

Site name(s): Pyramid

Site type: Prospect

ARDF no.: PM023

Latitude: 55.6298 **Quadrangle:** PM C-3

Longitude: 160.6753

Location description and accuracy:

The Pyramid prospect is on the south flank of Pyramid Mountain, about 3.3 miles northwest of the mouth of Bishop Creek near the head of Albatross Anchorage. It is centered about 0.3 mile southeast of the center of section 35, T. 53 S., R. 75 W., of the Seward Meridian. The location is accurate to within 1000 feet.

Commodities:

Main: Cu, Mo

Other: Ag, Au, Pb, Sb, Zn

Ore minerals: Chalcocite, chalcopyrite, covellite, molybdenite, pyrite

Gangue minerals: Quartz

Geologic description:

The Pyramid copper-molybdenum deposit is associated with a quartz diorite pluton that cuts Paleocene to Eocene sedimentary rock of the Tolstoy Formation (Wilson and others, 1995). The stock has been dated at 6 million years (Wilson and others, 1996). The molybdenum mineralization has also been dated at 6 million years by Re-Os methods (Wilkins, 2011).

The prospect is a classic copper-molybdenum deposit having a potassic core surrounded by a phyllic zone and an outer propylitic zone. The central potassic core contains secondary biotite after mafic minerals and 2 to 10 percent magnetite as fracture fillings and disseminated clots and grains. The potassic alteration core in the intrusive, is roughly 800 by 1,700 feet in plan. It is essentially barren with less than 0.25 percent sulfides and copper and molybdenum in the 0.001 to 0.01 percent range (Christie, 1975). The phyllic zone is characterized by sericite, quartz, and andalusite in a zone surrounding the potassic core. It occurs mostly in the intrusive rocks and measures 700 to 2,500 feet in width. The propylitic zone is characterized by chlorite, magnetite, epidote, and calcite.

The highest total sulfide content, 5 to 10 percent, occurs in the inner part of the propylitic zone and outer part of the quartz-sericite zone. Pyrite:chalcopyrite ratios are 50:1 or greater and are associated with copper grades of 0.15 percent or less (Christie, 1975). Toward the inner part of the phyllic zone, pyrite-chalcopyrite ratios decrease and copper grades increase to 0.3 to 0.4 percent; molybdenum grades are 0.03 to 0.04 percent. In the copper-rich part of the system, the sulfides occur as disseminations and thin fracture fillings.

The deposit has been oxidized to depths of 0 to 450 feet and exhibits a supergene blanket of secondary copper enrichment as much as 300 feet thick. The enriched zone contains chalcocite, covellite, and bornite, as well as some chalcopyrite. The best grades of copper, as much as 0.8 percent, occur in the upper 100 feet of the supergene blanket. The thickest enrichment zones are not necessarily associated with the thickest zones of oxidation. Lead, antimony, and zinc are also reported in some assays. The supergene blanket is overlain by a leached capping up to 100 meters thick.

A Quintana-Duval-Aleut joint venture mapped, sampled, and drilled this deposit in 1974 and 1975. They diamond-drilled 19 holes for a total of 5,565 feet. As a result of this work they outlined an estimated resource of 126,000,000 tons of with a grade of 0.403 percent copper and 0.025 percent molybdenum, with potential for another 49 million tons of chalcocite-enriched ore (Christie, 1975).

Pyramid was drilled By Battle Mountain in the late 1980s and they identified gold values that improved

the economics of the deposit. Metallica Resources did additional surface sampling in 2005 and 2006 that reinforced the added gold value of Pyramid.

Full Metal Minerals in a joint venture with Antotagasta Minerals S.A. drilled 5 core holes at Pyramid in 2010 to test the lateral and vertical extent of the mineralization (Full Metal Minerals, 2010 and 2011). The mineralization and alteration persisted to the bottom of these holes. Some notable intercepts were: 1) 468 meters that contained 0.272 percent copper, 0.058 gram of gold per tonne, and 0.019 percent molybdenum; 2) 356 meters that contained 0.343 percent copper, 0.078 gram of gold per tonne, and 0.008 percent molybdenum; 3) 289 meters that contained 0.299 percent copper, 0.082 gram of gold per ton, and 0.032 percent molybdenum; and 4) 195 meters that contained 0.63 percent copper, 0.141 gram of gold per tonne, and 0.018 percent molybdenum.

In 2011, the joint venture of Full Metal Minerals of Antofagasta Minerals drilled 12 more core holes that totaled 2,576 meters with results that expanded the mineralization (Wilkins, 2011; Full Metal Minerals, 2012). Including these holes, the mineralization covers an area about 1,100 meters by 900 meters in size and is open in all directions and at depth. The best intercept in the 2011 drilling was 155.9 meters with 0.709 percent copper, 0.024 percent molybdenum, and 0.18 gram of gold per tonne. Most of the drilling through 2011 has been relatively shallow to identify the zone of supergene enrichment and most of the holes have bottomed in mineralized rock.

Alteration:

The alteration consists of a barren, potassically-altered core zone, an intermediate zone characterized by pervasive quartz and sericite, and a propylitic outer zone (Christie, 1975).

Age of mineralization:

The stock that hosts the mineralization has been dated at 6 Ma by K/Ar methods; molybdenite has also been dated at 6 Ma by Re-Os methods (Wilkins, 2011).

Generic deposit model:

Deposit model:

Porphyry Cu, Porphyry Cu-Mo-Au (Cox and Singer, 1986; models 17, 21a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17, 21a

Production Status: None

Site Status: Active

Workings/exploration:

In 1975-1975, Quintana-Duval mapped, sampled, and diamond-drilled 19 holes totaling 5,565 feet. The U.S. Geological Survey sampled the deposit in the 1980s. Battle Mountain drilled in the 1980s and Metallica Resources collected surface samples in 2005 and 2006. In 2010, Full Metal Minerals in a joint venture with Antotagasta Minerals S.A. drilled 5 core holes at Pyramid to test the lateral and vertical extent of the mineralization. They drilled 12 more holes in 2011 that totaled 2,576 meters.

In 2012, Full Metal Minerals (FMM) drilled 13 diamond core holes with a total drilled depth of 3,241 meters (Farrow and Arseneau, 2013).

Production notes:

None.

Reserves:

In 2013, a 43-101 Technical report, including mineral resource estimate, was published (Full Metal Minerals, 2014). These are: an inferred resource of 94,000,000 tonnes with a grade of 0.092 gram of gold per tonne, 823,000,000 pounds with a grade of 0.40 percent copper, and 40,000,000 pounds with a grade of

0.02 percent molybdenum in the supergene part of deposit, plus an inferred resource of 79,000,000 tonnes with a grade of 0.083 gram of gold per tonne, 515,000,000 pounds with a grade of 0.30 percent copper, and 34,000,000 pounds with a grade of 0.02 percent molybdenum in the hypogene part of the deposit, for a total inferred resource of 173,000,000 tonnes with a grade of 0.088 gram of gold per tonne, 1,338,000,000 pounds with a grade of 0.088 percent copper, and 74,000,000 pounds with a grade of 0.02 percent molybdenum (Farrow and Arseneau, 2013). (Conversion Note: 10,000 pounds = 4.54 tonnes)

Additional comments:

The subsurface of the property is controlled by the Aleut Corporation; the surface is controlled by the Shumigan and the TDX (St Paul) native corporations.

Site name(s): Zachary Bay; Unga

Site type: Prospect

ARDF no.: PM054

Latitude: 55.2729 **Quadrangle:** PM B-2

Longitude: 160.6628

Location description and accuracy:

The Zachary Bay is prospect is is about 2.0 miles south of the south end of Zachary Bay and about 4.9 miles northwest of the seaplane anchorage at Squaw Harbor on Baralof Bay. It is near the center of section 3, T. 57 S., R. 74 W. The location is probably accurate to within a half mile.

Commodities:

Main: Ag, Pb, Zn

Other: Cu

Ore minerals: Chalcopyrite, galena, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks around the Zachary Bay prospect are part of the Eocene to Oligocene, Popof volcanic unit (Wilson and others, 1995). The deposit is in the northeast section of the Aquila-Shumagin fault system, which strikes northeast across Unga Island.

Rock-chip samples taken at the surface in 1974 across 46 meters averaged 0.36 percent copper and 0.550 gram of gold per tonne (Redstar Gold Corp., 2012, January 18]; 2012 [March 20]) . Four holes less than 20 meters deep drilled in 1975 by Quintana Minerals Corp. and Duval Corp. cut disseminated copper-gold mineralization in intrusive rocks. The deepest hole, 17 meters deep, was mineralized over its entire length; 10.7 meters averaged 0.11 percent copper and 0.280 gram of gold per tonne.

The core was reanalyzed and reexamined by Resource Associates of Alaska in 1981. They also located a 50-foot-wide zone of brecciated, silicified, pyritic andesite that may be a breccia pipe (Trujillo and others, 1981). The breccia fragments are filled in by a matrix of chalcopyrite, sphalerite, and galena over a 35-foot width of the zone. One sample of mineralized rock assayed 1.09 ounces of silver per ton, 2.07 percent zinc, and 0.58 percent lead.

In 2011, Redstar Gold Corp. (2012, January 18]; 2012 [March 20]) began work in the area in a joint venture with Full Metal Minerals Inc. on land they were purchasing and land leased from the Aleut Native Corporation. They proposed that the deposit is a classic porphyry copper-gold deposit with abundant disseminated hydrothermal biotite, magnetite and chalcopyrite in a quartz-diorite porphyry with pink potassium feldspar phenocrysts.

Alteration:

The mineralization is accompanied by strong silicification and hydrothermal biotite.

Age of mineralization:

Eocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Copper-gold porphyry (Cox and Singer, 1986, model 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

Surface rock-chip samples were taken in 1974 and four holes less than 20 meters deep were drilled in 1975 by Quintana Minerals Corp. and Duval Corp. The core was reanalyzed and reexamined by Resource Associates of Alaska in 1981 and they sampled the surface. In 2011, Redstar Gold Corp. (2012, January 18]; 2012 [March 20]) began work in the area in a joint venture with Full Metal Minerals Inc.

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.’s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II’s drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). A total of 1,505 meters were drilled in 7 holes spaced over ~750 meters of strike length. All drill holes intersected the target structure, which includes multi-generational phreatomagmatic breccias, hydrothermal breccias, and late breccias and veins with colloform-crustiform- to cockade-textured quartz-adularia-carbonate (± rhodochrosite, ± green clay). Select intervals from drill holes 16SH019 and 16SH020 include 0.9 meter at 14.95 grams of gold per tonne and 1.15 meters at 11.3 grams of gold per tonne; release of full assay results is planned for late January 2017 (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Additional comments:

The land belongs to the Aleut Native Corporation; in early 2012, the property was being explored under lease by a joint venture of Redstar Gold Corp. and Full Metals Inc.

Site name(s): Shumagin; Choumagin; Unga

Site type: Prospect

ARDF no.: PM064

Latitude: 55.2253 **Quadrangle:** PM A-2

Longitude: 160.5737

Location description and accuracy:

The Shumagin prospect is a southwest-trending mineralized zone approximately 1.4 miles southwest of the seaplane anchorage at Squaw Harbor on Baralof Bay. It is about 0.4 mile southeast of the center of section 19, T. 57 S., R. 74 W. of the Seward Meridian. The location is near the northeast end of drilling that has been completed along the strike of mineralization and is accurate to within 500 feet.

Commodities:

Main: Ag, Au

Other: As, Cu, Hg, Pb, Te, Zn

Ore minerals: Arsenopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The host rock of the Shumagin deposit is Eocene to Oligocene (Popof) volcanic rocks (Wilson and others, 1995). The deposit is in the northeast section of the Aquila-Shumagin fault system, which strikes southwest across Unga Island.

The deposit consists of auriferous, sulfide-bearing quartz-calcite veins in a fault that trends N 60 E and dips 80 to 85 SE. The veins and fault can be traced approximately 4,000 feet along strike over a vertical distance of 765 feet. The mineralization is interpreted as a fault-controlled epithermal, volcanic-hosted vein deposit (White and Queen, 1989). The hanging wall is tuff and the footwall is andesite. Movement on the fault is probably high-angle reverse.

The deposit consists of four veins, two vein systems, and two fault breccias. Within the fault, the mapped units from oldest to youngest are pyrite-rich cataclastic, clast-supported fault breccia, the Union vein, and matrix-supported quartz breccia (White and Queen, 1989). The total thickness of these units averages about 40 feet. Veins that are peripheral to or cut the main vein-fault system include the Lucky Friday and Greenbaum veins, the Vuggy Watercourse vein, and several carbonate veins. Gold is most abundant in the Union vein, which generally is considered to be the principal gold deposit.

The Union vein is a composite vein consisting of a 10-foot-wide zone of closely-spaced quartz veins in the hanging wall tuff. Individual veins are sinuous, vuggy, and generally less than 30 inches wide. Native gold occurs, with finely crystalline arsenopyrite, pyrite, galena, and sphalerite. Precious-metal grades range from a trace in wide zones to more than 10 ounces of gold and 150 ounces of silver per ton in narrow zones. There is a strong correlation between gold, silver, and tellurium, indicating that some of the precious metals probably occur as tellurides (White and Queen, 1989). Singer (1999) suggests that this is a Sado-type gold deposit.

In 2014 after a detailed review of the existing drill core, Redstar Gold Corp. (Redstar) observed evidence of a phreatomagmatic (hydrothermal-magmatic) breccia system interpreted to be intimately associated with a nearby dacitic, hypabyssal dome mapped along Bloomer Ridge to the southeast. The phreatomagmatic breccia phases are interpreted to be pre- to syn-mineralization. A protracted multi-phase, anastomosing and bifurcating, precious metal-bearing quartz ± carbonate (rhodochrosite) + adularia hydrothermal system is part of, and is superimposed upon the breccia phases. The hydrothermal system either intensely replaced

and/or re-brecciated the phreatomagmatic breccias evident by open space veins, vein breccias and stockwork zones exhibiting crustiform, cockade and banded textures. At depths of between 30 meters to 105 meters below sea level, the hydrothermal system (as well as the breccia bodies) widens and bifurcates exhibiting an increase in stockwork veining within the hanging wall to the breccia system. Above this level, the hydrothermal system narrows and has been telescoped up section along the footwall and along specific breccia phases (Redstar Gold Corp., 2014b).

Sulfide minerals when present occur as very fine-grained pyrite, sphalerite, galena, visible gold and blue-grey metallic sulfides locally within crustiform layers or in stockwork and crackle breccia systems. Pervasive phyllic alteration (quartz-sericite-pyrite), zones of variable silicification, quartz-adularia-carbonate stockworks and patchy disseminated pyrite occurs throughout the breccia and outbound into the hanging wall overprinting epiclastic sediments and dacite (Redstar Gold Corp., 2014b).

After drilling several holes in 2015, Redstar discovered an older, Ginguro-style (crustiform-colloform pyrite +/- marcasite) epithermal breccia vein system in the footwall below the younger Shumagin-style quartz veining. This new vein system is anomalous in gold and silver (1 to 4 grams per tonne gold) where Ginguro-sulfides are encountered (both veins and clasts) and exhibits contrasting epithermal geochemical signatures to Shumagin-style breccia veins with distinctly higher levels of arsenic, antimony, and mercury (Redstar Gold Corp., 2015a).

Alteration:

Strong argillic alteration is present as much as 148 feet from the Shumagin deposit. Quartz-sericite-pyrite alteration extends outward from Union vein and the matrix-supported quartz breccia (White and Queen, 1989). Zones of variable silicification, quartz-adularia-carbonate stockworks and patchy disseminated pyrite occurs throughout the breccia and outbound into the hanging wall overprinting epiclastic sediments and dacite (Redstar Gold Corp., 2014b).

Age of mineralization:

Eocene or younger, based on the age of the host rock (Wilson and others, 1995).

Generic deposit model:

Deposit model:

Sado-type epithermal gold vein (Cox and Singer, 1986; model 25d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25d

Production Status: None

Site Status: Active

Workings/exploration:

Atwood (1909) first described the prospect, whose workings at that time consisted of two tunnels 150 feet apart vertically. The lower one was 365 feet in length with a 75-foot crosscut. The upper tunnel was 79 feet in length with a 169-foot crosscut.

From 1983 to 1987, Alaska Apollo Gold Mines diamond drilled 23 holes totaling 9,269 feet, drilled 44 percussion holes, and cut 13 trenches through the vein and fault. At that time the deposit was estimated to contain 300,000 tons of ore grading 0.5 ounce of gold per ton. In 1989 Ballatar Exploration core-drilled approximately 6,000 feet.

In 1986 Battle Mountain Exploration Company mapped and sampled the deposit and relogged the core. The data indicated that an ore shoot approximately 400 feet long, 5 to 30 feet thick, plunging 45 degrees to the northeast in the plane of the fault (Ellis and Apel, 1990). A deep hole drilled by Alaska Apollo Gold Mines 600 feet down the dip of the vein intersected 27 feet of rock that averaged 0.46 ounce of gold per ton. The deposit was estimated by Battle Mountain to contain 352,000 tons of ore with an average grade of 0.299 ounce of gold per ton. In 1990 Battle Mountain Exploration Company drilled a 1,022-foot core hole

collared on Aleut Corporation land that was inclined to hit the deposit at depth. At a depth of 900 feet, the hole cut 18 feet of rock that averaged 0.47 ounce of gold per ton.

In 1987 during road building, a 500-foot-long, faulted eastern extension of the Shumagin vein was uncovered, mostly on Aleut Corporation land. Battle Mountain Exploration Company mapped and sampled this section of vein. It was found to be a large, weakly mineralized, south-dipping veined structure, locally as much as 50 feet thick. Samples contained up to 680 parts per billion (ppb) gold, 12.1 parts per million (ppm) silver, 234 ppm arsenic and 2,000 ppb mercury (Ellis and Apel, 1990).

In 2011, Redstar Gold Corp. (Redstar) (2012a; 2012b) began work in the area in a joint venture with Full Metal Minerals Inc. on land they were purchasing and on land leased from the Aleut Native Corporation. They drilled 10 holes and did extensive surface sampling. Some notable intercepts in the holes were: 1) 21 meters that averaged 4.02 grams of gold per tonne, this included a 1 meter interval with 43.90 grams of gold per tonne; and 2) 30 meters that averaged 14.98 grams of gold per tonne, this included 0.55 meter with 738 grams of gold per tonne.

In 2014 Redstar completed a soil sample grid of approximately 750 m by 200 m at Shumagin to test the western extension of known surface and sub-surface mineralization along inferred structures, as documented by historic geological maps and trench data. Results from the survey showed a gold and silver geochemical soil signature that averaged 20 to 50 parts per billion (ppb) gold with up to 615 ppb gold and averaged over 0.5 grams per tonne (g/t) silver with up to 6.8 g/t silver over areas of historical trenching. This anomaly has been extended to the southwest by approximately 400 meters, where anomalous values occur along the southwestern flank of a low lying ridge that abuts against an active, north draining flood plain (Redstar Gold Corp., 2014a). Rock chip sampling collected from quartz vein breccias and stockwork found in surface outcrops produced results of up to 9.93 g/t gold and 74.4 g/t silver (Redstar Gold Corp., 2014b).

Redstar drilled eight holes along the Shumagin vein system in May 2015. The first four drill holes were infill holes across an area of historic drilling used in a non-43-101 compliant resource estimation. The last four drill holes target high-grade mineralization down plunge and along strike of the known Shumagin vein system. These drill holes revealed an older, Ginguro-sulfide textured epithermal breccia vein that was not destroyed by late-stage Shumagin-style vein breccias. Notable intercepts from this drilling were: 1) 1.9 meters that averaged 202 g/t gold and 82 g/t silver; 2) 6.35 meters that averaged 9.45 g/t gold and 103 g/t silver, including 3.0 meters with 16.95 g/t gold and 183 g/t silver; 3) 4 meters that averaged 11.62 g/t gold and 95.6 g/t silver, including 1.0 meter with 20.90 g/t gold and 232 g/t silver; and 4) 5 meters that averaged 9.35 g/t gold and 27.62 g/t silver, including 1.0 meter with 41.2 g/t gold and 130 g/t silver (Redstar Gold Corp., 2015a).

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.'s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II's drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). A total of 1,505 meters were drilled in 7 holes spaced over ~750 meters of strike length. All drill holes intersected the target structure, which includes multi-generational phreatomagmatic breccias, hydrothermal breccias, and late breccias and veins with colloform-crustiform- to cockade-textured quartz-adularia-carbonate (± rhodochrosite, ± green clay). Select intervals from drill holes 16SH019 and 16SH020 include 0.9 meter at 14.95 grams of gold per tonne and 1.15 meters at 11.3 grams of gold per tonne; release of full assay results is planned for late January 2017 (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

A resource of 300,000 tons grading 0.5 ounce of gold per ton was estimated from the exploration work done by Alaska Apollo Gold Mines in 1983 to 1987. In 1986, Battle Mountain Exploration Company

estimated that the deposit contained 352,000 tons of material that averages 0.299 ounce of gold per ton. Queen (1988) estimated a resource of 270,000 tons that averages 0.49 ounce of gold per ton and 1.97 ounces of silver per ton.

Additional comments:

The Shumagin prospect lies on state mining claims however the surrounding surface rights belong to the Unga Corporation and the subsurface rights belong to the Aleut Corporation (Redstar Gold Corp., 2015b).

Last report date: 2017-08-26

Site name(s): Orange Mountain; Unga

Site type: Prospect

ARDF no.: PM067

Latitude: 55.209 **Quadrangle:** PM A-2

Longitude: 160.621

Location description and accuracy:

This prospect is on southeastern Unga Island approximately 4,000 feet southwest of Red Mountain (Wilson and others, 1988, locality 29). The map site is at an elevation of 1,060 feet, at the top of a hill marked by a large color anomaly. Orange Mountain is informally named for the color anomaly; it is not named on the topographic map. The location is accurate.

Commodities:

Main: Ag, Au

Other:

Ore minerals: Gold, pyrite, tetrahedrite

Gangue minerals: Barite, quartz

Geologic description:

This prospect, marked by a 2.7-square-mile color anomaly, is the largest single area of alteration on Unga Island. It is in rocks mapped as the late Eocene to early Oligocene Popof volcanic rocks (Wilson and others, 1995). From 1979 to 1983, it was explored first by Resource Associates of Alaska and then by UNC Teton Exploration Drilling Company (Peterson and others, 1983).

The prospect consists of a gently-dipping, interbedded sequence of silica-replaced felsic tuffs and argillically altered andesite tuffs and flows. The alteration extends over a vertical range of at least 500 feet (Ellis and Apel, 1990). Numerous shears, faults, fracture zones, and breccias result in structural complexities (Peterson and others, 1983).

The silica-replaced tuffs contain 5 percent disseminated pyrite. They also contain veins, disseminations, and pods of barite, and veinlets and pods of quartz. In brecciated areas, the quartz and barite veins locally occur together, and some of the quartz is replaced by barite. The argillically altered andesite contains 25 percent pyrite as veinlets and disseminations. Tetrahedrite has also been reported.

There is a positive correlation between precious metal values and the silicified rock; the highest values are associated with shears and breccias. The highest precious metal values obtained from surface samples were 2.85 ppm gold and 26 ppm silver; their mean value was 0.045 ppm gold and 0.4 ppm silver (Peterson and others, 1983). Detectable and weakly anomalous gold values occur in drill holes in sections 100 or more feet thick (115 feet in OM-2 and 370 feet in OM-3). The highest subsurface precious metal values were 0.41 ppm gold and 3.4 ppm silver. Mean values of base metals were at 40 ppm copper, 20 ppm lead, 20 ppm zinc, and 50 ppm arsenic. The entire area is enriched in mercury, and values of as much as 107 ppm of mercury occur in silicified tuffs. The mean mercury value is 1.6 ppm. Thallium, tellurium, antimony, and bismuth were also detected.

In 1990 Battle Mountain Exploration Company mapped the site and collected approximately 117 rock chip samples. Their mapping indicated that the silicified rock forms a cap overlying argillically altered tuffs containing as much as 70 percent pyrite (Ellis and Apel, 1990). Gold values in quartz veins cutting the silicified tuffs ranged from 0.05 to 0.25 ppm.

Alteration:

The alteration consists of as pervasive argillization and pyritization of andesite tuffs and silicification of felsic tuffs.

Age of mineralization:

Eocene or younger.

Generic deposit model:

Deposit model:

Epithermal gold veins

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

During the period 1979 to 1983 Resource Associates of Alaska and UNC Teton Exploration Drilling Company conducted 8.5 miles of grid mapping, collected and analyzed 750 rock and soil samples, conducted 1.4 miles of VLF-EM survey, and drilled 3 core holes for a total of 2,453 feet. The highest metal values of surface samples were 2.85 ppm gold and 26 ppm silver. The mean values were 0.045 ppm gold and 0.4 ppm silver. The highest subsurface values were 0.41 ppm gold and 3.4 ppm silver.

In 1990 Battle Mountain Exploration mapped the site in detail and collected approximately 150 rock samples. A cluster of low-level gold anomalies was outlined at the top of Orange Mountain. Individual quartz veinlets assayed 0.05 to 0.25 ppm gold.

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.'s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II's drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). Site name(s): Sitka; Sitka Gold Mine; Unga

Site type: Mine

ARDF no.: PM076

Latitude: 55.194 **Quadrangle:** PM A-2

Longitude: 160.554

Location description and accuracy:

This mine is located on the southeast part of Unga Island approximately 2,600 feet northwest of the head of Delarof Harbor and 1,500 feet northeast of the Apollo mine (Berg and Cobb, 1967, locality 7; Cobb, 1972, locality 5; MacKevett and Holloway, 1977, locality 5; Nokleberg and others, 1987, locality AP4; Wilson and others, 1988, locality 4). The mine is near the north edge of section 5, T. 58 S., R. 74 W. of the Seward Meridian. The location is based on aerial photographs showing where the entrance to the adit is and is accurate to 100 feet.

Commodities:

Main: Ag, Au

Other: Cu, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Adularia, calcite, quartz

Geologic description:

The Sitka deposit is a 5- to 10-foot-wide zone of auriferous quartz-sulfide veins in an east-west-striking shear that cuts rocks mapped as andesite of the Eocene to Oligocene Popof volcanic rocks (Wilson and others, 1995). The shear zone dips 65 to 80 degrees to the south. The Sitka gold vein system is part of the northeast mineralized Apollo-Sitka trend which extends over 5,000 feet across Unga Island. Anomalous gold and silver values in rock, soil, and talus samples correlate to zones of pervasive silicification and quartz-adularia-carbonate veins within an envelope of intense argillic alteration (Redstar Gold Corp., 2014b).

Mineralization is found in stockwork quartz veins containing pyrite and as much as 5 percent chalcopyrite and galena, along with lesser amounts of sphalerite. They are vuggy and show evidence of open-space filling, resulting in inward-facing euhedral quartz crystals. The sulfides occur mostly at the base of the quartz crystals. The stockwork quartz veins are within volcanic rocks and appears to be extensive though the width of mineralization is not known. Trenches expose some of the stockwork quartz veining indicating a minimum width of 50 meters (Redstar Gold Corp., 2012).

Alteration:

Anomalous gold and silver values in rock, soil, and talus samples correlate to zones of pervasive silicification and quartz-adularia-carbonate veins within an envelope of intense argillic alteration (Redstar Gold Corp., 2014b).

Age of mineralization:

Eocene or younger, based on age of host rocks (Wilson and others, 1995).

Generic deposit model:

Deposit model:

Sado epithermal gold veins (Cox and Singer, 1986; model 25d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25d

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Sitka mine was operated in conjunction with the Apollo mine (PM079) from 1900 until about 1915. Workings at that time consisted in part of a 400-foot shaft, a 360-foot adit, stopes as much as 150 feet long and 15 feet wide on the 55-foot level, and numerous crosscuts (Wilson and others, 1988). Production to that time was estimated at 15,000 tons of unknown grade (Brown, 1947). The gold, where mined, was free-milling (Atwood, 1911). In 1983 Alaska Apollo Mines cut six trenches and drilled three core holes for a total of 1,571 feet. The remaining resource is said to be 140,000 tons (Wilson and others, 1996).

In 2011 Redstar Gold Corp. (Redstar) collected several rock samples from the Sitka mine shaft across the gold-silver vein that contained 13.2 grams per tonne (g/t) gold and 398 g/t silver over 2 meters. Vein material sampled from the mine dump returned 15.2 g/t gold and 316 g/t silver (Redstar Gold Corp., 2012).

Redstar remapped and collected continuous chip and select rock samples in 2014 from 235 meters of the historic trenches at Sitka to better understand the characteristics of historic mining activities (Redstar Gold Corp., 2014a). Continuous rock chip trench sampling of intense quartz-adularia-carbonate stockwork veins within a stope at Sitka contained up to 30.5 g/t gold and 128 g/t silver. Sampling along the Apollo-Sitka trend showed a continuous gold and silver soil anomaly of over 100 parts per billion (ppb) gold and over 1.3 g/t silver, extending 1,300 meters to the southwest of Apollo (PM079) (Redstar Gold Corp., 2014b).

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.'s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II's drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). A total of 1,505 meters were drilled in 7 holes spaced over ~750 meters of strike length. All drill holes intersected the target structure, which includes multi-generational phreatomagmatic breccias, hydrothermal breccias, and late breccias and veins with colloform-crustiform- to cockade-textured quartz-adularia-carbonate (± rhodochrosite, ± green clay). Select intervals from drill holes 16SH019 and 16SH020 include 0.9 meter at 14.95 grams of gold per tonne and 1.15 meters at 11.3 grams of gold per tonne; release of full assay results is planned for late January 2017 (Athey and Werdon, 2017).

Production notes:

The estimated production is about 15,000 tons of unknown grade (Brown, 1947).

Reserves:

The resource is estimated 140,000 tons (reported in Alaska Construction and Oil, 1984). The grade is not available.

Additional comments:

The Sitka mine is located on patented mining claims owned by Redstar Gold Corp. (Redstar Gold Corp., 2015).

Site name(s): Apollo; Unga

Site type: Mine

ARDF no.: PM079

Latitude: 55.1905 **Quadrangle:** PM A-2

Longitude: 160.5642

Location description and accuracy:

The Apollo Mine is shown by mine adit symbol on the 1:63,360-scale topographic map. It is about 0.6 mile northwest of the head of Delarof Bay on Unga Island and about 0.4 mile northwest of the center of section 5, T. 58 S., R. 74 W. of the Seward Meridian. The location is well known and accurate.

Commodities:

Main: Ag, Au

Other: Cu, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, native copper, pyrite, sphalerite

Gangue minerals: Adularia, calcite, chlorite, quartz

Geologic description:

The host rock of the Apollo Mine veins are the Eocene to Oligocene Popof volcanic rocks, which are equivalent to the Meshik Volcanics (Wilson and others, 1995). The deposit was discovered in 1891. It was first described by Becker (1897) as a steeply-dipping, reticulated vein zone at the northeast end of the northeast-striking 'Apollo trend', which is a system of faults and linears that cuts across the Unga Island.

Three subparallel veins were mined. The veins cut altered andesite, strike N 20 E and dip steeply south. Riehle (1999), however, reports that they strike N 43 E. The veins are generally less than 60 feet apart. They tend to be vuggy and contain euhedral quartz crystals, indicating deposition in open spaces. Other minerals in the veins include gold, chalcopyrite, sphalerite, galena, pyrite, native copper, calcite, chlorite, and rare adularia. Singer (1999) suggests that this is a Sado-type gold deposit. Anomalous gold and silver values in rock, soil, and talus samples correlate to zones of pervasive silicification and quartz-adularia-carbonate veins within an envelope of intense argillic alteration (Redstar Gold Corp., 2014b).

An anonymous review written in 1935 and included in Brown (1947) suggested that there were four ore shoots 400 to 800 feet long that were spread along strike for over 5,000 feet and extend to a depth of 1,400 feet. Most of the ore mined apparently came from two shoots, the largest of which was 800 feet long, 8 to 16 feet wide, and extended down dip for 500 feet (Wilson and others, 1996). The shoots plunged 60 to 70 degrees to the northeast (Butherus and others, 1979).

Alteration:

The wall rock exhibits extensive propylitization. According to Butherus and others (1979), some silicification is also present. Anomalous gold and silver values in rock, soil, and talus samples correlate to zones of pervasive silicification and quartz-adularia-carbonate veins within an envelope of intense argillic alteration (Redstar Gold Corp., 2014b).

Age of mineralization:

Eocene or younger, based on the age of the host rock (Wilson and others, 1995).

Generic deposit model:

Deposit model:

Sado-type epithermal gold veins (Cox and singer, 1986; model 25d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25d

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Apollo mine was in production from 1892 to 1904 and from 1908 to 1913. By 1913, the workings consisted of two tunnels, one 1,200 feet and the other 3,200 feet in length; two shafts, 450 and 811 feet deep; and numerous subsidiary crosscuts (Wilson and others, 1988). A 60-stamp mill was in operation in the 1890s and early 1900s. Small amounts of ore were mined in 1916 and 1922. Most of the ore was free milling; however, at depth most of the gold was apparently in the sulfides and could not be recovered in the old mill. Some of this ore was concentrated and sent to the Tacoma smelter in Washington. A small cyanide plant was installed at the mine in 1916 to process the tailings.

In 1983, the Alaska-Apollo Gold mines did extensively trenching, sampled the underground workings, and drilled nine core holes that totaled 9,483 feet. Based on this data, the deposit was estimated to have inferred reserves of 748,000 tons that average 0.76 ounce of gold and 2.16 ounces of silver per ton (Bundtzen and others, 1991).

In 2014 Redstar Gold Corp. (Redstar) completed a surface sampling program collecting 405 rock samples and 670 soil and fine talus samples covering over 3 kilometers along the Apollo-Sitka trend (Redstar Gold Corp., 2014a). Rock chip samples collected from bedrock exposures of quartz-adularia-carbonate stockwork veins returned gold and silver values up to 401 grams per tonne (g/t) gold and 266 g/t silver. Sampling along the Apollo-Sitka trend showed a continuous gold and silver soil anomaly of over 100 parts per billion (ppb) gold and over 1.3 g/t silver, extending 1,300 meters to the southwest of Apollo (Redstar Gold Corp., 2014b).

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.'s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II's drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). A total of 1,505 meters were drilled in 7 holes spaced over ~750 meters of strike length. All drill holes intersected the target structure, which includes multi-generational phreatomagmatic breccias, hydrothermal breccias, and late breccias and veins with colloform-crustiform- to cockade-textured quartz-adularia-carbonate (± rhodochrosite, ± green clay). Select intervals from drill holes 16SH019 and 16SH020 include 0.9 meter at 14.95 grams of gold per tonne and 1.15 meters at 11.3 grams of gold per tonne; release of full assay results is planned for late January 2017 (Athey and Werdon, 2017).

Production notes:

Estimates of the total production are: 1) 500,000 tons that averaged 0.25 ounce of gold per ton (Wilson and others, 1996); 2) 490,000 tons that averaged 0.22 ounce of gold per ton (Bundtzen and others, 1987); and 3)242,000 tons that averaged 0.4 ounce of gold per ton (Berg and Cobb, 1967).

Reserves:

In the early 1980s, the mine was estimated to have 748,000 tons of inferred reserves with an average grade of 0.76 ounce gold per ton and 2.16 ounces of silver per ton (Bundtzen and others, 1991).

Additional comments:

The Apollo mine is located on patented mining claims owned by Redstar Gold Corp. (Redstar Gold Corp., 2015).

Site name(s): Apollo Mountain; Unga

Site type: Occurrence

ARDF no.: PM084

Latitude: 55.18 **Quadrangle:** PM A-2

Longitude: 160.61

Location description and accuracy:

This occurrence is approximately located. The map site is at an elevation of about 700 feet, due south of 1,630 foot peak of Apollo Mountain on southeastern Unga Island (MacKevett and Holloway, 1977, locality 13; Wilson and others, 1988, locality 13). The location is accurate to within 2 miles.

Commodities:

Main: Au, Cu

Other:

Ore minerals:

Gangue minerals: Quartz

Geologic description:

This occurrence consists of quartz veins less than 12 inches thick that crop out discontinuously along stike for 2,500 feet. It also includes a knoblike, 100- by 1,000-foot area of brecciated and silicified andesite containing numerous quartz-filled vugs and limonitic shears. The vein system cuts rocks mapped as Popof volcanic rocks of late Eocene to early Oligocene age (Wilson and others, 1995). Grab samples of the quartz contained as much as 0.23 ppm gold and 10 ppm silver (Wilson and others, 1988). Base metal values are low.

Alteration:

Age of mineralization:

Eocene or younger.

Generic deposit model:

Deposit model:

Epithermal gold veins

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Some evaluation work may have been done by UNC Teton Exploration Drilling Company for the Aleut Corporation in 1979, 1981, and 1982 (Wilson and others, 1988). Grab samples contained as much as 0.23 ppm gold and 10 ppm silver. Base metal values were low.

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.'s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II's drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). Site name(s): Aquila; Unga

Site type: Prospect

ARDF no.: PM086

Latitude: 55.19 **Quadrangle:** PM A-2

Longitude: 160.654

Location description and accuracy:

The Aquila prospect is located on southeastern Unga Island one mile east of Acheredin Bay (Nokleberg and others, 1987, locality AP3; Wilson and others, 1988, locality 37). The map site is at an elevation just over 700 feet, 0.25 mile north of the center of sec. 3, T. 58 S., R. 75 W. of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Au

Other: As, Cu, Hg, Pb, Sb, Zn

Ore minerals: Chalcopyrite, galena, gold, galena, sphalerite

Gangue minerals: Quartz

Geologic description:

The Aquila prospect is one of several northeast-striking epithermal vein systems in an area approximately 1,000 by 2,000 feet. The systems include veins on the Origin (PM087), Freds (PM088), Surprise (PM089), Ankle Creek (PM090), Altair (PM091), and Amethyst (PM092) prospects.

The Aquila vein system cuts andesite flows and tuffs of the late Eocene to early Oligocene Popof volcanic rocks (Wilson and others, 1995). It is as much as 100 feet in width and can be traced along strike for as much as 2,000 feet. It exhibits evidence of open-space filling and repeated phases of fracturing and deposition, resulting in vein breccias and quartz stockworks (Peterson and others, 1982). The veins contain pyrite, and, locally free gold, along with trace amounts of chalcopyrite, galena, and sphalerite.

Many sets of lineaments characterize the prospect area. The widest and richest zones of veins seem to occur at the intersection of these lineaments with northwest-striking faults. Higher gold values are also associated with zones of multiple brecciation. The gold is free-milling and ranges in size from 20 to 40 microns (Peterson and others, 1982).

Alteration:

The alteration is zoned outward from the veins from silicification to argillization to propylitization (source unknown, from previous reporting).

Age of mineralization:

Eocene or younger, based on the age of the host rock (Wilson and others, 1995).

Generic deposit model:

Deposit model:

Sado-type epithermal gold vein (Cox and Singer, 1986; model 25d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25d

Production Status: None

Site Status: Active

Workings/exploration:

This prospect was explored by Resource Associates of Alaska and UNC Teton Exploration Drilling Company during the period 1979 to 1982. During that time they mapped the area; conducted magnetometer, Very Low Frequency Electromagnetic (VLF-EM) and Induced Polarization (IP) surveys; drilled 12 core holes for a total of 4,446 feet; collected 675 rock samples; cut 17 trenches for a total of 3,310 feet; and took 472 trench samples. Precious metal values in trench samples include 0.335 ounce per ton (oz/t) gold and 1.56 oz/t silver over 12 feet, 0.242 oz/t gold and 0.68 oz/t silver over 12 feet, 0.105 oz/t gold and 0.17 oz/t silver 12 feet, and 0.165 oz/t gold and 0.18 oz/t silver 10 feet. Selected drill core assays include 0.20 oz/t gold and 0.4 oz/t silver over 31.2 feet, 0.19 oz/t gold and 0.51 oz/t silver over 17.5 feet, and 3.31 oz/t gold and 3.2 oz/t silver over 1.4 feet (Peterson and others, 1982).

In 1986 Battle Mountain Exploration Company examined the vein systems and later mapped and sampled some of them. In 1990 they explored the area looking for large zones of argillic and silicic alteration having potential for disseminated gold mineralization. Argillically altered and silicified tuffs were found to be anomalous in arsenic and mercury and had spotty gold values as much as 0.025 parts per million (ppm) (Ellis and Apel, 1990).

In 2014 Redstar Gold Corp. collected approximately 150 soil and fine talus samples and over 50 rock samples covering the Aquila prospect (Redstar Gold Corp., 2014a). The soil and fine talus samples returned gold values ranging from 50 parts per billion (ppb) to 197 ppb and silver values from 0.5 grams per tonne (g/t) to 1.3 g/t. A rock sample from a narrow breccia vein with strong argillic alteration contained 90.2 g/t silver (Redstar Gold Corp., 2014b).

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.'s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II's drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). A total of 1,505 meters were drilled in 7 holes spaced over ~750 meters of strike length. All drill holes intersected the target structure, which includes multi-generational phreatomagmatic breccias, hydrothermal breccias, and late breccias and veins with colloform-crustiform- to cockade-textured quartz-adularia-carbonate (± rhodochrosite, ± green clay). Select intervals from drill holes 16SH019 and 16SH020 include 0.9 meter at 14.95 grams of gold per tonne and 1.15 meters at 11.3 grams of gold per tonne; release of full assay results is planned for late January 2017 (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Additional comments:

The Aquila prospect lies land where the surface rights belong to the Unga Corporation and the subsurface rights belong to the Aleut Corporation (Redstar Gold Corp., 2015).

Site name(s): Amethyst; Unga

Site type: Prospect

ARDF no.: PM092

Latitude: 55.188

Quadrangle: PM A-2

Longitude: 160.654

Location description and accuracy:

The map site of the Amethyst prospect is at an elevation of 500 feet, 500 feet northwest of the center of sec 3, T. 58 S., R. 75 W., Seward Meridian. The location is accurate to within 1,200 feet.

Commodities:

Main: Ag, Au

Other: As, Cu, Hg, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The northeast-striking Amethyst vein at its westernmost end is located approximately 200 feet south of the Altair vein (PM091); however, it has a more northerly strike, and farther to the northeast it intersects both the Altair (PM091) and the Ankle Creek (PM090) veins (Peterson and others, 1982, figure 11). The Amethyst vein has been traced for approximately 2,000 feet on strike. The vein is a braided system, generally 15 to 20 feet in width, composed of numerous quartz veins of varying widths. Individual veins in the system branch, interweave, pinch, and swell (Trujillo and others, 1982). It exhibits evidence of crushing, brecciation, and partial rehealing. Vein quartz generally makes up 20 to 50 percent of the system. Sulfide minerals include pyrite, chalcopyrite, galena, and sphalerite. The host rocks are propylitized and argillized, pyritic andesite flows and tuffs of the late Eocene to early Oligocene Popof volcanic rocks (Wilson and others, 1995).

An ore shoot at the intersection of the Amethyst and Ankle Creek veins has been drilled and trenched It is approximately 300 feet long, 12 feet wide, and extends to a depth of 100 feet. Ore intercepts of three core holes include 16.3 feet grading 0.20 ounce of gold and 0.6 ounce of silver per ton, 31 feet grading 0.20 ounce of gold and 0.4 ounce of silver per ton, and 10 feet grading 0.08 ounce of gold and 0.6 ounce of silver per ton (Anderson and others, 1980). The assays also show up to 1,120 ppm copper, 2,300 ppm lead, 670 ppm zinc, 1,100 ppm arsenic, and 0.64 ppm mercury. Trench samples include 12 feet grading 0.105 ounce of gold and 0.17 ounce of silver per ton, 12 feet grading 0.242 ounce of gold and 0.68 ounce of silver per ton, and 12 feet grading 0.335 ounce of gold and 1.56 ounces of silver per ton (Trujillo and others, 1981). The resource is estimated to be 30,000 tons of ore grading 0.23 ounce of gold and 0.8 ounce of silver per ton.

Other trenches and drill holes along the system indicate anomalous, but not sub-ore-grade precious metal values.

Alteration:

The host rocks exhibit weak to strong propylitic and argillic alteration. The propylitic alteration is accompanied by 2 to 5 percent disseminated pyrite.

Age of mineralization:

Eocene or younger.

Generic deposit model:

Deposit model:

Epithermal gold vein

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

During the period 1980 to 1982 Resource Associates of Alaska and UNC Teton Exploration Drilling Company mapped and sampled the prospect conducted VLF-EM, IP, and magnetometer surveys, core drilled 11 holes for a total of 4,446 feet, and cut 11 trenches. One ore shoot was outlined and evaluated at 30,000 tons grading 0.23 ounce of gold and 0.8 ounce of silver per ton (Trujillo and others, 1981).

In 1986 Battle Mountain Exploration Company carried out orientation soil, magnetometer, and VLF surveys over the prospect.

Redstar Gold Corp. conducted two phases of exploration in 2016 on their Unga project, which includes the Shumagin (PM064), Apollo (PM079; PM084), Centennial, Orange Mountain (PM067), Zachary Bay (PM054), Amethyst (PM092), and Aquila (PM086) epithermal gold-silver prospects. The Shumagin trend parallels the historically mined Apollo–Sitka vein system (PM079; PM084; PM076), which between 1886 and 1922 produced approximately 150,000 ounces of gold at a grade of approximately 0.292 ounce of gold per ton (Athey and Werdon, 2017).

In June 2016, Redstar Gold Corp.’s Phase I surface program included classifying alteration assemblages and conducting other geologic work to identify drill targets. From October through November, Phase II’s drilling program tested the down-dip and along-strike expansion potential of high-grade vein/breccia mineralization within the Shumigan Gold Zone (PM064). A total of 1,505 meters were drilled in 7 holes spaced over ~750 meters of strike length. All drill holes intersected the target structure, which includes multi-generational phreatomagmatic breccias, hydrothermal breccias, and late breccias and veins with colloform-crustiform- to cockade-textured quartz-adularia-carbonate (± rhodochrosite, ± green clay). Select intervals from drill holes 16SH019 and 16SH020 include 0.9 meter at 14.95 grams of gold per tonne and 1.15 meters at 11.3 grams of gold per tonne; release of full assay results is planned for late January 2017 (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

An ore shoot on the prospect contains an estimated 30,000 tons grading 0.23 ounce of gold and 0.8 ounce of silver per ton.

Additional comments:

This prospect is located on land patented by, or interim-conveyed to, the Aleut Corporation.

Site name(s): Centennial; Herman Lode; Trench; Popof Island Gold

Site type: Prospect

ARDF no.: PM096

Latitude: 55.308 **Quadrangle:** PM B-2

Longitude: 160.4975

Location description and accuracy:

The Centennial prospect is at an elevation of about 300 feet, approximately 2 miles south of the town of Sand Point. It is in the upper half of section 29, T. 56 S., R. 73 W. The location is accurate.

Commodities:

Main: Ag, Au

Other: As, Cu, Hg, Pb, Zn

Ore minerals:

Gangue minerals: Calcite, quartz

Geologic description:

The host rock at the Centennial prospect is Eocene to Oligocene Popof volcanic rocks (Wilson and others, 1995). At this locality they consist mostly of basalt flows and tuffs.

The names Herman Lode and Trench refer to prospects explored by several adits, pits, and a trench in the early 1900s. A mineralized zone 5 to 10 feet wide was reported to contain free gold (Atwood, 1909). The name Centennial was given to a gold deposit discovered in the same area in 1987 by Battle Mountain Exploration Company. Battle Mountain evaluated the property by detailed mapping and sampling, 484 auger holes, 59 diamond drill holes, 7,275 feet of trenching, and magnetic and VLF-EM geophysical surveys. Battle Mountain estimated that within 175 of the surface, the deposit has a resource of 4.8 million tons with an average grade of 0.042 ounce of gold per ton (Ellis and Harris, 1989).

The Centennial deposit is a large, low grade, disseminated gold lode. The country rocks consist of basalt flows, plugs, dikes, tuffs, and epiclastic deposits that overlie a sedimentary complex. The main mineralized zone occurs in a window eroded through a basalt flow. The mineralization is thought to be controlled in part by a plug margin, and in part by north-northeast-trending high-angle faults and fracture zones from which mineralizing fluids spread out into surrounding permeable rock (Ellis and Harris, 1989). The gold is disseminated in the matrix of the basaltic tuffs and also occurs in fractures and veins that cut the flows. The mineralization seems to have a lower limit at 240 to 400 feet above the sedimentary rocks that are beneath the volcanic rocks. The gold is free and occurs in the plus-25-micron range (Ellis and Harris, 1989). Silver, mercury, and arsenic are associated with the gold in analyses of the samples. Quartz and quartz-calcite veins and veinlets containing galena, sphalerite, pyrite, and some chalcopyrite were cut in some of the drill holes. Their relationship to the gold mineralization is not known. The rocks exhibit pervasive propylitic alteration. The mineralization is accompanied by enrichment in silica and potassium, resulting in deposition of adularia, sericite, and quartz. Argillic alteration is locally present. Calcite stockwork veining is widespread.

Alteration:

The host rocks in the area exhibit pervasive propylitic alteration. The mineralization is accompanied by enrichment in silica and potassium, resulting in deposition of adularia, sericite, and quartz. Argillic alteration is locally present. Calcite stockwork veining is widespread.

Age of mineralization:

Eocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Volcanic-hosted disseminated gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In the early 1900s the prospect area was explored by tunnels, trenches, and pits. In the late 1980s, Battle Mountain Exploration Company evaluated the property by detailed mapping and sampling, 484 auger holes, 59 diamond drill holes, 7,275 feet of trenching, and magnetic and VLF-EM geophysical surveys.

Production notes:

None.

Reserves:

Battle Mountain Exploration Company estimated that within 175 of the surface, the deposit has a resource of 4.8 million tons with an average grade of 0.042 ounce of gold per ton (Ellis and Harris, 1989).

Additional comments:

This prospect is on land owned by the Aleut Native Corporation.

Site name(s): Propolov

Site type: Prospect

ARDF no.: PM110

Latitude: 55.2942 **Quadrangle:** PM B-2

Longitude: 160.4851

Location description and accuracy:

This prospect is exposed in the beach cliffs about 2.4 miles southeast of the Sand Point light; it is near the southeast corner of section 29, T. 56 S., R. 73 W. The location is accurate. It is at the southwest end of what Redstar Gold Corp. calls the Propolov prospect.

Commodities:

Main: Ag, Au

Other:

Ore minerals:

Gangue minerals: Quartz

Geologic description:

A zone of north-striking quartz-sulfide veins cuts tuffs and overlying flows in the sea cliffs south of the Centennial deposit (PM096) (Ellis and Harris, 1989). The host rocks are Eocene to Oligocene Popof volcanic rocks (Wilson and others, 1995). At the base of the cliff, a veined structure 10.5 feet wide, consists of five sulfide-bearing veins. At 175 feet above the base of the cliff, the zone is 50 feet wide and consists of 12 narrow, poorly mineralized veins (Redstar Gold Corp., 2002 [high-grade]). In the early 1900s a short adit was driven at the base of the zone. Samples taken in 1982 across 0.6 meter contained 21.39 grams of gold per tonne across 0.6 meters and 16.11 grams of gold per tonne. These veins have variously been seen as the feeder system to the Centennial deposit (Ellis and Harris, 1989) or as the southwest end of a northeast-trending belt of gold mineralization that Redstar calls the Propolov prospect (2012 [Growth]).

Alteration:

Not specified but probably associated with altered rocks.

Age of mineralization:

Eocene or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Sado-type epithermal gold vein? (Cox and Singer, 1986; model 25d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25d

Production Status: None

Site Status: Active

Workings/exploration:

A short adit was driven about 1900. Probably repeatedly examined if not sampled from the 1980s to the present (early 2012) in conjunction with work at the Centennial prospect (PM096) about 2 kilometers to the northwest.

Production notes:

None.

Reserves:

None.

Site name(s): Nelson and Tift

Site type: Mine

ARDF no.: PR005

Latitude: 54.8017 **Quadrangle:** PR D-6

Longitude: 131.9743

Location description and accuracy:

The Nelson and Tift Mine is on the north shore of McLean Arm, 0.8 mile west of Island Point at the entrance to the arm; it is in Sec. 33, T. 81 S., R. 90 E., of the Copper River Meridian. The location is accurate and the mine is shown by symbol on the current US Geological Survey 1:63,360-scale topographic map.

Commodities:

Main: Ag, Au, Cu, Pb

Other:

Ore minerals: Bornite, chalcopyrite, galena?, gold, magnetite, pyrite

Gangue minerals: Calc-silicate minerals, quartz

Geologic description:

The Nelson and Tift Mine was unusual in that it was found by two prospectors, mostly mined by them at low cost, and returned a profit with little legal or operational complications (Wilcox, 1937; Roehm, 1939, Roehm, 1942,; Roppel, 2005). The deposit was found in 1935 by two fishermen, Otto Nelson and R.C. Tiff along the exposed shoreline in an area that previously had been prospected for many years. A 2,150-pound test shipment was sent to the Tacoma smelter and assayed 0.785 ounce of gold per ton. Nelson and Tift then proceeded to mine in a pit just above sea level with a small compressor and jackhammer and sent a 50-ton ore shipment to the smelter in 1936. They then leased the property to the Anaconda Copper Company who mined for a year, periodically sending out barges of sulfide rich ore that proved to be worth $50 to $770 a ton. Anaconda drilled four holes on the deposit and concluded that while rich, it was small. At the end of the year, the property reverted to Nelson and Tift who continued to mine. In 1938, they shipped 1,076 tons of ore to the smelter with a return of $34,000 in gold and silver. A small flotation mill was set up to concentrate the sulfides in the ore and a search continued into the 40s for more mineralization with no success. Nelson reported that about 1,300 tons of ore was mined and that the total return was about $111,000 in gold and silver with some copper and lead.

The rocks in the area of the Nelson and Tift mine (MacKevett, 1963, pl. 1) consist of a Cretaceous quartz diorite stock; thin roof pendants of Devonian (?) marble and calc-silicate rock; and numerous Tertiary andesite or dacite dikes that cut both the stock and the roof pendants.

The deposit (MacKevett, 1963, p. 99-100) consisted of a sulfide lens 75 feet long, 30 feet deep, and 9 feet wide, in a steeply dipping, 20- to 40-ft wide roof pendant of marble that has been intruded by quartz diorite. Near the intrusive contacts, parts of the pendant have been converted to calc-hornfels. The ore consisted largely of auriferous pyrite, accompanied by small amounts of chalcopyrite and bornite. A few pyrite-bearing quartz veins up to 6 inches thick that cut the pendant contain gold. Pyrite and a little magnetite are disseminated in parts of the marble.

Alteration:

Age of mineralization:

Probably Cretaceous or younger.

Generic deposit model:

Deposit model:

Au skarn (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

The Nelson and Tift Mine was unusual in that it was found by two prospectors, mostly mined by them at low cost, and returned a profit with little legal or operational complications (Wilcox, 1937; Roehm, 1939, Roehm, 1942; Roppel, 2005). The deposit was found in 1935 by two fishermen, Otto Nelson and R.C. Tiff along the exposed shoreline in an area that previously had been prospected for many years. A 2,150-pound test shipment was sent to the Tacoma smelter and assayed 0.785 ounce of gold per ton. Nelson and Tift then proceeded to mine in a pit just above sea level with a small compressor and jackhammer and sent a 50-ton ore shipment to the smelter in 1936. They then leased the property to the Anaconda Copper Company who mined for a year, periodically sending out barges of sulfide rich ore that proved to be worth $50 to $770 a ton. Anaconda drilled four holes on the deposit and concluded that while rich, it was small. At the end of the year, the property reverted to Nelson and Tift who continued to mine it. In 1938, they shipped 1,076 tons of ore to the smelter with a return of $34,000 in gold and silver. A small floatation mill was set up to concentrate the sulfides in the ore and a search continued into the 40s for more mineralization with no success.

Production notes:

Nelson (Roehm, 1942) reported that about 1,300 tons of ore was mined and the total return was about $111,000 in gold and silver with some copper and lead.

Reserves:

The ore body was apparently mined out.

Site name(s): Maquis Zone; Potato Patch

Site type: Prospects

ARDF no.: PR007

Latitude: 54.9397 **Quadrangle:** PR D-5

Longitude: 131.3961

Location description and accuracy:

The Maquis Zone prospect is about 1.8 miles northwest of the north end of Hall Cove on Duke Island. It is at the northeast corner of section 16, T. 80 S., R. 93 E. at an elevation of about 450 feet. The location is accurate.

Commodities:

Main: Co, Cu, Ni, Pd, Pt

Other:

Ore minerals: Chalcopyrite, pentlandite, platinum-group minerals, pyrrhotite

Gangue minerals:

Geologic description:

The Maquis Zone prospect is on northwestern Duke Island, well known as the type locality of the Alaska-type, Cretaceous zoned ultramafic complex (Irvine, 1974). The ultramafic complex is concentrically zoned outward from a core of dunite and peridotite, succeeded by shells of olivine pyroxenite and hornblende pyroxenite. The complex is distinguished by locally conspicuous graded layering and other cumulate features, especially in the dunite, peridotite, and olivine pyroxenite. It has long been known (Berg and Cobb, 1967) that the dunite contains small lenses and disseminated chromite; the hornblende pyroxenite contained segregations of titaniferous magnetite that have been drilled; and rare specks of pyrrhotite, pyrite, pentlandite, and chalcopyrite occur widely (PR001). However, until recently no deposit of substantial size had been identified on Duke Island.

In 2001 and 2005, Quaterra Resources (2011) drilled 11 holes totaling 5,971 feet in two area: 8 holes in the the Maquis Zone and 3 in the Raven Zone (PE121) on mineralization they consider unlike anything that had previously been identified on Duke Island (Freeman, 2006). They interpret the mineralization as possibly related to the layered mafic complex.

The Maquis Zone mineralization is in a small plug of dunite about a half mile in diameter between hornblende-magnetite pyroxenite and gabbro (Freeman, 2006; Quaterra Resources, Inc., 2011). The best intercept in the 2001 drilling at the Maquis Zone was 99.5 feet that averaged 2,230 parts per million (ppm) copper and 140 parts per billion platinum and palladium, 40 to 608 ppm cobalt, and 102 to 2,730 ppm nickel (Quaterra Resources, 2005). The mineralization consists of disseminated chalcopyrite, pyrrhotite, and pentlandite in serpentinized clinopyroxenite and olivine pyroxenite. Rounded and tear-drop-shaped sulfide blebs suggest sulfide-silicate immiscibility during sulfide deposition. Additional drilling was done on the Maquis Zone in 2005 and also at the Potato Patch area about 1.1 kilometer to the west. The best intercept in the drilling was 149 feet that contained 2,086 ppm copper.

No drilling was done in 2007. However, the data was reviewed and several other areas of interest were identified. In February, 2008, Quaterra had a 388-line-mile airborne geophysical survey flown over the area. Quaterra's work suggest that the mineralization extends for 14.5 kilometers along strike and is 3.8 kilometers wide.

In 2010, Quaterra optioned the property to Copper Ridge Explorations Inc. (2010 [News, June 16]) and they drilled five holes that totaled 1,537 meters (Copper Ridge Explorations Inc., 2010 [News, Sept. 10]).

The drilling was designed to test mineralization along the basal contact of the mafic-ultramafic complex or within the feeder of the Maquis zone. The drill targets were based on geologic mapping, historical drilling, and three-dimensional modeling from several geophysical surveys. No significant mineralization was intersected in 4 of the holes. However one hole intersected 4.9 meters with 0.294 percent copper and 0.075 percent nickel, and 13.4 meters with 0.148 percent copper and 0.039 percent nickel. That hole collared in pyroxenite and was in gabbro for about 48 meters at the bottom of the hole. The gabbro contained 1-15 percent pyrrhotite and masses of graphitic country rock. The drilling indicated that the zoning within the complex is more complicated than was expected and what had been thought to be the basal contact of the complex from geophysical interpretations was in fact a contact with disseminated sulfides and sedimentary rocks with a high graphite content.

Alteration:

The host rocks are serpentinized.

Age of mineralization:

The Duke Island complex is about 110 Ma; this mineralization is probably genetically related to it.

Generic deposit model:

Deposit model:

Disseminated copper, nickel, and platinum-group elements in a layered mafic complex.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): Owhat (Cobalt Creek)

Site type: Prospect

ARDF no.: RM016

Latitude: 61.6622 **Quadrangle:** RM C-1

Longitude: 159.1114

Location description and accuracy:

The Owhat prospect is in the Russian Mountains in the cirque valley at the head of Cobalt Creek. The map site is at the approximate center of sec. 8, T. 18 N., R. 54 W., of the Seward Meridian.

Commodities:

Main: Ag, Au, Cu, Sb, Sn

Other: Bi, Co, Pb, Zn

Ore minerals: Arsenopyrite, aramayoite, bismuth, bismuthinite, bornite, chalcopyrite, galena, gold, marcasite, pekoite or gladite, pyrite, sphalerite, stephanite, stetefeldtite, tetrahedrite

Gangue minerals: Axinite, quartz, tourmaline

Geologic description:

The Owhat, or Cobalt Creek prospect was discovered by Native prospectors before 1900 (Maddren, 1915; Holzheimer, 1926). The deposits include 8 to 10 sulfide-tourmaline-axinite-quartz veins or greisens in syeno-monzonite (Bundtzen and Laird, 1991). The individual greisens are several inches to more than 3 feet thick in a zone that is 5 to 26 feet thick; the average width of the zone is about 8 feet and it has been traced more than 280 feet vertically. The greisens trend northwest and dip steeply northeast near a contact with an axinite-bearing andesite porphyry dike. The mineralized zone has been traced on the surface for a distance of 870 feet, and extensions totaling 650 feet in both directions are indicated by the distribution of mineralized float. The deposit is mineralogically complex and includes arsenopyrite, aramayoite, bismuth, bismuthinite, bornite, chalcopyrite, galena, gold, marcasite, pekoite or gladite, pyrite, sphalerite, stephanite, stetefeldite and tetrahedrite in the sulfide-rich material in the quartz-tourmaline-axinite greisen. Multiple episodes of mineralization are indicated by cross-cutting relations among the veins. Late-forming minerals include arsenopyrite, chalcopyrite, and pyrite, but the youngest cross-cutting assemblages include bornite, stephanite, tetrahedrite, sphalerite, and lead-bismuth sulfides (Bundtzen and Laird, 1991). Microprobe analyses indicate that arsenopyrite contains 0.1 to 0.2 weight percent gold in its lattice structures. Bundtzen and Laird (1991) collected 16 chip-channel samples averaging 4.4 feet wide, along 860 feet of the greisen zone. The samples average 5.3 parts per million (ppm) gold, 13.4 percent arsenic, 0.21 percent antimony, 0.39 percent copper, 0.07 percent tin, 0.05 percent zinc, and 0.017 percent cobalt. Assuming dimensions, in feet, of 4.4 x 280 x 870, Bundtzen and Laird (1991) estimated that the resource at this prospect is 63,000 tons of material with the stated average grades. The syeno-monzonite host rocks are part of the Upper Cretaceous intrusive complex of the Russian Mountains (Bundtzen and Laird, 1991).

In August, 2009, Full Metal Minerals Corp. and Kinross Gold formed an alliance to explore properties in the Russian Mountains, northwest of Aniak (Full Metal Minerals Corp., 2009b, 2010). Six holes were drilled at the Owhat prospect to test a structure more than 200 meters long. Gold-silver-copper mineralization associated with quartz-tourmaline veining was cut in all the holes. The best intercepts are 1.1 meters with 8.59 grams of gold per tonne, 185.6 grams of silver per tonne, and 6.03 percent copper; 0.94 meters with 5.35 grams of gold per tonne, 150.0 grams of silver per tonne, and 9.97 percent copper; and 0.52 meters with 8.59 grams of gold per tonne, 680.0 grams of silver per tonne, and 10.35 percent copper.

Alteration:

Silicification and tourmalinization.

Age of mineralization:

Late Cretaceous or Tertiary. The veins crosscut part of the intrusive complex of the Russian Mountains; quartz monzonite from this complex has a K/Ar age of 70.3 +/- 2.1 Ma (Bundtzen and Laird, 1991).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Prior to 2009, the only workings were three shallow shafts as much as 40 feet deep and several surface trenches and pits, along about 800 feet of the deposit. Full Metal Minerals drilled 6 holes in late 2009.

Production notes:

None.

Reserves:

Assuming the deposit is 4.4 feet deep, 280 feet wide, and 870 feet long, Bundtzen and Laird (1991) estimate that the resource at this prospect is 63,000 tons of material with average grades of 5.3 ppm gold, 13.4 percent arsenic, 0.21 percent antimony, 0.39 percent copper, 0.07 percent tin, 0.05 percent zinc, and 0.017 percent cobalt.

Site name(s): Wallace

Site type: Prospect

ARDF no.: RM025

Latitude: 61.0559 **Quadrangle:** RM A-3

Longitude: 159.928

Location description and accuracy:

The Wallace prospect is on the crest of the ridge along the northwest side of lower California Creek near its junction with the Tuluksak River. It is at an elevation of about 1,000 feet about 0.2 mile southeast of the center of section 9, T. 11 N., R. 60 W., of the Seward Meridian. It is accurately located.

Commodities:

Main: Au

Other: Bi, Cu, Te, Zn

Ore minerals: Chalcopyrite, gold, pyrrhotite, sphalerite, tellurobismuthite, tetradymite

Gangue minerals: Calcite, chlorite, quartz

Geologic description:

In 1945, R. E. Wallace of the U.S. Geological Survey discovered free gold in quartz veins cutting a granitic dike at this site. He described the deposit in unpublished notes and memoranda and the U.S. Geological Survey announced the discovery in a press release on August 4, 1945. The steeply dipping or vertical, granitic dike is about 40 feet wide and trends N 20 E, subparallel to the ridge. Wallace traced it along strike for about 300 feet. He noted that quartz veinlets were localized in the southeastern half of the dike and that the gold occupied open spaces in the interior of the veinlets. He collected two samples. One contained 0.59 ounce of gold per ton and the other 1.3 ounces of gold per ton. The gold was associated with a slightly more abundant, soft (hardness of 2 to 3), silvery-white mineral with laminar cleavage. This mineral was tentatively identified as a telluride. Limonite and traces of sphalerite, chlorite, and amphibole were also present in the veins. The dike, which may be an apophysis of a nearby mid-Cretaceous pluton, intrudes Jurassic volcanic rocks (Box and others, 1993).

Frost (1990) described gold- and pyrite-bearing quartz veins at this site as cutting sericitized andesite and volcaniclastic hornfels. The veins are vuggy and contain euhedral quartz prisms extending into open spaces. Other gangue minerals in the iron oxide-stained veins are commonly calcite and sprays of chlorite. A sample from a quartz vein contained 4.5 parts per million (ppm) gold (Frost, 1990, sample locality 3). Bedrock in the area includes thermally metamorphosed Jurassic volcanic or volcaniclastic rocks and a small granitic stock or dike (Box and others, 1993).

Wenz (2004, 2005) reported tellurobismuthite , gold, tetradymite, and very minor amounts of chalcopyrite in quartz veins at the Wallace prospect. Alteration was not present next to the veins.

In 2005, Tonogold Resources, Inc. negotiated a mining lease agreement with Calista Corporation covering the general Nyac area. They completed detailed soil geochemical surveys in several areas including the Wallace prospect in the summer of 2005. A rock chip sample from the Wallace prospect contained 7.2 ppm gold. Strachan (2005) shows a map of soil sample sites in the general area of the Wallace prospect; several samples contained a few hundred parts per billion gold.

Tonogold (2007) drilled two holes on the Wallace prospect in the summer of 2006 and did considerable trenching Both holes cut quartz-calcite-pyrrhotite-chalcopyrite veins at depth that are unlike other mineralization in the area. The veins are in Jurassic andesitic volcanic rocks and have narrow chalcedonic envelopes surrounded by wide propylitic zones.

Alteration:

Chalcedonic and propylitic.

Age of mineralization:

Cretaceous or Tertiary. The gold-bearing quartz veins crosscut a granitic dike that may be mid-Cretaceous in age. The dike intrudes Jurassic volcanic rocks.

Generic deposit model:

Deposit model:

Au-Bi-Te veins; pyrrhotite-chalcopyrite-pyrite veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

As of 2005, Tonogold Resources, Inc. has a mining lease agreement with Calista Corporation covering the general Nyac area. They completed detailed soil geochemical surveys in several areas including the Wallace prospect in the summer of 2005. Strachan (2005) shows a map of soil sample sites in the general area of the Wallace prospect; two or three samples contained a few hundred parts per billion gold. Tonogold drilled two holes on the Wallace prospect in 2006 and did considerable trenching.

Location description and accuracy:

Several reports from the 1990s assumed that this prospect was different from the Wallace prospect (WI025) and two records were compiled for nearby prospects. More recent work from 2004 to 2008 substantiates that the prospect described in this record is the Wallace prospect. The information originally in this record as well as much new information, including drilling, on the Wallace prospect has been used to update the record for it. This site number is only retained for accounting purposes.

Site name(s): Tuluksak River

Site type: Mine

ARDF no.: RM028

Latitude: 61.0039 **Quadrangle:** RM A-3

Longitude: 159.9304

Location description and accuracy:

The Tuluksak River has been almost continuously mined by dredge and mechanized equipment for more than 8 miles downstream from the mouth of California Creek to about a mile upstream from the mouth of Granite Creek. Somewhat arbitrarily, the coordinates for the mine are placed near the center of the mining on the river near Nyac, which was the location of the town headquarters of the New York-Alaska Company that mined the Tuluksak River for many years and remains the headquarters camp for current mining. The town is in the northwest corner of section 33, T. 11 N., R. 60 W., of the Seward Meridian. The mine is locality 17 of Hoare and Cobb (1972, 1977). The location is probably accurate within 1000 feet.

Commodities:

Main: Au

Other: Pt

Ore minerals: Gold

Gangue minerals:

Geologic description:

Gold was first discovered in the Nyac district on Bear Creek (RM032), a tributary of the Tuluksak River, near the mouth of Bonanza Creek in 1907 or 1908 and soon after gold was discovered on the Tuluksak River. Dredging began on the Tuluksak River in 1936 and for many years the mining in the district, which was mainly on the Tuluksak River, was carried out by the New York-Alaska Company and its successor the New York-Alaska Gold Dredging Company. The company built a company town, Nyac and an extensive physical plant and community facilities including a hydroelectric power station to power the dredges, the town, and other mining in the district. In 1965, the property was taken over by the Tuluksak Dredging Company and since 1990, the Nyac Mining Company has been actively mining in the area under an agreement with the Calista Native Corporation, which now owns most of the placer claims in the district.

Parts from a small wood-hulled dredge that had operated on Bear Creek between 1928 and 1935 were used to build a steel-hulled dredge on the Tuluksak River in 1936. In 1937, another steel-hulled dredge was built and began mining (Mining World, 1941). Dredging continued in the 1960s by the New York-Alaska Dredging Company. There has also been extensive mechanized mining using draglines, tractors, and non-floating washing plants over the years along the Tuluksak. As of 2006, the Tuluksak River is marked by dredge tailings a thousand feet or more wide that extend almost continuously from the mouth of California Creek to about five miles below Nyac. In recent years, there apparently has been little mining along the Tuluksak River itself. However in the early 1980s, Tuluksak Dredging and Northland Dredging rebuilt the steel-hulled dredge about 5 miles downstream from Nyac; they operated it for a year or more until they shut down as a result of a water-quality dispute. There apparently is no public record of it but the conventional wisdom in 2006 among those familiar with the district was that Northland Dredging had drilled out reserves that contained (still contain?) about 37,000 ounces of gold in the vicinity of their dredge above the mouth of Granite Creek (D.J. Grybeck, conversations with miners and knowledgeable individuals during field work, 2006).

There is no public record of the production specifically from the Tuluksak River. But the district

produced a minimum of 600,000 ounces of gold (Calista Corp, 2008), all from placers, and a large part of that, perhaps more than half, came from the Tuluksak River judging on the extent of the tailings.
Joesting (1942) reported that some platinum was produced with the gold and that asbestos and graphite were dredged from bedrock. There is no evidence that a any significant amount of platinum was produced. Inquiries in 2006 about platinum (D.J. Grybeck, conversations with local miners) at best indicated a vague knowledge that someone may have found some platinum in the gold placers but it has not been a component of placer concentrates in recent years.
Most of the rocks in the drainage basin of the Tuluksak River are hornfelsed or metamorphosed Jurassic volcanic and sedimentary rocks cut by mid-Cretaceous granitic plutons and Jurassic gabbro (Box and others, 1993; Wenz, 2005).
Historic field work at Tuluksak River included rock and soil sampling (Calista Corp., 2000).
In 2012, the property was operated by Nyac Gold LLC. Work performed at Tuluksak River includes magnetic susceptibility readings on outcrops (Flanders and others, 2012).

Alteration:

Not reported.

Age of mineralization:

Quaternary (Wenz, 2005).

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; medium

Site Status: Undetermined

ARDF no.: RM030

Latitude: 61.0972 **Quadrangle:** RM A-3

Longitude: 159.7768

Location description and accuracy:

The Saddle prospect is at an elevation of about 2,440 feet on the crest of a ridge east of upper Bonanza Creek. It is about 0.5 mile south-southwest of hill 2765 and about 0.3 mile east-southeast of the center of section 29, T. 12 N., R. 59 W., of the Seward Meridian. The location is probably accurate to within 1,000 feet.

Commodities:

Main: Au

Other: Cu

Ore minerals: Chalcopyrite, gold, magnetite, pyrite

Gangue minerals: Calcite, chalcedony, chlorite, quartz

Geologic description:

Frost (1990) describes gold- and pyrite-bearing quartz veins cutting sericitized andesite and volcaniclastic hornfels at this site. The veins are vuggy and contain euhedral quartz prisms extending into open spaces. The other common gangue minerals in the iron-oxide stained veins are calcite and chlorite. A quartz vein at this prospect contained 20 parts per million (ppm) gold (Frost, 1990, sample locality 2). The rocks in the area include thermally metamorphosed Jurassic volcanic or volcaniclastic rocks near the contact with a small granitic stock (Box and others, 1993). The thermal metamorphism is caused by a large mid-Cretaceous granitic pluton exposed to the the north in the headwaters of the Tuluksak River.

Wenz (2004, 2005) describes both high and low temperature mineralization at this prospect. Quartz-chlorite-calcite veins with magnetite, chalcopyrite, and native gold are part of the higher temperature suite. Fluid inclusions in these veins have first homogenization temperatures of 282 to 557 degrees centigrade and salinities of 17 to 57 weight percent NaCl. Samples of this mineralization contain up to 10.9 ppm gold. The lower temperature mineralization includes vuggy chalcedony-bearing veins that are known to contain up to 723 parts per billion (ppb) gold, 9.88 ppm silver, and 280 ppb mercury. Sericite-altered dikes and carbonate-replaced fault breccia are also considered part of the lower temperature mineralization. Altered fault breccia contains up to 15.1 ppm gold and 1.6 ppm mercury.

In 2005, Tonogold Resources, Inc. (2006) negotiated a mining lease agreement with Calista Corporation covering the Nyac area. They completed detailed soil geochemical surveys in several areas including this prospect in the summer of 2005. Strachan (2005) shows a map of soil samples in the area of this prospect. He reported that 58 of 518 surface samples contained 0.105 to 2.86 ppm gold. Seven rock chip samples contained 0.121 to 15.1 ppm gold.

In 2006, Tonogold (2007) expanded their geochemical coverage of the area considerably, did surface mapping and sampling, and cut several trenches. Some outcrop and float samples which had visible gold contained more than 1,000 ppm gold. Wenz (2004, 2005) also maps a large area of gaudy, orange-weathering altered volcanic rocks with anomalous gold values in the flat saddle between this prospect and hill 2046 to the southeast and on the hillside between that saddle and this prospect.

In 2010, Nyac Mining LLC, drilled several hole near the Saddle prospect (Flanders, 2010). The holes penetrated 1,500 feet of intensely quartz-sericite-pyrite-magnetite-gypsum-anhydrite-biotite altered Jurassic

andesite with large intervals of hydrothermal breccia and some porphyry and granite dikes Some notable intercepts were 18 feet with 1.88 grams of gold per tonne, 3.7 feet with 5.89 grams of gold per ton, and 24.9 feet with 1.21 grams of gold per ton. Flanders suggest that the rocks overlay a buried intrusive that is the source of the gold.

In 2011, Nyac Gold LLC performed prospecting and diamond drilling at Saddle Mountain to test a mineralized breccia pipe with deep holes. Reconnaissance mapping was conducted, in addition to magnetic susceptibility readings at outcrops and talus exposures (Flanders and others, 2011).

In 2012, Nyac Gold LLC completed prospecting activities, reconnaissance mapping, in addition to diamond drilling at Saddle Mountain to test a mineralized breccia pipe with deep holes (Flanders and others, 2012).

In 2013, Nyac Gold LLC completed prospecting activities and seven diamond drill holes totaling 8,248 feet. Major oxide and trace element analyses were conducted on plutonic rocks but the results were not available as of the revision date of this report (Flanders, 2013).

Alteration:

Silicification, sericitization, and carbonate replacement (Wenz 2004, 2005).

Age of mineralization:

Wenz (2004) reports Ar-Ar ages of 113 +/- 1 Ma of intrusive rocks near this prospect.

Generic deposit model:

Deposit model:

Gold-quartz veins over a possible intrusion-related-gold deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 2005, Tonogold Resources, Inc. (2006) negotiated a mining lease agreement with Calista Corporation covering the Nyac area. They completed detailed soil geochemical surveys in several areas including this prospect in the summer of 2005. In 2006, they markedly expanded the soil survey around this prospect, mapped the surface in the vicinity, and cut several trenches. In 2010, Nyac Mining LLC, drilled several hole near the Saddle prospect (Flanders, 2010).

In 2011, Nyac Gold LLC performed prospecting and diamond drilling at Saddle Mountain to test a mineralized breccia pipe with deep holes. Reconnaissance mapping was conducted, in addition to magnetic susceptibility readings at outcrops and talus exposures (Flanders and others, 2011).

In 2012, Nyac Gold LLC completed prospecting activities, reconnaissance mapping, in addition to diamond drilling at Saddle Mountain to test a mineralized breccia pipe with deep holes (Flanders and others, 2012).

In 2013, Nyac Gold LLC completed prospecting activities and seven diamond drill holes totaling 8,248 feet. Major oxide and trace element analyses were conducted on plutonic rocks but the results were not available as of the revision date of this report (Flanders, 2013).

Production notes:

None.

Reserves:

None.

Site name(s): Bonanza Creek

Site type: Mine

ARDF no.: RM031

Latitude: 61.0704 **Quadrangle:** RM A-3

Longitude: 159.7587

Location description and accuracy:

Bonanza Creek is a southeast-flowing. tributary to upper Bear Creek. The coordinates are at about the center of the tailings on lower Bonanza Creek in about the center of section 4, T. 11 N., R. 59 W., of the Seward Meridian.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Most of the early placer mining on Bonanza Creek was near the mouth of the creek where it cuts through bench and flood-plain deposits of Bear Creek (Maddren, (1915). It is not well documented but there was some mechanized mining for about a half mile up from the mouth of the creek in the 1980s or 1990s (?) based on the presence of tailings, the abandoned heavy equipment, and a small camp in the NW1/4 of section 4 (D.J. Grybeck, field work, 2006). There does not appear to be any significant dredging on Bonanza Creek above its mouth. In 2006, the local miners considered upper Bonanza Creek as too deep and wet to placer mine (personal communications to D.J. Grybeck, 2006).

The bedrock on Bonanza Creek includes granitic rock with malachite-bearing quartz stringers (Maddren, 1915), but most of the bedrock in the Bonanza Creek drainage is Jurassic volcanic rocks locally intruded and thermally metamorphosed by mid-Cretaceous granitic rocks (Box and others, 1993; Wenz, 2005).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

There was at least some mining near the mouth of Bonanza Creek prior to 1915. There was also considerable mechanized mining for about a half mile above its mouth in the 1980s or 1990s (?) but apparently there has been no significant dredging on Bonanza Creek.

Production notes:

Some unrecorded production into the 1990s but probably not large.

Reserves:

None.

Site name(s): Bear Creek

Site type: Mine

ARDF no.: RM032

Latitude: 61.0513 **Quadrangle:** RM A-3

Longitude: 159.7887

Location description and accuracy:

Bear Creek is a large, northeast headwater tributary to the Tuluksak River. Bear Creek has been mined extensively by dredge and mechanized equipment for about 7 miles from about 2 miles above the mouth of Bonanza Creek, downstream to just below the mouth of Shamrock Creek. The coordinates are at about the midpoint of the productive part of the creek, about 0.5 mile south of the center of section 8, T. 11 N., R. 59 W., of the Seward Meridian. This is locality 20 of Hoare and Cobb (1972, 1977). The location is probably accurate to within 1,000 feet.

Commodities:

Main: Au

Other: Hg, Pt

Ore minerals: Cinnabar, gold, platinum

Gangue minerals:

Geologic description:

Gold was first discovered in the Nyac district on Bear Creek near the mouth of Bonanza Creek in 1907 or 1908 (Maddren (1915; Mining World, 1941) and gold was discovered soon after on the Tuluksak River (RM028). For many years thereafter the mining in the district, including on Bear Creek, was carried out by the New York-Alaska Company and its successor the New York Gold Dredging Company, which built a company town at Nyac on the Tuluksak River. In 1990, Nyac Mining Company began mining in the area, primarily on Spruce Creek and Bear Creek under an agreement with the Calista Native Corporation which owns most of the placer claims in the district.

A small wood-hulled dredge mined on Bear Creek from 1926 to 1936 when its parts were used to build another dredge on the Tuluksak River (Mining World, 1941). Another steel-hulled dredge operated from at least 1973(?) to 1991 on upper Bear Creek; it mined to about a mile above the mouth of Bonanza Creek where it remained in 2006 (Bundtzen and others, 1991; Tom Ratledge, personal communication, 2006). In addition to dredging there has been extensive mining using various mechanized equipment from soon after gold was discovered to as late as 2004 or 2005. In many places the workings extend for a thousand feet or more across the creek. A year or more prior to 2006, the Nyac Mining Company mined a cut with mechanized equipment about 2 miles above the mouth of Bonanza Creek; the area has now been reclaimed (D.J. Grybeck, personal observation, 2006).

There seems to be little indication of mining on Bear Creek from below the mouth of Shamrock Creek to the Tuluksak River. The reasons are unclear and several explanations are currently held among the miners in the area (D.J. Grybeck, personal conversations during field work, 2006). One is that the area was drilled and the gold values were not encouraging; another is that the ground is too deep and/or too wet to dredge.

Production figures are not available for the long history of mining on Bear Creek but the district as a whole has produced more than 600,000 ounces of gold and a significant portion of that came from Bear Creek (Calista Corporation, 2008).

Joesting (1942) reported that some platinum was produced with the gold and that asbestos and graphite were dredged from bedrock. There is little evidence that a significant amount of platinum was produced.

Cinnabar is common in placer concentrates from Bear Creek (Jim Anderson, personal communication, 2006) and quartz veins with cinnabar that cut boulders can be found in the tailings along Bear Creek (Melanie Werdon, personal communication, 2006).

Most of the rocks in the drainage basin of Bear Creek are hornfelsed or regionally metamorphosed Jurassic volcanic and sedimentary rocks cut by mid-Cretaceous granitic plutons and Jurassic gabbro (Box and others, 1993; Wenz, 2005).

A small wood-hulled dredge mined on Bear Creek from 1926 to 1936 when its parts were used to build another dredge on the Tuluksak River (Mining World, 1941). Another steel-hulled dredge operated from at least 1973(?) to 1991 on upper Bear Creek; it mined to about a mile above the mouth of Bonanza Creek where it remained in 2006 (Bundtzen and others, 1991; Tom Ratledge, personal communication, 2006). In addition to dredging there has been extensive mining using various mechanized equipment from soon after gold was discovered to as late as 2004 or 2005. In many places the workings extend for a thousand feet or more across the creek. A year or more prior to 2006, the Nyac Mining Company mined a cut with mechanized equipment about 2 miles above the mouth of Bonanza Creek; the area has now been reclaimed (D.J. Grybeck, personal observation, 2006).

There seems to be little indication of mining on Bear Creek from below the mouth of Shamrock Creek to the Tuluksak River. The reasons are unclear and several explanations are currently held among the miners in the area (D.J. Grybeck, personal conversations during field work, 2006). One is that the area was drilled and the gold values were not encouraging; another is that the ground is too deep and/or too wet to dredge.

The first hardrock exploration holes at Nyac were drilled by Placer Dome Exploration Inc. in 1996. Placer Dome drilled eleven reverse circulation holes through the gold-bearing valley gravels of Bear Creek (Strachan, 2008). Placer Dome’s drill holes were restricted to the valleys in the apparent belief that Nyac’s placers were derived directly from the underlying bedrock (Wenz, 2005).

Production notes:

Production figures are not available for the long history of mining on Bear Creek but the district as a whole has more than 600,000 ounces of gold; a significant portion of that came from Bear Creek (Calista,

2008).

Reserves:

None a matter of public record but some gold probably remains to be mined.

Site name(s): Spruce Creek

Site type: Mine

ARDF no.: RM033

Latitude: 61.0671 **Quadrangle:** RM A-3

Longitude: 159.7804

Location description and accuracy:

The location of Spruce Creek is probably incorrect on the USGS 1:63,360 topographic map. It is probably the first creek southwest of Bonanza Creek (RM031); both are east-flowing tributaries of upper Bear Creek. In 2006, the local miners place Spruce Creek in sections 5 and 8, T. 11 N., R. 59 W., of the Seward Meridian (D.J. Grybeck, field work and discussions with miners in the area, 2006).

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Early reports indicated that the lower part of Spruce Creek was placer mined where it crosses bench deposits along Bear Creek. As described by Maddren (1915), gravel deposits at the mouth of the creek are as much as 400 feet thick. Gravels along the active drainage are 20 to 30 feet thick 1,500 feet upstream of the mouth, and the headwaters of the creek cut into bedrock. Where the alluvial deposits are 20 to 30 feet thick, they consist of 2 to 4 feet of muck, 2 to 3 feet of coarse gravel with boulders as much as 1 foot in diameter, 1 to 1.5 feet of blue clay, and brown sandy and pebbly clay to bedrock. Most of the gold occurred in the blue and brown pebbly clays and on bedrock. Some of the gold was coarse and attached to quartz. Maddren (1915) thought that the gold could have been derived from the contact zone around an intrusion at the head of the creek. Bedrock in the Spruce Creek drainage includes thermally metamorphosed Jurassic volcanic rocks developed around a mid-Cretaceous granitic stock (Box and others, 1993; Wenz, 2005).

The location of the Spruce Creek that Maddren (1915) described is somewhat uncertain. The Spruce Creek labeled on the current USGS 1:63,360-scale topographic map is not in the same location as the Spruce Creek known to the miners working in the area in 2006. The Spruce Creek on the topographic map is generally parallel to and about two miles to the southwest of Bonanza Creek. The local miners consider Spruce Creek to be the creek generally parallel to and about 1 mile southwest of Bonanza Creek in sections 5 and 8.

In the late 1990s Nyac Mining Company mined extensively on the Spruce Creek about a mile southwest of Bonanza Creek and produced a minimum of 25,000 ounces of gold (Wenz, 2005). The area has now been reclaimed. It is uncertain whether the mining prior to 1915 was on the Spruce Creek as labeled on the current topographic maps or on the parallel nearby creek about a mile southwest of Bonanza Creek that was mined by Nyac Mining Company in the 1990s.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

Open-cut placer mining took place along lower Spruce Creek until about 1920. Some of this work included a 280-foot long, 15- to 20-foot wide, and 10-foot-deep trench built as a bedrock drain. In the 1990s, Nyac Mining Company mined extensively on Spruce Creek from surface cuts. (But see the location and geologic description for the uncertainty of the location of Spruce Creek.)

Production notes:

In the 1990s, Nyac Mining Company produced a minimum of 25,000 ounces of gold from Spruce Creek. (But see the location and geologic description for the uncertainty of the location of Spruce Creek.)

Reserves:

None.

Last report date: 2008-03-04

Site name(s): Pipe

Site type: Prospect

ARDF no.: RM035

Latitude: 61.0764 **Quadrangle:** RM A-3

Longitude: 159.8952

Location description and accuracy:

This prospect is on the east flank of the ridge on the west side of California Creek. It is about 0.4 mile northeast of the center of section 3, T. 11 N., R. 60 W., of the Seward Meridian. The prospect occupies most of this NE 1/4 section. The location is probably accurate to within 1,000 feet.

Commodities:

Main: Au

Other:

Ore minerals: Gold, magnetite, pyrite

Gangue minerals: Anhydrite, biotite, quartz, sericite

Geologic description:

The Pipe prospect was identified by a soil sample survey completed by Tonogold Resources, Inc. in the summer of 2005 (Strachan, 2005). Regional mapping by Box and others (1993) was supplemented by more detailed mapping by Wenz (2005) who inferred presence of Jurassic plutons not recognized by Box and others (1993).

The rocks at the Pipe prospect are Jurassic volcanic rocks that have been hornfelsed by inferred Jurassic diorite sills intruding them (Wenz, 2004, 2005). The Pipe prospect lies west of Rocky Ridge (RM036) along a structural strike which intersects a northeast structural trend. This northeast structural trend is marked by magnetics, dacite dikes, veins, and geochemistry at Wallace (RM025) (Strachan, 2005).

As of 2009, Nyac Gold LLC has a mining lease agreement with Calista Corporation covering the Nyac area, which includes this prospect (Flanders and others, 2009).

Alteration:

Hornfels of sedimentary rocks by intruding Jurassic diorite sills and Cretaceous intermediate composition plutons (Wenz, 2004, 2005).

Age of mineralization:

Probably mid-Cretaceous as at the Bonanza Ridge prospect, ARDF number RM037 (Wenz, 2004, 2005).

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Tonogold completed detailed soil geochemical surveys in several areas in 2005 and the Pipe prospect was identified by that survey (Strachan, 2005).

As of 2009, Nyac Gold LLC has a mining lease agreement with Calista Corporation covering the Nyac area, which includes this prospect (Flanders and others, 2009).

Production notes:

None.

Reserves:

None.

Additional comments:

Tonogold Resources, Inc. (2006) has a mining lease agreement with Calista Corporation covering the Nyac area, which includes this prospect.

Last report date: 2016-03-15

Site name(s): Rocky Ridge

Site type: Prospect

ARDF no.: RM036

Latitude: 61.0753

Quadrangle: RM A-3

Longitude: 159.8733

Location description and accuracy:

The Rocky Ridge prospect is on the ridge between Rocky Creek and California Creek, about 1.0 mile southwest of triangulation station Bonanza. It is about 0.2 mile north of the center of section 2, T. 11 N., R. 60 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

The Rocky Ridge prospect is an area of anomalous soil and rock samples on the ridge between Rocky Creek and California Creek. Bedrock in the area is Jurassic sedimentary and volcanic rocks (Box and others, 1993; Wenz, 2004, 2005; Strachan, 2005). Tonogold Resources, Inc. (2006) has a mining lease agreement with Calista Corporation covering the Nyac area. They completed detailed soil geochemical surveys in several areas including this prospect in the summer of 2005. Strachan (2005) shows a map of soil sample sites in the area of this prospect; several samples contain several hundred parts per billion gold.

Alteration:

Age of mineralization:

Probably mid-Cretaceous as at the Bonanza Ridge prospect (RM037).

Generic deposit model:

Deposit model:

Low-sulfide Au-Bi-Te-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Tonogold Resources, Inc. has a mining lease agreement with Calista Corporation covering the Nyac area (http://www.tonogold.com/s/Nyac.asp; Apr. 2006). They completed detailed soil geochemical surveys in several areas including this prospect in the summer of 2005 and 2006.

Production notes:

None.

Reserves:

None.

Site name(s): VABM Bonanza; Bonanza Ridge

Site type: Prospect

ARDF no.: RM037

Latitude: 61.0729 **Quadrangle:** RM A-3

Longitude: 159.8453

Location description and accuracy:

This prospect about a half mile east of the head of Rocky Creek in the Nyac district. It is at an elevation of about 2650 feet, about 0.3 mile southwest of triangulation station Bonanza near the center of section 1, T. 11 N., R. 60 W., of the Seward Meridian. This location is accurate to within 1000 feet of the center of the prospect.

Commodities:

Main: Au

Other:

Ore minerals: Bismuthinite, chalcopyrite, gold, magnetite, molybdenite, pyrite

Gangue minerals: Carbonate, chlorite, quartz, sericite

Geologic description:

At this prospect, gold-bearing quartz veins cut granitic rocks of the Bonanza pluton (Wenz, 2004, 2005). The Bonanza pluton is a composite intrusion; it has a margin of diorite, quartz diorite, tonalite, and monzodiorite around a core of granodiorite and granite. Mafic minerals make up 10 to 25 percent of the intrusive; they include biotite, hornblende, and minor pyroxene. The more mafic parts of the pluton can have up to one percent apatite. Argon-argon radiometric ages reported by Wenz (2004, 2005) for this pluton are 109 +/- 1 Ma, 113 +/- 0.4 Ma, and 113 +/- 1 Ma.

As described by Wenz, quartz veining makes up to one to two percent of the more strongly mineralized rocks. Potassic alteration includes narrow K-feldspar-bearing selvages along barren quartz veins. Gold-bearing veins with sericite-chlorite-carbonate alteration overprint the potassic alteration. Ore minerals in the gold-bearing veins include pyrite, chalcopyrite, magnetite, bismuthinite, molybdenite, and native gold; pyrite and chalcopyrite are the most abundant. The highest gold value reported by Wenz (2004, 2005) is 20.8 parts per million (ppm). Both bismuth and tellurium correlate closely with gold. Primary fluid inclusions indicate a wide range of homogenization temperatures of from 221 to 486 degrees centigrade and the salinities vary from 21.3 to 54.7 weight percent NaCl.

Tonogold Resources, Inc. has a mining lease agreement with Calista Corporation covering the Nyac area (Tonogold Resources, Inc., 2006). They completed detailed soil geochemical surveys in several areas including this prospect in the summer of 2005. Tonogold reported that 58 of 518 surface samples contained 0.105 to 2.86 ppm gold. Seven rock chip samples contained 0.121 to 15.1 ppm gold. There is a strong correlation of bismuth and gold values in these samples. Arsenic values are low.

Tonogold (2007) drilled 4 holes at the Bonanza prospect in the summer of 2006. The drilling encountered a series of quartz-calcite-pyrite-chalcopyrite veinlets associated with an aplite dike in sericitically-altered granodiorite. The alteration increases downward in each of the holes. Numerous veinlets and mineralized fractures were cut; there were several 2-meter intercepts with up to 1.0 gram of gold per ton and the best intercept was 0.6 meter with 8.6 gram of gold per ton.

Since at least as early as 2009, Nyac Gold LLC has been operating summer exploration programs on behalf of Calista Corporation (Flanders and others, 2009).

In 2009, Nyac Gold LLC completed prospecting and drilling at VABM Bonanza. This work resulted in

identifying various mineralized breccias that were tentatively interpreted to result from breccia-hosted or porphyry-style gold mineralization (Flanders and others, 2009). In 2010, Nyac performed reconnaissance prospecting and drilling at VABM Bonanza. The prospecting generated additional understanding of the plutonic rocks and their contacts in the areas, while the drilling resulted in identification of gold mineralization subsurface (Flanders and others, 2010).

Alteration:

The gold-bearing quartz veins are accompanied by envelopes of sericite-chlorite-carbonate alteration. These veins and alteration overprint earlier quartz veins with some narrow K-feldspar-bearing alteration selvages (Wenz, 2005).

Age of mineralization:

The Bonanza pluton that hosts the deposit is 109 to 113 Ma (Wenz, 2004, 2005). Wenz also reports a Ar-Ar age of 111 +/- 1 Ma for muscovite from a gold-bearing quartz vein in the Bonanza pluton.

Generic deposit model:

Deposit model:

Low-sulfide Au-Bi-Te-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): Shamrock Head

Site type: Prospect

ARDF no.: RM038

Latitude: 61.065 **Quadrangle:** RM A-3

Longitude: 159.8508

Location description and accuracy:

The Shamrock Head prospect is a drill site at an elevation of about 2,240 feet on a west-trending ridge about 1.0 mile south of triangulation station Bonanza. There are several other drill sites about a half mile to the west along Rocky Creek. The geochemical anomaly that defines this prospect extends west for about 1,500 feet and east for about a mile. The prospect is about 0.5 mile north-northwest of the center of section 12, T. 11 S., R. 60 W. The location is accurate.

Commodities:

Main: As, Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

The Shamrock Head prospect is outlined by a soil-geochemistry survey completed for Tonogold Resources, Inc. during the summer of 2005 (Strachan, 2005). Several samples contained a few hundred to several hundred parts per billion gold. The anomalous samples suggest a general east-west trend to the mineralized zone. At this prospect elevated arsenic correlates with gold in contrast to the high bismuth as at the Bonanza Ridge prospect about one mile to the north (RM037). Arsenic values in soils reach 1,390 parts per million. The rocks in the prospect area consist of Jurassic volcanic and intrusive rocks (Box and others, 1993; Wenz, 2004, 2005).

Tonogold (2007) drilled two holes at an elevation of about 2,240 feet on a west-trending ridge about 1 mile south of triangulation station Bonanza and three holes along Rocky Creek to the west.

Alteration:

Age of mineralization:

Probably mid-Cretaceous as at the Bonanza Ridge prospect (RM New A1014).

Generic deposit model:

Deposit model:

Low-sulfide Au-Bi-Te-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Shamrock Head prospect is defined by a soil geochemistry survey completed by Tonogold Resources, Inc. during the summer of 2005 (Strachan, 2005). Five holes were drilled on this prospect in 2006.

Production notes:

None.

Reserves:

None.

Site name(s): Shamrock Creek

Site type: Mine

ARDF no.: RM039

Latitude: 61.0364 **Quadrangle:** RM

Longitude: 159.8621

Location description and accuracy:

Shamrock Creek is a south-flowing tributary to Bear Creek in the Nyac area. The coordinates are at about the center of the area that was drilled in 2005 and 2006; the site is about 0.6 mile northeast of section 23, T. 11 N., R. 60 W. It is unclear how much of the creek will be mined but the drilling continued for about 0.8 mile above and below this point on the creek. Mining began near the upper end of the drilling in August 2006 but more drilling is likely or has already been done above the mining. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

There apparently is no public record of early mining or even prospecting on Shamrock Creek although it probably was at least prospected in view of the rich placers nearby that have been known for many years (D.J. Grybeck, personal observation, 2006). Nyac Mining Company mined a cut near the mouth of Shamrock Creek a few years prior to 2006. In 2005 and 2006, they churn drilled rows of holes across the creek from near its mouth to the northeast corner of section 14, i.e., about 1.6 miles above its mouth. The drill results were encouraging and in August, 2006, they began mining with mechanized equipment about 1.6 miles above the mouth of the creek and continued churn drilling above that. The gravel is fairly thin but contains much clay and Nyac Mining Company built a new washing plant in 2006 to deal with the clay.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer gold (Cox and Singer, 1986, model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Active

Site name(s): Blueberry

Site type: Prospect

ARDF no.: RM040

Latitude: 61.0691 **Quadrangle:** RM A-5

Longitude: 160.0637

Location description and accuracy:

This prospect is on the southwest flank of the ridge on the west side of Sabula Creek. It is located about 0.1 mile northeast of peak 'Granite', about 0.5 mile west-southwest of the center of section 2, T. 11 N., R. 60 W., of the Seward Meridian. This location is accurate to within 1000 feet of the center of the prospect.

Commodities:

Main: Cu

Other: Mo

Ore minerals: Chalcopyrite, molybdenite, pyrite

Gangue minerals: Biotite, chlorite, hornblende, sericite

Geologic description:

The Blueberry prospect comprises disseminated sulfide minerals in sericite- and chlorite-altered hornblende-biotite granite intruded into Cretaceous hornblende-biotite granodiorite of the Nyac Batholith. Mineralized rock has dominantly coarse-grained seriate to porphyritic textures and less abundant fine grained granular to quartz phyric (porphyry) and aplite. Distinctive features of the mineralized rock include common aquamarine-colored (blue-green) sericite-altered plagioclase phenocrysts in coarse-grained seriate and porphyritic varieties and chlorite alteration of biotite and hornblende. Sulfide minerals include pyrite, chalcopyrite and molybdenite. Chalcopyrite is far more abundant than molybdenite, but the fine-grained textural variety tends to be enriched in molybdenite relative to chalcopyrite. Molybdenite also appears to be more abundant in weakly altered coarse-grained granite distal from the more strongly altered and mineralized core. In some cases, the disseminated sulfide minerals are concentrated in altered hornblende crystals. These rocks and the finer aplite and quartz porphyry tend to be unusually hard and difficult to break, even with sledge hammers. The finer-grained varieties are commonly found at the margins of the mineralized surface exposure (Foley, 2011).

Soil samples collected and assayed in 2010 from several sites adjacent the Blueberry prospect have elevated copper and molybdenum values. It is anticipated that additional concentrations of sulfide minerals might be found in this area with additional prospecting (Foley, 2011).

Preliminary IP and resistivity plots show anomalies in the vicinity of the Blueberry prospect. Where shallow, these anomalies are coincident with observed sulfide minerals in altered rocks similar to those described in the core of the prospect. Furthermore, the preliminary plots indicate that the feature plunges to the east, and extends for approximately 1600 meters east to west (Foley, 2011).

It has been suggested that the physical properties of the mineralized rock, perhaps because of silicification that causes the unusual hardness, may explain the resistive characteristics as indicated by the preliminary data. It is further surmised that the relatively low sulfide content may account for the low to moderate IP signature of the feature (Foley, 2011).

Alteration:

Sericite-altered plagioclase, chlorite-altered biotite and hornblende. Molybdenite appears more abundant in the weakly altered zones (Foley, 2011).

Age of mineralization:

Younger than the Cretaceous host granodiorite of the Nyac Batholith that the mineralized granite is intruded into (Foley, 2011).

Generic deposit model:

Deposit model:

Unknown.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Undetermined

Site Status: Active

Workings/exploration:

Nyac Gold LLC operated summer exploration programs in 2010 and 2011 at Blueberry Prospect on behalf of Calista Corporation focused on prospecting and sampling (Foley, 2011; Flanders and others, 2011). In 2011, Zonge International conducted a geophysical field survey including acquisition of both gradient and pole-dipole array resistivity and induced polarization (IP) data. The objective of the geophysical program was to provide information on the distribution and occurrence of sulfides associated with poly-metallic mineral deposits (Zonge International, 2011).

In 2010, soil samples were collected and assayed; values for copper and molybdenum were elevated. The surface extent of exposed mineralized rock measured about 230 feet along the north-south axis and about 500 ft along the east-west axis. One result of the 2011 program was to the discovery of additional mineralized rock found outward of the core area at several sites. The presence of elevated copper and molybdenum values detected in soil samples at several sites outside the Blueberry prospect suggests that additional concentrations of sulfide minerals might be found with additional prospecting (Foley, 2011).

Production notes:

None.

Reserves:

None.

Site name(s): Spruce Creek (lode)

Site type: Occurrence

ARDF no.: RM041

Latitude: 61.0671

Quadrangle: RM A-3

Longitude: 159.7804

Location description and accuracy:

The location of Spruce Creek is probably incorrect on the USGS 1:63,360 topographic map. It is probably the first creek southwest of Bonanza Creek (RM031); both are east-flowing tributaries of upper Bear Creek. In 2006, the local miners place Spruce Creek in sections 5 and 8, T. 11 N., R. 59 W., of the Seward Meridian (D.J. Grybeck, field work and discussions with miners in the area, 2006). The location is probably accurate to within 1,000 feet.

Commodities:

Main: Ag, Au

Other: Pb, Zn

Ore minerals: Gold, galena, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

Spruce Creek has been known as a placer deposit (see RM033) since before 1915, when the earliest known report of mining evidence was made by Maddren (1915). The Spruce Creek occurrence may be the potential source for Spruce Creek placer gold. Bedrock in the Spruce Creek drainage includes thermally metamorphosed Jurassic volcanic rocks developed around a mid-Cretaceous granitic stock (Box and others, 1993; Wenz, 2005). Massive, unlayered porphyritic mafic flows varying in color from dark green to reddish to a distinct dark purple and interbedded layered, intermediate to felsic pyroclastics and poly-lithic volcaniclastics were encountered in two drill holes drilled by Nyac Gold LLC in 2013 (Flanders, 2013). The alteration observed in these two drill holes was silicification and silica-carbonate flooding adjacent to quartz veining and stockwork tectonized zones. Mineralization was found in yellowish-white calcite and quartz veining and translucent chalcedonic quartz veining in a foliated tectonized zone (Flanders, 2013).

In 2005-2006, a soils sampling program was conducted. In 2010, Nyac Gold LLC collected stream sediment samples at Spruce Creek (Flanders, 2013).

Alteration:

Alteration observed is silicification and silica-carbonate flooding adjacent to quartz veining and stockwork tectonized zones (Flanders, 2013).

Age of mineralization:

Mineralization likely associated with Cretaceous plutons (Flanders, 2013).

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Undetermined

Workings/exploration:

Open-cut placer mining took place along lower Spruce Creek until about 1920. Some of this work included a 280-foot long, 15- to 20-foot wide, and 10-foot-deep trench built as a bedrock drain. In the 1990s, Nyac Mining Company mined extensively on Spruce Creek from surface cuts.

In 2005-2006, a soil sampling program was conducted covering approximately half of a subtle aeromagnetic anomaly. In 2010, stream sediment samples were collected at Spruce Creek by Nyac Gold LLC (Flanders, 2013).

In 2013 Nyac Gold LLC drilled two holes targeting a fault zone exposed during placer mining and thought to be mineralized. Drill hole NYC13-03 intersected a 10-foot zone from 457 to 467 feet containing 32 ppb Au, 2.7 ppm Ag, 134 ppm Pb, 256 ppm Zn, and 4 ppm Mo. Another 10-foot mineralized interval in the same drill hole from 507 to 517 feet contained 0.220 gpt Au, 2.2 ppm Ag, 98 ppm Pb, 288 ppm Zn, and 6.1 ppm Cd (Flanders, 2013).

Production notes:

None.

Reserves:

None.

Geologic description:

This record is about the lode prospect near Shamrock Creek placer (RM039).

The host rock at Shamrock is Jurassic volcanic and volcaniclastic rock that has undergone mesothermal alteration. Mesothermal facies developed in the Nyac host rock are pervasive propylitic, hornfelsic, and silicic alteration, along with silica-sericite selvages enveloping mesothermal veins, veinlets, and fractures. Brown biotite hornfels developed in the andesitic volcanics represent a higher degree of mesothermal alteration, surrounded by pervasive greenish quartz-calcite-chlorite propylitic alteration (Strachan, 2008).

Mineralization occurs in auriferous quartz-calcite-pyrrhotite-chalcopyrite-pyrite veins and veinlets. Another vein type with a mineral assemblage associated with gold is quartz-chlorite-calcite-pyrite-chalcopyrite-bismuthinite-molybdenite-native gold. These veins and veinlets are later than the pervasive sericitic alteration. Silica selvage is well developed away from the vein in biotite hornfels (Strachan, 2008).

Alteration:

The host rock at Shamrock is Jurassic volcanic and volcaniclastic rock that has undergone mesothermal alteration. Mesothermal facies developed in the Nyac host rock are pervasive propylitic, hornfelsic, and silicic alteration, along with silica-sericite selvages enveloping mesothermal veins, veinlets, and fractures. Brown biotite hornfels developed in the andesitic volcanics represent a higher degree of mesothermal alteration, surrounded by pervasive greenish quartz-calcite-chlorite propylitic alteration (Strachan, 2008).

Age of mineralization:

Probably mid-Cretaceous as at the Bonanza Ridge prospect, ARDF number RM037 (Wenz, 2004, 2005).

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Systematic geochemical surveys have been completed in the Nyac Gold District by many entities, including Research Associates of Alaska, Placer Dome Exploration, Calista Native Corporation, Zachary Wenz, and Tonogold Resources, Inc. These surveys included collection and assaying of rock chip, soil, stream, alluvial, and pan concentrate samples (Strachan, 2008).

In 2005-2006, Tonogold Resources Inc. explored for the bedrock source of gold from the productive drainages near active placer Shamrock Creek (RM039). This effort included outcrop mapping and sampling. 3,149 grid soils samples collected in 2005 resulted in 323 (10.3 percent) assaying more than 0.1 parts per million (ppm) gold. 3,594 samples collected in 2006 resulted in 122 (5.2 percent) assaying over 0.1 ppm gold (Strachan, 2008).

In 2013, Nyac Gold LLC conducted prospecting, drilling, sampling, and petrographic work at Shamrock Creek in order to determine the extent of and complex nature of the intrusive and gold mineralization (Flanders, 2013).

Production notes:

None.

Reserves:

None.

Additional comments:

Mining on the placer Shamrock Creek (RM039) began in August 2006 (Strachan, 2008).

Site name(s): Ivanof; Kawisgag

Site type: Prospect

ARDF no.: SB001

Latitude: 55.8876 **Quadrangle:** SB D-5

Longitude: 159.4223

Location description and accuracy:

The Ivanof prospect is on a peninsula between Humpback and Ivanof Bays. It covers an area several miles in diameter, northwest of triangulation station Short. It is at an elevation of about 1,250 feet, at the midpoint of the boundary between secs. 1 and 36, T. 49 and 50 S., R. 65 W, of the Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Mo

Other: As, Pb, Zn

Ore minerals: Arsenopyrite, bornite, chalcopyrite, covellite, gold, molybdenite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The Ivanof prospect is in sandstone, grits, and conglomerates of the Eocene to Paleocene Tolstoi Formation which is are cut by an intrusive complex (Fields, 1977; Wilson and others, 1995). Biotite from the complex has been dated at 7 million years (Wilson and others, 1994). The sedimentary rock near the complex exhibits intense thermal metamorphism which formed biotite-quartz hornfels.

The intrusive complex, best exposed in two cirque basins, consists of an early diorite porphyry phase and a later, more extensive, quartz porphyry phase. The quartz porphyry intrudes the diorite as well as the Tolstoy Formation. Peripheral sills and dikes similar in composition to the intrusive complex cut the sedimentary units.

Both intrusive phases are mineralized, but only the diorite porphyry contains copper-molybdenum values. The sulfide mineralization, which includes arsenopyrite, pyrite, pyrrhotite, chalcopyrite, bornite, and covellite, covers an area of approximately 2 by 2.5 miles. In the quartz porphyry, pyrite is pervasive as disseminations and fracture fillings as well as in the sedimentary rocks throughout a 3-square-mile area. Two zones of copper-molybdenum-quartz stockwork mineralization were outlined by Bear Creek Mining (Fields, 1977); each extends over an area of approximately 2,000 by 600 feet and occurs in the diorite as well as in the surrounding sedimentary rocks. Base metal values in rock samples collected at the surface were from 500 to 1,700 parts per million (ppm) copper and 20 to 240 ppm molybdenum, with weakly anomalous gold values. Fields describes the pyrite:chalcopyrite ratio as 1:1 to 2:1 in the main mineralized areas and 5:1 to 10:1 in surrounding areas. Rock samples collected by Resource Associates of Alaska in 1979 in the northern cirque contained as much as to 790 parts per million (ppm) copper, 2,400 ppm molybdenum, and 2.4 ppm silver.

Farnstrom (1991) associates the mineralization with two separate, intersecting quartz-sulfide stockworks. The older stockwork consists of quartz-sulfide-chlorite veinlets in the diorite porphyry that are traceable for as much as to 3,000 feet into the sedimentary rocks. These veinlets contain pyrite, pyrrhotite, and chalcopyrite. Pyrite:chalcopyrite ratios exceed 5:1. The younger stockwork consists of veinlets as much as 0.4 inch wide containing pyrite, molybdenite, and only trace amounts of chalcopyrite, covellite, bornite, and malachite. According to Farnstrom (1991), the distribution of the copper-rich stockwork is spotty; the best deposits are at the contact of the diorite porphyry and the sedimentary country rocks.

In 1979, Resource Associates of Alaska discovered quartz veins with gold and arsenopyrite in areas peripheral to the copper-molybdenum mineralization (Moller and others, 1982). Some of these veins are as much as 30 feet wide and can be traced for as much as 2,400 feet along strike. They typically are 5 to 8 feet. wide and contain 0.08 to 0.20 ounce of gold per ton.

Strong secondary biotite is localized in and around the diorite porphyry over an area approximately 1,000 feet in diameter. Widespread sericitic alteration surrounds the biotite zone and coincides with the pyritic halo. Propylitic alteration forms an outer zone of alteration (Fields, 1977).

Farnstrom (1991) described the alteration in and around the diorite porphyry as relatively slight. Mineralized areas, however, are marked by intense bleaching and silicification. According to Farnstrom, chlorite replaces mafic minerals, and also occurs in stockwork veinlets in both intrusive phases. In the diorite, the chlorite is accompanied by epidote. Feldspars in both intrusive phases are altered to sericite, but this type of alteration tends to be more intense in the quartz porphyry. In contrast to Field's (1977) pattern, Farnstrom did not recognize a zonal pattern of alteration. Some of the alteration she describes may be deuteric in origin rather than hydrothermal.

In 2005 and 2006, Metallica Resource Inc. (2008) under an option agreement with Full Metal Minerals that in turn has access to the land under an agreement with several Native corporations, mapped and sampled the prospect and carried out ground geophysical surveys to define targets for future drilling.

Alteration:

According to Fields (1977), the alteration exhibits a zonal pattern with a central potassic core surrounded by a phyllic zone and an outer propylitic zone. Farnstrom (1991) describes sericitic (phyllic) alteration that is related in part to mineralization. The mineralized areas are also marked by intense bleaching and silicification.

Age of mineralization:

Seven million years or younger, based on radiometric dating.

Generic deposit model:

Deposit model:

Porphyry Cu, Porphyry Cu-Mo, Porphyry Cu-Au (Cox and Singer, 1986; models 17, 21a, 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

17, 21a, 20c

Production Status: None

Site Status: Active

Workings/exploration:

Bear Creek Mining mapped and sampled this prospect for Bristol Bay Native Corporation in the 1970s (Fields, 1977). Resource Associates of Alaska mapped and sampled the deposit in the mid 1980s, and ran approximately 9 line miles of VLF-EM and magnetic surveys. The U.S. Geological Survey sampled the deposit in the mid-1980s. Cominco mapped and sampled the deposit in 1990 (Farnstrom, 1991). In 2005 and 2006, Metallica Resource Inc. (2008) mapped and sampled the prospect and carried out ground geophysical surveys to define targets for future drilling.

Production notes:

None.

Reserves:

None.

Additional comments:

This prospect is on land interim-conveyed to, or patented by the Bristol Bay Native Corporation.

Last report date: 2008-06-05

Site name(s): Unnamed (near Pinta Point)

Site type: Occurrence

ARDF no.: SD070

Latitude: 57.0981 **Quadrangle:** SD A-6

Longitude: 133.8839

Location description and accuracy:

This occurrence is along about 500 feet of the shoreline just east of Pinta Point on the northern tip of Kupreanof Island. It is near the northeast corner of section 24, T. 85 S., R. 72 E. The location is accurate.

Commodities:

Main: Au, Cu, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, pyrrhotite, sphalerite.

Gangue minerals:

Geologic description:

This occurrence was discovered and first described by Still and others (2002) as part of a Bureau of Land Management mineral assessment. The rocks at the occurrence consist of siliceous, dark gray, well-foliated graphitic schist that is tightly folded and multiply deformed. Nearby, the unit includes limestone, chert, felsic schist, and greenstone; Brew and others (1984) mapped it as metamorphosed Stephens Passage Group of late Mesozoic age.

The schist near Pinta Point contains finely disseminated sulfides and sulfide-rich layers for about 500 feet of shoreline. The sulfides locally make up as much as 30 percent of the schist in layers up to 1 foot thick. One 15-foot-thick layer consists of about 10 percent sulfides across its entire width. The sulfides are mainly pyrite and pyrrhotite with minor sphalerite and chalcopyrite. A representative sample across 11 feet of the 15-foot-thick layer contained 43 parts per billion gold, 143 parts per million (ppm) copper, and 624 ppm zinc.

Alteration:

Age of mineralization:

Probably contemporaneous with the Upper Mesozoic host rock.

Generic deposit model:

Deposit model:

Sulfides in layers and disseminations in schist; possibly a volcanogenic massive sulfide deposit.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only sampling by government geologists who first discovered the occurrences in the late 1990s.

Production notes:

None.

Reserves:

None.

Location description and accuracy:

The Boundary prospect is along and just to the east of the Alaska-Canada border, about 1.8 miles south of Mt. Henry Clay at 5,700 to 6,000 feet elevation. It is about 0.4 mile south-southeast of the center of section 15, T. 29 S., R. 53 E. The location is accurate.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other: As, Co

Ore minerals: Barite, chalcopyrite, pyrite, pyrrhotite

Gangue minerals: Barite, calcite, quartz

Geologic description:

Mineralization in this area was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies including Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and 1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004. It was also mapped and sampled by the U.S. Geological Survey (MacKevett 1974) and the U.S. Bureau of Mines (Still, 1984), and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources acquired the property under a long-term lease and they have been actively explored it to the present (early 2011). Their work has included detailed geologic mapping and sampling, and ground geochemical and geophysical surveys. The Boundary prospect, the southwestern-most prospect in the area has almost certainly been mapped, sampled, and covered by geochemical and geophysical surveys by several of the companies that have worked in the area. It is now part of the large block of claims held by Constantine. It has not been drilled.

The rocks in the region are part of the Upper Triassic Hyd Group that hosts similar volcanic massive sulfide deposits the length of southeastern Alaska (Newberry and others, 1997). The rocks are predominantly massive and pillow basalts and fragmental basalt and andesite(?), intercalated with siltston, tuff, and rare rhyolite flows and dikes. They have been subject to greenschist-facies metamorphism; folding and faulting locally repeats the stratigraphy in places, and the rocks are highly altered.

Still and others (1991) describe this prospect as: 'Narrow bands of iron-stained metasedimentary rocks and altered metabasalt that crop out through glacial ice. Float and bedrock samples of sedimentary and volcanic rocks contained up to 0.034 parts per million (ppm) gold, 1.214 ppm silver, 280 ppm zinc, 1,390 ppm copper, 390 ppm cobalt, 400 ppm arsenic, and 200 ppm nickel. A barite-rich band in white phyllite contained 47 percent barium. Rubicon Minerals (1998) in an unpublished Executive Summary, cites work by Kennecott Alaska Exploration that describes the Boundary prospect as: '...quartz-sericite-pyrite schist and felsite with chalcopyrite.' Rubicon also cites Kennecott samples that contained up to 6.5 percent copper, 16 ppm lead, 3,610 ppm zinc, 12 ppm silver, and 1.980 ppm gold. More recently, Constantine found barite-sulfide boulders that contained up to 2.28 percent copper, 19.7 percent zinc, and 0.61 parts per million gold.

There have been several published studies of the mineral deposits in the area by government and academe (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that the they are Late Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

Quartz-sericite-pyrite alteration associated with baritic massive-sulfide mineralization.

Age of mineralization:

Late Triassic by analogy with other similar deposits of that age along the length of southeastern Alaska and into Canada.

Generic deposit model:

Deposit model:

Besshi- or Kuroko-type massive sulfide? (Cox and Singer, 1986; models 28a? or 24b?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a? or 24b?

Production Status: None

Site Status: Active

Ore minerals: Barite, chalcopyrite, galena, gold, pyrite, sphalerite, sulfosalts?

Gangue minerals: Quartz, sericite

Geologic description:

Mineralization in this area was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies including Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and 1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004. It was also mapped and sampled by the U.S. Geological Survey (MacKevett 1974) and the U.S. Bureau of Mines (Still, 1984), and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources acquired the property under a long-term lease and they have been actively explored it to the present (early 2011). Their work has included detailed geologic mapping and sampling, ground geochemical and geophysical surveys. The Nunatak prospect has been mapped, sampled, and covered by geochemical and geophysical surveys by several of the companies that have worked in the area. It is now part of the large block of claims held by Constantine. It has not been drilled.

The rocks in the region are part of the Upper Triassic Hyd Group that hosts similar volcanic massive sulfide deposits the length of southeastern Alaska (Newberry and others, 1997). The rocks are predominantly massive and pillow basalts and fragmental basalt and andesite(?), intercalated with siltston, tuff, and rare rhyolite flows and dikes. They have been subject to greenschist-facies metamorphism; folding and faulting locally repeats the stratigraphy in places, and the rocks are highly altered.

The prospect is in intensely quartz-sericite-pyrite-altered and iron-stained schist and altered volcanic rocks more than 100 feet thick exposed for 1,500 feet across the face of a nunatak (MacKevett and others, 1974; Still, 1984; Greig and Giroux, 2010). Barite lenses and beds up to 6 meters thick occur in the altered rocks. The mineral assemblage and field relationships are similar to those at the Glacier Creek prospect (SK066) (MacKevett and others, 1974). Samples of the baritic rock contain up to 2.58 parts per million (ppm) gold, 335.3 ppm silver, 2.38 percent zinc, 1,820 ppm copper, 2.0 percent lead, 48 percent barite, and 1,000 ppm arsenic. A 200-pound sample collected by Merrill Palmer was divided into 13 parts and analyzed by Newmont Gold Company. The samples averaged 11.84 ounces of silver per ton and 0.092 ounce of gold per ton. This prospect lies along a northwesterly mineral trend that extends through the Cap prospect (SK060) to the Mount Henry Clay prospect (SK068). Rubicon Minerals believed that these prospects occur at the same mineralized stratigraphic horizon and attributes their distribution to a

northwest-trending, gently plunging antiform that brings the massive-sulfide horizon close to the surface (Rubicon Minerals, 1998).

There have been several published studies of the mineral deposits in the area by government and academe (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that the they are Late Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

Intense quartz-sericite-pyrite alteration adjacent to baritic massive-sulfide layers.

Age of mineralization:

Late Triassic by analogy with other similar deposits of that age along the length of southeastern Alaska and into Canada.

Generic deposit model:

Deposit model:

Besshi- or Kuroko-type volcanogenic massive sulfide deposit (Cox and Singer, 1986; models 24b or 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b or 28a

Production Status: None

Site Status: Active

Workings/exploration:

Mineralization in this area was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies including Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and 1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004. It was also mapped and sampled by the U.S. Geological Survey (MacKevett 1974) and the U.S. Bureau of Mines (Still, 1984), and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources acquired the property under a long-term lease and they have been actively explored it to the present (early 2011). Their work has included detailed geologic mapping and sampling, and ground geochemical and geophysical surveys. The Nunatak prospect has undoubtedly been mapped, sampled, and covered by geochemical and geophysical surveys by several of the companies that have worked in the area. It is now part of the large block of claims held by Constantine. It has not been drilled.

Production notes:

None.

Reserves:

None.

Site name(s): Cap

Site type: Prospect

ARDF no.: SK060

Latitude: 59.3775 **Quadrangle:** SK B-4

Longitude: 136.4185

Location description and accuracy:

The Cap prospect is near the north edge of Saksaia Glacier at an elevation of about 3,800 feet. It is approximately 2.1 miles east of Mt. Henry Clay and about 0.6 mile south-southwest of the center of Section 1, T. 29 E., R. 53 E., of the Copper River Meridian. The location is accurate within 500 feet.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other: Co, Sb

Ore minerals: Acanthite, barite, galena, pyrargyrite, pyrite, sphalerite, tetrahedrite

Gangue minerals: Calcite, quartz

Geologic description:

The rocks in the region are part of the Upper Triassic Hyd Group that hosts similar volcanic massive sulfide deposits the length of southeastern Alaska (Newberry and others, 1997). The rocks are predominantly massive and pillow basalts and fragmental basalt and andesite(?), intercalated with siltstone, tuff, and rare rhyolite flows and dikes. They have been subject to greenschist-facies metamorphism; folding and faulting locally repeats the stratigraphy in places, and the rocks are highly altered.

As described by Still (1984) and Still and others (1991), the Cap prospect consists of barite-rich sulfide lenses up to 8 feet thick in a 50-foot-thick, 220-foot-long, iron-stained zone capped by volcanics that outcrop above the Saksaia glacier. The full extent of the prospect is hidden by glacier and surficial material. The barite lenses contain pyrite, sphalerite, galena, and tetrahedrite. Samples contained up to 50 percent barium, 1.1 percent zinc, 0.33 percent lead, 277.7 parts per million (ppm) silver, 1.371 ppm gold, and 100 ppm cobalt.

Rubicon Minerals (1998) cites a 43-foot channel sample that contained 247.6 ppm silver, 0.263 ppm gold, 2,753 ppm zinc, 1,803 ppm lead, and 174 ppm copper. They also report a drill hole with a 76.3-foot-thick intercept that averaged 3.7 ounces of silver per ton. Rubicon (1998) concluded that the Cap prospect lies along a northwest-trending mineral belt that includes the Nunatak (SK058), Cap, and MHC (SK068) prospects. They believe that these deposits are at the same stratigraphic horizon and attribute their distribution to a northwest-trending, shallowly plunging antiform that brings the massive-sulfide horizon close to the surface (Rubicon Minerals, 1998).

As described by Constantine Metal Resources, Ltd., (2007, 2008) and Greig and Giroux (2010), the Cap prospect is a silver-rich, barite-zinc-lead-gold massive-sulfide horizon 7 to 8 meters thick, in a veined and brecciated, amygdaloidal basalt. The deposit is marked by intense quartz-sericite-pyrite alteration. The basalt is capped by a bed of massive pyritic barite. Mineralized seams, veins, and layers up to 4.2 meters thick of massive barite with some chert occur throughout the section of altered basalt. In the core of the altered zone the basalt is completely replaced by quartz, sericite, and pyrite, and only the amygdules remain of the unaltered basalt. The amygdules are filled with quartz, minor barite, and sericite and are locally cored with sphalerite and galena. Veins and the matrix of the breccia in the altered basalt consist mainly of barite, quartz, pyrite, and sericite. The veins commonly have irregular, ‘wormy’ forms and typically are zoned, with pyrite margins and quartz-barite cores. The veins contain pyrite, sphalerite, galena, acanthite, and

possibly pyrargyrite. The highest metal values are associated with the barite lenses. Constantine (2007) drilled two holes in 2007 that cut sections 730- and 300-feet thick of altered pyritic rocks. The best intersect was a 25.5-foot interval with 43 grams of silver per tonne, 0.29 gram of gold per tonne, 1.2 percent zinc, and 0.60 percent lead; this interval included a 6.3-foot section that contained 3.75 percent zinc, 1.91 percent lead, 0.18 percent copper, 92.1 grams of silver per tonne, and 0.47 grams of gold per tonne.

There have been several published studies of the mineral deposits in the area by government and academia (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that they are Late Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

The deposit is associated with a basalt layer that is intensely altered to quartz, sericite, and pyrite (Constantine Metal Resources, Ltd., 2007, 2008 and Greig and Giroux, 2010).

Age of mineralization:

Late Triassic by analogy with other similar deposits of that age along the length of southeastern Alaska and into Canada (Greig and Giroux, 2010).

Generic deposit model:

Deposit model:

Kuroko- or Besshi-type volcanogenic massive sulfide (Cox and Singer, 1986; models 28a or 24b)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 24b

Production Status: None

Site Status: Active

Workings/exploration:

Mineralization in this area was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies including Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and 1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004 (Greig and Giroux, 2010). It was also mapped and sampled by the U.S. Geological Survey (MacKevett and others, 1974) and the U.S. Bureau of Mines (Still, 1984), and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources acquired the property under a long-term lease and began actively exploring it. Their work has included detailed geologic mapping and sampling, ground geochemical and geophysical surveys (Greig and Giroux, 2010).

The Cap prospect has been explored by a number of companies including Newmont Gold Company and Rubicon Minerals since at least the late 1990s; their work included surface mapping, trenching, and at least three drill holes. As of early 2011, it was actively being explored by Constantine Metal Resources Ltd., who drilled two holes in 2007 (Greig and Giroux, 2010).

In 2014, Constantine reported assay highlights at Cap of 1) 134 grams of silver per tonne over 23.2. meters (3.9 ounces per ton over 75 feet) from drill holes CAP01, and 2) 31 grams of silver per tonne over 90.6 meters (0.9 ounce per ton over 294 feet) (Constantine Metal Resources Ltd., 2014).

Site name(s): Hanging Glacier

Site type: Prospect

ARDF no.: SK061

Latitude: 59.387

Quadrangle: SK B-4

Longitude: 136.4248

Location description and accuracy:

The Hanging Glacier prospect is between an elevation of 5,100 and 5,700 feet above a small unnamed hanging glacier that is about a mile and a half west of the terminus of the Saksaia Glacier. It is about 0.5 mile south-southwest of the center of section 1, T. 29 S., R. 53 E.

Commodities:

Main: Ag, Au, barite, Cu, Pb, Zn

Other:

Ore minerals: Barite, chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals:

Geologic description:

Mineralization in this area was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies including Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and 1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004. It was also mapped and sampled by the U.S. Geological Survey (MacKevett 1974) and the U.S. Bureau of Mines (Still, 1984), and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources acquired the property under a long-term lease and they have been actively explored it to the present (early 2011). Their work has included detailed geologic mapping and sampling, and ground geochemical and geophysical surveys. The Hanging Glacier prospect has almost certainly been mapped, sampled, and covered by geochemical and geophysical surveys by several of the companies that have worked in the area. It is now part of the large block of claims held by Constantine. It has not been drilled.

As described by Still (1984 [OF 118-84]) and Still and others (1991), the Hanging Glacier prospect is an iron-stained zone of Late Triassic, Hyd Group metasediments and hydrothermally altered metabasalt several hundred feet thick and about 2,000 feet long that strikes northeast and dips steeply north. The mineralization consists of barite lenses up to several feet thick and quartz-calcite ladder veins up to 0.5 feet thick. Both lenses and veins contain barite, pyrite, sphalerite, galena, and minor chalcopyrite. Samples from the lenses and veins contain up to 54 percent barium, 14.1 percent zinc, 0.35 percent copper, 0.37 percent lead, 19.36 parts per million (ppm) silver, and 0.244 ppm gold. MacKevett and others (1974) note that ladder veins occur within a 4- to 8-foot-thick altered dike that cuts the metavolcanic rocks. The ladder veins are as much as 6 inches thick and contain quartz, calcite, sphalerite, galena and minor chalcopyrite. They describe the barite lenses as a baritic footwall vein that contains abundant galena and minor pyrite, sphalerite, and chalcopyrite.

Samples collected by Rubicon Minerals (1998) contained up to 18.25 percent zinc, 0.11 percent copper, 0.05 percent lead, 0.49 ppm gold, and 36.2 ppm silver. Rubicon surmised that the Hanging Glacier prospect was a volcanogenic massive-sulfide system that could be stratigraphically higher than the Cap (SK060) and Nunatak (SK058) prospects or, alternatively, a structural repetition of the Cap-Nunatak horizon (Rubicon

Minerals, 1998).

There have been several published studies of the mineral deposits in the area by government and academe (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that the they are Late Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

Quartz-sericite-pyrite alteration associated with baritic massive-sulfide mineralization.

Age of mineralization:

Late Triassic by analogy with other similar deposits of that age along the length of southeastern Alaska and into Canada.

Generic deposit model:

Deposit model:

Probably a volcanogenic massive-sulfide deposit with associated veining, some of which may be due to remobilization during deformation and metamorphism (Cox and Singer, 1986; models 28a or 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 24b

Production Status: None

Site Status: Active

Workings/exploration:

Mineralization in this area was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies including Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and 1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004. It was also mapped and sampled by the U.S. Geological Survey (MacKevett 1974) and the U.S. Bureau of Mines (Still, 1984), and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). Last report date: 2011-02-28

Site name(s): Red Creek; Wolf Den

Site type: Prospect

ARDF no.: SK063

Latitude: 59.4001 **Quadrangle:** SK B-4

Longitude: 136.3221

Location description and accuracy:

The Red Creek or Wolf Den prospect is at an elevation of about 2,500 feet on the north slope of the ridge that trends north-northeast from Flower Mountain. It is about 2.0 miles south-southwest of the mouth of Glacier Creek on the Klehini river and about 0.2 mile southeast of the center of section 36, T. 28 S., R. 53 E. of the Copper River Meridian. This location follows Still (1991); the exact location is somewhat uncertain and several reports, for example Constantine Metal Resources Ltd. (2008), place the Red Creek prospect about 3 miles east of the Main Zone deposit (SK066) or about a half mile east of the coordinates given here.

Commodities:

Main: Ag, Au, Ba, Pb, Zn

Other: Hg

Ore minerals: Arsenopyrite, barite, galena, pyrite, sphalerite

Gangue minerals: Barite, calcite, quartz

Geologic description:

Two sources, Still and others (1991) and Rubicon Minerals (1998), provide similar locations for this prospect but name it differently and describe it's geology differently. Still and others (1991) describe the Wolf Den prospect as quartz-pyrite-arsenopyrite-sphalerite veins in a tan dike less than 10 feet thick. The veins are up to 0.3 feet thick, are up to 5 feet long, and are confined to the dike. Samples from the veins contained up to 11.4 parts per million (ppm) gold and 3,500 ppm zinc. A 5-foot-long chip sample of slate with pyrite bands collected upstream form the dike contained 0.103 ppm gold and 225 ppm zinc.

Rubicon Minerals (1998) refers to an unpublished Cominco Alaska report that describes the Red Creek prospect as a '...rhyolite fragmental with a small two-foot-thick exposure of a massive pyrite breccia in a creek bed.' They also report the discovery in 1998 of barite and semi-massive pyrite and cite samples with 2,080 ppm zinc and 12.83 ppm mercury. Rubicon Minerals (1998) and Constantine Metal Resources Ltd. (2008) consider the Red Creek deposit to be at the end of a belt of massive sulfide deposits that extends northwest for about 5 miles through the Main Zone (SK066), RW Zone (SK067), and Little Jarvis (SK069) prospect.

The descriptions for this prospect suggest that the deposit is either: 1) a volcanogenic massive-sulfide deposit of probable Late Triassic age (Still, 1984; Newberry and others, 1997), or 2) Cretaceous or younger, auriferous quartz-sulfide veins in a northwest- trending zone of quartz-sulfide veining in metasedimentary rocks (Wright, 1904; Eakin, 1918 and 1919; MacKevett and others, 1974).

Alteration:

Based on its similarity to the Golden Eagle prospect (SK047) and other occurrences in the area, the tan dike is probably a mafic dike that has been altered to a silica-carbonate rock (Still and others, 1991).

Age of mineralization:

The Wolf Den prospect, if different from Red Creek prospect, may be related to Cretaceous plutonism. The description of the Red Creek prospect suggests it is a volcanogenic massive-sulfide deposit correlative

with the Upper Triassic, Windy Craggy deposit in British Columbia and the Greens Creek deposit near Juneau (Still, 1984; Newberry and others, 1997).

Generic deposit model:

Deposit model:

The deposit has been described as both a polymetallic quartz-sulfide vein or a volcanogenic massive sulfide. There may be two different types of deposits (Cox and Singer, 1986; models 22c,? 24b?, 28a?.)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?, 24b?, 28a?

Production Status: None

Site Status: Active

Workings/exploration:

The Red Creek prospect was discovered by Cominco Alaska in 1990. Additional prospecting by Rubicon Minerals and its associates in 1998 discovered barite and semi-massive pyrite breccia (Rubicon Minerals, 1998). Constantine Metal Resources Ltd. (2008) currently holds the claims in the area. The Wolf Den prospect, which may or may not be a different deposit, has been known since at least 1904, but apparently little has been done on it since.

Production notes:

None.

Reserves:

None.

Site type:

Prospect

ARDF no.: SK066

Latitude: 59.3966 **Quadrangle:** SK B-4

Longitude: 136.3919

Location description and accuracy:

The various parts of the Glacier Creek prospect as defined in 2011 are often referred to separately as the Main Zone, RW Zone, and South Wall Zone, but recent work has united them geologically in an overall estimate of their mineral resources. In plan view, this prospect extends east-west for about 900 meters; the center is about 500 meters east-southeast of Peak 1745 (meters), locally called Mount Morian, which is east of the head of the Little Jarvis Glacier. The center is about 0.6 mile southwest of the center of section 34, T. 28 S., R. 55 E., of the Copper River Meridian. A map of the prospect is figure 8 of Greig and Giroux (2010). This location is accurate within 50 feet.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other:

Ore minerals: Barite, arsenopyrite, chalcopyrite, galena, gold, magnetite, pyrite, pyrrhotite, sphalerite, tennantite, tetrahedrite

Gangue minerals: Calcite, quartz

Geologic description:

The rocks in the region are part of the Upper Triassic Hyd Group that hosts similar volcanic massive sulfide deposits the length of southeastern Alaska (Newberry and others, 1997). The rocks are predominantly massive and pillow basalts and fragmental basalt and andesite(?), intercalated with siltstone, tuff, and rare rhyolite flows and dikes. They have been subject to greenschist-facies metamorphism; folding and faulting locally repeats the stratigraphy in places, and the rocks are highly altered.

In 2006, Constantine Metal Resources acquired the property under a long-term lease and began actively exploring it. Their work has included detailed geologic mapping and sampling, ground geochemical and geophysical surveys, and through 2009, they had drilled 32 holes totaling more than 12,000 meters (Constantine Metal Resources Ltd., 2010).

There have been several published studies of the Glacier Creek prospect by government and academia (MacKevett and others, 1974; Still, 1984; Still and others, 1991; Newberry and others, 1997) and unpublished studies by industry. The consensus has long been that the prospect is a Late Triassic, stratiform volcanogenic massive-sulfide deposit. However, many of the earlier studies suffered from the complexity of the geology, the lack of systematic geologic control at depth, and the difficulty in producing an overall synthesis from the scattered outcrops of mineralization at the surface. While questions remain, the recent synthesis by Greig and Giroux (2010), based on the drilling and other work by Constantine Metal Resources Inc., presents the best description of the deposit to date.

As described by Greig and Giroux (2010) most of the mineralization at the Glacier Creek prospect is in two massive-sulfide horizons: 1) the (upper) RW Zone which is up to 15 meters thick, consists of baritic massive sulfides +/- chert, tuff, and argillite; and 2) the (lower) Main Zone with drill intercepts of up to 35 meters of baritic massive sulfides. The ore minerals in the massive-sulfide horizons are mainly coarse-grained barite, with sphalerite, pyrite, chalcopyrite, and galena, along with less abundant magnetite,

pyrrhotite, arsenopyrite, tetrahedrite, and tennantite. Quartz is conspicuous, calcite less so. The two massive sulfide horizons are separated by 70 to 135 feet of rhyolite and basalt that are intensely altered to quartz, sericite, and pyrite (or QSP alteration as it is locally called), and are cut by scattered vein and stockwork mineralization. Basalt underlies the Main Zone and the rocks above the RW zone are more than 150 feet of massive and pillow basalts, a thick gabbro sill, and thin tuffaceous limestone beds.

The structure of the Glacier Creek prospect is a large overturned antiform that trends about east-west for at least 500 meters. The north limb is nearly horizontal but the south limb dips steeply north and is overturned. The hinge of the fault is displaced by a north-dipping thrust fault.

The mineralization in the RW and Main zones persist along both limbs of the antiform but its geometry and grade remain to be worked out. (Constantine refers to the mineralization on the flat north limb of the fold as the RW and Main Zones; the mineralization along the steep overturn south limb as the South Wall Zone.) As known in 2010, the mineralization has been traced along strike for 450 meters down to a depth of 525 meters and was open at both ends and down dip.

Constantine drilled 10 more holes in the summer of 2010 (Constantine Metal Resources Ltd., 2010). Some notable intercepts were 20.8 meters with 1.03 percent copper, 5.01 percent zinc, 0.14 gram of gold per tonne, and 11.3 grams of silver per tonne; and 10.15 meters with 0.70 percent copper, 6.51 percent zinc, 1.02 percent lead, 0.39 gram of gold per tonne, and 89.7 grams of silver per tonne. While noteworthy in themselves, the intercepts also give the general tenor of intercepts in the many holes drilled previously.

In 2014, Constantine drilled 5 holes to test a 400 meter by 400 meter target area modeled from borehole geophysical data. All 5 holes intersected significant mineralization, including drillhole CMR14-65, which yielded the widest intersection drilled to date – 89 meters grading 0.79 percent copper, 5.03 percent zinc, 21.1 grams of silver per tonne and 0.32 gram of gold per tonne. These results have extended the South Wall Zone a further 100 meters west and 50 meters lower in elevation (Constantine Metal Resources Ltd., 2014).

In 2016, Dowa funded a $3.7 million exploration program. Two holes were drilled at the CAP prospect (SK060) totaling 595 m; they intersected semi-massive pyrite, and intervals with anomalous silver and other pathfinder elements. Constantine also sampled rocks at the CAP (SK060), Nunatak (SK058), Gullies (SK070), MHC (SK068), Jag, Waterfall, Boundary (SK057), and Tsirku prospects and obtained many promising assays. Constantine completed environmental assessment work for the U.S. Bureau of Land Management and began construction of its Glacier Creek access road, which will connect the resource area to the Haines highway (Athey and Werdon, 2017).

Alteration:

Quartz-sericite-pyrite (phyllic) alteration and chloritic alteration developed within mafic metavolcanics (Greig and Giroux, 2010).

Age of mineralization:

Late Triassic by analogy with other similar deposits of that age along the length of southeastern Alaska and into Canada (Greig and Giroux, 2010).

Generic deposit model:

Deposit model:

Besshi- or Kuroko-type volcanogenic massive sulfide (Cox and Singer, 1986; models 24b or 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

24b or 28a

Production Status: None

Site Status: Active

Workings/exploration:

The deposit was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies. These include Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and

1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004 (Greig and Giroux, 2010). It was also mapped and sampled by the U.S. Geological Survey (MacKevett, 1971; MacKevett and others, 1974) and the U.S. Bureau of Mines (Still, 1984) and by the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources acquired the property under a long-term lease and began actively exploring it. Their work has included detailed geologic mapping and sampling and ground geochemical and geophysical surveys. Through 2009, they had drilled 32 holes totaling more than 12,000 meters. Constantine drilled 10 more holes in the summer of 2010 (Constantine Metal Resources Ltd., 2010).

Constantine drilled 10 more holes in 2013, targeting open edges of the South Wall and RW zones of the 2010 resource estimate, with step-out distances ranging from 30 to 100 meters. Focus was on targets at elevations above the 1,100 meter level. These holes provided further confirmation of the geological model. Highlights of results are 1) South Wall Zone I step-out hole CMR13-49 intersected 24.7 meters (80.9 feet) near true width of 2.02 percent copper, 8.47 percent zinc, 31.7 grams of silver per tonne and 0.51 gram of gold per tonne, and 2) drill holes CMR13-50, which intersected precious metal-rich RW Zone oxide mineralization including 37.5 meters (123 feet) of 123.2 grams of silver per tonne and 0.62 gram of gold per tonne. The intersection includes a partially unoxidized subinterval of 13.7 meters (45 feet) grading 0.51 percent copper, 4.97 percent zinc, 1.61 percent lead, 134.3 grams of silver per tonne and 0.71 gram of gold per tonne (Constantine Metal Resources Ltd., 2013).

As of September 29, 2014, Constantine's 2014 drill program had drilled 11 holes totaling approximately 6,913 meters, focused on increasing inferred mineral resources and expanding the footprint of the mineralized system. Five of the holes drilled were to test a 400 meter by 400 meter target area modeled from borehole geophysical data. All 5 holes intersected significant mineralization, including drillhole CMR14-65, which yielded the widest intersection drilled to date – 89 meters grading 0.79 percent copper, 5.03 percent zinc, 21.1 grams of silver per tonne and 0.32 gram of gold per tonne. These results have extended the South Wall Zone a further 100 meters west and 50 meters lower in elevation (Constantine Metal Resources Ltd., 2014).

In 2016, Dowa Metals and Mining Co., Ltd. completed its $22 million earn-in and has exercised its option to participate as a joint-venture partner on the Palmer project. Constantine Metal Resources Ltd. owns 51 percent participating interest and Dowa 49 percent, with Constantine as operator. In 2016, Dowa funded a $3.7 million exploration program. Two holes were drilled at the CAP prospect (SK060) totaling 595 m; they intersected semi-massive pyrite, and intervals with anomalous silver and other pathfinder elements. Constantine also sampled rocks at the CAP (SK060), Nunatak (SK058), Gullies (SK070), MHC (SK068), Jag, Waterfall, Boundary (SK057), and Tsirku prospects and obtained many promising assays. Constantine completed environmental assessment work for the U.S. Bureau of Land Management and began construction of its Glacier Creek access road, which will connect the resource area to the Haines highway (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

Greig and Giroux (2010) estimated the resources of the Glacier Creek prospect. Using a Net Smelter Return (NSR) cutoff of 50 US dollars, the RW and South Wall zones have an inferred resource of 4.750 million tonnes with an average grade of 1.84 percent copper, 4.57 percent zinc, 0.28 gram of gold per tonne, and 29.1 grams of silver per tonne; at a NSR of 75 US dollars, there is an inferred resource of 4.120 millions tonnes with an average grade of 2.01 percent copper, 4.79 percent zinc, 0.16 percent lead, 0.30 gram of gold per tonne, and 30.5 grams of silver per tonne; and at a NSR of 100 US dollars, the inferred resource is 3 million tonnes with an average grade of 2.31 percent copper, 5.14 percent zinc, 0.17 percent lead, 0.33 gram of gold per tonne, and 33.3 grams of silver per tonne.

At the Palmer project, Constantine Metal Resources Ltd. has delineated an inferred resource of 8.1 million tonnes at 1.41 percent Cu, 5.25 percent Zn, 31.7 grams of silver per tonne, and 0.32 gram of gold per tonne (Gray and Cunningham-Dunlop, 2015).

Site name(s): Little Jarvis; RW

Site type: Prospect

ARDF no.: SK067

Latitude: 59.4001 **Quadrangle:** SK B-4

Longitude: 136.4133

Location description and accuracy:

The Little Jarvis prospect is probably the prospect that Rubicon Minerals drilled in 1999 as the RW. It is of the east side of the Little Jarvis Glacier about 0.7 mile northwest of peak 1745 (meters) which is locally called Mt. Moorian. It is about 0.2 mile southwest of the center of section 33, T. 28 S., R. 55 E.

Commodities:

Main: Ag, Cu, Zn

Other: Au

Ore minerals: Barite, chalcopyrite, pyrite, sphalerite

Gangue minerals: Chlorite, quartz, sericite

Geologic description:

Mineralization in this area was discovered in 1969 by Merrill Palmer and associates and has been explored by a succession of companies including Alyu Mining in 1976 and 1977; Anaconda Minerals in 1979 and 1980; Southeastern Minerals from 1980 to 1983; Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004. It was also mapped and sampled by the U.S. Geological Survey (MacKevett 1974) and the U.S. Bureau of Mines (Still, 1984), and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources acquired the property under a long-term lease and they have been actively explored it to the present (early 2011). Their work has included detailed geologic mapping and sampling, ground geochemical and geophysical surveys, and through 2009 they had drilled 32 holes just a mile to the east on the Glacier Creek prospect (SK066). The Jarvis Creek prospect was probably found early in the history of the work in the area. Kennecott Minerals drilled one hole in 1994 and Rubicon Minerals Ltd. drilled 6 holes in 1999 under the name RW. It is now part of the large block of claims held by Constantine who call it the Little Jarvis prospect.

The rocks in the region are part of the Upper Triassic Hyd Group that hosts similar volcanic massive sulfide deposits the length of southeastern Alaska (Newberry and others, 1997). The rocks are predominantly massive and pillow basalts and fragmental basalt and andesite(?), intercalated with siltston, tuff, and rare rhyolite flows and dikes. They have been subject to greenschist-facies metamorphism; folding and faulting locally repeats the stratigraphy in places, and the rocks are highly altered.

The drilling by Rubicon Minerals in 1999 (Rubicon Minerals (1998) discovered massive sulfide mineralization. Mineralization intersected in drill holes occurs as: 1) chalcopyrite-sphalerite massive-sulfide mineralization, and 2) chalcopyrite-bearing, stringer in a zone of strong chloritic alteration. The massive-sulfide, drill-intersect thicknesses ranged from 7.2 feet to 15 feet and contained up to 13.48 percent zinc, 1.89 percent copper, 2.98 ounces of silver per ton, and 0.02 ounces of gold per ton. Massive-sulfide drill intercepts extend along a dip length of 420 feet. The stringer mineralization is beneath the massive sulfide horizon. One drill hole intersected 156 feet of stringer mineralization that included a 67.8-foot-thick interval with an average grade of 0.62 percent copper. In this interval, there was a 16.2-foot interval that contained 1.50 percent copper. There has not been any drilling on the Little Jarvis prospect since 1999, but there has

been extensive drilling and exploration on the nearby Glacier Creek prospect (SK066) where the RW zone is extensive. Although it is likely that the mineralization at this prospect is a continuation of the mineralization of the Glacier Peak prospect whose orientation is controlled by a large overturned east-west-trending antiform, recent mapping by Constantine (figure 8 of Greig and Giroux, 2010) suggests that the Little Jarvis mineralization trends north-northwest.

There have been several published studies of the mineral deposits in the area by government and academe (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that the they are Late Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

Intense sericitic and chloritic alteration associated with the layers of massive sulfides.

Age of mineralization:

Late Triassic by analogy with other similar deposits of that age along the length of southeastern Alaska and into Canada.

Generic deposit model:

Deposit model:

Kuroko- or Besshi-type volcanogenic massive-sulfide deposit (Cox and Singer, 1986; models 28a or 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 24b

Production Status: None

Site Status: Active

Location description and accuracy:

The MHC prospect consists of a 1/2-mile-long arcuate pattern of mineralized float below a small hanging glacier. Most of the mineralized float is between about 4,200 and 4,400 feet elevation in a narrow septum of rock and talus between glaciers. It is about 1 mile north-northeast of Mt. Henry Clay in section 3, T. 29 S., R. 53 E., of the Copper River Meridian. Figure 11 of Greig and Giroux (2010) is a geologic map of the prospect. The location is accurate within 500 feet.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other:

Ore minerals: Barite, bornite, chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Calcite, chlorite, epidote, quartz

Geologic description:

The MHC prospect was found at the base of a retreating glacier by Merrill Palmer in 1984 as numerous high-grade massive-sulfide boulders (Greig and Giroux, 2010).

The rocks in the region are part of the Upper Triassic Hyd Group that hosts similar volcanic massive sulfide deposits the length of southeastern Alaska (Newberry and others, 1997). The rocks are predominantly massive and pillow basalts and fragmental basalt and andesite(?), intercalated with siltstone, tuff, and rare rhyolite flows and dikes. They have been subject to greenschist-facies metamorphism; folding and faulting locally repeats the stratigraphy in places, and the rocks are highly altered.

Still (1984) reported that more than 30 high-grade sphalerite-barite-pyrite-chalcopyrite boulders up to 6 feet in diameter had been found in float over an area about 800 meters in diameter. Assays of the boulders varied. The highest grade contained 20 to 44 percent zinc, 5 percent barium, and several percent copper. No ore-grade mineralization was found in place but altered andesite in the area contained elevated zinc, copper, barium, lead, silver, and gold. None of 13 holes drilled by Kennecott, Granges, and Rubicon cut mineralization as high grade as the boulders (Greig and Giroux, 2010). Several of the drill holes intersected lower-grade mineralization in broad quartz-sericite-pyrite-chlorite alteration zones. The better intercepts were 49.1 meters with 0.19 percent copper, 10.7 meters with 0.44 percent copper, and 36.6 feet with 0.29 percent copper. Drilling by Stryker Resources and Freeport Resources nearby in Canada showed similar values (Still and others, 1991; Rosenkrans and Jones, 1985).

There have been several published studies of the mineral deposits in the area by government and academia (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that they are Late Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

Intense quartz-sericite-pyrite and chloritic alteration near mineralization (Greig and Giroux, 2010).

Age of mineralization:

Late Triassic by analogy with the many other similar deposits in Hyd Group rocks of that age spread along the length of southeastern Alaska and into Canada (Greig and Giroux, 2010).

Generic deposit model:

Deposit model:

Kuroko- or Besshi-type volcanogenic massive-sulfide deposit (Cox and Singer, 1986; models 28a or 24b)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 24b

Production Status: None

Site Status: Active

Workings/exploration:

The MHC prospect was found by Merrill Palmer in 1984 at the base of a retreating glacier as numerous high-grade massive-sulfide boulders. Subsequently, a succession of companies explored in the general area including Bear Creek Mining from 1983 to 1985; Newmont Exploration from 1987 to 1989; Granges Exploration Ltd. in 1989; Cominco Alaska from 1990 to 1993; Kennecott Minerals from 1993 to 1997, Rubicon Minerals from 1998 to 2000; and Toquima Minerals Corp. in 2004 (Greig and Giroux, 2010). Kennecott Exploration drilled 7 holes at MHC; Ganges Exploration Ltd. drilled 4 holes, and Rubicon Minerals Corp. drilled 2 holes. The holes totaled 2,957 feet. The area was also mapped and sampled by the U.S. Geological Survey (MacKevett and other, 1974) and the U.S. Bureau of Mines (Still, 1984) and the Alaska Division of Geological and Geophysical Surveys (Still and others, 1991). In 2006, Constantine Metal Resources Ltd. acquired the property under a long-term lease and began actively exploring it. Their work has included detailed geologic mapping and sampling, ground geochemical and geophysical surveys (Greig and Giroux, 2010). In 1985, Stryker Resources drilled 5 holes totaling 2,787 feet in length on extensions of this prospect on the Canadian side of the border (Still and others, 1991; Rosenkrans and Jones, 1985).

In 2013, Constantine conducted a two day massive sulfide boulder survey where the glacier had retreated; 311 samples were counted. These boulders were newly exposed and 'upstream' from the samples collected by the US Bureau of Mines in 1985 where the average of 26 boulders sampled were 19.3 percent zinc, 1.0 percent copper, 0.22 gram of gold per tonne and 38.2 grams of silver per tonne (individual boulders up to 6 feet in diameter) (Constantine Metal Resources Ltd., 2014).

Production notes:

Site name(s): Unnamed (on west side of Little Jarvis Glacier)

Site type: Prospect

ARDF no.: SK069

Latitude: 59.4095 **Quadrangle:** SK B-4

Longitude: 136.4258

Location description and accuracy:

This prospect is about 3 miles northeast of the summit of Mt. Henry Clay at an elevation of approximately 3,500 feet. It is near the southeast corner of section 29, T. 28 S., R. 53 E. Still and others (1991) informally named this the Little Jarvis prospect For this record, it is not named to distinguish it from the better known prospect of that name to the southeast on the other side of the Little Jarvis Glacier (SK067).

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other:

Ore minerals: Barite, galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

Still and others (1991) describe this prospect as small discontinuous sulfide bands in metasedimentary and metavolcanic rocks. Their samples contained up to 0.345 parts per million (ppm) gold, 11.8 ppm silver, 13.6 percent zinc, 1,900 ppm copper, 3.8 percent lead, 1.44 percent barium, and 2,000 ppm arsenic. This prospect is not specifically mentioned in Greig and Giroux (2010). However, it is at the southeast end of a 3-mile-long line of massive sulfide occurrences and they suggest that all of the volcanic massive sulfide deposits in this area are related, if they were not originally continuous.

The rocks in the region are part of the Upper Triassic Hyd Group that hosts similar volcanic massive sulfide deposits the length of southeastern Alaska (Newberry and others, 1997). The rocks are predominantly massive and pillow basalts and fragmental basalt and andesite(?), intercalated with siltston, tuff, and rare rhyolite flows and dikes. They have been subject to greenschist-facies metamorphism; folding and faulting locally repeats the stratigraphy in places, and the rocks are highly altered.

There have been several published studies of the mineral deposits in the area by government and academe (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that the they are Late Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

Age of mineralization:

Late Triassic by analogy with other similar deposits of that age along the length of southeastern Alaska and into Canada.

Generic deposit model:

Deposit model:

Probably a Besshi- or Kuroko-type volcanogenic massive sulfide (Cox and Singer, 1986; models 28a or 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 24b

Production Status: None

Site Status: Active

Workings/exploration:

The only published record of work at this prospect was sampling by Still (1991). However, it is in a large block of claims in an area that has been intensely explored by government and industry for several decades (Greig and Giroux, 2010).

Production notes:

None.

Reserves:

None.

Site name(s): Gullies; Jarvis Glacier Gulches

Site type: Occurrences

ARDF no.: SK070

Latitude: 59.4204 **Quadrangle:** SK B-4

Longitude: 136.4517

Location description and accuracy:

The Gullies prospect includes several mineralized exposures on the south side of the Jarvis Glacier in a steep walled canyon about 4 miles east-southeast of the Pleasant Camp border station on the Haines Highway. They are in the NE1/4, section 30, T. 28 S., R. 53 E. The prospect was informally called the 'Jarvis Glacier Gulches' prospect by Still and others (1991); Constantine Metal Resources Ltd. (2008) called it the Gullies prospect.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other:

Ore minerals: Barite, chalcopyrite, galena, goethite, gold, pyrite, pyrrhotite, sphalerite

Gangue minerals: Calcite, chlorite, quartz

Geologic description:

Sulfide float found by the U. S. Bureau of Mines at the mouth of a steep north-draining canyon led to the initial discovery of some of the occurrences in August, 1983. Other occurrences were discovered by Alyu Mining Corporation in September, 1983.

According to Still (1984), the occurrences are located in the Little Jarvis volcanic-sedimentary sequence that consists of basalt, andesite, and metasediments and slate and limestone (Redman, 1983). Most of the occurrences are in slate, limestone and andesite, capped by andesite and pillow basalt. The Little Jarvis sequence probably correlate with the Glacier Creek sequence which hosts the Glacier Creek prospect (SK066) (Redman, 1983). They are part of the Late Triassic Hyd Group which hosts similar deposits the length of southeastern Alaska and into Canada(Newberry and others, 1997).

Still (1984) describes a mineralized exposure at an elevation of about 3,600 feet on the southwest side of the canyon (his number 109 on figure 8). The exposure consits of a zone of metasediments and andesite altered to chlorite that contains lenses of massive and disseminated sulfides. The zone follows bedding, is up to 5 feet thick, and contains massive-sulfide lenses up to 0.5 foot thick. It can be traced at least 100 feet. The sulfide lenses consist of pyrite, sphalerite, chalcopyrite, and galena in calcite- and quartz-rich rock. Samples contained up to 17.8 percent zinc, 0.3 percent lead, 1.3 percent copper, 11.56 parts per million (ppm) silver, and 0.163 ppm gold (Still, 1984; Still and others, 1991). On the northeast side of the canyon at an elevation of 3,200 feet are quartz-stringer zones and sulfide zones. Samples of the sulfide zones contained up to 6.1 percent zinc, 0.76 percent copper, 110 ppm cobalt, 4.64 ppm silver, and 0.127 ppm gold (Still, 1984; Still and others, 1991).

Greig and Giroux (2010) note that this mineralization may be the northwest extension of the important RW and South Wall mineralized horizons at the Glacier Creek prospect (SK066) about 3 miles to the southeast. Their map (figure 5) also shows that these mineral occurrences extend northwest for about 3 kilometers to the Little Jarvis Glacier and ARDF site SK069.

There have been several published studies of the mineral deposits in the area by government and academe (MacKevett and others, 1974; Still, 1984, Still and others, 1991; Newberry and others, 1997; Greig and Giroux, 2010) and unpublished studies by industry. The consensus from early on was that the they are Late

Triassic, stratiform volcanogenic massive-sulfide deposits.

Alteration:

Chloritic.

Age of mineralization:

Late Triassic by analogy with the many other similar deposits of that age spread along the length of southeastern Alaska and into Canada.

Generic deposit model:

Deposit model:

Probably a Kuroko- or Besshi-type volcanogenic massive sulfide system with associated veining (Cox and Singer, 1986; models 28a or 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 24b

Production Status: None

Site Status: Active

Workings/exploration:

Sulfide float found by the U.S. Bureau of Mines lead to the initial discovery of some of these occurrences here in August, 1983. Other occurrences were discovered by Alyu Mining Corporation in September, 1983. The deposit has probably been visited and sampled by several of the succession of companies who have worked in the area. It has not been drilled.

Production notes:

None.

Site name(s): 737 Zone

Site type: Prospect

ARDF no.: SK079

Latitude: 59.399 **Quadrangle:** SK

Longitude: 136.3731

Location description and accuracy:

The 737 prospect is about 0.7 mile north of the terminus of the Saksaia Glacier at an elevation of about 3,200 feet. It is about 0.5 mile east-southeast of the center of section 34, T. 28 S., R. 54 E. The location is accurate.

Commodities:

Main: Ag, Pb, Zn

Other:

Ore minerals: Galena, sphalerite

Gangue minerals: Calcite, quartz

Geologic description:

The 737 Prospect was first identified as a volcanogenic, massive-sulfide deposit by Constantine Metal Resources (2008); it is one of several along a well defined belt of similar Upper Triassic deposits that extend southeast for about 5 miles from unnamed prospects near the Jarvis Glacier (SK070), through the Little Jarvis Glacier prospect (SK069), the RW Zone (SK067) , the Main Zone prospect (SK066), and the 737 prospect, to the Red Creek prospect (SK063). Relatively little is known about the 737 prospect specifically although it clearly is similar to others along the belt. It is on a Pulse EM, geophysical anomaly that indicated a buried massive-sulfide deposit. One drill hole on the 737 prospect did not intersect mineralization but a surface sample collected across 0.5 feet of massive sulfides contained 12.0 percent zinc, 2.66 percent lead, and 47.6 gram of silver per ton.

Alteration:

None specifically noted.

Age of mineralization:

Late Triassic; correlative with similar deposits nearby along a belt of massive-sulfide mineralization.

Generic deposit model:

Deposit model:

Probably a Besshi- or Kuroko-type volcanogenic massive sulfide (Cox and Singer, 1986; models 28a or 24b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a or 24b

Production Status: None

Site Status: Active

Workings/exploration:

Sampled at the surface and covered by a pulse EM geophysical survey. One hole drilled in 1998.

Production notes:

None.

Reserves:

None.

Site name(s): Koyana Creek

Site type: Mine

ARDF no.: SO004

Latitude: 64.5703 **Quadrangle:** SO C-4

Longitude: 163.6712

Location description and accuracy:
A limited amount of mining at unknown locations took place along Koyana Creek until about 1930. Koyana Creek is a small drainage that flows south to Norton Sound; the mouth of the creek is about 2.5 miles east of the old town of Bluff at the mouth of Daniels Creek. The location is accurate.

Commodities:

Main: Au

Other: Hg

Ore minerals: Cinnabar, gold

Gangue minerals:

Geologic description:
Small-scale placer mining took place on Koyana Creek in the early part of the 1900s (Collier, 1908) and between 1928 and 1930 (Cobb, 1978). The placer deposits were shallow and apparently low grade. Mulligan (1971) estimates that less than 100 ounces of gold were produced. Cinnabar was recovered in the placer concentrates (Cathcart, 1922). Bedrock in the area is a lower Paleozoic metasedimentary sequence that includes marble and schist (Till and others, 1986). As of early 2010, there has apparently not been any placer mining on Koryana Creek for decades but it is on a large block of ground that was being explored for its lode gold potential by Millrock Resources Inc. (2010). Much of the creek is only slightly above the present sea level and the placer deposits may have been reworked by Quaternary sea level fluctuations.

Alteration:

Age of mineralization:
Quaternary. Much of the creek is only slightly above the present sea level and the placer deposits may have been reworked by Quaternary sea level fluctuations.

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer Au-PGE (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Small open-cut placer mining until about 1930. As of early 2010, there has apparently not been any placer mining on Koryana Creek for decades but it is on a large block of ground that was being explored for its lode gold potential by Millrock Resources Inc. (2010).

Production notes:

Mulligan (1971) estimates that less than 100 ounces of gold were produced.

Reserves:

Swede Creek (Gulch) is a small, 0.4 mile long drainage that flows south to Norton Sound, 1.7 miles east of Bluff. It is about 0.5 mile east of the center of section 5, T. 11 S., R. 25 W. The location is accurate.

Commodities:

Main: Au

Other: Hg

Ore minerals:

Gangue minerals:

Geologic description:
Placer gold was discovered on Swede Creek between 1900 and 1902 (Collier and others, 1908) but most mining was between 1918 and WW II (Mulligan, 1971). The placer workings were shallow and extended 600 feet upstream from the steep sea cliffs along Norton Sound (Herreid, 1965). The documented gold production from Swede Creek is less than 1,000 ounces but the extent of the workings suggested to Mulligan (1971) that production could have been greater. Bedrock in the area is Paleozoic marble to both sides of a wide band of schist (Herreid, 1965; Mulligan, 1971; Till and others, 1986). Cinnabar was reported in the placer deposits as early as 1922 (Cathcart, 1922) and a lode cinnabar deposit (SO133) was subsequently identified within about a hundred feet of the point that Swede Creek cascades down the almost vertical sea cliffs that are several hundred feet high.

Alteration:

Age of mineralization:
Quaternary.

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer gold (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The placer workings were shallow and extend about 600 feet upstream from the coastal bluff (Herreid, 1965).

Production notes:

The documented gold production from Swede Creek is less than 1,000 ounces but the extent of the workings suggested to Mulligan (1971) that production could have been greater.

Reserves:

None.

Site name(s): Daniels Creek

Site type: Mine

ARDF no.: SO006

Latitude: 64.5727 **Quadrangle:** SO C-4

Longitude: 163.7447

Location description and accuracy:

Daniels Creek, a famous early placer on the Seward Peninsula, enters Norton Sound at the now-abandoned settlement of Bluff. About 3,000 feet was placer mined above the mouth of the creek. There was also considerable early mining in the beach sands at its mouth. During the 1930s there was considerable mining offshore in the winter through the ice to exploit the offshore extension of Daniels Creek into Norton Sound. Most of the mining took place through the center of the southeast quarter of section 32, T. 10 W., R. 25 W. The location is accurate.

Commodities:

Main: Au

Other: Hg, W

Ore minerals: Cinnabar, gold, scheelite

Gangue minerals:

Geologic description:

Placer gold was discovered in beach sand at the mouth of Daniels Creek in 1899 but within a year the beach placer was largely mined out (Brooks and others, 1901; Mulligan, 1971). Placer gold was soon discovered on Daniels Creek but little mining took place until water was brought in by an extensive ditch system. This supported hydraulic mining. Most of the mining took place in the lower 3,000 feet or so of the creek which flows on Paleozoic marble. The marble bedrock is characterized by irregular solution channels, crevices, sink holes, pits, and collapsed caverns that are in places tens of feet deep and below sea level. The mining was probably difficult and Mulligan (1971) notes the many buckets left along Daniels Creek that were used in mining the sink holes, pits, and caverns. In addition to the usual magnetite and ilmenite, the placer concentrates contained abundant cinnabar and some scheelite. (Onshore) Daniels Creek was probably largely mined out by World War I.

As early as 1901, it was known that the channel of Daniels Creek continued offshore as miners had cut holes in the ice in the winter and sent divers down to mine (Spence, 1996). By the 1930s, the marine extension of Daniels Creek was being mined through the ice in the winter with churn drills and drag lines through a system of hoists, towers, and cableways. Apparently, the sink holes and pits of the onshore portion Daniels Creek persisted in its extension in Norton Sound; this made the mining difficult and hindered gold recovery. The winter, offshore mining persisted until about the beginning of World War II.

Mulligan (1971) notes 4 phases of the gold mining on Daniels Creek and its marine extension. From 1899 to 1900, about 30,000 ounces of gold was produced, largely from the beach placers. From 1900 to 1920, about 45,000 ounces of gold was produced, almost all from the onshore portion of Daniels Creek. From 1920 to 1940, about 16,500 ounces of gold was produced, most from the marine extension of Daniels Creek. Perhaps another 60 ounces was produced from 1940 to 1965 from the onshore channel of Daniels Creek and beach placers. Thus the total gold production from Daniels Creek and its marine extension is about 90,000 ounces of gold.

The Daniels Creek placer was rich but allowing that it is short, it is well defined, and the intensity of the prospecting and mining effort was so great, is unlikely that there is any substantial amount of placer gold

remaining in (onshore) Daniels Creek. However, there were attempts during the 1970s at offshore mining using various dredge technology. None were successful and the remains of a large screw dredge on a barge rusts on the beach a few hundred yards west of the mouth of Daniels Creek (D.J. Grybeck, personal observation, 2008). As of early 2010, there is no placer mining or exploration on Daniels Creek; however, it is in a large block of ground that is being explored by Millrock Resources Inc. for lode gold (Stevens, 2010; Millrock Resources Inc., 2010). The head of Daniels Creek is one of the important targets (SO177) of the lode exploration as well as being a potential source for the placer gold in lower Daniels Creek.

Alteration:

Age of mineralization:

Quaternary; the placer deposits have clearly been influenced by Quaternary sea level fluctuations.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Beach placer; marine channel placer, alluvial placer (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; medium

Site Status: Active

Workings/exploration:

Placer gold was discovered in beach sand at the mouth of Daniels Creek in 1899 but within a year the beach placer was largely mined out (Brooks and others, 1901; Mulligan, 1971). Site name(s): Big Hurrah

Site type: Mine

ARDF no.: SO023

Latitude: 64.6514 **Quadrangle:** SO C-5

Longitude: 164.2398

Location description and accuracy:

The Big Hurrah mine is located on the south side of Big Hurrah Creek (SO022) and the east side of Little Hurrah Creek at an elevation of about 275 feet. It is about 1/4 mile southeast of the confluence of Little and Big Hurrah creeks. It is locality 17 of Cobb (1972, MF 445; 1978, OF 78-181).

Commodities:

Main: Au

Other: Ag, Cu, W, Zn

Ore minerals: Arsenopyrite, chalcopyrite, electrum, gold, pyrite, scheelite, sphalerite

Gangue minerals: Albite, carbonate, quartz, sericite

Geologic description:

The Big Hurrah mine has been the most productive lode gold mine on the Seward Peninsula to date. Gold-quartz veins in slaty graphitic schist produced about 27,000 ounces of gold (Read and Meinert, 1986) primarily between 1903 and 1907, when a 20-stamp mill was in operation (Smith, 1910). The ore that was mined averaged a little less than 1 ounce of gold per ton (Cobb, 1978); six samples collected underground in 1952 from the 70 foot level contained 0.08 to 5.2 ounces of gold per ton and 0.5 to 17.2 ounces of silver per ton (Asher, 1969). The mill tailings were cyanided and there were attempts to restart underground mining in the 1950s. A fire and unstable ground prevented further underground work and all workings are now (2007) flooded. However, considerable core drilling and surface trenching has taken place in recent years, primarily in the 1980s.

NovaGold Resources, Inc. (2006) acquired the Big Hurrah deposit in mid-2004. In 2004 and 2005, they drilled a total of 17,750 meters in 292 core and rotary holes. The objective was to define an open-pittable resource of 100,000 to 200,000 ounces of gold in ore that contains 5 to 7 grams of gold per ton. Production of this resource is being evaluated as part of the Rock Creek (NM207) feasibility study. In this scenario, the Big Hurrah ore would be trucked 48 miles to the proposed Rock Creek mill for processing. As of March 28, 2007, NovaGold (2007) listed a measured and indicated resource in the Big Hurrah mine as 1.8 millions tons of ore with a grade of 4.61 grams of gold per metric ton; there was an additional inferred resource of 0.6 million tons of material with a grade of 3.05 grams of gold per metric ton.

Read and Meinert (1986) describe five types of veins: 1) quartz +/- carbonate lenses, 2 to 7 centimeters thick, locally contain minor sphalerite, chlorite and arsenopyrite; 2) quartz, carbonate, pyrite, sphalerite and chalcopyrite form tabular veins 2 to 5 millimeters thick; 3) ribbon quartz veins up to 4 meters wide that average about 0.5 meters wide occupy NW-trending faults and contain more than 90 percent quartz, dolomite, albite, sericite, scheelite, arsenopyrite, pyrite and native gold; the total sulfide content is less than 2 to 3 percent and scheelite is less than 1 percent; 4) quartz-albite +/- arsenopyrite veins 5 to 25 centimeters wide contain up to 25 percent albite, up to 20 percent arsenopyrite and minor gold; thought to be syngenetic; 5) post-mineralization carbonate-quartz veinlets 2 to 3 millimeters thick that cut all other vein types. Coats (1944) estimated that the scheelite content of gold ore that remained in the bins was 0.25 percent by volume. Some veins are up to several hundred feet long; the larger veins strike northwest and dip southwest (Asher, 1969, DGGS R33). Fluid inclusion data from these veins indicate multiple generations of fluids; early veins

contain CO_2-CH_4 and later veins are rich in H_2O-NaCl. Homogenization temperatures vary from 390 to 90 degrees C. The available data suggests that the gold-bearing fluids were produced by regional metamorphic processes. The country rock is part of a lower Paleozoic metasedimentary assemblage (Sainsbury and others, 1972; Till and others, 1986) that includes a distinctive black, very fine-grained, graphitic schist that early workers called the Hurrah Slate.

The Big Hurrah veins are probably similar in age to some other gold-quartz veins of southern Seward Peninsula. The other southern Seward Peninsula lode gold deposits formed as a result of mid-Cretaceous metamorphism (Apodoca, 1994; Ford, 1993, Ford and Snee, 1996; Goldfarb and others, 1997) that accompanied regional extension (Miller and Hudson, 1991) and crustal melting (Hudson, 1994). This higher temperature metamorphism was superimposed on high pressure/low temperature metamorphic rocks of the region.

Alteration:

Silicification, carbonatization, and development of quartz-carbonate stockworks.

Age of mineralization:

Cretaceous?

Generic deposit model:

Deposit model:

Gold-quartz vein in metamorphic rocks; low sulfide-Au quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

A 60-degree inclined shaft extended to the 250 foot level; there are about 1,800 feet of lateral workings developed off it on the 70, 150, and 250 foot-levels. In 1954, a 105-foot-long sublevel was driven at 20 feet below the 150-East level (Asher, 1969, DGGS R33). There are also numerous surface prospecting pits and trenches on the property.

NovaGold Resources, Inc. acquired the Big Hurrah deposit in mid-2004. In 2004 and 2005, they drilled a total of 17,750 meters in 292 core and rotary holes. The objective is to define an open-pittable resource of 100,000 to 200,000 ounces of gold in ore that contains 5 to 7 grams of gold per ton. Production of this resource is being evaluated as part of the Rock Creek (NM207) feasibility study. In this scenario, the Big Hurrah ore would be trucked 48 miles to the proposed Rock Creek mill for processing.

Production notes:

The Big Hurrah mine is the only lode gold mine on Seward Peninsula. The gold-quartz veins in slaty graphitic schist produced about 27,000 ounces of gold (Read and Meinert, 1986), primarily between 1903 and 1907, when a 20-stamp mill was in operation (Smith, 1910).

Reserves:

As of March 28, 2007, NovaGold (2007) listed a measured and indicated resource in the Big Hurrah mine as 1.8 millions tons of ore with a grade of 4.61 grams of gold per metric ton; there was an additional inferred resource of 0.6 milllion tons of material with a grade of 3.05 grams of gold per metric ton.

Site type: Mine

ARDF no.: SO132

Latitude: 64.9775 **Quadrangle:** SO D-6

Longitude: 164.6444

Location description and accuracy:

This prospect is on the Pilgrim River just below the mouth of Iron Creek. It is cut into two parts, one north of the river and the other south. The coordinates are at the north part about 0.7 mile southeast of the center of section 12, T. 6 S., R. 30 W. The location is accurate.

Commodities:

Main: Ag, Au, Pb, Zn

Other:

Ore minerals: Boulangerite?, galena, pyrite, sphalerite

Gangue minerals: Ankerite?, calcite, quartz

Geologic description:

This locality has two parts, one on each side of the Pilgrim (Kruzgamepa) River, just downstream from the mouth of Iron Creek (SO127). They are separated by 1,000 feet of the Pilgrim River floodplain. The mineralization on the north side of the river consists of lenses of massive galena in marble near a contact with schist (Smith, 1908). One lens exposed over a distance of 3 feet in a prospect trench contain pyrite, finely crystalline galena, and minor sphalerite. A 2-foot sample across the highest-grade part contained 0.30 ounce of gold per ton, 2.3 ounces of silver per ton and 2.95 percent lead (Asher, 1969). Two samples reported by the owner contained 22.87 percent lead and 20.0 ounces of silver per ton and 14.2 percent lead and 14.5 ounces of silver per ton. The deposits on the south side of the river also include discontinuous lenses of massive galena. An 8- to 10-foot long, 6-foot wide,and 1.5-foot- thick lens of pyrite, fine galena, and limonite with siliceous marble, calcite, and quartz gangue was mined from a 25-foot-long adit and a few tons of ore were apparently shipped. Some boulangerite may also be present (Sainsbury and others, 1972). Pb-isotope analysis of one galena sample gave results identical to samples from the Red Dog (DL001) and Drenchwater Creek (DL002-004) deposits of the western Brooks Range (Church and others, 1985). The mineralization is preferentially developed in the marble but nearby quartz mica schist contains pyrite. The schist/marble contacts appear sheared (Cathcart, 1922). The massive galena is described as a replacement of the host marble (Smith, 1908).

Till and others (2011) map the host rocks as part of the Devonian Nome Complex that consists of pelitic, calcareous, and graphitic schist. Slack and others (2011) reject a volcanogenic massive sulfide origin for the deposit. Their work on this and similar deposits in the Nome Complex indicates that the protolith of the metamorphic rocks that host the deposits are sedimentary and they see no evidence of volcanic rocks associated with them. They base their conclusion: 1) sulfur isotope analysis of the sulfides that indicate a marine origin for the sulfur, 2) isotopic analysis of the barite in some of the deposits that indicate the probable source of the sulfur is Devonian or Mississippi(?) sea water, and 3) whole-rock analyses of the host rocks of the mineralization that indicate that they were originally clastic sedimentary rocks. They propose a sedimentary-exhalative (SEDEX) origin for the deposit during Devonian rifting of the continental margin. Subsequently, the rocks in the area were subjected to blueschist facies metamorphism, then retrograded to greenschist-grade metamorphic rocks in the Jurassic and early Cretaceous.

Alteration:

Oxidation to gossan with abundant limonite, and possible silicification.

Age of mineralization:

Deposited syngenetically in a marine environment during the Devonian; metamorphosed in the Jurassic or early Cretaceous.

Generic deposit model:

Deposit model:

Sedimentary exhalative (SEDEX) lead-zinc-silver-fluorite deposit (Cox and Singer, 1986, model 31a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

31a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

An adit, prospect trenches, and a 2- foot-deep pit are present on the northwest side of the Pilgrim River. On the southeast side of the river, a 25-foot-long adit and numerous prospect pits explored the deposit. Some diamond drilling appears to have occurred in 1971 or 1972 (Sainsbury and others, 1972).

Production notes:

A few tons of ore apparently were mined and shipped.

Reserves:

None.

Last report date: 2012-04-01

Site name(s): Unnamed (near mouth of Swede Creek)

Site type: Prospect

ARDF no.: SO133

Latitude: 64.5669 **Quadrangle:** SO C-4

Longitude: 163.6984

Location description and accuracy:

This prospect extends for several hundred feet east of where Swede Creek cascades over the steep beach cliffs along Norton Sound. Swede Creek is an informal name for the south-flowing drainage no more than a half mile long whose mouth is about a mile west of the mouth of Koyana Creek. It is about 0.3 mile south of the northeast corner of section 5, T. 11 S., R. 25 W. The location is accurate.

Commodities:

Main: Hg

Other:

Ore minerals: Cinnabar

Gangue minerals: Carbonates

Geologic description:

Cinnabar was reported in the placer gold deposits of Swede Creek in 1922 (Cathcart, 1922) and lode prospecting began by at least 1929 (Smith, 1932). The rocks in the area are Paleozoic marble (Herreid, 1965; Mulligan, 1971; Till and others, 1986). In early 2010, the Swede Creek mercury prospect was not being actively explored. However, it is within a large block of ground that is being explored by Millrock Resources Inc. for lode gold (Stevens, 2010; Millrock Resources Inc., 2010).

Two short adits and a shaft explore cinnabar-bearing lodes exposed in the sea cliff 400 feet east of the mouth of Swede Creek (Anderson, 1947; Mulligan, 1971). The portals to the two adits are about 30 or 40 feet below the top of the steep sea cliffs. The adits are short, one was 70 feet long and one 20 feet long (Malone, 1962). The 55-foot-deep vertical shaft is about 50 feet inland from the sea cliff (Malone, 1962; Mulligan, 1971). Cinnabar occurs along two, narrow fault zones; they are about 70 feet apart stratigraphically, subparallel to layering in marble, and dip 10 to 15 degrees north. The lenses are 5-10 inches thick and a few feet long; the longest dimension of an individual lens is 7 feet (Anderson, 1947). Samples of pinkish marble with disseminated cinnabar contained form 0.04 to 0.14 percent mercury; an 18-inch chip sample across a cinnabar-bearing lens contained 6.76 percent mercury; and a 7-foot chip sample across the same lens and adjacent lower grade mineralized rock contained 2.36 percent mercury (Anderson, 1947).

Mulligan (1971) noted that a rotary retort to process mercury ore lies several miles away on the hillside just above the mouth of Daniels Creek; apparently it was never used.

Alteration:

Age of mineralization:

Unknown; possibly Cretaceous or Tertiary.

Generic deposit model:

Deposit model:

Cinnabar in lenses and disseminated along a shallow-dipping fault in marble.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Cinnabar was reported in the placer gold deposits of Swede Creek in 1922 (Cathcart, 1922) and lode prospecting began by at least 1929 (Smith, 1932). In early 2010, the Swede Creek mercury prospect was not being actively explored. However, it is within a large block of ground that is being explored by Millrock Resources Inc. for lode gold (Stevens, 2010; Millrock Resources Inc., 2010). Two short adits and a shaft were driven sometime before 1947 in the sea cliff 400 feet east of the mouth of Swede Creek (Anderson, 1947; Mulligan, 1971). The portals to the two adits are about 30 or 40 feet below the top of the steep sea cliffs. The adits are short, one was 70 feet long and one 20 feet long (Malone, 1962).

Production notes:

Probably none but a few pounds of mercury could easily have been retorted for local use.

Reserves:

None.

Site type: Mine

ARDF no.: SO135

Latitude: 64.5698 **Quadrangle:** SO C-4

Longitude: 163.75

Location description and accuracy:

This prospect is exposed about 1,000 feet east of the mouth of Daniels Creek at the base of the cliffs along Norton Sound. It is about 0.7 mile south of the center of section 31, T. 11 S., R. 25 W. The location is accurate.

Commodities:

Main: Ag, As, Au Bi, Cd, Cu, Pb, Sb, W

Other: W

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, scheelite

Gangue minerals: Clay, quartz

Geologic description:

This prospect has long been known but few details have been published. It was discovered after 1908 inasmuch as Brooks (1908) makes a point of the absence of any nearby lode source for the placer gold in Daniels Creek (SO006). In 1939, the Alaska Homestake Gold Mining Company began work on the lode deposits in the vicinity of Daniels Creek (Stevens, 2010). They identified three vein systems in the beach cliffs just east of the mouth of Daniels Creek that they called the Idaho, Eskimo, and Seagull lodes (which are shown by name on figure 3 of Mulligan,1971). Their work extended inland for a considerable distance, probably into what is now included in the Daniels prospect (SO177).

The veins just east of the mouth of Daniels Creek have been sampled several times and restaked at least once (Mulligan, 1971; Herreid, 1965; Stevens, 2010). The sea cliff exposures include a subhorizontal, massive arsenopyrite-pyrite lens 4 feet wide and 20 feet long that pinches down to a foot or less at its ends. The east end of this lens becomes a foot-wide quartz vein. A 4-foot chip sample by Herreid (1965) across the sulfide lens contained 0.18 ounce of gold per ton and 0.35 ounce of silver per ton. Other grab samples from the sea cliff exposures contained 0.02 to 0.42 ounce of gold per ton and 0.16 to 0.55 ounce of silver per ton (Herreid, 1965). Four samples collected by Millrock Resources Ltd. in 2008 contained up to 0.1 part per million (ppm) silver, 13.82 ppm gold, more than 10,000 ppm arsenic, 140 ppm bismuth, 1,000 ppm cadmium, 265 ppm copper, 611 ppm lead, 597 ppm antimony, and 17 ppm zinc (Stevens, 2010). The Bureau of Mines cut a trench 946 feet long, oriented nearly east-west, on the hillside above the beach cliffs, about 500-1000 feet north of the veins exposed at the bottom of the sea cliffs. The trench was systematically sampled; most samples had 'Nil' to 'Trace' gold, the highest value was 0.085 ounce of gold per ton over 10 feet. Millrock Resources Inc. drilled one hole 458 feet deep in schist on the hillside about 600 feet north of the lode exposed at the bottom of the sea cliffs. The best intercept was 4.5 feet that contained 3.819 grams per ton of gold. The only other notable intercept was 1.2 feet with 7.689 grams of gold per tonne.

A sample of white mica from a quartz vein nearby at the Saddle prospect SO175) gave a Ar/Ar plateau date of 109.1 +/- 0.2 Ma and metamorphic white mica in the host schist gave Ar/Ar total gas dates of 122.6 +/- 0.4 Ma and 122.4 +/- 0.2 Ma (Ford and Snee, 1996). This indicates that the mineralization in the Bluff area is Late Cretaceous and probably related to regional metamorphism, as are many other deposits on the Seward Peninsula (Apodoca, 1994; Ford, 1993, Ford and Snee, 1996; Goldfarb and others, 1997).

Alteration:

The surface and near-surface gold-bearing rocks are oxidized and iron-staining is common. The quartz veins often contain clay.

Age of mineralization:

Cretaceous; at the nearby Saddle prospect (SO175) which is probably of the same age, a sample of white mica from a quartz vein nearby at the Saddle prospect SO175) gave a Ar/Ar plateau date of 109.1 +/- 0.2 Ma (Ford and Snee, 1996).

Generic deposit model:

Deposit model:

Discontinuous, irregular to joint-con tolled arsenopyrite-quartz veins and breccia with disseminated arsenopyrite and pyrite in host rocks; low sulfide-Au quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: Undetermined

Site Status: Active

Workings/exploration:

This prospect has long been known but few details have been published. It was discovered after 1908 inasmuch as Brooks (1908) makes a point of the absence of any nearby lode source for the placer gold in Daniels Creek (SO006). In 1939, the Alaska Homestake Gold Mining Company began work on the lode deposits in the vicinity of Daniels Creek (Stevens, 2010). They identified three vein systems in the beach cliffs just east of the mouth of Daniels Creek that they called the Idaho, Eskimo, and Seagull lodes (which are shown by name on figure 3 of Mulligan, 1971). Their work extended inland for a considerable distance, probably into what is now included in the Daniels prospect (SO New D1014). In 2008. Millrock Resources Inc. drilled one hole 458 feet deep in schist on the hillside about 600 feet north of the lode exposed at the bottom of the sea cliffs (Stevens, 2010).

Production notes:

Probably none.

Reserves:

None.

Last report date: 2010-04-02

Site name(s): Unnamed (near mouth of Koyana Creek)

Site type: Prospect

ARDF no.: SO136

Latitude: 64.5688 **Quadrangle:** SO C-4

Longitude: 163.6651

Location description and accuracy:

This lode gold prospect is about 500 feet east of the mouth of Koyana Creek in the beach cliffs just above the high-tide line. Koyana Creek is a small drainage that flows south to its mouth on Norton Sound; it is about 2.6 miles east of the old community of Bluff. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Arsenopyrite, gold

Gangue minerals: Quartz

Geologic description:

This prospect is at the east end of an arcuate band of Paleozoic schist about three miles long and up to a half mile wide that hosts most of the lode deposits in the Bluff area, including the Koryana (SO176) , Saddle (SO175), Daniels Creek (SO New D1014), and Idaho (SO135) prospects. The schist is bordered to the north and south by thick, extensive marble; the contacts are probably thrust faults.

Gold-bearing lode mineralization was discovered near the mouth of Koryana creek in the early 1900s (Collier and others, 1908). Three short adits and a shallow shaft were developed, probably before WWII (Mulligan, 1971). In early 2010, the prospect was on a large block of ground being explored by Millrock Resources, Inc.; the prospect was sampled in 2008 (Stevens, 2010).

Exposures in the beach cliffs expose the portal of a 30-foot-long adit into a zone about 20 feet wide in schist with a network of ramifying quartz veins and breccia (Cathcart, 1922). Thin quartz veins extend along joints oblique to the foliation of the schist for a considerable distance from the main mineralization. Pyrite and arsenopyrite are common in the quartz and are disseminated in the schist wall rock. The largest crosscutting quartz vein observed by Herreid (1965) was 4 inches wide and 10 feet long. Seven grab and chip samples contained 0.01 to 0.32 ounce of gold per ton and 0.16 to 0.65 ounce of silver per ton. One composite chip sample of schist, collected every 10 feet over a distance of 700 feet, contained 0.07 ounce of gold per ton. Thirteen samples collected in 2008 across the mineralization contained up to 35.6 parts per million (ppm) gold, less than 0.1 ppm silver, 10,000 ppm or more arsenic, up to 177 ppm bismuth, up to 1000 ppm cadmium, and barely above background copper lead, and zinc (Stevens, 2010).

This prospect is probably similar to the nearby Saddle prospect (SO175) and Koryana prospect (SO176) which have been described by Ford (1993) and Ford and Snee (1996). Samples of white mica from a vein at the Saddle prospect has a Ar/Ar plateau age of 109.3 +/- 0.3 Ma and metamorphic white mica in the host schist have Ar/Ar plateau ages of 122.6 +/- 0.4 Ma and 122.4 +/- 0.2 Ma (Ford and Snee, 1996). The deposit is thus probably mid-Cretaceous, as are many of the other lode gold deposits on southern Seward Peninsula (Apodoca, 1994; Ford, 1993, Hudson, 1994; Ford and Snee, 1996; Goldfarb and others, 1997).

Alteration:

Quartz veining; much bright orange staining, probably from oxidization of pyrite.

Age of mineralization:

Mid-Cretaceous; Samples of white mica from a vein at the Saddle prospect has a Ar/Ar plateau age of 109.3 +/- 0.3 Ma.

Generic deposit model:

Deposit model:

Discontinuous, irregular to joint-con tolled arsenopyrite-quartz veins and breccia with disseminated arsenopyrite and pyrite in host rocks; low sulfide-Au quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

Developed by three short adits, one 30 feet long, and a shallow shaft Mulligan, 1971). The prospect was sampled in 2008 and in early 2010, the prospect was on a large block of ground being explored by Millrock Resources, Inc. (Stevens, 2010).

Production notes:

A few tons of ore were reported to have been sacked but it is not known if this was shipped (Smith and Eakin, 1911).

Reserves:

None.

Site name(s): Saddle

Site type: Prospect

ARDF no.: SO175

Latitude: 64.5766 **Quadrangle:** SO C-4

Longitude: 163.7203

Location description and accuracy:

The Saddle prospect is an area about 800 meters long by 300 meters wide. It was originally defined by anomalous arsenic and gold in soil samples; later 14 scattered holes were drilled in it. The center of the area is about 1.0 mile northeast of the abandoned settlement of Bluff. It is about 0.2 mile southwest of the center of section 32, T. 10 S., R. 25 W. The location is accurate.

Commodities:

Main: As, Au

Other:

Ore minerals: Arsenopyrite, gold, marcasite, pyrite, pyrrhotite

Gangue minerals: Carbonates, quartz

Geologic description:

The Saddle prospect was first identified by BHP-Utah in 1995 as an area anomalous in arsenic and gold in soils. Subsequently they drilled 10 holes in the area before they dropped the property in 1990. In 2008, Millrock Resources Inc. (2010) began exploring in the area under an agreement with Bering Straits Native Corporation. Millrock's work on the Saddle prospect included geologic mapping and sampling, reanalysis of some of the BHP core, and geochemical soil surveys.

The Saddle prospect is near the center of an arcuate band of Paleozoic schist about three miles long and up to a half mile wide that extends from the mouth of Koryana Creek to the mouth of Daniels Creek (Herreid, 1965; Mulligan, 1971; Till and others, 1986; Stevens, 2010)) . This schist unit hosts most of the lode deposits in the Bluff area, including the Koryana (SO176), Daniels Creek (SO177), and Idaho (SO135) prospects. The schist is bordered to the north and south by thick, extensive marble; the schist-marble contacts are probably thrust faults.

There is little outcrop in the Saddle area and most of the information about it comes from the 10 BHP-Utah drill holes. As described by Ford (1993) and Ford and Snee (1996), the mineralization at the Saddle prospect is localized in extensional joints that strike easterly and dip moderately to the south in quartz-muscovite schist. The veins are discontinuous and commonly less than 3 inches thick. Gold grades are irregularly distributed; vein intersections up to 3.3 feet across contain up to 1.8 ounces of gold per ton. The quartz veins frequently contain a few percent of ore minerals, mainly arsenopyrite, but marcasite, pyrite, and pyrrhotite occur in small amounts. The veins are commonly bordered by altered zones with plagioclase, chlorite, carbonate, white mica, biotite, titanite, and tourmaline. A sample of white mica from a quartz vein gave an Ar/Ar plateau date of 109.1 +/- 0.2 Ma and metamorphic white mica in the host schist gave Ar/Ar total gas dates of 122.6 +/- 0.4 Ma and 122.4 +/- 0.2 Ma (Ford and Snee, 1996). This indicates that the mineralization at Saddle is Late Cretaceous and probably related to regional metamorphism as are many other deposits on the Seward Peninsula (Apodoca, 1994; Ford, 1993, Ford and Snee, 1996; Goldfarb and others, 1997).

On the basis of their drilling, BHP-Utah concluded that the resources of the Saddle prospect was 1,500,000 tons of material with a grade of 7.77 grams of gold per tonne, or a total resource of 165,000 ounces of gold (Heine and Kell, 1991; Stevens, 2010). (However, Stevens also emphasized that the BHP-

Utah 'resource' for Saddle was not 43-101 compliant.)

Alteration:

Quartz veining; the veins are commonly bordered by altered zones with plagioclase, chlorite, carbonate, white mica, biotite, titanite, and tourmaline.

Age of mineralization:

Mid-Cretaceous; a sample of white mica from a quartz vein gave an Ar/Ar plateau date of 109.1 +/- 0.2 Ma (Ford and Snee, 1996).

Generic deposit model:

Deposit model:

Discontinuous, irregular to joint-con tolled arsenopyrite-quartz veins and breccia with disseminated arsenopyrite and pyrite in host rocks; low sulfide-Au quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

The Saddle prospect was first identified by BHP-Utah in 1995 as an area anomalous in arsenic and gold in soils. Subsequently they drilled 10 holes in the area before they dropped the property in 1990. As of early 2010, Millrock's work on the Saddle prospect included geologic mapping and sampling, reanalysis of some of the BHP-Utah core, and geochemical soil surveys.

Production notes:

None.

Reserves:

On the basis of their drilling, BHP-Utah concluded that the resource of the Saddle prospect was 1,500,000 tons of material with a grade of 7.77 grams of gold per tonne or a total resource of 165,000 ounces of gold (Heine and Kell, 1991; Stevens, 2010). However, Stevens also emphasized that the BHP-Utah 'resource' for Saddle was not 43-101 compliant.

Site type: Prospect

ARDF no.: SO176

Latitude: 64.5717 **Quadrangle:** SO C-4

Longitude: 163.6859

Location description and accuracy:

The Koyana prospect is an area about 1,100 meters long by 300 meters wide. It was originally defined by anomalous arsenic and gold in soil samples and 10 scattered holes were drilled in it. The center of the area is about 0.5 mile west-northwest of the mouth of Koyana Creek and 0.5 mile south of the center of section 33, T.10 S., R. 25 W., of the Kateel River Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Au

Other: As

Ore minerals:

Gangue minerals: Carbonates, quartz

Geologic description:

The Koyana prospect was first identified by BHP-Utah in 1986 as an area anomalous in arsenic and gold in soils. Subsequently they drilled 10 holes in the area before they dropped the property in 1990 (Stevens, 2010). The Koyana prospect is at the east end of an arcuate band of Paleozoic schist about three miles long and up to a half mile wide that extends from the mouth of Koyana Creek to the mouth of Daniel's Creek (Herreid, 1965; Mulligan, 1971; Till and others, 1986). This schist unit hosts most of the lode deposits in the Bluff area, including the Saddle (SO175), Daniel's Creek (SO006), and Idaho (SO135) prospects. The schist is bordered to the north and south by thick, extensive marble; the schist-marble contacts are probably thrust faults.

There is little outcrop in the Koyana area and most of the information about it comes from 10 BHP-Utah drill holes. As described by Ford (1993) and Ford and Snee (1996), the mineralization at the Koyana prospect is localized in extensional joints that strike easterly and dip moderately to the south in quartz-muscovite schist. The veins are discontinuous and commonly less than 3 inches thick. Gold grades are irregularly distributed; vein intersections up to 3.3 feet across contain up to 1.8 ounces of gold per ton. The quartz veins frequently contain a few percent of ore minerals, mainly arsenopyrite, but marcasite, pyrite, and pyrrhotite occur in small amounts. The veins are commonly bordered by altered zones with plagioclase, chlorite, carbonate, white mica, biotite, titanite, and tourmaline. A sample of white mica from a quartz vein gave an Ar/Ar plateau date of 109.1 +/- 0.2 Ma and metamorphic white mica in the host schist gave Ar/Ar total gas dates of 122.6 +/- 0.4 Ma and 122.4 +/- 0.2 Ma (Ford and Snee, 1996). This indicates that the mineralization at Saddle is Late Cretaceous and probably related to regional metamorphism as are many other deposits on the Seward Peninsula (Apodoca, 1994; Hudson, 1994; Ford, 1993, Ford and Snee, 1996; Goldfarb and others, 1997).

Based on their 10 drill holes, BHP-Utah concluded that the resource of the Koyana prospect was 1.81 million tonnes of material with a grade of 0.69 gram of gold per tonne, or a total resource of 1.24 million grams of gold (Heine and Kell, 1991; Stevens, 2010). However, Stevens also emphasized that the BHP-Utah 'resource' for Koyana was not 43-101 compliant.

In 2008, Millrock Resources Inc. began exploring in the area under an agreement with Bering Straits Native Corporation. As of early 2010, Millrock's work on the Koyana prospect included geologic mapping

and sampling, reanalysis of some of the BHP core, and geochemical soil surveys (Stevens, 2010).
A field exploration program undertaken in 2010 by Millrock Resources Inc. extended the known areas of anomalous values into areas not previously sampled. The anomalies included gold values of up to 483 parts per billion (ppb) and a positive correlation with arsenic values. This work identified a conformable, depositional contact of graphitic schist with the carbonaceous marble on a cliff face, despite poor outcrop due to recessive weathering (Negri, 2011).

Alteration:

Quartz veins are commonly bordered by altered zones with plagioclase, chlorite, carbonate, white mica, biotite, titanite, and tourmaline (Stevens, 2010).

Age of mineralization:

Mid-Cretaceous; white mica from similar quartz veins nearby in the Koyana Creek area gave Ar/Ar plateau dates of 109.1 +/- 0.7 Ma and 109.6 +/- 0.2 Ma (Ford and Snee, 1996).

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active?

Site name(s): Daniels

Site type: Prospect

ARDF no.: SO177

Latitude: 64.5789

Quadrangle: SO C-4

Longitude: 163.7356

Location description and accuracy:

The Daniels prospect is an area about 960 meters long by 300 meters wide that was originally defined by anomalous arsenic and gold in soil samples. There is little outcrop but it has been drilled several times. The center of the area is in the headwaters of Daniels Creek about 0.7 mile northeast of the abandoned settlement of Bluff. It is about 0.5 mile east of the center of section 31, T. 10 S., R. 25 W. The location is accurate.

Commodities:

Main: As, Au

Other: Ag, Bi, Cd, Cu, Pb, Sb, W, Zn

Ore minerals: Arsenopyrite, gold, marcasite, pyrite, pyrrhotite, scheelite

Gangue minerals: Carbonates, quartz

Geologic description:

The Daniels prospect was first identified by BHP-Utah in 1995 as an area anomalous in arsenic and gold in soils. Subsequently, they drilled 10 holes in the area before they dropped the property in 1990 (Stevens, 2010). In 2008, Millrock Resources Inc. began exploring in the area under an agreement with Bering Straits Native Corporation. As of early 2010, Millrace's work on the Daniels prospect included geologic mapping and sampling, reanalysis of some of the BHP core, and geochemical soil surveys (Millrock Resources Inc., 2010 [Bering Straits]). They also drilled 4 short holes in 2008 that totaled only 809 feet. The drilling was poorly done and the core recovery was poor. In 2010, Millrock and its partner Valdez Gold Inc. drilled 24 holes, 130-meters deep, in fences of holes (Millrock, 2010 [Millrock and Valdez Gold]).

There was at least some early exploration in the area as there is a small dump at a caved shaft near the center of the area; parts for a small mill are nearby but it apparently was never put in operation. The Bureau of Mines dug several trenches about 1970 Mulligan (1971). The Daniels prospect is essentially contiguous to and a geologic extension of the Saddle prospect (SO175); they were described separately by BHP-Utah as a convenience.

The Daniels prospect is near the center of an arcuate band of Paleozoic schist about three miles long and up to a half mile wide that extends from the mouth of Korean Creek to the mouth of Daniels Creek (Herreid, 1965; Mulligan, 1971; Till and others, 1986). This schist unit hosts most of the lode deposits in the Bluff area, including the Koyana (SO176), Saddle (SO175), and Idaho (SO135) prospects. The schist is bordered to the north and south by thick, extensive marble; the schist-marble contacts are probably thrust fault.

There is little outcrop in the Daniels prospect area and much of the information about the mineralization comes from the 10 BHP-Utah drill holes, the 4 holes drilled by Millrock in 2008, and the 24 holes drilled by Millrock and Valdez Gold in 2010. As described by Ford (1993) and Ford and Snee (1996), the mineralization at the Daniels prospect consists of quartz veins localized in extensional joints that strike easterly and dip moderately to the south in quartz-muscovite schist. The veins are discontinuous and commonly less than 3 inches thick. Gold grades are erratic but vein intersections up to 3.3 feet across contain up to 1.8 ounces of gold per ton. The quartz veins frequently contain a few percent of ore minerals, mainly arsenopyrite, but marcasite, pyrite, and pyrrhotite occur in small amounts.

The four short holes drilled by Millrock in 2008 were in quartz-muscovite schist, graphitic schist, marble and gouge (Stevens, 2009). The best intercepts were 5.94 meters that contained 1.397 grams of gold per tonne and 1.37 meters that contained 3.819 grams of gold per tonne. The 2010 drilling (Millrock, 2010 [Millrock and Valdez Gold]) extended the mineralized zone to a strike length of 960 meters. The best intersection was 32.0 meters with 3.8 grams of gold per tonne.

A sample of oxidized arsenopyrite-rich dump material beside an old shaft in about the center of the Daniels prospect contained 2.76 ounces of gold per ton and 1.49 ounces of silver per ton; eight other samples of dump materials contained 0.03 to 0.23 ounces of gold per ton and 0.03 to 1.57 ounces of silver per ton (Herreid, 1965). Herreid (1965) reports that scheelite can be panned from some dump materials. Several chip samples from dozer trenches cut across the north-trending schist belt in the area were locally mineralized and included some 10-foot intervals with up to 0.04 ounce of gold Au per ton (Mulligan, 1971). Quartz-clay veinlets were common in the mineralized parts of the trench exposures. One high grade sample collected in 2009 near or at the old shaft contained 0.1 part per million (ppm) silver, 13.82 ppm gold, 10,000 or more ppm arsenic, 140 ppm bismuth, 1,000 ppm cadmium, 265 ppm copper, 611 ppm lead, 597 ppm antimony, and 27 ppm zinc.

The veins are commonly bordered by altered zones with plagioclase, chlorite, carbonate, white mica, biotite, titanite, and tourmaline. A sample of white mica from a quartz vein gave a Ar/Ar plateau date of 109.1 +/- 0.2 Ma and metamorphic white mica in the host schist gave Ar/Ar total gas dates of 122.6 +/- 0.4 Ma and 122.4 +/- 0.2 Ma (Ford and Snee, 1996). This indicates that the mineralization at Saddle is Late Cretaceous and probably related to regional metamorphism as are many other deposits on the Seward Peninsula (Apodoca, 1994; Hudson, 1994; Ford, 1993, Ford and Snee, 1996; Goldfarb and others, 1997).

On the basis of their drilling, BHP-Utah concluded that the resources of the Daniels prospect was 3,000,000 tons of material with a grade of 3.43 grams of gold per tonne, or a total resource of 300,000 ounces of gold (Heinz and Keel, 1991; Stevens, 2010). (However, Stevens also emphasized that the BHP-Utah 'resource' for Daniels was not 43-101 compliant.)

Alteration:

The quartz veins are commonly bordered by altered zones with plagioclase, chlorite, carbonate, white mica, biotite, titanite, and tourmaline. The drill holes commonly cut gouge.

Age of mineralization:

Cretaceous; a sample of white mica from a quartz vein gave a Ar/Ar plateau date of 109.1 +/- 0.2 Ma (Ford and Snee, 1996).

Generic deposit model:

Deposit model:

Discontinuous, irregular to joint-con tolled arsenopyrite-quartz veins and breccia with disseminated arsenopyrite and pyrite in host rocks; low sulfide-Au quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Active

Workings/exploration:

The Daniels prospect was first identified by BHP-Utah in 1995 as an area anomalous in arsenic and gold in soils. Subsequently, they drilled 10 holes in the area before they dropped the property in 1990 (Stevens, 2010). Last report date: 2011-02-28

Site name(s): Unnamed (near Peak 3231, Darby Ridge)

Site type: Occurrence

ARDF no.: SO178

Latitude: 64.8365 **Quadrangle:** SO D-1

Longitude: 162.4615

Location description and accuracy:

This occurrence is on a rugged east-west ridge that intersects the principal north-south divide crest of the Darby Mountains. Elevations in the area of the occurrence range more than 2,000 feet up to 3,243 feet at the top of an unnamed mountain about one mile northwest of the prospect. Drainage from the area is into the upper tributaries of Clear Creek. The main site is a high saddle on the east flank of peak 3231 in the S1/2 sec. 35, T. 5 S., R. 19 W. of the Kateel River Meridian, and additional sample sites are located at a cirque at 64.8653 N, 162.4624 W in section 26.

Accuracy of the location is about 1,500 feet.

Commodities:

Main: U

Other: Pb

Ore minerals:

Gangue minerals: Carbonate, chlorite, clay minerals, epidote, hematite, magnetite, pyrrhotite, quartz, sericite

Geologic description:

The Darby pluton is relatively homogeneous, mostly quartz monzonite and minor granite. Locally there are segregations of quartz-deficient, potassium-rich rocks including syenite and alkali granite. In the vicinity of Clear Creek, the rocks of the Darby pluton are mostly quartz monzonite containing biotite and lesser hornblende. The quartz monzonite is cut by tourmaline aplite, and rhyolite and tourmaline-bearing pegmatite dikes and a swarm of lamprophyre and apparently related variants of dark-colored sub-alkaline porphyritic dikes.

This occurrence consists of altered quartz monzonite intruded by a syenite dike. Radiometric measurements over argillic alteration in the quartz monzonite were two times background and a sample assayed 47 parts per million (ppm) uranium. A second sample of altered quartz monzonite from about 2,500 feet to the east reported 24 ppm uranium. Hawley and others (1978) reported up to 80 ppm uranium in soil samples from a gossan near the divide between Clear and Dry Canyon Creeks believed to be immediately north of this occurrence but the site was not re-located. Similar alteration occurs along the Darby Ridge two miles north (two samples of altered andesite assayed 40 and 50 ppm uranium) and three miles south of the Peak 3231 occurrence (soil sample assayed 77 ppm uranium) (Foley and Barker, 1986).

Alteration:

Greisen float, locally intense argillic alteration, locations with hematitic staining with silicification formed in shear zones; discrete zones of sericite development, epidote, and chlorite alteration. Adjacent quartz monzonite exhibits propylitic alteration. Oxidation and clay minerals after argillic alteration (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generic deposit model:

Deposit model:

Granite-hosted veins with uranium generally much greater than thorium; minimal REE and tin; uranium does not concentrate in resistant minerals as indicated by heavy mineral survey (Foley and Barker, 1986); mineralized shear zones with structural control, spatial association with lamprophyre dikes; no clear comparable examples available.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

This occurrence consists of altered quartz monzonite intruded by a syenite dike. Radiometric measurements over argillic alteration in the quartz monzonite were two times background and a sample assayed 47 parts per million (ppm) uranium. A second sample of altered quartz monzonite from about 2,500 feet to the east reported 24 ppm uranium. No reserves.

Additional comments:

The Darby Mountain area was selected for study by the U.S. Bureau of Mines in 1979 as part of ongoing mineral land assessments in Alaska and land designations proposed by Congress, and because recent (1970s) private sector exploration had discovered sedimentary uranium in the Boulder Creek basin at the southern end of Death Valley about 10 miles to the northeast (Dickinson and others, 1987). No further work was performed; claims are active in southern Death Valley, in the Boulder Creek basin area.

Site name(s): West Vulcan Creek No. 1

Site type: Occurrence

ARDF no.: SO179

Latitude: 64.9274

Quadrangle: SO D-1

Longitude: 162.2591

Location description and accuracy:

The West Vulcan Creek No. 1 consists of a group of mineral showings located on a north-facing promontory on the ridge that forms the south side of a tributary to Vulcan Creek. Elevation of the occurrence ranges from 1,500 to 2,000 feet.

Vulcan Creek is a headwater drainage of the Tubutulik River located east of the report area. The creek is one of several that drain the east flank of the Darby Mountains. The occurrence site is in the N1/2 sec. 35, T. 6 S., R. 18 W. of the Kateel River Meridian and the coordinates given above are the approximate midpoint of the east-northeast trend of alteration and mineral showings. Accuracy of the location is about 1,000 feet.

Commodities:

Main: U

Other: Pb

Ore minerals:

Gangue minerals: Chlorite, clay minerals, epidote, hematite, magnetite, plagioclase, pyrrhotite, quartz, sericite

Geologic description:

The Darby pluton is a relatively homogeneous intrusion, mostly composed of quartz monzonite and minor granite. Locally there are segregations of quartz-deficient, potassium-rich rocks, including syenite and alkali granite. The pluton is further cut by rhyolite, aplite, and tourmaline-bearing pegmatite dikes.

In the Vulcan Creek and adjacent Rock Creek area, the Darby pluton is quartz monzonite containing include biotite and lesser hornblende and is cut by tourmaline aplite and a swarm of lamprophyre and apparently related variants of sub-alkaline dikes (Foley and Barker, 1986). These dark-colored, porphyritic dikes contain euhedral biotite, amphibole, corroded quartz xenocrysts and, more rarely, clinopyroxenite or olivine in a groundmass of altered plagioclase, and minor potassium feldspar.

Generally, the Vulcan Creek and Rock Creek area has higher radiometric levels than the surrounding region. At outcrop scale, mineralized zones will give radiometric responses of 2 to 10 times background.

At West Vulcan Creek no. 1, radiometric measurements up to six times background occur over frost boils along the ridge top. Downslope from these several groundwater seeps apparently emit radon. Altered shear zones and secondary quartz occurs along the ridge that descends east-northeast-oriented and is intruded by a dark-green fine-grained dike. Test pits encountered high levels of radiation and revealed hematitic mud, clay, and regolith containing quartz crystals variably altered to a sooty black color. Fragments of quartz-sericite greisen with boxwork after sulfides were found in several nearby test pits. Fourteen assayed samples ranged up to 1,290 parts per million (ppm) uranium. The highest uranium values are from test pit sites that expose decomposed, clayey, quartz monzonite that has a secondary matrix of varicolored earthy oxides. Several pits dug to 5.5 feet depth encountered residual stratified gruss with layers of varying radiometric response suggestive of localized secondary uranium. Distinctly higher radiometric measurements were recorded over hydrothermally altered veins and were structurally controlled by high-angle shear zones and breccia masses. Radiometric response locally exceeded the calibration limits of handheld scintillometers. These radiometric anomalies generally featured hematite, black iridescent manganese staining, quartz stockwork, ferruginous quartz, jasper, drusy and vuggy quartz. A sample from a nearby carbonate-altered,

dark green porphyry contained 68 ppm uranium. The anomalous radiometric response apparently reflects uranium, as very little thorium was reported in any of the samples. Some samples containing elevated uranium values also contained anomalous lead (Foley and Barker, 1986).

Gangue minerals include chlorite, various clay minerals, hematite, secondary drusy and vein quartz, sericite, epidote, and plagioclase that is partly to mostly altered to white mica and carbonate and opaque minerals, which include magnetite, and pyrrhotite.

Alteration:

Greisen, locally argillic, pervasive hematitic staining and corroded quartz, wide zones of sericite, argillite, and chlorite alteration. Alteration is best exposed in avalanche gullies and/or some structurally controlled swales along exposed ridges (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous with some subordinate granitic rocks (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generic deposit model:

Deposit model:

Granite-hosted veins with uranium values generally much greater than thorium; minimal REE, tin; uranium values that do not concentrate in resistant minerals as indicated by heavy mineral survey (Foley and Barker, 1986); mineralized shear zones by structural control, spatial association with lamprophyre dikes; no clear comparable examples available.

Ore minerals:

Gangue minerals: Chlorite, clay minerals, epidote, hematite, magnetite, plagioclase, pyrrhotite, quartz, sericite

Geologic description:

The Darby pluton is relatively homogeneous, mostly quartz monzonite and minor granite. Locally there are segregations of quartz-deficient, potassium-rich rocks including syenite and alkali granite.

In the Vulcan Creek and adjacent Rock Creek area the Darby pluton is quartz monzonite containing biotite and lesser hornblende. The pluton is also cut by lamprophyre, rhyolite, aplite, and tourmaline-bearing pegmatite dikes. These later dikes contain euhedral biotite, amphibole, corroded quartz xenocrysts and, more rarely, clinopyroxenite or olivine in a groundmass of altered plagioclase and minor potassium feldspar (Foley and Barker, 1986).

Generally, the Vulcan and Creek Rock Creek area has higher radiometric levels than the surrounding region. At West Vulcan Creek No. 2 radiometric measurements vary from 1.5 to 6 times background over frost boils along the 300 foot-long exposed strike of the northeast-trending quartz system in a small avalanche gully. The zone goes under surficial cover on both ends but where exposed it appears to be about 40 feet wide. The prospect is marginal to silica-poor sheared chloritic, argillic-altered quartz monzonite.

Test pits exposed irregular replacement-style masses of red hematitic quartz pods 6-10 feet wide mixed in a kaolinized and sheared biotite quartz monzonite and quartz stockwork marginal to the shear zone. The altered shear zone and secondary quartz occur where exposed by erosion along the steeply descending, northeast trending gully. Test pits encountered intense radiation. Fragments of quartz-sericite-chlorite greisen with boxwork after sulfides were also found in additional nearby test pits along strike. Assays of fourteen samples ranged up to 435 parts per million (ppm) uranium. An unidentified radioactive yellow oxide was also noted within the silicified zone. Higher uranium values are associated with lead values up to 3,000 ppm lead, and slightly elevated copper values; these are from the silicified masses, whereas altered marginal quartz monzonite assayed lower uranium values, between 10 to 24 ppm. Very little thorium was reported in any of the quartz-rich samples, though slightly elevated thorium values (up to 76 ppm) are found in the altered quartz monzonite.

No ore minerals were identified but there was a radioactive yellow oxide noted in the silicified shear zone. Gangue minerals include chlorite, clay minerals, hematite, replacement quartz, and sericite. Epidote, plagioclase that is generally altered to carbonate and white mica with opaque minerals including clay minerals, magnetite, and pyrrhotite.

Alteration:

Greisen, locally argillic, pervasive hematitic staining and corroded quartz occurring in wide zones of sericite and chlorite alteration. Alteration is best exposed in avalanche gullies and/or some structurally controlled swales along exposed ridges (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generally, the Rock Creek and West Vulcan Creek area has higher radiometric levels than the surrounding region.

At West Vulcan Creek No. 3 radiometric measurements vary up to three times background over altered sub-crop, and ground water seeps from fractures along an altered, deeply leached shear zone in a north-trending gully and avalanche chutes. Propylitic- and argillic-altered zones occur in the quartz monzonite and closely spaced shear zones strike north and are exposed over 40 feet of width and 800 feet along strike at this location. Unlike other occurrences in the area, only minor silica and hematite replacements are noted at this site (Foley and Barker, 1986).

Grab samples of altered monzonite and discontinuous quartz fracture fillings assayed 37 to 89 parts per million (ppm) uranium. Sediment from a seep contained 76 ppm uranium.

Gangue minerals include chlorite, clay minerals, hematite, sericite. Quartz forms drusy replacement fillings. Epidote, plagioclase generally altered to carbonate and white mica, with opaque minerals including clay minerals, magnetite, and pyrrhotite.

Alteration:

Greisen, locally argillic, local hematitic staining and corroded quartz, wider zones of sericite and chlorite alteration in the quartz monzonite. Alteration is best exposed in avalanche gullies and/or some structurally

Site type: Occurrence

ARDF no.: SO182

Latitude: 64.9371 **Quadrangle:** SO D-1

Longitude: 162.3755

Location description and accuracy:

The Rock Creek No. 4 consists of a group of mineral showings located on a prominent north-facing buttress above an upper cirque near the head of Rock Creek. Elevations in the area of the occurrence range from about 1,500 feet up to 2,400 feet at the top of the buttress.

Rock Creek is one of several creeks that drain the east flank of the north-trending Darby Mountains and is a tributary to the Tubutulik River, which is located east of the report area. The occurrence site is in W1/2SW1/4 sec. 29, T. 6 S., R. 18 W. of the Kateel River Meridian and is the approximate midpoint of several vein and alteration features along the 2,000-foot north trend of alteration and mineral showings across the top of the buttress.

Accuracy of the location is about 1,000 feet.

Commodities:

Main: U

Other: Pb, Zn

Ore minerals:

Gangue minerals: Chlorite, clay minerals, epidote, hematite, magnetite, plagioclase, pyrrhotite, sericite

Geologic description:

The Darby pluton is relatively homogeneous, mostly quartz monzonite and minor granite. Locally there are segregations of quartz-deficient, potassium-rich rocks including syenite and alkali granite.

In to the Vulcan Creek and adjacent Rock Creek area the Darby pluton is quartz monzonite containing biotite and lesser hornblende. The pluton is also cut by lamprophyre, rhyolite, aplite, and tourmaline-bearing pegmatite dikes. These later dikes contain euhedral biotite, amphibole, corroded quartz xenocrysts and, more rarely, clinopyroxenite or olivine in a groundmass of altered plagioclase and minor potassium feldspar (Foley and Barker, 1986).

Generally, the Rock Creek and West Vulcan Creek area has higher radiometric levels than the surrounding region. At this occurrence numerous quartz veins and abundant vein quartz rubble occur along a high cirque wall for 1,000 feet and at several sites of alteration on the top of the buttress. In bedrock showings, the veins are leached and the wall rock variably altered to hematitic clay residue and drusy quartz. Veins dip vertically and range from less than an inch up to several feet thick. Veins are contain secondary drusy quartz, relic pyrite and traces of other sulfide minerals. A grab sample from a hematitic quartz vein contained 153 parts per million (ppm) uranium and 236 ppm thorium. No radiometric readings were collected due to weather conditions at the time. Random samples of altered granitic and vein rock contained 10 to 53 ppm uranium (Foley and Barker, 1986).

Gangue minerals include chlorite, clay minerals, hematite, and sericite. Epidote and plagioclase, are generally altered to carbonate and white mica, occurs with opaque minerals including pyrrhotite and magnetite. Generally the entire area of the occurrence is variably hydrothermally altered and discolored. Fine-grained epidote and chlorite impart a light green color to the less altered rocks. Locally, the granitic rocks contain quartz stockwork and veins, cryptocrystalline silica coatings and segregated masses, abundant hematite, clay minerals, carbonate, and sericite. More highly altered rocks are various shades of red due to

iron oxide minerals.

Alteration:

Greisen, locally argillic, pervasive hematitic staining and corroded quartz after silicification, quartz stockwork and veining; discrete zones of sericite development, epidote, and chlorite alteration (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generic deposit model:

Deposit model:

Granite-hosted veins with uranium values generally much greater than thorium; minimal REE and tin; uranium does not concentrate in resistant minerals as indicated by heavy mineral survey (Foley and Barker, 1986); mineralized shear zones by structural control, spatial association with lamprophyre dikes; no clear comparable examples available.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

A grab sample from a hematitic quartz vein contained 153 parts per million (ppm) uranium and 236 ppm thorium. No radiometric readings were collected due to weather conditions at the time. Random samples, of altered granitic and vein rock contained 10 to 53 ppm uranium (Foley and Barker, 1986).

Production notes:

None.

Reserves:

No reserves.

Additional comments:

The West Fork Vulcan and Rock Creek area was selected for study by the U.S. Bureau of Mines in 1979 as part of ongoing mineral land assessments in Alaska and land designations proposed by Congress, and because recent (1970s) private sector exploration had discovered sedimentary uranium in the Boulder Creek basin of southern Death Valley about 6 miles to the north (Dickinson and others, 1987). No further work was performed.

Last report date: 2016-12-15

Site name(s): Rock Creek No. 5

Site type: Occurrence

ARDF no.: SO183

Latitude: 64.9426

Quadrangle: SO D-1

Longitude: 162.3461

Location description and accuracy:

The Rock Creek No. 5 occurs in a steep, narrow gully above a northwest-facing cirque on the right limit of upper Rock Creek. Elevations in the area of the occurrence range from about 1,700 feet up to 2,800 feet at the top of the cirque wall. Rock Creek is one of several creeks that drain the east flank of the north-trending Darby Mountains and is a tributary to the Tubutulik River, which is located east of the report area. The occurrence site is in E1/2NE1/4 sec. 29, T. 6 S., R. 18 W. of the Kateel River Meridian and coordinates are the approximate midpoint of several vein and alteration features.

Accuracy of the location is about 1,000 feet.

Commodities:

Main: U

Other: Pb

Ore minerals:

Gangue minerals: Chlorite, clay minerals, epidote, hematite, magnetite, plagioclase, pyrrhotite, quartz, sericite

Geologic description:

The Darby pluton is relatively homogeneous, mostly quartz monzonite and minor granite. Locally there are segregations of quartz-deficient, potassium-rich rocks including syenite and alkali granite.

In to the Vulcan Creek and adjacent Rock Creek area the Darby pluton is quartz monzonite containing biotite and lesser hornblende. The pluton is also cut by lamprophyre, rhyolite, aplite, and tourmaline-bearing pegmatite dikes. These later dikes contain euhedral biotite, amphibole, corroded quartz xenocrysts and, more rarely, clinopyroxenite or olivine in a groundmass of altered plagioclase and minor potassium feldspar (Foley and Barker, 1986). Generally, the Rock Creek and West Vulcan Creek area has higher radiometric levels than the surrounding region.

Rock Creek No. 5 consists of several closely spaced, parallel, silicified shear zones that are poorly exposed in a steep, narrow avalanche chute above the northwest-facing cirque on the right limit of upper Rock Creek. The zones strike west-northwest with a steep northerly dip. At one outcrop within the chute, a 1.5 foot-wide silicified zone with hematite, chlorite, and secondary quartz veins contains disseminated pyrite and rare chalcopyrite. Other outcrops and float are leached of sulfide minerals. The presence of boulder-sized rubble in the chute indicates that silicified shear zones range in width from 1 to 4 feet or more and are bordered by narrow zones of clay and fault gouge. Generally the leached and silicified zones yield radiometric values of 2 times background. Two chip samples of leached hematitic quartz vein rubble contained 140 and 170 parts per million (ppm) uranium and anomalous lead concentrations (Foley and Barker, 1986).

Gangue minerals include chlorite, clay minerals, hematite, quartz, and sericite. Epidote and plagioclase generally altered to white mica and carbonate occurs with opaque minerals including magnetite and pyrrhotite.

Alteration:

Greisen, locally argillic, pervasive hematitic staining and corroded quartz after silicification, quartz

stockwork and veining with silicification formed in sheared clay and crushed granitic host rock zones; discrete zones of sericite development, epidote, and chlorite alteration were observed (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generic deposit model:

Commodities:

Main: U

Other: Pb

Ore minerals: Pitchblende

Gangue minerals: Banded jasper, chlorite, clay minerals, epidote, hematite, magnetite, plagioclase, pyrrhotite, quartz, sericite

Geologic description:

The Darby pluton is a relatively homogeneous, mostly quartz monzonite and minor granite. Locally there are segregations of quartz-deficient, potassium-rich rocks including syenite and alkali granite. The pluton is cut by rhyolite, aplite, and tourmaline-bearing pegmatite dikes. In to the Vulcan Creek and adjacent Rock Creek area, the Darby pluton is quartz monzonite containing biotite and lesser hornblende and cut by tourmaline aplite and a swarm of lamprophyre and apparently related variants of dark-colored sub-alkaline intermediate composition porphyritic dikes. The dikes contain euhedral biotite, amphibole, corroded quartz xenocrysts and, more rarely, clinopyroxenite or olivine in a groundmass of altered plagioclase and minor potassium feldspar. Generally, the Rock Creek and West Vulcan Creek area has higher radiometric levels than the surrounding region (Foley and Barker, 1986).

Rock Creek No. 6 consists of several silicified and iron-stained, northeast-striking shear zones exposed for 500 vertical feet in a steep, east-facing gully in a cirque wall. Steeply dipping quartz veins, containing banded jasper with hematite and narrow, parallel seams of pyrite-bearing fluorite greisen, occur in the altered quartz monzonite. Jasper bands up to 2 inches thick are concentrated in a 1 foot-wide central portion of the quartz veins, which pinch and swell to about 4 feet. Pitchblende was identified by the U.S. Bureau of Mines Reno Metallurgical Center in a high-grade sample of radioactive greisen that assayed 1,961 parts per million (ppm) uranium. Isolated float of highly radioactive jasper vein material was also found and samples assayed up to 0.76 percent uranium. Surrounding quartz monzonite cut by the shear zones is hydrothermally altered and contains chlorite and hematite with disseminated pyrite and clay minerals (samples assayed 253, 190, 565, and 18 ppm). Carbonate-altered biotite and olivine lamprophyre dike(s) underlie the vicinity with unknown orientations (Foley and Barker, 1986).

Gangue minerals include chlorite, clay minerals, hematite, banded jasper, quartz, sericite. Epidote and plagioclase generally altered to white mica and carbonate occur with opaque minerals including magnetite

and pyrrhotite.

Alteration:

Greisen, locally argillic, sooty fluorite also noted at several sites. Banded jasper, pervasive hematitic staining, and corroded quartz after silicification, were also noted. Quartz stockwork and veining occurs with silicification in shear zones; also noted were discrete zones of sericite, epidote, and chlorite alteration. Clay minerals and iron oxides occur in all vein showings and adjoining quartz monzonite wall rock (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generic deposit model:

Location description and accuracy:

Rock Creek No. 7 occurs on the crest of the northwest-facing valley wall above the right limit of upper Rock Creek. Elevations in the area of the occurrence range from near 1,000 feet up to 1,700 feet at the top of the ridge. Rock Creek is a tributary to the Tubutulik River, which is located east of the report area. Rock Creek is one of several creeks that drain the east flank of the north-trending Darby Mountains. The occurrence site is in NE1/4, NE1/4 sec. 20, T. 6 S., R. 18 W. of the Kateel River Meridian and coordinates are the approximate midpoint of several vein and alteration features on this northwest-facing slope.

Accuracy of the location is about 1,500 feet.

Commodities:

Main: U

Other: Bi, Mo, Pb

Ore minerals: Galena

Gangue minerals: Chlorite, clay minerals, epidote, hematite, magnetite, plagioclase, pyrrhotite, quartz, sericite

Geologic description:

The Darby pluton is relatively homogeneous, mostly quartz monzonite and minor granite. Locally there are segregations of quartz-deficient, potassium-rich rocks including syenite and alkali granite. The pluton is cut by rhyolite, aplite, and tourmaline-bearing pegmatite dikes. In the Vulcan Creek and adjacent Rock Creek area the rocks of the Darby pluton is quartz monzonite containing biotite and lesser hornblende and is cut by tourmaline aplite and a swarm of lamprophyre and apparently related variants of dark-colored sub-alkaline porphyritic dikes. The dikes contain euhedral biotite, amphibole, corroded quartz xenocrysts and, more rarely, clinopyroxenite or olivine in a dike groundmass of altered plagioclase and minor potassium feldspar. Generally, the Rock Creek and West Vulcan Creek area has higher radiometric levels than the surrounding region (Foley and Barker, 1986), but inclement weather prevented radiometric measurements at this occurrence.

This poorly exposed occurrence is a silicified hematitic and iron-stained, northeast-striking shear zone exposed near the crest of the northwest-facing slope above upper Rock Creek. The shear zone cuts propylitically-altered, medium-grained quartz monzonite. Because of the poor exposure, the dimensions of the occurrence are unknown. Hematite-rich quartz boulders occur on the slope and appear to be derived from the shear zone(s). Samples assayed 7 to 155 parts per million uranium (Foley and Barker, 1986).

Gangue minerals include chlorite, clay minerals, hematite, quartz, sericite were noted. Plagioclase generally altered to white mica, epidote, and carbonate occur with opaque minerals including magnetite and pyrrhotite.

Alteration:

A greisen quartz hematitic shear zone, locally argillic altered, is apparently present under surficial cover. Adjacent quartz monzonite exhibits propylitic alteration. Oxidation and clay minerals, after argillic alteration, infill between the vein and replacement lenses occurrences (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generic deposit model:

Deposit model:

Granite-hosted veins that contain generally much greater uranium than thorium and have minimal REE and tin. Uranium does not concentrate in resistant minerals as indicated by heavy mineral survey (Foley and Barker, 1986). Occurs as mineralized structurally controlled shear zones. There is a spatial association with lamprophyre dikes. No clear comparable deposit model examples are available.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Samples assayed 7 to 155 parts per million uranium (Foley and Barker, 1986).

Generally, the Rock Creek and West Vulcan Creek area has higher radiometric levels than the surrounding region (Foley and Barker, 1986).

Rock Creek No. 8 consists of several silicified and iron-stained, shear zones about 2,000 feet along strike and exposed high on the northwest-facing slope above upper Rock Creek. Radiometric readings were up to 5 times background over hematite-rich quartz boulders from east- and southeast-striking zones aligned in shallow steep gullies best exposed between elevations of 1,600 and 2,500 feet. There are at least two systems of veins exposed that trend to the ridge crest where they are exposed in place; each exhibits closely spaced quartz veins, quartzose replacement lens, and leached hematitic lenses with relic pyrite. One system strikes N 85 E, dips steeply to the north, and is 12 feet wide with individual hematitic quartz lenses up to 10 inches thick. Two chip samples were analyzed; one contained 447 parts per million (ppm) uranium and the other 430 ppm uranium. A second hematitic quartz-biotite system is spaced 10 feet away; this zone is 12 to15 feet wide and soil assayed 229 ppm uranium. Samples of hematite-rich quartz boulders downslope assayed 270 and 1,000 ppm uranium (Foley and Barker, 1986).

Alteration:

Greisen showing banded jasper, pervasive hematitic staining, and corroded quartz is locally argillic. Quartz stockwork and veining forms in shear zones; discrete zones of sericite development, epidote, and

chlorite alteration are apparent. Adjacent quartz monzonite exhibits propylitic alteration. Oxidation and clay minerals, after argillic alteration, infill between the vein and replacement lenses occurrences (Foley and Barker, 1986).

Age of mineralization:

Quartz monzonite of the Darby pluton is reported to be Late Cretaceous (Miller and Bunker, 1975; Eakins and others, 1977; Wilson and others, 2015).

Generic deposit model:

Site name(s): Lucky Six Creek

Site type: Mine

ARDF no.: SP011

Latitude: 67.5841 **Quadrangle:** SP C-4

Longitude: 154.8833

Location description and accuracy:

This site is based on a 1904 report by Schrader of several mineral occurrences and minor placer gold mining on Lucky Six Creek. The prospects were apparently not visited by Schrader; his description was based on reports of prospectors. The exact location of these deposits cannot now be determined. Lucky Six Creek was examined by Kurtak and others (2002) and they found signs of placer mining along 50 feet of the creek but give no exact location. Arbitrarily this site is located in about the middle of the 4 miles of Lucky Six Creek, about 0.6 mile southwest of the center of section 18, R. 25 N., R. 18 E. (See also ARDF site SP012 which may be the same deposit.)

Commodities:

Main: Ag, Au

Other: Graphite

Ore minerals: Gold

Gangue minerals:

Geologic description:

Schrader (1904) reported that gold was discovered on Lucky Six Creek in 1898 and a few ounces of coarse placer gold was recovered. A small lens of high-grade silver ore and graphite was reported by prospectors prior to World War I (Smith, 1913). Kurtak and others (2002) examined the creek and found evidence of sluice mining for about 50 feet. Their panned samples did not contain any gold. (See also ARDF site SP012 which may be the same deposit.)

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer gold (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Scant evidence of mining prior to 1904. No record of any mining since.

Production notes:

Lucky Six Creek produced a few ounces of gold prior to 1904.

Reserves:

None.

Additional comments:

Located within Gates of the Arctic National Park.

Last report date: 2011-02-01

Site name(s): Unnamed (head Lucky Six Creek near Gull Pass)

Site type: Prospect

ARDF no.: SP012

Latitude: 67.628 **Quadrangle:** SP C-4

Longitude: 154.8167

Location description and accuracy:

The site is based on early descriptions of several mineral prospects and minor placer gold production on Lucky Six Creek (Schrader 1904). The prospects apparently were not visited by Schrader who based their location on reports by prospectors. Their exact location remains undetermined. The coordinates are that of a sample with metal values collected by Kurtak and others (2002). Their sample site is about 1.7 miles north of Gull Pass and about 0.5 mile east of the center of section 33, T. 26 N., R. 18 E. Kurtak's location is accurate but the old Schrader location is vague. Also see ARDF SP012, Lucky Six Creek, which is nearby and may refer to the same site.

Commodities:

Main: Ag, Au, Cu, Sb

Other:

Ore minerals: Bornite, chalcopyrite, malachite, pyrite, stibnite

Gangue minerals:

Geologic description:

Based solely on information from prospectors, Schrader (1904) reported that six or more quartz veins, 10 to 75 ft. thick, occur in a belt 6 miles long. Samples given to him by prospectors contained pyrite, chalcopyrite, bornite, malachite, and stibnite. The veins were reported to have been discovered in 1902-1903. The country rock in the area is marble interlayered with chlorite schist of the Devonian and Silurian Skajit Limestone (Nelson and Grybeck, 1980). Kurtak and others (2002) collected a sample of quartz-carbonate float with tetrahedrite(?), malachite, and azurite in Lucky Six Creek about 1.7 miles north of Gull Pass. The sample contained 43 parts per million (ppm) silver, 672 ppm arsenic, and 3,580 ppm antimony.

Alteration:

None.

Age of mineralization:

Silurian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Unclear; only a vague early report of mineralization.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Undetermined

Site Status: Inactive

Workings/exploration:

Minor prospecting in the early 1900s. The area was examined by several government parties from the early 1980 to 2002; none found any significant mineralization.

Production notes:

None.

Reserves:

None.

Additional comments:

Located in Gates of the Arctic National Park.

Last report date: 2011-02-01

Site name(s): Unnamed (north of Arrigetch Peaks)

Site type: Occurrence

ARDF no.: SP015

Latitude: 67.4499 **Quadrangle:** SP B-3

Longitude: 154.1653

Location description and accuracy:

This occurrence is an elevation of about 3,700 feet near the head of an unnamed creek 3 miles northeast of the Arrigetch Peaks. It is near the southeast corner of section 32, T. 24 N., R. 22 E., The site corresponds to locality 32 of Grybeck and Nelson (1981) and area 1 of the SP2 site of Kurtak and others (2002).

Commodities:

Main: As, Cu, Sn, Zn

Other: Bi

Ore minerals: Arsenopyrite, chalcopyrite, magnetite, pyrite, pyrrhotite

Gangue minerals: Calc-silicates

Geologic description:

This occurrence consists of selected float samples of iron-stained Paleozoic schist and skarn. The source of the float probably is a contact-metamorphic zone adjacent to Devonian granite that crops out to the south. Selected samples contained up to 5,000 parts per million (ppm) arsenic, 20 ppm bismuth, and 1000 ppm tin (Grybeck and Nelson, 1981). This occurrence probably is similar in origin to other Devonian contact-metamorphic deposits in nearby areas of the Brooks Range (Newberry and others, 1986). Kurtak and others (2002) collected several samples in the vicinity, notably of magnetite-calc-silicate ribbon rock, with pyrite, chalcopyrite, pyrrhotite, and arsenopyrite. . Samples contained up to 4,492 ppm copper, 4,052 ppm tin, and 859 ppm bismuth, and 7,782 ppm zinc.

Alteration:

Calc-silicate minerals in skarn and related contact metamorphic rocks adjacent to a Devonian granite.

Age of mineralization:

Probably related to nearby Devonian granite.

Generic deposit model:

Deposit model:

Skarn (Cox and Singer, 1986; model 14b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

14b

Production Status: None

Site Status: Inactive

Workings/exploration:

The site was briefly visited and sampled during regional geologic mapping by the USGS in the late 1970s and visited and sampled by the Bureau of Land Management in about 2000.

Production notes:

None.

Reserves:

None.

Additional comments:

Located in the heart of a notable scenic part of the Gates of the Arctic National Park.

Last report date: 2011-02-01

Site name(s): Unnamed (south of Arrigetch Creek)

Site type: Occurrences

ARDF no.: SP016

Latitude: 67.4303 **Quadrangle:** SP B-3

Longitude: 154.0242

Location description and accuracy:

This site includes several occurrences that extend east for several miles along the east-trending contact of a granite. The area is about 5.8 miles southwest of the mouth of Arrigetch Creek. The coordinates are for the approximate center of the area in sec. 5, T. 23 N., R. 22 E. The location is accurate. The site corresponds to localities 33 through 35 of Grybeck and Nelson (1981).

Commodities:

Main: Ag, Cu, Pb, Sn, Zn

Other: As, Bi, F, W

Ore minerals: Chacopyrite, sphalerite

Gangue minerals: Calc-silicate minerals, magnetite

Geologic description:

This site consists of three contact-metamorphic, skarn deposits adjacent to Devonian granite (Grybeck and Nelson, 1981). At one locality several skarn bodies up to 700 m long and 70 m thick at a granite-carbonate contact contain lenses and pods of magnetite, and minor disseminated chalcopyrite, sphalerite and unspecified tungsten minerals. At another locality, heterogeneous contact-metamorphic rocks include fluorite-magnetite rock, quartz-epidote skarn, epidote-garnet skarn and sphalerite-epidote skarn. Selected samples contained up to 150 parts per million (ppm) silver, 1000 ppm bismuth, and more than 1 percent each of tin, lead, and zinc. A brief reconnaissance of a granite-phyllite contact revealed several tactite pods less than 5 meters wide. The most prominent consists of magnetite with copper staining. Grab samples contained up to 1000 ppm each of arsenic, copper, tin, and zinc. These occurrences probably are similar in origin to other Devonian contact-metamorphic deposits in nearby areas of the Brooks Range (Newberry and others, 1986).

Kurtak and others (2002) collected several samples of mineralized skarn and thin quartz veins for about a mile along the north side of the Devonian granite. Their samples contained up to 3,042 ppm copper, 269 ppm cobalt, and 1,080 ppm tin.

Alteration:

Calc-silicate minerals in skarn and related contact metamorphic rocks adjacent to Devonian granite.

Age of mineralization:

Devonian; related to the intrusion of Devonian pluton.

Generic deposit model:

Deposit model:

Skarn (Cox and Singer, 1986; model 14b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
14b

Production Status: None

Site Status: Inactive

Workings/exploration:
The sites were briefly visited and sampled during regional geologic mapping by the USGS in the late 1970s and again visited and sampled by the Bureau of Land Management in about 2000.

Production notes:
None.

Reserves:
None.

Additional comments:
Located in the heart of a notable scenic part of the Gates of the Arctic National Park.

Site name(s): Cynbad

Site type: Prospect

ARDF no.: SP033

Latitude: 67.118 **Quadrangle:** SP A-6

Longitude: 155.734

Location description and accuracy:

This prospect is at an elevation of about 3600 feet on a ridge 5 miles north of Avaraart Lake. It is in section 23, T. 20. N., R. 14 E., of the Kateel River Meridian. The location is and accurate to within 1000 ft. The site corresponds to locality 61 of Grybeck and Nelson (1981).

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

This prospect explores a silver-base metal volcanogenic massive sulfide deposits in a sequence of low to medium grade metamorphosed basaltic and rhyolitic rocks, submarine ash flow tuffs, and pelitic and carbonaceous sedimentary rocks known as the Ambler schist belt. The deposit is Devonian or Mississippian in age, based on fossil evidence and U-Pb radiometric dating (Hitzman and others, 1986). Numerous copper-stained zones in the schists have been explored by prospect pits and several diamond drill holes. The deposit is similar to, and probably an extension of, the deposits at SP032 (Grybeck and Nelson, 1981).

Two distinct mineralized zones were noted, separated stratigraphically by approximately 1,500 feet, which are referred to as the north and south mineral zones (Ellis, 1983).

The south mineral zone lies within a white schist unit about 150 feet thick overlying country rock schist and underlying a thick metasediment unit. Along the ridge an upper horizon 5 feet thick of disseminated and banded sulfide along with another lower zone of approximately 30 feet thick of banded and disseminated sulfides is present as outcrop and subcrop. The south mineral zone can be traced approximately 3,500 feet from the ridge to the east by gossan float and outcrop (Ellis, 1983).

The north mineral zone lies within a black schist unit approximately 100 feet thick overlying a country rock schist and underlying a siliceous rock unit approximately 100 feet thick. This unit is mineralized for at least 3000 feet where the zone is covered to the east by a large rock slide. To the east gossan boulder samples collected indicate massive sulfides of ore grade with a minimum thickness of 1 foot. Many boulders of mineralized black schist were noted in the rock slide. Along the 3000 feet strike of the black schist outcropping or sub-outcropping, mineralization of banded sulfides up to 1/4 inch to 7 inches thick along with disseminated sphalerite, galena, and pyrite. Rock chip samples collected from a massive sulfide lens contained from 2 to 14 percent lead, 1.6 to 5.5 ounces silver, 6 to 10 percent zinc, and 1.5 to 3.4 percent copper (Ellis, 1983).

Alteration:

Locally prominent copper-staining (Grybeck and Nelson, 1981).

Age of mineralization:

Syngenetic massive sulfide deposit in Devonian or Mississippian host rocks (Grybeck and Nelson, 1981).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

The deposit has been explored by a number of prospect pits and several diamond drill holes (Grybeck and Nelson, 1981).

Approximately 110 soil samples were collected during the early 1980’s over a previously discovered magnetic/geochemical anomalous zone. Results of this work showed an anomalous copper and lead trend, which is open ended to the north. This open-end anomaly is believed to be caused by a metal bearing meta-chert unit contained in rocks of the 'Middle Felsic Belt'. Rock chip samples collected from a massive sulfide lens contained from 2 to 14 percent lead, 1.6 to 5.5 ounces silver, 6 to 10 percent zinc, and 1.5 to 3.4 percent copper (Ellis, 1983).

Production notes:

None.

Reserves:

None.

Additional comments:

Prior to being named Cymbad (in 2014), this site was known as 'Unnamed (north of Avaraat Lake)'.

Last report date: 2014-12-04

Site name(s): Sun; Main Sun; Hot

Site type: Prospects

ARDF no.: SP039

Latitude: 67.0704

Quadrangle: SP A-5

Longitude: 155.0431

Location description and accuracy:

This site includes several prospects in an approximately 12-square-mile area northeast of Beaver Creek. The best known and most studied is the Sun prospect. The coordinates of the Sun prospect are about 0.3 mile south of the center of section 1, T. 19 N., R. 17 E., of the Kateel River Meridian. The location is accurate to within about 500 feet.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Ba

Ore minerals: Arsenopyrite, bornite, chalcopyrite, enargite, galena, sphalerite

Gangue minerals: Barite, chlorite, ferroan calcite, ferroan dolomite, quartz

Geologic description:

This site includes several prospects in an approximately 12-square-mile area northeast of Beaver Creek. The best known and most studied is the Sun prospect (called 'Hot' by Noranda). The Sun deposit consists of stratiform, banded, massive to semi-massive sulfides in a series of elongate, southwest-plunging, lenticular bodies along three distinct mineral horizons. An upper horizon is silver, lead, and zinc rich, a middle horizon is copper rich, and a lower horizon is copper and zinc rich. According to Zdepski (1980), the Sun prospect is in a 5,000-foot-thick sequence of Devonian felsic to andesitic volcanic, volcaniclastic and intercalated pelitic sedimentary rocks separated into upper and lower units by calcareous metabasite beds of variable thickness. The upper unit of metarhyolite and related rocks contains all of the identified massive sulfides; the lower unit is dominantly pelitic schist and metarhyolite.

As described by Andover Ventures (2008), the Sun deposit was found in the mid 1970s by Sunshine Mining Company and has been variously studied by Anaconda Minerals, Noranda Mining, and Teck Cominco. The Sun deposit consists of 13 SUN claims and 12 HOT claims and has been extensively drilled. As of June 2007, Andover had staked 68, 160-acre claims adjacent to the Sun deposit and drilled 20 holes in 2007 (Andover Ventures, 2007; 2008). The results for 13 of the holes have been released. Some notable intercepts include: 10.94 meters of 2.34 percent copper, 0.77 percent lead, 5.98 percent zinc, 68.1 grams of silver per ton, and 0.266 gram of gold per tonne; 5.08 meters with 4.34 percent copper, 0.58 percent lead, 2.76 percent zinc, 99.1 grams of silver per ton, and 0.199 gram of gold per tonne; 37.01 meters of 1.17 percent copper, 1.85 percent lead, 7.26 percent zinc, 44.0 grams of silver per ton and 0.179 gram of gold per tonne; and 11.0 meters of 1.07 percent copper, 5.38 percent lead, 16.54 percent zinc, 88.6 grams of silver per tonne, and 0.210 gram of gold per tonne.

Andover drilled 6 holes in 2011 (Andover Ventures, 2011 [July 21]; 2011 [August 12]; 2011 [August 31]. Some notable intercepts were: 1) 16.5 meters with 1.60 percent copper, 3.49 percent lead, 10.25 percent zinc, 86.6 grams of silver per tonne, and 0.24 grams of gold per tonne; 2) 1.60 meters with 6.08 percent copper, 1.08 percent lead, 3.81 percent zinc, 692.9 grams of silver per tonne, and 1.792 grams of silver per tonne; and 3) 10.65 meters with 2.56 percent copper, 0.81 percent led, 4.47 percent zinc, 63.8 grams of silver per tonne, and 0.216 grams of gold per tonne.

Including the 6 holes drilled by Andover Ventures in 2011, the Sun deposit has had 76 holes drilled on it

that total about 49,000 feet. Andover drilled 27 of the holes; the other were by previous operators including Anaconda, Noranda, Sunshine Mining Company, Cominco, and Bear Creek Mining Company. The deposit extends along strike for more than 1 kilometer and is open to the northeast and down dip.

Andover (2011 [Corporate presentation]) cites a 1977, Anaconda preliminary feasibility study that gives: 1) an inferred resource amenable to open-pit mining of 2.399 million tons with an average grade of 1.93 percent copper, 4.51 percent zinc, 2.39 ounces of silver per ton, and 1.20 percent lead; and 2) an inferred resource of 17.891 million tons amenable to underground mining with an average grade of 1.91 percent copper, 4.46 percent zinc, 2.37 ounces of silver per ton, and 1.18 percent lead.

A 2013 updated resource estimate was published. The copper-zinc-silver-lead-gold resources, which are comprised of massive sulfide and related mineralization, are estimated to total 2,165,000 tonnes (2,387,000 tons) at 1.42 percent copper, 1.06 percent lead, 4.11 percent zinc, 57.6 grams of silver per tonne and 0.21 gram of gold per tonne (3.9 percent copper equivalent). The inferred resources are 11,648,000 tonnes (12.84 million tons) at 1.14 percent copper, 1.37 percent lead and 3.91 percent zinc, 76.8 grams of silver per tonne and 0.24 gram of gold per tonne (3.9 percent copper equivalent) (Gustin and Ronning, 2013).

Alteration:

There is a discordant chloritic alteration zone at the northeastern end of the Main Sun deposit that consists primarily of chlorite with lesser talc, siderite, ankerite, and barite and contains minor disseminated pyrrhotite and chalcopyrite. This alteration zone occurs below what may be the upper sulfide horizon, and it has a maximum known thickness of 20 meters (Gustin and Ronning, 2013).

Age of mineralization:

Devonian, based on radiometric and fossil determinations (Gustin and Ronning, 2013).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active?

Workings/exploration:

Including the 6 holes drilled by Andover Ventures in 2011, the Sun deposit has had 76 holes drilled on it that total about 49,000 feet. Andover drilled 27 of the holes; the others going back into the 1970s were by previous operators including Anaconda, Noranda, Sunshine Mining Company, Cominco, and Bear Creek Mining Company.

Andover Mining Corp. drilled 20 core holes in 2012, identifying at least six new prospects. Resampling of some mineralized intervals of historic (pre-Andover) drill core was also completed in 2012. A 43-101 technical report was published with an updated resource estimate in 2013. The mineral resources were modeled and estimated in accordance with Canadian Institute of Mining, Metallurgy and Petroleum ('CIM') definitions. The copper-zinc-silver-lead-gold resources, which are comprised of massive sulfide and related mineralization, are estimated to total 2,165,000 tonnes (2,387,000 tons) at 1.42 percent copper, 1.06 percent lead, 4.11 percent zinc, 57.6 grams of silver per tonne and 0.21 gram of gold per tonne (3.9 percent copper equivalent). The inferred resources are 11,648,000 tonnes (12.84 million tons) at 1.14 percent copper, 1.37 percent lead and 3.91 percent zinc, 76.8 grams of silver per tonne and 0.24 gram of gold per tonne (3.9 percent copper equivalent) (Gustin and Ronning, 2013).

Production notes:

None.

Reserves:

Andover (2011 [Corporate presentation]) cites a 1977, Anaconda preliminary feasibility study that gives: 1) an inferred resource amenable to open-pit mining of 2.399 million tons with an average grade of 1.93 percent copper, 4.51 percent zinc, 2.39 ounces of silver per ton, and 1.20 percent lead; and 2) an inferred resource of 17.891 million tons tons amenable to underground mining with a grade of 1.91 percent copper, 4.46 percent zinc, 2.37 ounces of silver per ton, and 1.18 percent lead.

A National Instrument 43-101, prepared by Mine Development Associates of Reno, Nev., provided the first NI 43-101-compliant mineral resource estimate for Sun. The report was completed on September 30, 2013 (Gustin and Ronning, 2013).

Using a cut-off of $75 per tonne in-ground value, the combined Main Sun and Southwest Sun deposits indicated resources are estimated to total 2,165,000 tonnes (2,387,000 tons) at 1.42 percent copper, 1.06 percent lead, 4.11 percent zinc, 57.6 grams of silver per tonne and 0.21 gram of gold per tonne (3.9 percent copper equivalent). The inferred resources are 11,648,000 tonnes (12.84 million tons) at 1.14 percent copper, 1.37 percent lead and 3.91 percent zinc, 76.8 grams of silver per tonne and 0.24 gram of gold per tonne (3.9 percent copper equivalent). This resource estimation indicates a minimum deposit size as the Main Sun remains open to the northeast and down dip and the Southwest Sun remains open to the southwest and down dip. The copper equivalent grades were calculated based on metal prices of $3 per pound copper, 95 cents per pound lead, 95 cents per pound zinc, $25 per ounce silver and $1,300 per ounce gold, and assume 100 percent recoveries (Gustin and Ronning, 2013).

The resource estimation utilized the database of 97 drill holes totaling 19,123 meters. Andover Mining Corp. has drilled 48 of the holes, totaling 10,311 meters. The remainder are historic drill holes drilled by previous operators, including Cominco (Teck Resources), Anaconda, Sunshine, Noranda and Bear Creek (Kennecott) (Gustin and Ronning, 2013).

Additional comments:

The prospect Picnic Creek was removed from this record and made its own record because drilling has shown the deposit is not continuous between the two. The site name 'Hot' was used by Noranda (W.T. Ellis, Vice President, Alaska Earth Sciences, oral commun., 2014).

Last report date: 2014-12-08

Site name(s): SW Sun

Site type: Prospect

ARDF no.: SP044

Latitude: 67.066 **Quadrangle:** SP A-5

Longitude: 155.052

Location description and accuracy:

This prospect is located 9.6 miles south of Akurekvik Pass, in NE1/4NW1/4 of section 12, T. 19 N., R. 17 E., of the Kateel River Meridian. This location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Arsenopyrite, bornite, chalcopyrite, enargite, galena, pyrite, pyrrhotite, sphalerite, tennantite

Gangue minerals: Barite, chlorite, ferroan calcite, ferroan dolomite, quartz, talc

Geologic description:

Southwest (SW) Sun was discovered in 1974 by the discovery of gossan by Sunshine Mining Company. The SW Sun prospect is characterized by volcanogenic massive-sulfide mineralization. The property is located at the eastern end of the Ambler district. The deposit is comprised of multiple individual lenses that are spatially related; two primary horizons of massive-sulfide mineralization have been identified. The massive sulfides are comprised primarily of sphalerite, tennantite, galena, chalcopyrite, bornite, enargite, pyrite, pyrrhotite, and arsenopyrite. Based on drilling, the SW deposit is currently known to be comprised of two thin massive-sulfide horizons, with the lower one again being less continuous (Gustin and Ronning, 2013).

SW Sun, approximately 2,888 feet southwest of Main Sun (SP039), was thought for a long time to be the offset extension of Main Sun. However, drilling to the west of the Tour Ridge Fault has not confirmed this relationship. Southwest Sun may be a separate hydrothermal center, based on the lack of physical connection to Main Sun and on the presence of talc alteration in the footwall rocks (Gustin and Ronning, 2013).

Mineralization occurs in a northeast-trending belt of felsic metavolcanic and metasedimentary rocks generally dipping 30 degrees to 45 degrees southeast and extending about 13 kilometers from Beaver Creek on the west to Picnic Creek on the east. The volcanic rock package is up to 1.5 kilometers thick and is both overlain and underlain by quartz-chlorite-mica schist. Known massive-sulfide mineralization is limited to the upper portion of the felsic volcanic rocks. Almost all of the mineralization lies beneath glacial cover, with exposures at only three locations (Marrs, 1978).

Massive-sulfide mineralization at the SW Sun is primarily hosted within the felsic schist (Dsf) and sparsely porphyritic rhyolite (Dr) units of the Ambler Sequence. At Sun, the Ambler Sequence is comprised almost entirely of lithologies found in the sequence elsewhere in the district, with the notable exception of the distinctive rhyolite porphyry (Dbs), which is rare elsewhere (although this unit does occur in the Beaver Creek Valley 9.6 kilometers to the west of Sun). Volcanic rocks constitute about 84 percent of the Ambler Sequence at SW Sun. The deposit lies on the north limb of an overturned syncline (Gustin and Ronning, 2013).

Mineralization occurs near a local thickening in the felsic to andesitic volcanic and volcaniclastic rocks of the Ambler Sequence, where the sequence is dissected by the Jewel Creek drainage. The mineralized portion of the Ambler Sequence has been mapped for 5,800 meters along strike and varies in thickness from

750 to 1,500 meters. Significant thicknesses of mineralization have been traced by drilling including across some 2,700 meters including Picnic Creek, Main Sun, and SW Sun (Gustin and Ronning, 2013).

Alteration:

Talc alteration is present in footwall rocks (Gustin and Ronning, 2013).

Age of mineralization:

Devonian, based on age of host rock (Gustin and Ronning, 2013).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Active?

Workings/exploration:

Diamond core drilling was completed by the Ambler Mining Company between 1975-1981. At SW Sun two sulfide horizons totaling 3.2 meters (10.5 feet) were encountered in drillhole Sun 14 while three horizons totaling up to 7.3 meters (24.8 feet) were encountered in drillholes Sun 28 and Sun 29 to the southwest. The uppermost horizon in the three holes comprised: 0.8 meter (2.5 feet) of 2.73 percent copper, 3.15 percent lead, 6.60 percent zinc, and 265.3 grams of silver per tonne in Sun 14; 6.2 meters (20.4 feet) of 0.10 percent copper, 3.04 percent lead, 5.96 percent zinc and 190.8 grams of silver per tonne in Sun 28; and 1.3 meters (4.2 feet) of 1.83 percent copper, 0.29 percent lead, 4.16 percent zinc and 20.3 grams of silver per tonne in Sun 29 (Gustin and Ronning, 2013).

Recent work by Andover Mining Corp. in 2007 and 2008 includes about 800 soil samples focused mostly on SW Sun. The initial and follow-up soil sampling program identified base-metal anomalies extending for three kilometers to the west of the SW Sun mineralized zone, along the southern edge of the felsic rock package (Gustin and Ronning, 2013).

In 2011, Andover Mining Corp. drilled three exploration holes at SW Sun; all encountered volcanogenic massive sulfide mineralization, and thereby extended the mineralized intersections by a strike length of 0.5 kilometer (Gustin and Ronning, 2013).

Production notes:

None.

Reserves:

A National Instrument 43-101, prepared by Mine Development Associates of Reno, Nevada for Andover Mining Corp., provided the first NI 43-101-compliant mineral resource estimate for Sun and SW Sun. The report was completed on September 30, 2013 (Gustin and Ronning, 2013).

Using a cut-off of $75 per tonne in-ground value, the combined Main Sun and Southwest Sun deposits indicated resources are estimated to total 2,165,000 tonnes (2,387,000 tons) at 1.42 percent copper, 1.06 percent lead, 4.11 percent zinc, 57.6 grams of silver per tonne and 0.21 gram of gold per tonne (3.9 percent copper equivalent). The inferred resources are 11,648,000 tonnes (12.84 million tons) at 1.14 percent copper, 1.37 percent lead and 3.91 percent zinc, 76.8 grams of silver per tonne and 0.24 gram of gold per tonne (3.9 percent copper equivalent). This resource estimation indicates a minimum deposit size as the Main Sun remains open to the northeast and down dip and the Southwest Sun remains open to the southwest and down dip. The copper equivalent grades were calculated based on metal prices of $3 per pound copper, 95 cents per pound lead, 95 cents per pound zinc, $25 per ounce silver and $1,300 per ounce gold, and

assume 100 percent recoveries (Gustin and Ronning, 2013).
The resource estimation utilized the database of 97 drill holes totaling 19,123 meters. Andover Mining Corp. has drilled 48 of the holes, totaling 10,311 meters. The remainder are historic drill holes drilled by previous operators, including Cominco (Teck Resources), Anaconda, Sunshine, Noranda and Bear Creek (Kennecott) (Gustin and Ronning, 2013).

Last report date: 2014-12-04

Site name(s): Picnic Creek; Picnic

Site type: Prospect

ARDF no.: SP045

Latitude: 67.086 **Quadrangle:** SP A-5

Longitude: 155.018

Location description and accuracy:

This prospect is located 8.2 miles south of Akurekvik Pass, SW 1/4 and 0.3 mile southwest from the center of section 31, T. 20 N., R.18 E., of the Kateel River Meridian. Picnic Creek is approximately 1 kilometer north of the Sun deposit (SP039) at an elevation of approximately 3,400 feet. This location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Ba

Ore minerals: Arsenopyrite, bornite, chalcopyrite, enargite, galena, sphalerite

Gangue minerals: Barite, chlorite, ferroan calcite, ferroan dolomite, quartz

Geologic description:

The Picnic Creek deposit was part of the general Sun site (SP039) until the 2012 update, however, drilling shows Picnic Creek to be discontinuous at depth from Sun (W.T. Ellis, Vice Pres., Alaska Earth Sciences, oral communication, 2014).

At the Picnic Creek prospect, located in the headwaters of Picnic Creek, approximately 1 kilometer north of the northern part of the drilled Sun Deposit (SP039), altered and iron stained gossanous rocks outcrop in a roughly 50 meter by 100 meter area. There is extensive talus covering. Ferrocrete gossan are currently forming from natural ground water springs, indicating weathering sulfides may be present under the talus cover (Gustin and Ronning, 2013).

The geology of Picnic Creek is characterized by a low-angle, extensional Picnic Creek fault with spoon-shaped geometry that terminates a belt of northeast-trending felsic metavolcanic and metasedimentary rocks generally dipping 30 degrees to 45 degrees southeast. The volcanic rock package is up to 1.5 kilometers thick and is both overlain and underlain by quartz-chlorite-mica schist. Known massive-sulfide mineralization is limited to the upper portion of the felsic volcanic rocks, extending about 2.4 kilometers along strike from the Picnic Creek saddle to west of drill hole Sun-14. Almost all of the mineralization lies beneath glacial cover, with exposures at only three locations (Marrs,1978).

Four horizons of sulfide mineralization have been recognized at the Picnic Creek prospect area. Grab samples of oxidized rocks have run up to 0.26 percent copper, 250 part per million (ppm) lead, 450 ppm zinc, 4.5 grams of silver per tonne, 0.42 grams of gold per tonne (Andover Mining Corp., 2012).

Alteration:

Chloritic (Gustin and Ronning, 2013).

Age of mineralization:

Devonian, based on age of host rock (Gustin and Ronning, 2013).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Bear Creek discovered the Picnic Creek massive-sulfide prospect, located in the northern part of the current Sun project, in 1966 and drilled five holes at the prospect from 1975 to 1983. This drilling encountered copper, lead, zinc, and silver mineralization. Exploration as consisted of field mapping, sampling of rock and soil, and diamond core drilling as part of the exploration efforts conducted at Sun. The majority of the work was completed during the mid-1970s through early 1980s (Gustin and Ronning, 2013).

Four horizons of sulfide mineralization have been recognized at the Picnic Creek prospect area. Grab samples of oxidized rocks have run up to 0.26 percent copper, 250 part per million (ppm) lead, 450 ppm zinc, 4.5 grams of silver per tonne, 0.42 grams of gold per tonne (Andover Mining Corp., 2012).

Production notes:

None.

Reserves:

None, a 2013 resource estimate was made for nearby Sun (SP039) (Gustin and Ronning, 2013).

Additional comments:

Exploration and discovery of volcanogenic massive-sulfide deposits and carbonate-hosted copper deposits were initiated by Bear Creek Mining Company ('Bear Creek'), the exploration arm of Kennecott Copper Corporation ('Kennecott'), in 1956, although the Ambler district had prior exploration and limited production of placer gold since the 1890s, production of copper in the early 1900s, and exploration for gold, uranium, and copper in the late 1940s. By 1966, Bear Creek had located geochemical anomalies at all of the major prospects now recognized in the Ambler district. Sunshine Mining Company ('Sunshine') entered the district in 1973, followed by Noranda Exploration Company ('Noranda'), as operator for a consortium that included GCO Minerals Company and Houston Oil & Minerals), the Anaconda Company ('Anaconda'), the Ambler Mining Company (a partnership of Sunshine and Anaconda), Cominco American Resources Inc. ('Cominco'), Falconbridge, and Union Carbide. By 1986, only Kennecott and Cominco remained active in the district. As recently as 2007, Teck Resources Limited, who acquired Cominco in 2001, still held property in the Ambler district, as did NovaGold Resources Inc., the regional native corporation for northwest Alaska, and Andover Mining Corp. No production has occurred in the Ambler district since the early 1900s (Gustin and Ronning, 2013).

Site name(s): STU

Site type: Prospect

ARDF no.: SP046

Latitude: 67.074 **Quadrangle:** SP A-5

Longitude: 155.225

Location description and accuracy:

The STU prospect is located 0.1 mile east-southeast from the center of section 6, T. 19 N., R. 17 E., of the Kateel River Meridian. The prospect is located at approximately 900 feet elevation. This location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Ba

Ore minerals: Arsenopyrite, bornite, chalcopyrite, enargite, galena, pyrite, pyrrhotite, sphalerite, tennantite

Gangue minerals: Barite, chlorite, ferroan calcite, ferroan dolomite, quartz

Geologic description:

The STU prospect is located about 8 kilometers west of the Sun project (SP039). The prospect is characterized by volcanogenic massive-sulfide mineralization. The property is located at the eastern end of the Ambler district. The massive sulfides are comprised primarily of sphalerite, tennantite, galena, chalcopyrite, bornite, enargite, pyrite, pyrrhotite, and arsenopyrite. Mineralization occurs in a northeast-trending belt of felsic metavolcanic and metasedimentary rocks. Massive-sulfide mineralization is primarily hosted within the felsic schist (Dsf) and sparsely porphyritic rhyolite (Dr) units of the Ambler Sequence. (Hitzman and others, 1982,Gustin and Ronning, 2013).

At STU, strong alteration and gossan have been mapped for approximately 100 meters along strike before disappearing beneath cover. There is extensive talus covering. Grab samples from the STU area returned values of up to 2.04 percent copper, 0.95 percent lead, 1.21 percent zinc, 64 grams of silver per tonne, and 0.49 grams of gold per tonne (Andover Mining Corporation, 2012).

Alteration:

Iron oxide alteration (Andover Mining Corporation, 2012).

Age of mineralization:

Devonian, based on age of host rock (Hitzman and others, 1982, Gustin and Ronning, 2013).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Exploration as consisted of field mapping and sampling of rock and soil, completed mostly during the mid 1970's through early 1980s. Andover completed one diamond core drillhole in 2012 at STU in addition to mapping and sampling. The drillhole included: 1) 8.1 meters of 0.49 percent copper, 0.71 percent lead, 2.75 percent zinc, 33.5 grams of silver per tonne, and 0.197 grams of gold per tonne (including 1.8 meters of 0.78 percent copper, 1.22 percent lead, 6.55 percent zinc, 81.4 grams of silver per tonne, and 0.478 grams of gold per tonne); and 2) 0.9 meters of 1.52 percent copper, 2.07 percent lead, 6.31 percent zinc, 71.8 grams of silver per tonne, and 0.637 grams of gold per tonne (Andover Mining Corporation, 2012).

Production notes:

None.

Reserves:

None, a 2013 resource estimate was made for nearby Sun (SP039) (Gustin and Ronning, 2013).

Site name(s): SAL

Site type: Prospect

ARDF no.: SP047

Latitude: 67.075 **Quadrangle:** SP A-5

Longitude: 155.232

Location description and accuracy:

The SAL prospect is located 0.1 mile east-northeast from the center of section 6, T. 19 N., R. 17 E., of the Kateel River Meridian. Located approximately 8 kilometers to the west of the Sun deposit (SP039) at approximately 700 feet elevation. This location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: Ba

Ore minerals:

Gangue minerals: Barite, ferroan calcite, ferroan dolomite, quartz

Geologic description:

The SAL prospect is located about 8.5 kilometers west of the Sun project (SP039). The prospect is characterized by volcanogenic massive-sulfide mineralization. The property is located at the eastern end of the Ambler district. The massive sulfides are comprised primarily of sphalerite, tennantite, galena, chalcopyrite, bornite, enargite, pyrite, pyrrhotite, and arsenopyrite. Mineralization occurs in a northeast-trending belt of felsic metavolcanic and metasedimentary rocks. Massive-sulfide mineralization is primarily hosted within the felsic schist (Dsf) and sparsely porphyritic rhyolite (Dr) units of the Ambler Sequence (Hitzman and others, 1982, Gustin and Ronning, 2013).

At SAL, strong alteration with strong iron staining within the highly prospective rock package has been mapped for approximately 200 meters along strike before disappearing underneath cover. There is extensive talus covering. Grab samples from gossan and altered rocks in the area have returned assay values of up to 1.8 percent copper, 1.48 percent lead, 1.34 percent zinc, 42 grams of silver per tonne, and 0.54 grams of gold per tonne (Andover Mining Corporation, 2012a).

Alteration:

Iron oxide alteration (Andover Mining Corporation, 2012a).

Age of mineralization:

Devonian, based on age of host rock (Hitzman and others, 1982, Gustin and Ronning, 2013).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Exploration has consisted of field mapping and sampling of rock and soil, completed mostly during the mid 1970s through early 1980s. Andover Mining Corporation completed one diamond core drillhole in 2012 at SAL, which targeted outcropping mineralization that was mapped and sampled by Andover's field team during the 2012 reconnaissance efforts at the Sun District. The drillhole included 2.1 meters of 0.69 percent copper, 0.84 percent lead, 2.99 percent zinc, 19.9 grams of silver per tonne, and 0.126 grams of gold per tonne (Andover Mining Corporation, 2012b).

Production notes:

None.

Reserves:

None, a 2013 resource estimate was made for nearby Sun (SP039) (Gustin and Ronning, 2013).

Reporter(s): A. Angel and V.C. Zinno (Alaska Earth Sciences, Inc.)

Last report date: 2014-12-08

Site name(s): Unnamed (on Red Mountain)

Site type: Mine

ARDF no.: SV014

Latitude: 59.35 **Quadrangle:** SV B-4

Longitude: 151.49

Location description and accuracy:

The Red Mountain deposits consist of at least 30 known occurrences within a seven-square-mile area of ultramafic rocks. The center of the ultramafic rocks is section 28, T. 9 S., R. 13 W., of the Seward Meridian, which is about seven air miles southeast of Seldovia, Alaska. The area is accessable by a gravel road from Seldovia through the Windy River valley. The location is accurate, though degree of accuracy was not reported.

Commodities:

Main: Cr

Other:

Ore minerals: Chromite

Gangue minerals:

Geologic description:

The Red Mountain ultramafic complex covers about 7 square miles and is part of the informally named Border Ranges ultramafic and mafic complex of Burns (1985). The Jurassic Border Ranges complex is thought to be the dismembered basal section of an island arc complex (Burns, 1985) which extends from the tip of the Kenai Peninsula to east of Sutton, Alaska.

The dunite body is a klippe thrust over the Cretaceous McHugh Complex graywackes and slates. The margin of the Red Mountain klippe is serpentinized and the gross overall structure of the klippe is an elongated basin.

The Red Mountain ultramafic body is mostly dunite with some pyroxenite and garnet-pyroxenite layers (Guild, 1942). Chromite layers and lens up to 300 feet long and 60 feet wide are found only within the dunite. Generally, the layers strike northwest and dip steeply near the margins of the klippe and are nearly flat lying near the center of the body.

There are over 30 identified chromite occurrences that occur in thin lens bands and pod within the dunite layers of the ultramafic body. Small scale folds and small scale normal faults commonly disrupt the chromite layers. The Cr/Fe ratio of the chromite generally varies from 2.6 to 3.6; at least 90 percent of the chromite is with these limits (Gill, 1922).

Alteration:

Serpentzation occurs along the margin of the ultramafic body.

Age of mineralization:

Jurassic; based on the age of the ultramafic body that hosts the deposit.

Generic deposit model:

Deposit model:

Podiform chromite (Cox and Singer, 1986; model 8a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
8a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

The area was discovered about 1910 to 1915, and some minor development and production occurred in 1920 (Brooks, 1921). During WW II, the Bureau of Mines drilled over thirty diamond drill holes to evaluate the deposits. From 1942 to 1944, the Chrome Queen mine produced 6,650 tons of 40 to 42 percent chromite ore.

Ongoing exploration continued through the late 1980s. Anaconda Minerals drilled six diamond drill holes in about 1982 and 83 which tested the Horseshoe Stringer Zone and the Turner Stringer Zone (Bill Ellis, 1999, Personal communication). Anaconda Minerals also flew regional airborne geophysics in the early 1980s.

Production notes:

Total production from 1943 to 1958 was 26,000 tonnes of ore containing 38 to 43 percent chrome (Foley and Barker, 1985).

Reserves:

From the Red Mountain area about 26,000 tonnes of ore containing from 38 to 43 percent chromite were produced between 1943 and 1958. The remaining reserve are estimated to be 1.5 million tonnes of contained chromic oxide in 33 deposits (Foley, 1992). About 88,000 tonnes of chromic oxide are contained in 20 relative high-grade deposits with more than 20 percent chromite. The bulk of the reserves, 1.35 million tonnes are in three low-grade deposits that contain 5 to 6 percent chromic oxide (Foley, 1992). These are the Turner Stringer Zone, (1.13 million tonnes chromic oxide), the Star Stringer Zone (189,000 tonnes chromic oxide) and the Horseshoe Stringer Zone (26,000 tonnes chromic oxide) (Foley, 1992).

Additional comments:

There is little information regarding the actual mining of this deposit.

The 03/09/1999 version of this record misquoted the Foley,1992, reference, which lists abbreviations of mt as metric tons not million tons. In addition, production notes for Chrome Queen mine and Star No. 4 mine (SV015) were moved to SV015.

The Red Mountain ultramafic complex covers about 7 square miles and is part of the informally named Border Ranges ultramafic and mafic complex of Burns (1985). The Jurassic Border Ranges complex is thought to be the dismembered basal section of an island arc complex (Burns, 1985) which extends from the tip of the Kenai Peninsula to east of Sutton, Alaska.

The dunite body is a klippe thrust over the Cretaceous McHugh Complex graywackes and slates. The margin of the Red Mountain klippe is serpentinized and the gross overall structure of the klippe is an elongated basin.

The Kenai Chrome mine is located on the Star No. 4 claim at an elevation of 2,600 feet on the north side of the ultramafic body. The chromite seams can be traced for almost 1,000 feet but it is less than a foot thick for over half this distance (Guild, 1941). The main ore body was 625 feet long and had a maxium thickness of 9.8 feet. The strike of the layering is N 10 W and the dip varies from 35 W to 70 W except where minor folding has caused variations. Several small faults strike more or less at right angle to the chromite banding. The Cr/Fe ratio of the chromite generally varies from 2.6 to 3.6; at least 90 percent of the chromite is with these limits (Gill, 1922).

Alteration:

Age of mineralization:

Jurassic; based on the age of the ultramafic body that hosts the deposit.

Last report date: 2016-03-15

Site name(s): Shotgun; Mose

Site type: Prospect

ARDF no.: TA007

Latitude: 60.386 **Quadrangle:** TA B-6

Longitude: 158.0687

Location description and accuracy:

The Shotgun prospect is in the southern part of the Shotgun Hills, a rugged, glaciated upland at the head of the King Salmon River. The prospect is near the center of the NW1/4 section 27, T. 4 N., R. 51 W., of the Seward Meridian. It is on the crest and eastern slope of a northwest-trending ridge at an elevation of about 2,500 feet. The location is accurate to within 500 feet.

Commodities:

Main: Au

Other: As, Bi, Ce, Cu, Te, W, Zn

Ore minerals: Arsenopyrite, bismuth, Bi-Te sulfides, chalcocite, chalcopyrite, copper, covellite, gold, lollingite, marcasite, pyrite, pyrrhotite, scheelite, sphalerite

Gangue minerals: Albite, carbonate, quartz, sericite, tourmaline

Geologic description:

This prospect was discovered in the 1980s in a regional exploration program by Cominco Alaska in joint venture with ENSTAR. They named this prospect Mose and completed surface mapping, sampling, and drilled six shallow diamond drill holes. In the 1990s, ENSTAR's interest was sold to NovaGold Resources Inc., the prospect was renamed Shotgun, and renewed exploration took place (NovaGold Resources Inc., 2000).

The Shotgun prospect is an intensely quartz-veined, felsic porphyry stock that sharply crosscuts biotite hornfels developed in mid-Cretaceous clastic sedimentary rocks of the Kuskokwim Group (Rombach, 2000). As exposed along the ridge crest and downslope to the east, the stock is an irregularly shaped composite intrusion that is about 1,000 feet long in a northwest direction and over 500 feet long in a northeast direction. The hornfels near the stock and across the ridge crest to the southwest commonly is breccia healed by a tourmaline-rich matrix and locally cut by veinlets that contain arsenopyrite, pyrite, and some chalcopyrite. In the stock, some zones near the contact are extensively silicified; quartz replacement is massive and complete in these zones. Elsewhere, the stock is cut by quartz veins that in places form an intense, anastomosing stockwork. Albite-sericite-quartz +/- carbonate replacement of host intrusive rocks accompanies the quartz veining. The deposit is deeply oxidized and iron-staining is widespread. Ore minerals identified at Shotgun include arsenopyrite, primary native gold and bismuth, Bi-Te sulfides, chalcopyrite, lollingite, pyrrhotite, pyrite, scheelite, sphalerite, and supergene covellite, chalcocite, native copper, and marcasite (Rombach, 2000).

Vapor-rich and saline-rich fluid inclusions coexist in the quartz veins. In order of abundance, the vapor-rich inclusions contain water, carbon dioxide, and methane; these inclusions homogenize to vapor at about 360 degrees C. The saline-rich inclusions have salinities of 40 to greater than 60 weight percent NaCl equivalent and homogenize to liquid at 280 to more than 600 degrees C (Rombach, 2000).

Surface rock samples define a large geochemical anomaly with several areas where gold values exceed 1 part per million. Examples of drill hole intercepts include 233 feet grading 0.077 ounce of gold per ton, 399 feet grading 0.050 ounce of gold per ton, and 43 feet grading 0.155 ounce of gold per ton (NovaGold Resources Inc., 2000; all drill hole intercepts are listed online at http://www.nrigold.com/shotgun.htm; Dec

2000). Preliminary metallurgical tests indicate that gold recoveries of more than 93 percent can be achieved using conventional cyanidation. Airborne and ground magnetometer surveys have been used in conjunction with extended mapping and sampling to evaluate the potential for additional mineralization in surrounding areas. As of March 28, 2007, NovaGold Resources, Inc. (2007) reports that the Shotgun prospect has 32.8 million tonnes of resources with a grade of 0.93 gram of gold per ton.

A large granitic pluton makes up the core of the Shotgun Hills. The contact between this pluton and the hornfels that surrounds the Shotgun prospect coincides with a northwest-trending linear swale and drainage less than 0.5 mile north of the prospect. The shallow-seated intrusive environment south of this contact (extensive hornfels locally cut by fine-grained porphyry) compared to that to the north, suggests that this contact is a large fault, dropped down to the south. K/Ar and Ar/Ar dating of intrusive rocks and mineralization in the Shotgun prospect area indicate that magmatism and mineralization is latest Cretaceous in age, about 68 to 70 Ma (Rombach, 2000; Travis Hudson, unpublished data, 2000).

TNR Gold Corporation optioned Shotgun (Mose) from NovaGold Resources, Inc. in 2003. A running history of TNR Gold's work to April 2007 can be seen in several news releases and project information at their web site (TNR Gold Corp., 2007). In 2011 and 2012, TNR collected 3D IP resistivity and chargeability geophysical surveys at Shotgun. In 2012, three drill holes totaling 814 meters were completed (Van Wyck and Armitage, 2013).

TNR Gold Corp. commissioned GeoVector Management Inc. ('GeoVetor') to produce a resource estimate on the Property in 2013. Geovector reported an Inferred Resource of 20,734,313 tonnes at 1.06 grams of gold per tonne for a total of 705,960 ounces gold using a 0.5 gram of gold per tonne cut-off grade (TNR Gold Corp., 2013; Athey and Werdon, 2017).

Alteration:

Silicification and albite-sericite-quartz +/- carbonate replacement of host intrusive rocks (Rombach, 2000).

Age of mineralization:

Latest Cretaceous, 68 to 70 Ma, based on K/Ar and Ar/Ar dating of intrusive rocks and mineralization (Rombach, 2000).

Generic deposit model:

Deposit model:

Gold-bearing quartz-stockwork veining in felsic porphyry.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

This prospect was discovered in the 1980s in a regional exploration program by Cominco Alaska in joint venture with ENSTAR. They named this prospect Mose and completed surface mapping, sampling, and drilled six shallow diamond drill holes. In the 1990s, ENSTAR's interest was sold to NovaGold Resources Inc., the prospect was renamed Shotgun, and renewed exploration took place. This exploration included extensive new diamond drilling in 1998 that included 20 drill holes totaling 10,192 feet. Airborne and ground magnetometer surveys have been used in conjunction with extended mapping and sampling to evaluate the potential for additional deposits in surrounding areas. Drilling results from this year included 14 drill holes intersecting over 20 meters that averaged over 1 gram of gold per tonne with the largest intercept at 121.5 meters at 1.41 grams of gold per tonne in drill hole 98-09 (Rombach, 2000).

TNR Gold Corporation optioned Shotgun (Mose) from NovaGold Resources, Inc. in 2003. A running history of TNR Gold's work to April 2007 can be seen in several news releases and project information at their web site (TNR Gold Corp., 2007). Initial exploration under this agreement was in September 2003 and

included surface geologic mapping and an airborne magnetic survey. TNR Gold Corporation's exploration work during the summer of 2004 included surface geologic mapping and sampling at Shotgun (Mose) and other prospects including Shot (TA031), King (TA030), and Beats Me (TA029). In the summer of 2005, the TNR Gold Corporation exploration program included drilling 6 holes to further refine and expand the resource at Shotgun (Mose) and evaluate other prospects in the area. In 2006, drilling from one drill hole (06-43) intersected 210.5 meters of 1.28 grams of gold per tonne (Harrop, 2008).

In 2011 and 2012, TNR collected 3D IP resistivity and chargeability geophysical surveys at Shotgun. In 2012, three drill holes totaling 814 meters were completed. A resource estimate and technical report followed in 2013. An Inferred Resource of 20,734,313 tonnes at 1.06 grams per tonne for a total of 705,960 ounces gold using a 0.5 gram of gold per tonne cut-off grade was estimated. Mineralization, as defined by a 3D computer model, is approximately 360 meters long trending at 55 degrees, and extends from the ground surface to a depth of up to 240 meters. Mineralization remains open at depth (Van Wyck and Armitage, 2013).

TNR Gold Corp. commissioned GeoVector Management Inc. ('GeoVetor') to produce a resource estimate on the Property in 2013. Geovector reported an Inferred Resource of 20,734,313 tonnes at 1.06 grams of gold per tonne for a total of 705,960 ounces gold using a 0.5 gram of gold per tonne cut-off grade (TNR Gold Corp., 2013; Athey and Werdon, 2017).

Production notes:

None.

Reserves:

In 2012, three drill holes totaling 814 meters were completed. A resource estimate and technical report followed in 2013. An Inferred Resource of 20,734,313 tonnes at 1.06 grams per tonne for a total of 705,960 ounces gold using a 0.5 gram of gold per tonne cut-off grade was estimated. Mineralization, as defined by a 3D computer model, is approximately 360 meters long trending at 55 degrees, and extends from the ground surface to a depth of up to 240 meters. Mineralization remains open at depth (Van Wyck and Armitage, 2013).

TNR Gold Corp. commissioned GeoVector Management Inc. ('GeoVetor') to produce a resource estimate on the Property in 2013. Gangue minerals:

Geologic description:

Placer gold mining has taken place along at least the upper 3 miles of Taylor Creek, although prospects have been noted as far as 1.5 miles below the mouth of Fork Creek, a south tributary (Cady and others, 1955, Plate 1). The alluvial gravels are about 10 feet thick, the pay streak is about 250 feet wide, and bedrock is mid-Cretaceous clastic sedimentary rocks of the Kuskokwim Group.

The heavy-mineral concentrates contain cinnabar and cassiterite; pyrite is abundant in concentrates from below the mouth of Fork Creek (Cady and others, 1955, p. 119). Cady and others (1955) reported that the Taylor Creek mine had produced a total of $90,000 worth of gold (about 2,500 ounces), mainly in 1950 and 1951. The mine has been active at different times since Cady and others' report, including small-scale mining and prospecting through the 1990s (M. Henning, personal communication, 2000). The Bureau of Land Management sampled the Taylor Creek placer deposit in 2004 (Ellefson and others, 2005). Two panned-concentrate samples contained 7.66 and 15.2 parts per million (ppm) gold, 0.25 and 0.24 ppm silver, 9.15 and 10.8 ppm mercury, 2280 and 1270 ppm manganese, 19 and 34 ppm tin, and less than 0.01 ppm tantalum.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:
Placer gold mining has taken place along at least the upper 3 miles of Taylor Creek, although prospects have been noted as far as 1.5 miles below the mouth of Fork Creek, a south tributary (Cady and others, 1955, Plate 1). An airstrip, water ditch, and mine buildings are present. Taylor Creek has been explored for a distance of about 1.5 miles downstream of the mouth of Fork Creek. The mine has been active at different times since Cady and others' report, including small-scale mining and prospecting through the 1990s (M. Henning, oral communication, 2000). Sampled by the Bureau of Land Management in 2004.

Production notes:
Cady and others (1955) reported that the Taylor Creek mine had produced a total of $90,000 worth of gold (about 2,500 ounces), mainly in 1950 and 1951. There has been an undocumented amount of production since 1951.

Reserves:
None.

Reporter(s): Travis L. Hudson (Applied Geology, Inc.)

Last report date: 2007-04-10

Site name(s): Sleitat

Site type: Prospect

ARDF no.: TA010

Latitude: 60.0439 **Quadrangle:** TA A-3

Longitude: 157.0882

Location description and accuracy:

The Sleitat prospect is centered on a saddle at an elevation of 1,725 feet, between the two high peaks of Sleitat Mountain. The prospect is near the center of section 31, T. 1 S, R. 45 W. The location is accurate.

Commodities:

Main: Sn, W

Other: Ag, Bi, Cu, Ta, W

Ore minerals: Arsenopyrite, bismite, cassiterite, chalcopyrite, ferrotantalite, loellingite, pyrite, sphalerite, stannite, wolframite

Gangue minerals: Clay, muscovite, quartz, topaz, tourmaline, zinnwaldite

Geologic description:

The occurrence of granite and peripheral gold-bearing quartz veins was reported on Sleitat Mountain by Mertie (1938), but subsequent exploration has shown that the principal mineralization is a tin-, tungsten-, and silver-bearing sheeted greisen system (Farnstrom, 1991; Burleigh, 1991; Hudson and Reed, 1997, Ellis, 2006). The greisen deposit was discovered during a Cominco Alaska regional exploration program in 1983, and subsequently evaluated in the mid-1980s by detailed surface mapping and sampling, and 9 drill holes (Farnstrom, 1991). Solomon Resources Ltd. staked 3,520 acres on the Sleitat prospect in the summer of 2005 (Brett Resources Inc., 2006). They subsequently worked out a joint venture agreement with Brett Resources, Inc., and geologic and geochemical field work began in Sept. 2005. In 2005, Brett commissioned a comprehensive NI 43-101 report on the deposit by William T. Ellis (2006), who analyzed and compiled the previous data on the deposit and did some limited verification sampling. In 2006, Brett drilled 5 holes.

A composite granite stock that hosts most of the greisen sharply crosscuts and thermally metamorphoses mid-Cretaceous clastic sedimentary rocks of the Kuskokwim Group. The stock has a discontinuous border zone of medium-grained biotite granite and biotite-muscovite granite, and a core of fine-grained zinnwaldite granite. Felsic porphyry dikes crosscut hornfels peripheral to the stock. A K/Ar age of 56.8 +/- 2.8 Ma on muscovite from a late veinlet was reported by Burleigh (1991). The cassiterite-bearing, greisen sheets trend east-west and are developed within the biotite-muscovite granite, zinnwaldite granite, and hornfels.

The greisen zones include nearly vertical quartz-topaz-tourmaline +/- white mica veins and tabular bodies that vary from inches to 20 feet in thickness and coalesce to greater thicknesses in places. They are mainly concentrated in the north half of the stock; a second zone along the south border includes some greisen sheets in peripheral hornfels. The individual greisen sheets are granular, massive, separated by less-altered granite, have disseminated clay-lined voids, and have cores that locally contain a few inches of coarse-grained quartz veins with concentrations of up to 50-60 percent cassiterite (Burleigh, 1991). Cassiterite is disseminated in the greisen, concentrated in cores of greisen veins, and is in quartz-topaz veins that fill fractures in hornfels. Cassiterite-bearing veins in hornfels are up to 1.5 feet wide and a few hundred feet long. Small amounts of wolframite are disseminated in the greisen but it also occurs with arsenopyrite in quartz veins, especially in hornfels peripheral to greisen zones. Arsenopyrite is common in the greisen and veins. Up to 5 percent loellingite with inclusions of bismite has been identified as disseminations in biotite-

muscovite granite (Burleigh, 1991). Sphalerite is a minor but common constituent of the greisen and some stannite and chalcopyrite are associated with the sphalerite. One small grain of ferrotantalite was identified during SEM analysis of the greisen (Burleigh, 1991). Individual greisen zones locally have high tin grades. For example, one 47.7-foot drill intercept averaged 1.56 percent tin, and included a 5-foot-thick section grading 12.6 percent tin and 5.7 ounces of silver per ton (Farnstrom, 1991; Burleigh, 1991). Four of the five holes drilled by Brett Resources (2006) in 2006 intersected mineralization comparable to the earlier Cominco results. The 2006 drilling including 104 meters with 0.24 percent tin and 6.48 grams of silver per ton, and 66 meters with 0.29 percent tin and 14.10 percent silver.

The Sleitat prospect is a deeply eroded tin-bearing system. The sheeted greisens, particularly those on the north side of the stock, are expected to diminish in size and in intensity of cassiterite mineralization at depth. However, mineralization in the relatively wide hornfels zone on the south side of the stock may indicate that the upper contact of the granite body is not steeply dipping there, or that a mineralizing zinnwaldite granite cupola could be present at depth (Hudson and Reed, 1997). Burleigh (1991) showed that much of the eroded tin-bearing material had migrated downslope and along the small streams that head in the Sleitat highland.

Burleigh (1991) estimated that the Sleitat deposit contained a total of 28.6 million tons of ore with an average grade of 0.37 percent tin, 0.04 percent tungsten, and 17 ppm silver. However, Ellis (2006) cautioned that these figures while not necessarily wrong, do not meet current industry standards for determining mineral resources.

Alteration:

Greisenization, late clay development, oxidation including iron- and scorodite-staining.

Age of mineralization:

Early Tertiary. A composite granite stock that hosts most of the greisen sharply crosscuts and thermally metamorphoses mid-Cretaceous clastic sedimentary rocks of the Kuskokwim Group. A K/Ar age of 56.8 +/- 2.8 Ma on muscovite from a late veinlet was reported by Burleigh (1991).

Generic deposit model:

Deposit model:

Sn greisen deposits (Cox and Singer, 1986; model 15c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

15c

Production Status: None

Site Status: Active

Workings/exploration:

The Sleitat prospect was discovered and explored by Cominco Alaska in the 1980s. This work included detailed surface mapping, sampling, and some diamond drilling (Farnstrom, 1991). In 1989, the U.S. Bureau of Mines conducted additional surface examinations, geochemical sampling, surface magnetometer and radiometric surveys, and a panned-concentrate survey in nearby drainages (Burleigh, 1991). Solomon Resources Ltd. staked 3,520 acres on the Sleitat prospect in the summer of 2005 (Brett Resources Inc., 2006). They subsequently worked out a joint venture agreement with Brett Resources, Inc., and geologic and geochemical field work began in Sept. 2005. In 2005, Brett commissioned a comprehensive NI 43-101 report on the deposit by William T. Ellis (2006) who analyzed and compiled the previous data on the deposit and did some limited verification sampling. Subsequently, Brett drilled 5 holes in 2006.

Production notes:

None.

Reserves:

Burleigh (1991) estimated that the Sleitat deposit contains a total of 28.6 million tons of ore with an average grade of 0.37 percent tin, 0.04 percent tungsten, and 17 ppm silver. However, Ellis (2006) cautioned that these figures, while not necessarily wrong, do not meet current industry standards for determining mineral resources.

Last report date: 2008-06-05

Site name(s): Unnamed (near peaks of Little Taylor Mountains)

Site type: Occurrence

ARDF no.: TA020

Latitude: 60.8494 **Quadrangle:** TA B-6

Longitude: 157.1924

Location description and accuracy:

This occurrence is on the crest of the Little Taylor Mountains, 3.1 miles southeast of the junction of Fork and Taylor creeks. The occurrence is near peak 2,100 at an elevation of about 2,100 feet, in the SW1/4 of section 24, T. 9 N., R. 45 W., of the Seward Meridian. This occurrence was included under the name 'Little Taylor Mts.' by Cobb (1976 [OF 76-606]).

Commodities:

Main: Au?

Other: As, Cu

Ore minerals: Arsenopyrite, gold, pyrite

Gangue minerals: Quartz, sericite

Geologic description:

Several Cretaceous or Tertiary felsic dikes or sills cut mid-Cretaceous clastic sedimentary rocks of the Kuskokwim Group in the higher parts of the Little Taylor Mountains (Cady and others, 1955, p. 71, plates 1 and 6). At a locality a little northwest of the summit of the Little Taylor Mountains, the felsic dikes or sills trend northwest, and dip southwest, parallel to the bedding of the enclosing sedimentary rocks. The felsic intrusions and the enclosing sedimentary rocks are strongly silicified and pyritized. 'Traces of copper' were also noted by Cady and others (1955, p. 122) in the Little Taylor Mountains. In 2005, T. K. Bundtzen (oral communication, 2005) found thin, arsenopyrite-bearing quartz veins in or near felsic intrusives on the southwest flank of the mountains at an elevation of about 1850 in SW1/4 sec. 24, T9N, R45W of the Seward Meridian. Gold is not specifically noted but possibly is present, probably in the quartz veins.

Alteration:

Silicification, pyritization, and sericitization.

Age of mineralization:

Late Cretaceous or early Tertiary, the age of the felsic plutons in southwest Alaska that intrude the mid-Cretaceous clastic sedimentary rocks of the Kuskokwim Group.

Generic deposit model:

Deposit model:

Gold?-bearing altered felsic intrusive rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only some surface examination and sampling.

Production notes:

None.

Reserves:

None.

Last report date: 2007-04-10

Site name(s): Shot

Site type: Prospect

ARDF no.: TA021

Latitude: 60.3694 **Quadrangle:** TA B-6

Longitude: 158.1524

Location description and accuracy:

This prospect is in the southern Shotgun Hills near the top of an upland west of the headwaters of an unnamed north tributary to the King Salmon River. It is in the NW1/4 section 9, T. 3 N., R. 51 W., of the Seward Meridian. The location is accurate to within 1/4 mile.

Commodities:

Main: Ag, Au, Sn

Other: As, B, Bi, Cu, Hg, Pb, Sb

Ore minerals: Arsenopyrite, gold, malachite

Gangue minerals: Quartz, tourmaline

Geologic description:

Clark and others (1970) collected rock samples for about 5,000 feet along the crest of this upland. Several of these samples have weakly to strongly anomalous concentrations of silver (to 7 parts per million (ppm)), arsenic, boron, bismuth, copper, lead, antimony, tin, gold (to 0.1 ppm), and mercury. Bedrock is mostly hornfels in mid-Cretaceous clastic sedimentary rocks of the Kuskokwim Group. Clark and others (1970) describe this hornfels as strongly limonite stained and cut by numerous small quartz veins rarely exceeding 1/8 inch in width. Some of the quartz veins carry minor amounts of arsenopyrite and arsenopyrite is also locally disseminated in the hornfels. Some scorodite and malachite are locally present.

Cominco examined the prospect during a reconnaissance exploration program in the early 1980s (Travis Hudson, personal knowledge, 2005). Felsic intrusives cut hornfels and intense tourmaline alteration is locally developed. Shot was originally considered a tin-silver prospect and stream sediments, panned concentrates, and rock samples do contain anomalous tin values. Rock samples collected during initial exploration contained up to 510 ppb gold. TNR Gold Corporation (2005) explored this prospect in 2005 as part of their district exploration program centered on the Shotgun prospect (TA007). TNR drilled 301 meters in 2005 (TNR Gold Corp., 2014). In 2008, a revised NI 43-101 technical report was published (Harrop, 2008). In 2013, another NI 43-101 Technical Report was published (Van Wyck and Armitage, 2013).

Alteration:

Silicification and tourmalinization (Rombach, 2000).

Age of mineralization:

Probably Latest Cretaceous, the age of intrusive rocks and mineralization in the similar Shotgun (TA007) prospect nearby (Rombach, 2000).

Generic deposit model:

Deposit model:

Quartz veins in hornfels and felsic intrusive rocks; possibly polymetallic veins? (Cox and Singer, 1986, model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active?

Workings/exploration:

Originally found during regional mapping by the U.S. Geological Survey in the late 1960s Examined by Cominco Exploration in 1981 during an initial reconnaissance of the area. TNR Gold Corporation was exploring this prospect in 2005 as part of their district exploration program centered on the Shotgun prospect (TA007).

TNR drilled 301 meters in 2005 (TNR Gold Corp., 2014). In 2008, a revised NI 43-101 technical report was published (Harrop, 2008). In 2013, another NI 43-101 technical report was published (Van Wyck and Armitage, 2013).

Production notes:

None.

Reserves:

Though the Shot prospect does not have any calculated resources or reserves, a resource estimate on the nearby Shotgun prospect (TA007) was completed in 2013 (Van Wyck and Armitage, 2013).

Additional comments:

In 2010, TNR Gold Corp. announced an increase to 100 percent undivided ownership interest in the Shotgun project through the acquisition of NovaGold Resources outstanding 50 percent (TNR Gold Corp., 2010).

Site name(s): Unnamed (in Taylor Mountains)

Site type: Occurrence

ARDF no.: TA023

Latitude: 60.9235 **Quadrangle:** TA D-4

Longitude: 157.4491

Location description and accuracy:

This occurrence is high in the Taylor Mountains about 1.2 miles west of peak 3581 (the highest peak in the Taylor Mountains) and about 0.1 mile north of elevation 3007. It is about 0.3 mile south of the center of section 28, T. 10 N., R,. 46 W. The location is accurate.

Commodities:

Main: B

Other: As, Cu, U

Ore minerals: Tourmaline

Gangue minerals: Quartz

Geologic description:

Black tourmaline and quartz-tourmaline rock partly to completely replace porphyritic biotite granite of the Cretaceous Taylor Mountains pluton (Travis Hudson, unpublished field data, 2005) Coarse euhedral tourmaline aggregates are well developed along a northwest-trending vertical fracture or fault in the granite. The tourmaline-rich zone is at least several feet wide; float blocks of tourmaline and quartz-tourmaline rock are up to 4 or 5 feet thick. These blocks are scattered on the surface in a line for about one to two hundred feet. The host granite has large euhedral K-feldspar phenocrysts up to 8 to 10 centimeters long in a fine- to medium-grained equigranular groundmass. The Bureau of Land Management sampled this occurrence in 2004 (Ellefson and others, 2005). Two rock samples contained 100 and 300 parts per million (ppm) arsenic, 107 and 106 ppm copper, less than 5 and 15 ppm tin, less than 0.01 tantalum, and 2.96 and 15.3 ppm uranium. These samples contained only 10 and 70 ppm boron and are therefore not representative of the tourmaline-rich rocks at this locality. T. K. Bundtzen (personal communication, 2005) also sampled these tourmaline-rich rocks in 2005.

Alteration:

Tourmaline and quartz replacement of porphyritic biotite granite.

Age of mineralization:

Late Cretaceous, the age of the Taylor Mountains granite pluton.

Generic deposit model:

Deposit model:

Tourmaline and quartz-tourmaline replacement in granite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited surface sampling.

Production notes:

None.

Reserves:

None.

Additional comments:

Ellefson, R. M., Hoppe, J. E., Kurtak, J. M., and Meyer, M. P., 2005, Mineral investigations in the Aniak mining district, southwestern Alaska, 2004 field season: Bureau of Land Management Open File Report, 100, 44 p.

Primary Reference: Ellefson and others, 2005

Reporter(s): Travis L. Hudson (Applied Geology, Inc.)

Last report date: 2005-10-10

Site name(s): Unnamed (west of upper Taylor Creek)

Site type: Mine

ARDF no.: TA024

Latitude: 60.872

Quadrangle: TA D-4

Longitude: 157.4382

Location description and accuracy:

This mine is in the headwaters of an unnamed north tributary to Kiknik Creek. A small saddle separates the mine from the headwaters of upper Taylor Creek (TA008) to the east. The mine, which was active as of August 2005, is in the NW1/4, section 16, T. 9 N., R. 46 W. of the Seward Meridian.

Commodities:

Main: Au

Other: Ag, Sn, W

Ore minerals: Gold, magnetite, scheelite, wolframite

Gangue minerals:

Geologic description:

Like Taylor Creek (TA008) to the east, this placer is in a drainage that marks the approximate boundary between hornfels associated with the Taylor Mountain pluton and non-metamorphosed clastic sedimentary rocks of the Kuskokwim Group. Bedrock in the mine area is non-metamorphosed Kuskokwim Group sedimentary rocks. In some recent years to at least 2005, open cut mining has taken place on this creek early in the summer when water is available.

The BLM sampled this deposit in 2004 (Ellefson and others, 2005). Their 2-pan, concentrate sample contained 40 to 60 very fine to fine gold colors. After removal of visible gold, this sample contained 305 parts per million (ppm) gold, 60.1 ppm silver, 267 ppm mercury, 1,660 ppm manganese, 2,350 ppm tin, less than 0.01 ppm tantalum, and 820 ppm tungsten. Two samples of sluice concentrate contained 556 and greater than 1,500 ppm silver, 37.1 and 171 ppm mercury, 5,130 and greater than 10,000 ppm manganese, 1,400 and 2,330 ppm tin, 0.6 ppm tantalum, and 15.7 and 36 percent tungsten. Abundant wolframite with minor magnetite and scheelite were identified in the concentrate samples.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

In some recent years to at least 2005, open cut mining has taken place on this creek early in the summer when water is available. The BLM sampled this placer in 2004.

Production notes:

In recent years and through 2005, this mine produced a small amount of gold each year. The concentrates also contain some tin and tungsten but neither commodity is recovered or marketed.

Reserves:

Unknown but probably some (in 2005).

Primary Reference: This record

Reporter(s): Travis L. Hudson (Applied Geology, Inc.)

Last report date: 2007-04-10

Site name(s): Unnamed (on Whitewater Creek)

Site type: Occurrence

ARDF no.: TA025

Latitude: 60.8707 **Quadrangle:** TA D-4

Longitude: 157.5539

Location description and accuracy:

This occurrence is at an elevation of about 500 feet on Whitewater Creek on the south flank of the Taylor Mountains. It is in section 14, T. 9 N., R. 47 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Whitewater Creek heads in the south contact zone of the Taylor Mountain granite pluton. The bedrock in the area is mostly hornfels developed from graywacke and shale of the Cretaceous Kuskokwim Group (Travis Hudson, unpublished field data, 2005). The Bureau of Land Management sampled the alluvial sediments at this location in the summer of 2004 (Ellefson and others, 2005). A stream-sediment sample contained 1,395 parts per billion gold A two-pan, panned-concentrate sample contained 6 very fine colors of gold. After removing the visible gold, this sample contained 2.25 parts per million (ppm) gold; tin and tantalum were below the detection limits of 5 ppm and 0.01 ppm respectively.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986, model 39a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

The only documented work in this area is reconnaissance sampling by the Bureau of Land Management in the summer of 2004.

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (on Kiknik Creek)

Site type: Occurrence

ARDF no.: TA026

Latitude: 60.8549 **Quadrangle:** TA D-5

Longitude: 157.5504

Location description and accuracy:

Kiknik Creek is the major drainage southwest of the Taylor Mountains. This placer occurrence is on Kiknik Creek at an elevation of about 440 feet. It is about 1.3 miles upstream from the mouth of Whitewater Creek and about 0.5 mile west of the center of section 24, T. 9 N., R. 47 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

This placer gold occurrence is in alluvial sediments mostly derived from clastic sedimentary rocks of the Kuskokwim Group in the headwaters of Kiknik Creek. This occurrence is about 1.5 miles downstream of the confluence of Kiknik Creek and an unnamed north tributary with a rich headwater placer (TA024). The Bureau of Land Management collected a stream- sediment sample that contained 0.192 part per million (ppm) gold and a panned-concentrate contained 5.55 ppm gold (Ellefson and others, 2005).

Alteration:

Age of mineralization:

Quaternary.

Last report date: 2005-10-10

Site name(s): Unnamed (headwaters of the Nushagak River)

Site type: Prospect

ARDF no.: TA027

Latitude: 60.6733 **Quadrangle:** TA C-1

Longitude: 156.1333

Location description and accuracy:

This prospect is on a ridge north of the head of the Nushagak River. It is at an elevation of about 1,675 feet about 0.4 miles north of the center of section 28, T. 7 N., R. 39 W.

Commodities:

Main: Au?

Other:

Ore minerals: Gold?

Gangue minerals: Quartz

Geologic description:

Sparse quartz veins up to a few centimeters wide cut graywacke and shale of the Cretaceous Kuskokwim Group at their contact with a granitic intrusion (Travis Hudson, unpublished field data, 2005). A small prospect pit has been dug but it does not expose outcrop. A composite, quartz vein sample was collected in 2005 by the U.S. Geological Survey.

Alteration:

Age of mineralization:

Late Cretaceous or Early Tertiary; probably related to the adjacent felsic intrusion which cuts the Cretaceous Kuskokwim Group.

Generic deposit model:

Deposit model:

Quartz veins in sedimentary rocks at contact with granitic intrusion.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

A small prospect pit has been dug on the contact of Kuskokwim Group and granitic rocks at this occurrence; outcrop is not exposed.

Production notes:

None.

Reserves:

None.

Site name(s): King

Site type: Prospect

ARDF no.: TA028

Latitude: 60.3319 **Quadrangle:** TA B-6

Longitude: 158.1362

Location description and accuracy:

The King prospect is in the isolated upland north of the upper King Salmon River, the highest point of which is marked by VABM King. The exact location of the prospect on the upland is unknown and is somewhat arbitrarily plotted at VABM King in the SE1/4 section 21, T. 3 N., R. 51 W., of the Seward Meridian. The prospect is probably within a mile of VABM King. The location is probably accurate to within a mile.

Commodities:

Main: Au

Other: Ag, Sn

Ore minerals: Gold

Gangue minerals: Quartz, tourmaline

Geologic description:

Cominco discovered and explored this prospect during a reconnaissance exploration program in the early 1980s (Travis Hudson, personal knowledge, 2005). The prospect is in an area of hornfels developed from the sedimentary rocks of the Cretaceous Kuskokwim Group. Felsic intrusions cut the hornfels and intense tourmaline alteration is locally developed. The prospect was originally considered to be a silver prospect. However, stream sediments and rock samples contain anomalous tin values and some contain anomalous gold values. TNR Gold Corporation (2005) was exploring this prospect in 2005 as part of their district exploration program centered on the Shotgun prospect (TA007).

In 2005, TNR drilled 145 meters at King (TNR Gold Corp., 2014). This drilling was targeting three talus samples that were collected on the north side of the mountain, which ran over 1 gram of gold per tonne. Prospecting and mapping in 2007 looked at a vein and breccia zone on the south side of the mountain where twelve rock samples were collected. Of these twelve samples, eight contained 0.208 to 2.985 grams of gold per tonne as stated in the NI 43-101 technical report by J. Harrop (2008). In 2013, another 43-101 Technical Report was published (Van Wyck and Armitage, 2013).

Alteration:

Silicification and tourmalinization (Rombach, 2000).

Age of mineralization:

Probably Latest Cretaceous, the age of intrusive rocks and mineralization in the nearby Shotgun (TA007) prospect area (Rombach, 2000).

Generic deposit model:

Deposit model:

Quartz veins in hornfels and felsic intrusive rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Joe Piekenbrock discovered this prospect in 1981 during an initial reconnaissance of the area for Cominco Exploration. Cominco mapped and sampled the prospect in the early 1980s (Travis Hudson, personal knowledge, 2005).

In 2005, TNR drilled 145 meters at King (TNR Gold Corp., 2014). This drilling was targeting three talus samples that were collected on the north side of the mountain which ran over 1 gram of gold per tonne. Prospecting and mapping in 2007 looked at a vein and breccia zone on the south side of the mountain where twelve rock samples were collected. Of these twelve samples, eight contained 0.208 to 2.985 grams of gold per tonne as stated in the NI 43-101 technical report by J. Harrop (2008). In 2013, another 43-101 Technical Report was published (Van Wyck and Armitage, 2013).

Production notes:

None.

Reserves:

Though the King prospect does not have any calculated resources or reserves, a resource estimate on the nearby Shotgun prospect (TA007) was completed in 2013 (Van Wyck and Armitage, 2013).

Additional comments:

In 2010, TNR Gold Corp. announced an increase to 100 percent undivided ownership interest in the Shotgun project through the acquisition of NovaGold Resources outstanding 50 percent (TNR Gold Corp., 2010).

Last report date: 2014-12-12

Site name(s): Winchester; Beats Me

Site type: Prospect

ARDF no.: TA029

Latitude: 60.2825 **Quadrangle:** TA B-6

Longitude: 158.1023

Location description and accuracy:

This prospect is on an upland south of the upper King Salmon River, possibly in section 10 and/or 11, T. 2 N., R. 51 W. The site of this prospect is arbitrarily chosen to be the summit of this upland at elevation 1606; it is probably within a mile of the true location of this prospect. The accuracy of this location has not been reported.

Commodities:

Main: Au

Other:

Ore minerals: Arsenopyrite, gold

Gangue minerals: Quartz

Geologic description:

Cominco Exploration discovered this prospect in the early 1980s (Travis Hudson, personal knowledge, 2005). It is in an upland area of hornfels developed from sedimentary rocks of the Cretaceous Kuskokwim Group that are cut by felsic dikes. Quartz stockwork veining and arsenopyrite mineralization are locally well-developed. Stream sediments in the area have anomalous gold values and several rock samples contain over 1 part per million gold. TNR Gold Corporation (2005) continued exploration of this prospect and core drilled in the summer of 2005. TNR announced the results of their 2005 drilling in October 2005. The six holes totaled 1754.3 feet and most went through medium-grained felsic intrusive rock into sedimentary rocks of the Cretaceous Kuskokwim Group. The felsic intrusive rocks were commonly anomalous in gold associated with arsenic, bismuth, copper, and tungsten. The highest grade interval in the holes was 1.60 grams of gold per ton over 14.3 meters; this included a 2.13 meter interval with 2.93 grams of gold per ton. The holes were drilled on a geochemical anomaly 500 by 1200 in area along the ridge. There is little outcrop in the area. TNR Gold Corporation (2007) drilled eleven more holes in 2006 with emphasis on the Winchester zone where they now have seven holes along a cross section through the zone and a clearer understanding of the geology of the deposit. The mineralization continues to be associated with light-gray felsic intrusive sills and is not restricted to brecciated zones or veins.

In 2010, TNR Gold Corp. announced an increase to 100 percent undivided ownership interest in the Shotgun project through the acquisition of NovaGold Resources outstanding 50 percent (TNR Gold Corp., 2010). In 2011 and 2012, TNR collected 3D IP resistivity and chargeability geophysical surveys at Winchester. A resource estimate for Shotgun and technical report followed in 2013 (Van Wyck and Armitage, 2013).

Alteration:

Silicification.

Age of mineralization:

Probably Latest Cretaceous, the age of intrusive rocks and mineralization in the nearby Shotgun (ARDF number TA007) prospect.

Generic deposit model:

Deposit model:

Arsenopyrite-bearing quartz veins in hornfels and felsic intrusive rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Winchester prospect was mapped and sampled by TNR Gold Corporation in 2005 and 6 holes were drilled that totaled 1754.3 feet. TNR drilled 11 more holes in 2006 with emphasis on the Winchester zone where they now have 7 holes along a cross section through the zone and a clearer understanding of the geology of the deposit.

In 2010, TNR Gold Corp. announced an increase to 100 percent undivided ownership interest in the Shotgun project through the acquisition of NovaGold Resources outstanding 50 percent (TNR Gold Corp., 2010). In 2011 and 2012, TNR collected 3D IP resistivity and chargeability geophysical surveys at Winchester. A resource estimate for Shotgun and technical report followed in 2013 (Van Wyck and Armitage, 2013).

Production notes:

None.

Reserves:

See ARDF site TA007 for 2012 resource estimate for the Shotgun Project; however, drillholes from King where not included in that estimate (TNR Gold Corp., 2008).

Site name(s): Kusk; Forlorn Hills

Site type: Prospect

ARDF no.: TA030

Latitude: 60.2695 **Quadrangle:** TA B-5

Longitude: 157.7671

Location description and accuracy:

This prospect is on an isolated upland south of the middle section of the Salmon River. It is near elevation 2280, about 0.4 mile north of the center of section 15, T. 2 N., R. 49 W.

Commodities:

Main: Sn

Other:

Ore minerals: Cassiterite

Gangue minerals: Quartz

Geologic description:

A zone of surface rubble about 50 feet long and 10 to 15 feet wide is marked by pieces of quartz-veined stockworks and breccia (Travis Hudson, unpublished field data, 2005). The upland in the area consists of hornfels developed in clastic sedimentary rocks of the Cretaceous Kuskokwim Group; porphyroblastic hornfels with cordierite and/or andalusite porphyroblasts is common. Sparse quartz and quartz-tourmaline veining is locally developed. Intrusive rocks are not exposed on hills 2280, 1866, and 1610. Float from a few-centimeter-thick felsic dike was found at an elevation of about 500 feet on the southwest flank of hill 1750. Cominco Exploration identified cassiterite and high-grade tin values in the quartz breccia.

Alteration:

Silicification of hornfels.

Age of mineralization:

Probably Early Tertiary, the age of the tin mineralization at the nearby Sleitat Mountain prospect (TA010).

Generic deposit model:

Deposit model:

Quartz vein breccia in hornfels.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Surface examination and rock sampling. This prospect was originally discovered by and staked during a reconnaissance exploration program by Cominco Exploration in the early 1980s.

Production notes:

None.

Reserves:

None.

Reporter(s): Travis L. Hudson (Applied Geology, Inc.)

Last report date: 2005-10-10

Site name(s): Triple Z; ASARCO; Tok; Dennis

Site type: Prospect

ARDF no.: TC001

Latitude: 63.3702 **Quadrangle:** TC B-4

Longitude: 142.5104

Location description and accuracy:

The prospect is on a north-facing hillside about 5 miles northeast of Tetlin Junction. It is at an elevation of about 3,000 feet in section 3, T. 19 N., R. 15 E. The location is known to within a mile.

Commodities:

Main: Au, Cu, Mo

Other: As, Bi

Ore minerals: Chalcopyrite?, gold, molybdenite, pyrite

Gangue minerals:

Geologic description:

As originally explored by ASARCO, the prospect was said to consist of silicified and deeply leached Tertiary quartz porphyry hypabyssal intrusive and extrusive rocks that contain disseminated molybdenite and copper sulfide minerals (Singer and others, 1976). The area consists of Tertiary felsic volcanic rocks surrounded by undivided granitic rocks (Foster, 1970). It is within the eastern Yukon-Tanana Y1 subterrane of Foster and Keith (1994). Cities Services Mineral Corp. drilled three holes in the prospect in 1971, and then dropped the project (David Hedderly-Smith, oral communication, 1998). A rhyolite flow near the ASARCO prospect has an age of 55-60 Ma (Newberry and others, 1996).

In 2011, Contango Ore Inc. (2012) was active on the property, calling it the Triple Z prospect, and sampled rocks and soils. Rock samples contained up to 9.07 grams of gold per tonne with anomalous copper, arsenic, and bismuth. Drilling is planned in 2012.

Alteration:

Alteration types include intense silicification and leaching of the hypabyssal intrusive (Singer and others, 1976).

Age of mineralization:

Early Tertiary (55-60 Ma), based on the prospect's similarity to the Taurus prospect (TC027) and the Pushbush prospect (TC024) nearby, as well as a radiometric date on a rhyolite flow near the prospect (Newberry and others, 1996).

Generic deposit model:

Deposit model:

Porphyry Cu deposit (Cox and Singer, 1986; model 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

21a

Production Status: None

Site Status: Undetermined

Workings/exploration:

Surface rock and geochemical sampling, some undocumented drilling in 1970 and 1971. In 2011, Contango Ore Inc. (2012) was active on the property as the Triple Z prospect and sampled rocks and soils.

Production notes:

None.

Reserves:

None.

Last report date: 2012-04-01

Site name(s): Mount Fairplay

Site type: Prospects

ARDF no.: TC008

Latitude: 63.6888 **Quadrangle:** TC C-3

Longitude: 142.2599

Location description and accuracy:

The Fairplay prospects are in a large block of claims that covered about 20 square miles near Mount Fairplay and were active in the 1970s. The center of the activity is in section 14, T. 22 N., R. 16 E., of the Copper River Meridian, about 2 miles northwest of the summit of Mount Fairplay. The location is accurate.

Commodities:

Main: Au, Mo, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, molybdenite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

There was considerable activity northwest of Mount Fairplay in the 1970s and a large block of claims was staked by WGM, Inc. Details are lacking but the work apparently consisted mainly of surface mapping, sampling, and geochemistry. More recent activity is possible, but apparently not extensive.

The Fairplay prospect is on the northern contact of the Mount Fairplay pluton whose surface exposure is about 4 miles in diameter (Foster, 1970; Kerin, 1976; Adams, 2009). The Mount Fairplay pluton is a Late Cretaceous to early Tertiary alkaline complex with well-developed ring structures. The pluton intrudes biotite schist and gneiss, probably of Mississippian and older age, and bimodal felsic and mafic volcanic rocks, probably of Late Cretaceous age. The Mount Fairplay complex was emplaced in three phases between 59 and 67 Ma: 1) an early alkaline ring phase that consists of diorite and several syenite units on the north side of the complex, 2) a later alkaline ring-dike phase that consists of several syenite units and perthosite on the south side of the complex; and 3) a calc-alkaline core that consists of hornblende-biotite quartz monzonite. The Fairplay prospects are in the Late Cretaceous felsic volcanic rocks just beyond the northern contact of the Mount Fairplay complex, that near this prospect is a hornblende-biotite quartz monzonite.

As described by Adams (2009), the Fairplay prospect includes both vein-type and disseminated mineralization. Samples contain anomalous copper, molybdenum, lead, and zinc. Kerin (1976) noted that three samples contained from 40 to 120 parts per billion gold. Singer and others (1976) suggested that the deposit is a copper-molybdenum porphyry.

Alteration:

Hydrothermal alteration (Singer and others, 1976).

Age of mineralization:

Late Cretaceous based on the age of the host rock and a possible genetic tie to the Mount Fairplay pluton.

Generic deposit model:

Deposit model:

Porphyry Cu-Mo deposit? (Cox and Singer, 1986; model 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

21a

Production Status: None

Site Status: Undetermined

Workings/exploration:

There was considerable activity northwest of Mount Fairplay in the 1970s and a large block of claims was staked by WGM, Inc. Details are lacking but the work apparently consisted mainly of surface mapping, sampling, and geochemistry. More recent activity is possible, but apparently not extensive.

Production notes:

None.

Reserves:

None.

Site name(s): South Pika; Fishhook

Site type: Prospect

ARDF no.: TC009

Latitude: 63.8071 **Quadrangle:** TC D-1

Longitude: 141.3389

Location description and accuracy:

The South Pika prospect, formerly called the Fishhook prospect, is located in a saddle northeast of hill 4455 at the headwaters of the Sixtymile River, west of Fishhook Bend. The prospect location has been updated from previous reporting to where a northeast trending gold soil anomaly was trenched in the northeast corner of section 4, T. 23 N., R. 21 E. of the Copper River Meridian.

Commodities:

Main: Ag, Au

Other: Barite, Cu, Mo, Pb, Sb

Ore minerals: Chalcopyrite, galena, gold, molybdenite, pyrite, silver, stibnite, sulfosalts

Gangue minerals: Hematite, quartz

Geologic description:

The dominant lithology within the South Pika prospect area is augen gneiss having a possible igneous protolith (Mertie, 1931; Foster, 1970). This protolith has a possible emplacement age (inferred from dating other exposures in the region) of Devonian to Mississippian (360 Ma), with resets in the Late Jurassic (190 Ma) and Early to Mid-Cretaceous (135-107 Ma) time (Dusel-Bacon and Aleinikoff, 1985). Cretaceous-Tertiary, fine-grained biotite granite, granodiorite, monzodiorite, and a coarse-grained alkali granite intrude the augen gneiss and are exposed in small outcrops at the prospect. Tertiary (?) volcanics are also present (Gill, 1977).

Local structures are dominated by numerous, high-angle, northeast-trending fault zones. Many subordinate fault zones in the area parallel the northeast strike and possibly reflect underlying igneous activity (Curt Freeman, unpublished data, 1998). A prominent northeast-trending fault cross-cutting South Pika is characterized by pervasive silicification and rare hydrothermal breccias, surrounded by a broader zone of strong clay alteration of feldspar augen porphyroblasts and matrix feldspar. Surrounding the clay alteration is a narrow zone of sericite alteration where schistose matrix biotite has been replaced by fine-grained muscovite. Reverse faults of unknown age are interpreted where graphitic and actinolite-chloritic schists are exposed (Siron and Grady, 2011).

The mineralization at South Pika appears to be structurally controlled by the northeast trending faults. Minerals include chalcopyrite, galena, gold, molybdenite, pyrite, silver, sulfosalts, and stibnite. The more highly mineralized areas occur as breccias along the northeast-trending faults. The Cretaceou-Tertiary plutonic rocks also contain elevated values of lead, silver, barium, antimony, and gold. Anomalous bismuth along some of the faults suggests a plutonic-source fluid (Curt Freeman, unpublished data, 1998). The strongly silicified augen gneiss at the core of the alteration zones exhibit a variety of textures, from solid massive silica, brecciated textures to vuggy silica. Two localities of silicified hydrothermal breccias have been identified. Each breccia contains rounded silica nodules with concentric rings of silica contained in silica groundmass. Disseminated and weathered sulfide minerals (pyrite) are present (Siron and Grady, 2011).

Meter-scale quartz veins are exposed throughout the prospect. These veins strike north to northeast and appear coincident with the main structural trend. Their origin is unclear, however, they are rarely

mineralized and are thought to have formed during reactivation of old structures during metamorphism. A gossanous barite-galena-silver-(gold) vein, containing highly anomalous gold, is oriented along a northeast-trending structure and is exposed near the 4455 foot summit. An additional galena-silver vein in float was uncovered at the base of the silicified fault to the west and is possibly a genetically related mineralized structure (Siron and Grady, 2011).

Alteration:

Alteration at South Pika is mostly along northeast-trending faults and is characterized by pervasive silicification and rare hydrothermal breccias, surrounded by a broader zone of clay alteration of feldspar augen porphyroblasts and matrix feldspar. Surrounding the clay alteration is a narrow zone of sericite alteration where schistose matrix biotite has been replaced by fine-grained muscovite (Siron and Grady, 2011).

Age of mineralization:

Mineralization was likely synchronous with faulting and magmatism during Late Cretaceous (70 to 68 Ma), indicated from dated hydrothermal mica (Allan and others, 2015).

Generic deposit model:

Deposit model:

Creede epithermal veins? (low-sulfidation epithermal) (Cox and Singer, 1986; model 25b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25b?

Production Status: None

Site Status: Inactive

Workings/exploration:

In the mid-1970s Cities Service Minerals Corporation (Cities Services) conducted regional reconnaissance exploration in the Tanacross quadrangle area. Several soil samples and rock samples were collected over the South Pika prospect area at this time (Hedderly-Smith, 2009). This prospect was examined as a porphyry copper deposit at that time, but no significant grades of copper were found (J.M. Messing, oral communication, 1998).

In 1978, one shallow drill hole was put in, but did not encounter significant mineralization. In the late 1980s to 1990s, soil and rock-chip sampling, geologic mapping, and a ground-based magnetometer survey were conducted (Curt Freeman, unpublished data, 1998).

In 2008 Full Metal Minerals (FMM), in a joint venture with BHP Billington, conducted follow-up ridge and spur soil sampling on historic Cities Services data and completed a 31,000 line-kilometer high-resolution airborne magnetic survey covering 1.05 million hectares of the Tanacross quadrangle encompassing the South Pika prospect. The survey shows a moderately high susceptibility anomaly bordering the edge of coincident anomalous gold-in-soil anomaly at South Pika (Siron and Grady, 2011).

FMM completed more reconnaissance-style soil and rock sampling and geologic mapping in 2010 which was followed by gridded soil sampling, targeting anomalous gold mineralization. A total of 625 soil samples and 77 rock samples were collected over South Pika. Additionally, four trenches were dug totaling 99 bulk-rock samples. Soil samples from the saddle at South Pika range between trace and 1.09 parts per million (ppm) gold, averaging 0.108 ppm gold. Overall, the characteristic of this soil anomaly exhibits subdued pathfinder element distributions, however, elevated signatures are evident (arsenic: up to 151 ppm; copper: up to 492 ppm; molybdenum: up to 40 ppm; lead: up to 2310 ppm). The northeast-trending barite-galena-silver-(gold) vein near hill 4455 carries upwards of 1.01 ppm gold and 52.1 ppm silver in rock samples and anomalous gold-in-soil over this vein is approximately 100 meters wide and traceable over 1,600 meters along strike (Siron and Grady, 2011).

Site name(s): Pika Canyon

Site type: Prospect

ARDF no.: TC023

Latitude: 63.8267 **Quadrangle:** TC D-1

Longitude: 141.4061

Location description and accuracy:

The Pika Canyon prospect is located in a saddle that is at the headwaters of a tributary of Dude Creek to the west and a tributary of Liberty Creek to the east. The prospect location covers about 1/2 square mile and has been updated from previous reporting based on recent work where mineralization in rocks and soils has been found in the southeast corner of section 30, T. 24 N., R. 21 E. of the Copper River Meridian.

Commodities:

Main: Ag, Au

Other: Cu, Pb

Ore minerals: Chalcopyrite, galena, malachite, pyrite, sphalerite?

Gangue minerals: Quartz

Geologic description:

The dominant lithology at the Pika Canyon prospect is augen gneiss having a possible igneous protolith (Mertie, 1931; Foster, 1970). This protolith has a possible emplacement age (inferred from dating other exposures in the region) of Devonian to Mississippian (360 Ma), with resets in the Late Jurassic (190 Ma) and Early to Mid-Cretaceous (135-107 Ma) time (Dusel-Bacon and Aleinikoff, 1985). A series of plugs and dikes which range in composition from diorite to monzodiorite intrude the augen gneiss. Based on cross-cutting relationships and minimal alteration within these units, these intrusions are interpreted to be syn- to post-mineralization in age. The mapped intrusions directly correspond with magnetic highs in the regional 1:50,000 scale magnetic survey conducted by Full Metal Minerals-BHP Billington (King and Tedeschi, 2012). Based on similarities to nearby dated plutons, the Pika Canyon intrusions are likely members of the Prospector Mountain Suite formed during the development of a volcanic arc during the Late Cretaceous (Selby and Creaser, 2001).

The alteration in the greater Pika Canyon area is patchy and somewhat irregular, but generally occurs in somewhat concentric zones of potassic, phyllic, and propylitic alteration (Gill, 1977). Significant brecciation and extensive alteration occurs along the contact of the diorite dike with the augen gneiss located in the saddle of Pika Canyon, indicating it was a conduit for hydrothermal fluids. Mineralization at Pika Canyon consists of gold-silver rich quartz vein stockwork in augen gneiss at and near the contact with the diorite dike. Alteration of the augen gneiss is zoned based on distance from the diorite contact. Distally, alteration is weak consisting of biotite destruction replaced by fine grained sericite and iron oxides. Weak alteration grades into strong to moderate sericite and silicification towards the contact. Silicification is most commonly manifested as thin sheeted veins and stockwork exploiting foliation, but occasionally crosscuts primary fabric, including augens. These foliation parallel veins range in thickness from 1 to 10 millimeters and occasionally contain jarosite and iron oxides, indicative of the former presence of sulfide minerals. Typically these veins are clear to bluish in color and are very fine grained (King and Tedeschi, 2012).

Alteration:

Site Status: Inactive

Workings/exploration:

During 1974 to 1976, soil, rock chip, and stream-sediment sampling were conducted on the prospect, as well as a ground magnetic survey on a 200- by 500-foot grid (Gill, 1977, p. 2).

In 2008 Full Metal Minerals (FMM) and BHP Billington completed a regional 1:50,000 scale magnetic survey that covered the Pika Canyon area. Magnetic highs at Pika Canyon correspond with mapped monzodiorite and diorite intrusions (King and Tedeschi, 2012).

FMM completed ridge and spur soil sampling and geologic mapping over the Pika Canyon prospect in the early part of the summer in 2011. Positive gold and silver results in these soil samples led to a soil grid put in place the same year over the Pika Canyon area with 190 more soil samples collected. With limited outcrop available, trenching over an area with altered float led to the discovery of the diorite dike with mineralized and brecciated contact zones with the augen gneiss (King and Tedeschi, 2012).

Site name(s): Silver Lining; Draken

Site type: Prospect

ARDF no.: TC026

Latitude: 63.6474 **Quadrangle:** TC C-3

Longitude: 142.286

Location description and accuracy:

The Silver Lining prospect is about 2.8 miles southwest of the top of Mount Fairplay and is exposed in a road cut beside the Taylor Highway. In early 2010, it was on a block of 6 claims called the Draken project that covered all of section 34 and the east half of section 33 of T. 22 N., R. 16 E. The Silver Lining prospect is about 0.3 mile north of the center of section 34. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb

Other: As, Sb, Zn

Ore minerals: Arsenopyrite, azurite, chalcophanite, chalcopyrite, chrysocolla, galena, malachite, scorodite, stibiconite

Gangue minerals: Clay, limonite, quartz

Geologic description:

Various companies explored in the Mount Fairplay area through the 1970s and 1980s, apparently with indifferent results. The Silver Lining prospect was discovered by two prospectors in 1990 in road cuts beside the Taylor Highway and a large group of claims were staked around it (Adams, 2009). However, by 1999 all the claims were abandoned. In 2006, six claims that covered the Silver Lining prospect and all of section 34 and the east half of section 33 of T. 22 N., R. 16 E. were staked by Anglo Alaska Gold Corporation as the Draken property. Fire River Gold Corporation acquired a 100 percent interest in the property in 2009.

The Silver Lining prospect is in the central portion of the Mount Fairplay pluton whose surface area is about 4 miles in diameter (Foster, 1970; Kerin, 1976; Adams, 2009). The Mount Fairplay pluton is a Late Cretaceous to early Tertiary alkaline complex with well-developed ring structures. The pluton intrudes biotite schist and gneiss, probably of Mississippian and older age, and bimodal felsic and mafic volcanic rocks, probably of Late Cretaceous age. The Mount Fairplay complex was emplaced in three phases between 59 and 67 Ma: 1) an early alkaline ring phase that consists of diorite and several syenite units on the north side of the complex; 2) a later alkaline ring phase that consists of several syenite units and perthosite on the south side of the complex; and 3) a calc-alkaline core phase that consists of hornblende-biotite quartz monzonite. The Silver Lining prospect is well within the quartz monzonite core, although several nearby unnamed prospects inside the Draken claims are in hornblende-biotite syenite.

The mineralization at the Silver Lining prospect is mainly gold-sulfide-quartz veins, with some indication of disseminated mineralization. High-grade samples contain up to 0.25 ounce of gold per ton along with high, silver, arsenic, bismuth, copper, lead, and antimony. The sulfide minerals include arsenopyrite, chalcopyrite, pyrite, and galena. The veins are 1 to 4 cm thick, strike about 35 to 60 degrees northeast, and dip 65 to 75 degrees northwest. The veins are oxidized at the surface and contain secondary copper and arsenic oxides and silicates.

Alteration:

Apparently not prominent but some clay alteration along the veins.

Age of mineralization:
Late Cretaceous or early Tertiary based on the age of the host rock.

Generic deposit model:

Deposit model:
Low sulfide, gold-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): Taurus; East Taurus; West Taurus

Site type: Prospect

ARDF no.: TC027

Latitude: 63.6474 **Quadrangle:** TC C-1

Longitude: 141.263

Location description and accuracy:

The Taurus prospect has two main centers of interest, West Taurus and East Taurus. Most of the work has been done at East Taurus at the coordinates of for this site. West Taurus is about 3,000 meters to the west. East Taurus is about 12.5 miles east-southeast of Prindle Volcano and about 0.6 mile northwest of the center of section 36, T. 22 N., R. 21 E.

Commodities:

Main: Au, Cu, Mo

Other:

Ore minerals: Azurite, chalcocite, chalcopyrite, covellite, magnetite, molybdenite, pyrite

Gangue minerals: Fluorite, quartz, sericite, tourmaline

Geologic description:

From 1970, when Taurus was discovered during a reconnaissance geochemical survey, to 1996, a succession of companies, notably International Minerals and Chemical Corp., Duval Minerals, Rioamex, City Services Minerals Corp., Noranda, and Cross Canada, explored the property with mapping and sampling, ground and aerial geophysical surveys, several geochemical programs, and by 30 drill holes (Harrington, 2010). By 1996, Taurus East had become the focus of interest and 8 holes were drilled there. In 2008, Senator Minerals Inc. drilled 3 more holes at East Taurus that totaled 3,179 feet. As of early 2011, Senator Minerals holds the property (Senator Minerals, Inc., 2011).

The Taurus property has two main centers of porphyry-type mineralization, West Taurus and East Taurus (Harrington, 2010). The property is underlain in part by a metamorphic basement complex possibly of Late Precambrian or early Paleozoic age that consists of biotite gneiss, augen gneiss, biotite schist, and quartzite, intruded by Cretaceous granodiorite (Foster, 1970). Two Early Tertiary stocks who outcrop areas roughly coincide with East and West Taurus intrude the metamorphic rocks and the granodiorite. Secondary biotite in one intrusion has been dated by K-Ar methods at 57 +/- 2 Ma (Nokleberg and others, 1995).

Two major faults have been identified. The Tourmaline fault strikes northeasterly and appears to have left-lateral movement with a possible displacement of up to 6.5 kilometers. The McCord Creek fault trends east across the claims. Porphyry intrusions, which host the mineralization at East and West Taurus, are near the McCord Creek fault, suggesting that the fault controlled their emplacement. Many northeast trending lineaments have been interpreted using satellite images and topographic maps (Leriche, 1995, p. 452).

The Taurus porphyry copper mineralization appears to be related to widespread, small bodies of early Tertiary, quartz monzonite porphyry, quartz latite, feldspar-quartz porphyry, intrusive breccia, quartz porphyry and dacite porphyry. Intrusive breccia crops out along the southern border of an altered, Late Cretaceous granodiorite pluton on the eastern side of the property. Quartz monzonite porphyry occurs along the southern contacts of the altered granodiorite, and intrusive breccia is in the central part of the property (Leriche, 1995; Harrington, 2010)).

The East Taurus ore body consists of an upper leached cap underlain by supergene and hypogene zones. The leached cap is up to 150 feet thick and shows pervasive argillic alteration due to groundwater leaching. The leached cap shows pervasive silicification, and quartz-sericite, and quartz-magnetite alteration. The

supergene and hypogene zones are marked by phyllic, silicic, propylitic, and potassic alteration (Leriche, 1995, Harrington, 2010).

Mineralization in the leached cap at East Taurus consists of minor remnant pyrite, chalcopyrite, and molybdenite in quartz stockworks and silicified zones. The supergene zone varies in thickness from 70 to 150 feet and contains chalcocite, covellite, pyrite, chalcopyrite, and molybdenite. The chalcocite is in fractures and in quartz veinlets. In the lower hypogene zone, pyrite, chalcopyrite, and molybdenite are disseminated along fractures and in the center of quartz veinlets (Leriche, 1995).

Some notable intercepts in the 2008 drilling at East Taurus are: 1) 772 feet of 0.309 percent copper, 0.036 percent molybdenum, and 0.245 grams of gold per tonne; 2) 179 feet of 0.258 percent copper, 0.026 percent molybdenum, and 0.149 grams of gold per tonne; 57 feet of 0.232 percent copper, 0.004 percent molybdenum, and 0.015 grams of gold per tonne (Harrington, 2010). The mineralization at East Taurus is open in all directions as well as below the deepest 1,400-foot drill hole.

Mineralization in the West Taurus area consists of pyrite and subordinate chalcopyrite, covellite, chalcocite, malachite, and azurite. Molybdenite is found in quartz-filled fractures in sericitically altered, quartz latite. Chalcopyrite and molybdenite are in fracture fillings near the Tourmaline and McCord Creek faults (Leriche, 1995, p. 454).

In 1993, Noranda indicated that the East Taurus zone contained a reserve of 23 million tons with an average grade of 0.3 percent copper and 0.039 percent molybdenum (Leriche, 1995). The 1996, 2008, and earlier drilling provided sufficient information for an estimate to modern standards of the size of the deposit. Harrington (2010) estimated that East Taurus has an inferred mineral resource of 75.2 million tons with an average grade of 0.275 copper, 0.032 percent molybdenum, and 0.166 gram of gold per tonne.

Alteration:

The leached cap, which is up to 150 feet thick, shows pervasive argillic alteration due to groundwater leaching. Other alteration types in the leached cap consist of pervasive silicification, quartz-sericite, and quartz-magnetite alteration. Supergene and hypogene zones are accompanied by phyllic, silicic, propylitic, and potassic alteration (Leriche, 1995, p. 453).

Age of mineralization:

Secondary biotite from one of the stocks associated with the mineralization has been dated by K-Ar techniques methods as 57 +/- 2 Ma (Nokleberg and others, 1995).

Generic deposit model:

Deposit model:

Porphyry Cu-Mo-Au deposit (Cox and Singer, 1986; model 21a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

21a

Production Status: None

None.

Reserves:

In 1993, Noranda indicated that the East Taurus zone contained a reserve of 23 million ton with an average grade of 0.3 percent copper and 0.039 percent molybdenum (Leriche, 1995). The 1996, 2008, and earlier drilling provided sufficient information for an estimate to modern standards of the size of the deposit. Harrington (2010) estimated that East Taurus has an inferred mineral resource of 75.2 million tons with an average grade of 0.275 copper, 0.032 percent molybdenum, and 0.166 gram of gold per tonne.

Site name(s): Stibnite Creek; Tok Antimony; Stibnite; A Lucky Leak; Gamblin; Caulk

Site type:

Mine

ARDF no.: TC029

Latitude: 63.2484 **Quadrangle:** TC A-6

Longitude: 143.7959

Location description and accuracy:

The Stibnite Creek deposit is about 1.5 mile upstream from the mouth of Stibnite Creek, a tributary to the Tok River. It is about 0.5 mile south of the center of section 13, T. 17 N., R. 8 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Au, Sb

Other:

Ore minerals: Pyrite, stibnite

Gangue minerals: Calcite, muscovite, quartz

Geologic description:

The Tok Antimony deposit, also called Boulder Creek, Stibnite, A Lucky Leak, and Stibnite Creek, was discovered in the early 1900s. A 12-foot adit was driven in 1914. In 1940, several tons of ore from the prospect were stockpiled by Boulder Creek awaiting transport. All of it was washed away by the river and was never processed (Ebbley and Wright, 1948). There was some mining from an open cut with a bulldozer in 1976 (York, 1980).

Stibnite Creek is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator, Triton Gold Ltd. (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. They soon staked claims over the Discovery Zone prospect (TC034) at the north end of the belt in what then was classified as massive-sulfide mineralization. Their work continued through 1987 in conjunction with several partners and consisted of geologic mapping, rock and soil sampling, and geophysical surveys along what became a belt of deposits. They drilled 17 holes along the belt in 1986 and 8 holes in 1987, totaling 3,390 meters. From 1998 to 2001, Inmet Mining Corporation and Pacific Northwest Resources Company did addition mapping, rock and soil surveys, and they drilled 8 more diamond drill holes totaling 1,489 meters. Two of these holes were drilled at the Stibnite Creek Mine at what is now the south end of the belt. The property was idle until 2007 when James DeMarchi staked 40 claims over the belt and transferred them to Tushtena Resources Ltd. In 2008, they entered into a joint agreement with Triton Gold.

The rocks along the belt consist of two main units: the Devonian to Precambrian, Macomb Belt unit to the east and the Devonian Tushtena Pass unit to the west. They are separated by the Itra Fault, a regional scale, shallowly to moderately dipping thrust fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The Macomb Belt rocks consist mainly of felsic metatuff and volcaniclastic rocks, and sericite-carbonate-quartz phyllonite. The Tushtena Pass unit consists of schist and phyllite, metadiorite, and lithic tuff.

There are two main styles of mineralization along the belt: 1) hanging-wall, bonanza-style vein systems; and 2) footwall, sulfide stockwork and breccia vein systems. The hanging-wall, vein-type mineralization

has an arsenic-lead-zinc association with narrow or no alteration envelopes and is characterized by quartz-carbonate-sulfide-gold-mica veins. The footwall, stockwork-breccia zones have a gold-rich core and peripheral antimony-rich mineralization. The deposits are correlative with others along the Tintina gold belt; the key characteristics are the low angle faults that trap the mineralization and the carbonaceous rocks that provide the right chemistry for deposition.

The mineralization at the Stibnite Creek Mine consists of quartz-stibnite-arsenopyrite veins and breccias along a shear zone that is probably part of a series of en echelon structures that splay off the Itra Fault (DiMarchi and others, 1987; Fonseca, 2009; Newkirk and others, 1986; York, 1980). The mineralization is in schist, gneiss and mylonite of the Macomb Belt. The host rocks are pervasively but variably altered to ankerite; this alteration is probably related to the Itra fault, not to the mineralization. The gold-bearing veins have narrow envelopes of sericitic alteration and silicification. Four types of veins occur at the Stibnite Creek Mine: 1) quartz-chlorite+/-sericite fracture fillings; 2) barren ankerite+/- quartz veinlets unrelated to the gold mineralization; 3) barren, white, drusy quartz stockworks; and 4) quartz-stibnite-pyrite+/-arsenopyrite veins that locally contain masses of crystalline stibnite. Two holes were drilled on the Stibnite Creek prospect; the best interval was 4.1 feet that contained 700 parts per billion gold, 2,260 parts per million (ppm) arsenic, and 7.40 ppm silver.

Alteration:

Ankeritic and sericitic alteration; silicification.

Age of mineralization:

About 70 to 105 Ma by analogy if Tintina Belt-style mineralization.

Generic deposit model:

Deposit model:

Tintina Belt-style, gold-arsenopyrite-stibnite quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes; small

Site Status: Active

Workings/exploration:

The Tok Antimony deposit, also called Boulder Creek, Stibnite, A Lucky Leak, and Stibnite Creek, was discovered in the early 1900s. A 12-foot adit was driven in 1914. In 1940, several tons of ore from the prospect were stockpiled by Boulder Creek awaiting transport. All of it was washed away by the river and was never processed (Ebbley and Wright, 1948). There was some mining from an open cut with a bulldozer in 1976 (York, 1980).

Stibnite Creek is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator, Triton Gold Ltd. (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. They soon staked claims over the Discovery Zone prospect (TC034) at the north end of the belt in what then was classified as massive-sulfide mineralization. Location description and accuracy:

This occurrence is about 2.7 miles south-southwest of the top of Mount Fairplay; it is at an elevation of about 4,000 feet, about 0.4 mile southwest of the center of section 35, T. 22 N., R. 16 E. The location is accurate.

Commodities:

Main: Be, La, Nb, Th, U, Y, Zr

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Various companies explored in the Mount Fairplay area from the 1970s to the 1990s, apparently with indifferent results. The Section 35 prospect dates from work begun in 2006, when Anglo Alaska Gold Corporation staked 6 claims known as the Draken project; the claims included the nearby Silver Lining prospect (TC026). Fire River Gold Corporation acquired the Draken claims in 2009. The Section 35 occurrence (which is just outside the Draken claims) was identified in their sampling.

The Section 35 prospect is in the outer portion of the Mount Fairplay pluton whose outcrop area is about 4 miles in diameter (Foster, 1970; Kerin, 1976; Adams, 2009). The pluton is a Late Cretaceous to early Tertiary alkaline complex with well-developed ring structures. It intrudes biotite schist and gneiss, probably of Mississippian and older age and bimodal felsic and mafic volcanic rocks, probably of Late Cretaceous age. The Mount Fairplay complex was emplaced in three phases between 59 and 67 Ma: 1) an early alkaline ring phase that consists of diorite and several syenite units on the north side of the complex; 2) a later alkaline ring phase that consists of several syenite units and perthosite on the south side of the complex; and 3) a calc-alkaline core phase that consists of hornblende-biotite quartz monzonite. The Section 35 occurrence is in a protoclastic hornblende-biotite syenite on the south side of the complex.

A sample of fine-grained syenite contained 16 parts per million beryllium, 172 ppm lanthanum, 145 ppm niobium, 235 ppm thorium, 157 ppm uranium, 33 ppm yttrium, and 291 ppm zirconium (Adams, 2009). The syenite is part of a ring dike complex with accessory apatite, fluorite, and monazite. Adams (2009) noted that some samples from the Silver Lining prospect (TC026), about a mile to the northwest, also contained anomalous uranium, thorium, and rare-earth elements.

Alteration:

None noted.

Age of mineralization:

Late Cretaceous or early Tertiary based on the age of the plutonic host rock.

Generic deposit model:

Deposit model:

REE in syenitic plutonic rocks.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only surface sampling and mapping.

Production notes:

None.

Reserves:

None.

Site name(s): Two Mile

Site type: Prospect

ARDF no.: TC033

Latitude: 63.665 **Quadrangle:** TC C-3

Longitude: 142.2742

Location description and accuracy:

The Two Mile prospect is about 1.8 miles west-northwest of the summit of Mount Fairplay. It is beside the Taylor Highway near the northeast corner of section 27, T. 22 N., R. 16 E. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb

Other: As, Sb, Zn

Ore minerals: Chalcopyrite, galena, molybdenite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

Several companies have explored in the Mount Fairplay area since 1970 (Adams, 2009; Kerin, 1976). The history of the Two Mile prospect is uncertain but there are fairly well known prospects along the Taylor Highway to the north, the Fairplay prospect (TC008), and to the south, the Silver Lining prospect (TC 026), which was active as of early 2010. It is likely that the Two Mile prospect has been staked at one time or another but it status in early 2010 was unknown.

The Two Mile prospect is in core zone of the Mount Fairplay pluton whose outcrop area is about 4 miles in diameter (Foster, 1970; Kerin, 1976; Adams, 2009). The Mount Fairplay pluton is a Late Cretaceous to early Tertiary alkaline complex with well-developed ring structures. The pluton intrudes biotite schist and gneiss, probably of Mississippian and older age and bimodal felsic and mafic volcanic rocks, probably of Late Cretaceous age. The Mount Fairplay complex was emplaced in three phases between 59 and 67 Ma: 1) an early alkaline ring phase that consists of diorite and several syenite units on the north side of the complex; 2) a later alkaline ring phase that consists of several syenite units and perthosite on the south side of the complex; and 3) a calc-alkaline core phase that consists of hornblende-biotite quartz monzonite. The Two Mile prospect is in the hornblende-biotite quartz monzonite in the central part of the complex.

The mineralization and hostrock at the Two Mile prospect are similar to that at the Silver Lining prospect (TC026) about a mile to the south (Adams, 2009). The mineralization consists of narrow gold-sulfide-quartz veins; that strike about N22E and dip 90SE; alteration and oxidation is pervasive. Two rock samples of quartz monzonite contained anomalous gold and sporadic, weak amounts of silver, copper, lead, molybdenum, thorium, uranium, and tungsten. Singer and others (1976) classified the deposit as a porphyry. However, more recent work by Adams (2009) suggest vein-type mineralization.

Alteration:

Unstated.

Age of mineralization:

Late Cretaceous or early Tertiary based on the age of the host rocks.

Generic deposit model:

Deposit model:

Low-sulfide gold-quartz vein; porphyry deposit?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Workings/exploration:

Several companies have explored in the Mount Fairplay area since 1970 (Adams, 2009; Kerin, 1976). The history of the Two Mile prospect is uncertain but there are fairly well known prospects along the Taylor Highway to the north, the Fairplay prospect (TC008), and to the south, the Silver Lining prospect (TC 026), which was active as of early 2010. It is likely that the Two Mile prospect has been staked at one time or another but it status in early 2010 was unknown. The exploration probably only consisted of some surface sampling and geologic mapping.

Site name(s): Discovery Zone

Site type: Prospect

ARDF no.: TC034

Latitude: 63.2846 **Quadrangle:** TC B-6

Longitude: 143.8329

Location description and accuracy:

The Discovery Zone prospect is about 3.6 miles north of the junction of the Tok River and Stibnite Creek. It is at an elevation of about 4350 feet and about 0.3 mile northwest of the center of section 2, T. 17 N., R. 8 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Cu, Pb, Sb, Zn

Other:

Ore minerals: Arsenopyrite, chalcopyrite, galena, gold, pyrite, sphalerite, stibnite

Gangue minerals: Carbonates, quartz

Geologic description:

The Discovery Zone prospect is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator, Triton Gold Ltd. (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. They soon staked claims over the Discovery Zone prospect on what was then considered massive-sulfide mineralization. Their work continued through 1987 in conjunction with several partners and consisted of geologic mapping, rock and soil sampling, and geophysical surveys along what became a belt of deposits. They drilled 17 holes along the belt in 1986 and 8 holes in 1987, totaling 3,390 meters. From 1998 to 2001, Inmet Mining Corporation and Pacific Northwest Resources Company did additional mapping and rock and soil surveys. They diamond drilled 8 more holes totaling 1,489 meters. The property was idle until 2007 when James DeMarchi staked 40 claims over the belt and transferred them to Tushtena Resources Ltd. In 2008, they entered into a joint agreement with Triton Gold.

The rocks along the belt consist of two main units: the Devonian to Precambrian, Macomb Belt unit to the east and the Devonian Tushtena Pass unit to the west. They are separated by the Itra Fault, a regional scale, shallowly to moderately dipping thrust fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The Macomb Belt rocks consist mainly of felsic metatuff and volcaniclastic rocks, and sericite-carbonate-quartz phyllonite. The Tushtena Pass unit consists of schist and phyllite, metadiorite, and lithic tuff.

There are two main styles of mineralization along the belt: 1) hanging-wall, bonanza-style vein systems; and 2) footwall, sulfide stockwork and breccia vein systems. The hanging-wall, vein-type mineralization has an arsenic-lead-zinc association with narrow or no alteration envelopes and is characterized by quartz-carbonate-sulfide-gold-mica veins. The footwall, stockwork-breccia zones have a gold-rich core and peripheral antimony-rich mineralization. The deposits are correlative with others along the Tintina gold belt; the key characteristics are the low angle faults that trap the mineralization and the carbonaceous rocks that provide the right chemistry for deposition.

The Discovery Zone was initially classified as a volcanogenic, exhalative and carbonate, massive-sulfide deposit. But magnetite skarns and gold veins were also identified (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009;). High grade mineralization is found only in Tushtena Unit rocks above the

Itra fault. Four types of veins are reported: 1) metamorphic, gold-deficient, quartz veins with disseminated base-metal minerals parallel to foliation; 2) post-metamorphic quartz-gold veins with base-metal sulfides; 3) quartz +/- carbonate veins with chalcedony, clay, and hematite; and 4) alunite-clay-iron oxide-quartz veins. The veins and vein breccias vary from 0.3 to 9 meters thick and are usually in short segments truncated by northeast-trending fractures. The veins have weak, thin alteration haloes with an inner zone of silicification and an outer zone of weak to moderate, iron-magnesium carbonate alteration. High gold values are typically related to abundant arsenopyrite. Numerous intervals in the 13 drill holes in the Discovery Zone prospect contained more than 400 parts per billion (ppb) gold, and many intervals had more than 1,000 ppb gold. The most notable were 116 feet with 1,064 ppb gold, 4,283 parts per million (ppm) arsenic, and 2.80 ppm silver; this included an 2.7-foot interval with 37,028 ppb gold, 33,018 ppm arsenic, and 48.40 ppm silver. An 8.0-foot zone contained 5,037 ppb gold, 11,736 ppm arsenic, and 1.55 ppm silver; this included 0.5 feet with 18,200 ppb gold, 27,500 ppm arsenic, and 5,80 ppm silver.

Alteration:

The veins have weak, thin alteration haloes with an inner zone of silicification and and an outer zone of weak to moderate, iron-magnesium carbonate alteration.

Age of mineralization:

About 70 to 105 Ma by analogy, if Tintina-style mineralization.

Generic deposit model:

Deposit model:

Tintina-style, gold-arsenopyrite-quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site name(s): RS

Site type: Prospect

ARDF no.: TC035

Latitude: 63.2902 **Quadrangle:** TC B-6

Longitude: 143.8509

Location description and accuracy:

The RS prospect is about 3.9 miles north of the junction of the Tok River and Stibnite Creek. It is at an elevation of about 4900 feet, about 0.5 mile north-northeast of the center of section 3, T. 17 N., R. 8 E., of the Copper River Meridian. The location is accurate.

Commodities:

Main: Ag, As, Au, Cu, Pb, Sb, Zn

Other:

Ore minerals:

Gangue minerals: Carbonates, quartz

Geologic description:

The RS prospect prospect is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator, Triton Gold Ltd. (DiMarchi and others, 1987; Fonseca, 2009; Newkirk and others, 1986). Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. They soon staked claims over the Discovery Zone prospect (TC034) on what was then was considered massive-sulfide mineralization. Their work continued through 1987 in conjunction with several partners and consisted of geologic mapping, rock and soil sampling, and geophysical surveys along what became a belt of deposits. They drilled 17 holes along the belt in 1986 and 8 holes in 1987, totaling 3,390 meters. From 1998 to 2001, Inmet Mining Corporation and Pacific Northwest Resources Company did addition mapping, rock and soil surveys, and they drilled 8 more diamond drill holes totaling 1,489 meters. The property was idle until 2007 when James DeMarchi staked 40 claims over the belt and transferred them to Tushtena Resources Ltd. In 2008, they entered into a joint agreement with Triton Gold.

The rocks along the belt consist of two main units: the Devonian to Precambrian, Macomb Belt unit to the east and the Devonian Tushtena Pass unit to the west. They are separated by the Itra Fault, a regional scale, shallowly to moderately dipping thrust fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The Macomb Belt rocks consist mainly of felsic metatuff and volcaniclastic rocks, and sericite-carbonate-quartz phyllonite. The Tushtena Pass unit consists of schist and phyllite, metadiorite, and lithic tuff.

There are two main styles of mineralization along the belt: 1) hanging-wall, bonanza-style vein systems; and 2) footwall, sulfide stockwork and breccia vein systems. The hanging-wall, vein-type mineralization has an arsenic-lead-zinc association with narrow or no alteration envelopes and is characterized by quartz-carbonate-sulfide-gold-mica veins. The footwall, stockwork-breccia zones have a gold-rich core and peripheral antimony-rich mineralization. The deposits are correlative with others along the Tintina gold belt; the key characteristics are the low angle faults that trap the mineralization and the carbonaceous rocks that provide the right chemistry for deposition.

The RS prospect is in the Tushtena Unit rocks above the Itra fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009. The mineralization consists of quartz-ankerite-arsenopyrite-pyrite-galena-gold veins in quartz-sericite calc-schist interbedded with minor quartzite and chlorite schist. The veins are

controlled by northeast-trending fractures. The veins are usually zoned with sulfides on the walls and a center of comb quartz and ankerite. Several intercepts in the 3 holes drilled on the RS prospect had gold values about 400 parts per billion (ppb) gold. The best intercept was 24.2 feet with 1,320 ppb gold, 6,282 parts per million (ppm) arsenic, and 0.40 ppm silver; this included 6.0 feet with 3,833 ppb gold, 6,360 ppm arsenic, and 1.30 ppm silver. A 1.0-foot intercept contained 22,100 ppb gold, 36,200 ppm arsenic, and 6.40 ppm silver.

Alteration:

Age of mineralization:

About 70 to 105 Ma by analogy if Tintina Belt-style mineralization.

Generic deposit model:

Deposit model:

Tintina Belt-style, gold-arsenopyrite-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The RS Zone prospect is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator Triton Gold Ltd. (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009. Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. Geologic description:

The Dave's Zone prospect prospect is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator, Triton Gold Ltd. (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. They soon staked claims over the Discovery Zone prospect (TC034) on what was then was classified as massive-sulfide mineralization. Their work continued through 1987 in conjunction with several partners and consisted of geologic mapping, rock and soil sampling, and geophysical surveys along what became a belt of deposits. They drilled 17 holes along the belt in 1986 along the belt and 8 holes in 1987, totaling 3,390 meters. From 1998 to 2001, Inmet Mining Corporation and Pacific Northwest Resources Company did addition mapping, rock and soil surveys, and they drilled 8 more diamond drill holes totaling 1,489 meters. Two holes were drilled at the Dave's Zone prospect. The property was idle until 2007 when James DeMarchi staked 40 claims over the belt and transferred them to Tushtena Resources Ltd. In 2008, they entered into a joint agreement with Triton Gold.

The rocks along the belt consist of two main units: the Devonian to Precambrian, Macomb Belt unit to the east and the Devonian Tushtena Pass unit to the west. They are separated by the Itra Fault, a regional scale, shallowly to moderately dipping thrust fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The Macomb Belt rocks consist mainly of felsic metatuff and volcaniclastic rocks, and sericite-carbonate-quartz phyllonite. The Tushtena Pass unit consists of schist and phyllite, metadiorite, and lithic tuff.

There are two main styles of mineralization along the belt: 1) hanging-wall, bonanza-style vein systems; and 2) footwall, sulfide stockwork and breccia vein systems. The hanging-wall, vein-type mineralization has an arsenic-lead-zinc association with narrow or no alteration envelopes and is characterized by quartz-carbonate-sulfide-gold-mica veins. The footwall, stockwork-breccia zones have a gold-rich core and peripheral antimony-rich mineralization. The deposits are correlative with others along the Tintina gold belt; the key characteristics are the low angle faults that trap the mineralization and the carbonaceous rocks that provide the right chemistry for deposition.

The mineralization at the Dave's Zone prospect consists of arsenic-gold-antimony-silver veins and silicified stockworks in Macomb Belt gneiss in the footwall of the Itra Fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). Many of the veins are parallel to foliation and increase in

abundance toward the fault. There are three varieties of the stockwork: 1) stockworks with massive stibnite in zones of silicification, 2) arsenopyrite-rich stockworks, and 3) low-gold stockworks with quartz and chalcedony. Four types of veins are present: 1) vuggy, quartz-pyrite-arsenopyrite-carbonate-mica+/-stibnite+/- gold; 2) vuggy quartz veins with lenses and pods of stibnite; 3) blue quartz veins with accessory carbonates, chlorite, and rare sulfides; and 4) thick, coarse-grained white quartz-carbonate+/-chalcopyrite-pyrite-sphalerite-gold veins. The main stage of quartz veining and stockworking postdate pervasive carbonate alteration which is controlled by faulting and fracturing. Extensive zones of silicification increase with depth.

Two holes were drilled at the Dave's Zone prospect. Several intercepts contained more than 400 parts per billion (ppb) gold. The most notable is 0.6 feet that contained 1,020 ppm gold, 6,450 parts per million (ppm) arsenic, and 2.50 ppm silver.

Alteration:

Silicification and carbonate alteration.

Age of mineralization:

About 70 to 105 Ma by analogy if Tintina Belt-style mineralization.

Generic deposit model:

Deposit model:

Tintina Belt-style, gold-arsenopyrite-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Their work continued through 1987 in conjunction with several partners and consisted of geologic mapping, rock and soil sampling, and geophysical surveys along what became a belt of deposits. They drilled 17 holes along the belt in 1986 along the belt and 8 holes in 1987, totaling 3,390 meters. From 1998 to 2001, Inmet Mining Corporation and Pacific Northwest Resources Company did addition mapping, and rock and soil surveys; they drilled 8 more diamond drill holes totaling 1,489 meters. None of the holes were at the Upper Com prospect. The property was idle until 2007 when James DeMarchi staked 40 claims over the belt and transferred them to Tushtena Resources Ltd. In 2008, they entered into a joint agreement with Triton Gold.

The rocks along the belt consist of two main units: the Devonian to Precambrian, Macomb Belt unit to the east and the Devonian Tushtena Pass unit to the west. They are separated by the Itra Fault, a regional scale, shallowly to moderately dipping thrust fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The Macomb Belt rocks consist mainly of felsic metatuff and volcaniclastic rocks, and sericite-carbonate-quartz phyllonite. The Tushtena Pass unit consists of schist and phyllite, metadiorite, and lithic tuff.

There are two main styles of mineralization along the belt: 1) hanging-wall, bonanza-style vein systems; and 2) footwall, sulfide stockwork and breccia vein systems. The hanging-wall, vein-type mineralization has an arsenic-lead-zinc association with narrow or no alteration envelopes and is characterized by quartz-carbonate-sulfide-gold-mica veins. The footwall, stockwork-breccia zones have a gold-rich core and peripheral antimony-rich mineralization. The deposits are correlative with others along the Tintina gold belt; the key characteristics are the low angle faults that trap the mineralization and the carbonaceous rocks that provide the right chemistry for deposition.

Mineralization at the Upper Com prospect is in schist, quartz, and exhalite of the Tushtena Pass unit in the hanging wall of the Itra fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The mineralization is similar to that at the Discovery Zone prospect (TC034). There are four types of veins: 1)

metamorphic gold-deficient, quartz veins with disseminated base metal minerals parallel to foliation; 2) post-metamorphic quartz-gold veins with base-metal sulfides; 3) quartz +/- carbonate veins with chalcedony, clay, hematite, and alunite; and 4) clay-iron oxide-quartz veins. The veins have weak, thin, alteration haloes with an inner zone of silicification and and an outer zone of weak to moderate, iron-magnesium carbonate alteration. High gold values are typically related to abundant arsenopyrite.

Alteration:

The veins have weak, thin alteration haloes with an inner zone of silicification and and an outer zone of weak to moderate, iron-magnesium carbonate alteration.

Geologic description:

The Lower Com prospect prospect is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator, Triton Gold Ltd. (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. They soon staked claims over the Discovery Zone prospect (TC034) what then was classified as massive-sulfide mineralization. Their work continued through 1987 in conjunction with several partners and consisted of geologic mapping, rock and soil sampling, and geophysical surveys along what became a belt of deposits. They drilled 17 holes along the belt in 1986 and 8 holes in 1987, totaling 3,390 meters. From 1998 to 2001, Inmet Mining Corporation and Pacific Northwest Resources Company did addition mapping, rock and soil surveys, and they drilled 8 more diamond drill holes totaling 1,489 meters. Eight holes were drilled at the Lower Com prospect. The property was idle until 2007 when James DeMarchi staked 40 claims over the belt and transferred them to Tushtena Resources Ltd. In 2008, they entered into a joint agreement with Triton Gold.

The rocks along the belt consist of two main units: the Devonian to Precambrian, Macomb Belt unit to the east and the Devonian Tushtena Pass unit to the west. They are separated by the Itra Fault, a regional scale, shallowly to moderately dipping thrust fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The Macomb Belt rocks consist mainly of felsic metatuff and volcaniclastic rocks, and sericite-carbonate-quartz phyllonite. The Tushtena Pass unit consists of schist and phyllite, metadiorite, and lithic tuff.

There are two main styles of mineralization along the belt: 1) hanging-wall, bonanza-style vein systems; and 2) footwall, sulfide stockwork and breccia vein systems. The hanging-wall, vein-type mineralization has an arsenic-lead-zinc association with narrow or no alteration envelopes and is characterized by quartz-carbonate-sulfide-gold-mica veins. The footwall, stockwork-breccia zones have a gold-rich core and peripheral antimony-rich mineralization. The deposits are correlative with others along the Tintina gold belt; the key characteristics are the low angle faults that trap the mineralization and the carbonaceous rocks that provide the right chemistry for deposition.

The Lower Com prospect is in the immediate footwall of the Itra Fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The host rock is quartz-mica schist, gneiss, and mylonite of the Macomb Belt rocks that outcrop along the creek at the prospect. The hanging wall above the fault is altered

meta-diorite. Mineralized, altered mylonite crops out for more than 240 meters along the creek. The mineralization and alteration consist of: 1) pre-mineral quartz stockworks; 2) synmineralization argillic alteration; 3) synmineralization quartz-dominated stockworks and breccias with up to 50 percent arsenopyrite, pyrite, stibnite; 4) post-mineral quartz stockworks; and 5) post-mineral iron-magnesium-carbonate veinlets. The mineralization is associated with brittle fracturing and faulting along the Itra fault. Drilling indicates that the gold, arsenic, and silver content increases down the dip of the mineralization.

Alteration:

Argillic alteration, silicification, carbonate alteration.

Age of mineralization:

About 70 to 105 Ma by analogy if Tintina Belt-style mineralization.

Generic deposit model:

Deposit model:

Tintina Belt-style, gold-arsenopyrite-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

The rocks along the belt consist of two main units: the Devonian to Precambrian, Macomb Belt unit to the east and the Devonian Tushtena Pass unit to the west. They are separated by the Itra Fault, a regional scale, shallowly to moderately dipping thrust fault (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The Macomb Belt rocks consist mainly of felsic metatuff and volcaniclastic rocks, and sericite-carbonate-quartz phyllonite. The Tushtena Pass unit consists of schist and phyllite, metadiorite, and lithic tuff.

There are two main styles of mineralization along the belt: 1) hanging-wall, bonanza-style vein systems; and 2) footwall, sulfide stockwork and breccia vein systems. The hanging-wall, vein-type mineralization has an arsenic-lead-zinc association with narrow or no alteration envelopes and is characterized by quartz-carbonate-sulfide-gold-mica veins. The footwall, stockwork-breccia zones have a gold-rich core and peripheral antimony-rich mineralization. The deposits are correlative with others along the Tintina gold belt; the key characteristics are the low angle faults that trap the mineralization and the carbonaceous rocks that provide the right chemistry for deposition.

The rocks at the Mobily prospect are gneiss of the Macomb Belt (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009). The mineralization consists of northeast-trending arsenopyrite-quartz stockworks, veins, and breccia that cut silicified gneiss. The rocks show a strong east to west alteration

zonation from Fe-carbonate alteration in the east, a central zone of sericite-ankerite+/-quartz+/-pyrite alteration, and a high silica outer zones with clay in the west. Grab and chip samples of stringer veins contained up to 920 parts per billion gold.

Alteration:

The rocks show a strong east to west alteration zonation from Fe-carbonate alteration in the east, to a central zone of sericite-ankerite+/-quartz+/-pyrite alteration, to high silica zones with clay in the west.

Age of mineralization:

About 70 to 105 Ma by analogy, if Tintina Belt-style mineralization.

Generic deposit model:

Deposit model:

Tintina Belt-style, gold-arsenopyrite-quartz vein.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Mobily prospect prospect is one of several similar deposits in a mineral belt about 4 miles long that is called the Tushtena project by the current (2010) operator, Triton Gold Ltd. (Newkirk and others, 1986; DiMarchi and others, 1987; Fonseca, 2009. Work along the belt began in 1976 when Resource Associates of Alaska began geochemical sampling in the area. They soon staked claims over the Discovery Zone prospect (TC034) what then was considered massive-sulfide mineralization. Their work continued through 1987 in conjunction with several partners and consisted of geologic mapping, rock and soil sampling, and geophysical surveys along what became a belt of deposits. They drilled 17 holes along the belt in 1986 and 8 holes in 1987, totaling 3,390 meters. From 1998 to 2001, Inmet Mining Corporation and Pacific Northwest Resources Company did addition mapping, and rock and soil surveys; They drilled 8 more diamond drill holes totaling 1,489 meters. The property was idle until 2007 when James DeMarchi staked 40 claims over the belt and transferred them to Tushtena Resources Ltd. In 2008, they entered into a joint agreement with Triton Gold. There has been no drilling on the Mobily prospect and the work has only been geologic mapping, geophysical and geochemical surveys, and surface sampling.

Production notes:

None.

Reserves:

None.

Reporter(s): D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-02

Site name(s): Chief Danny; Peak Zone

Site type: Prospect

ARDF no.: TC040

Latitude: 63.1795 **Quadrangle:** TC A-4

Longitude: 142.9162

Location description and accuracy:

The Chief Danny prospect is centered about 0.9 mile west-southwest of VABM 3345 'Tetlin', on the crest of the Tetlin Hills about 8 miles northwest of the center of Tetlin Lake. It covers much of the southwest quarter of section 10, T. 16 N., R. 13 E., of the Copper River Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu

Other: As, Bi, Co, Mo, Sn, Te, W

Ore minerals: Arsenopyrite, chalcopyrite, gold, malachite, native copper, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The Chief Danny prospect was first identified in 2009 in the search for the source of anomalous panned-concentrate stream-sediment samples (Contango Ore Inc., 2012). The prospect is divided into several zones with the Peak Zone in the east-central area. Samples collected in trenches along a zone 0.5 mile long contained up to 9 grams of gold per tonne and 1 percent copper. The samples also contained anomalous silver, arsenic, bismuth, tellurium, and tungsten. Soil augering and geochemical surveys in 2010 and 2011 expanded the potential area of mineralization. Eleven holes were drilled in 2011 that totaled 8,057 feet; 5 holes were in gold-copper mineralization. The notable intercepts were: 1) 10 feet with 0.94 gram of gold per tonne, 1.1 gram of silver per tonne, and 0.03 percent copper; 2) 21.2 feet with 7.4 grams of gold per tonne, 4.9 grams of silver per tonne, and 0.15 percent copper; and 3) 12 feet with 3.1 grams of gold per tonne, 300.2 grams of silver per tonne, and 0.26 percent copper. A 70-foot sample in a trench contained 0.69 gram of gold per tonne, 8.60 grams of silver per tonne, and 0.38 percent copper.

There is little detailed mapping in the area. Foster (1970) indicates that the rocks in the area are mainly Paleozoic or Precambrian biotite gneiss and schist or Paleozoic phyllite and schist. A cross-section through the drill holes (Contango Ore Inc., 2012) indicates that the rocks are mainly greenstone and schist. The deposit is centered on a strong magnetic low.

District and regional scale northeast and northwest trending faults are present on the project and are often associated with gold and copper mineralization in this terrane. The Peak zone is a distal, reduced gold skarn deposit, possibly related to a larger porphyry copper-gold system outlined by a 6.5 kilometers by 5.5 kilometers zoned soil anomaly. Peak zone mineralization consists of free gold in disseminated to semi-massive pyrrhotite, chalcopyrite, and arsenopyrite with an amphibole and chlorite alteration envelope (Avalon Development Corporation, 2014). Anomalous silver, bismuth, cobalt and sporadic anomalous molybdenum and tin are also found within the Peak Zone (Freeman, 2014).

Alteration:

In some locations, free gold is associated, within and adjacent, with banded pyrrhotite in chlorite-amphibole alteration (Freeman, 2014).

Age of mineralization:

Illig (2014) has dated skarn mineralization at the Peak zone to 70 million years.

Generic deposit model:

Deposit model:

Gold-copper skarn (Cox and Singer, 1986; model 18b)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b

Production Status: None

Site Status: Active

Workings/exploration:

The Chief Danny prospect was first identified in 2009 in the search for the source of anomalous panned-concentrate stream-sediment samples (Contango Ore Inc., 2012). Subsequently, samples were collected in trenches along a zone 0.5 mile long. Soil augering and geochemical surveys in 2010 and 2011 expanded the potential area of mineralization. Eleven holes were drilled in 2011 that totaled 8,057 feet. Five of eleven holes reached gold-silver-copper mineralization. In 2012, Contango conducted 36,000 feet of drilling, discovering a new high grade 'Peak Zone' skarn. In 2013, Contango conducted 47,000 feet of drilling, expanding the Peak zone (Freeman, 2014).

Significant Peak zone intercepts include 99.9 meters grading 3.935 grams of gold per tonne, 8.4 grams of silver per tonne and 0.104 percent copper in hole 12016 (discovery hole), 58.53 meters grading 14.452 grams of gold per tonne, 9.1 grams of silver per tonne and 0.243 percent copper in hole 12018, 44.2 meters grading 15.962 grams of gold per tonne, 11.0 grams of silver per tonne and 0.267 percent copper in hole 12036, 64.8 meters grading 13.101 grams of gold per tonne, 21.0 grams of silver per tonne and 0.482 percent copper in hole 13062, 138.02 meters grading 3.626 grams of gold per tonne, 11.4 grams of silver per tonne and 0.113 percent copper in hole 13088, 159.25 meters grading 7.010 grams of gold per tonne, 6.6 grams of silver per tonne and 0.102 percent copper in hole 13107, 96 meters grading 9.060 grams of gold per tonne, 4.3 grams of silver per tonne and 0.093 percent copper in hole 13110, and 134.82 meters grading 4.848 grams of gold per tonne, 2.9 grams of silver per tonne and 0.084 percent copper in hole 13117 (western limit of current drilling). High grade mineralization remains open to the west and at depth (Avalon Development Corporation, 2014).

A resource estimate was completed in 2013 for the Peak zone. The resource came from 78 of 140 holes, totaling 16,010 meters of drill core. An indicated resource with a 0.5 gram of gold per tonne equivalent cut-off yielded 5,970,000 tonnes at 3.46 grams of gold per tonne, 11.8 grams of silver per tonne, 0.25 percent copper, and a gold equivalent at 4.08 grams per tonne. The inferred resource also used a 0.5 gram of gold per tonne equivalent cut-off and yielded 3,850,000 tonnes at 2.07 grams of gold per tonne, 14.28 grams of silver per tonne, 0.23 percent copper, and 2.69 grams of gold per tonne equivalent (Freeman, 2014).

Peak Gold, LLC is a joint venture formed in 2015 between Contango ORE Inc. and Royal Alaska, LLC, a wholly owned subsidiary of Royal Gold Inc., to explore the Tetlin project area south of Tok, which contains the Peak and North Peak polymetallic gold-silver-copper skarn deposits (TC040), and numerous other prospects and prospective targets (including TC041). Royal Alaska has the option to invest up to $30 million through October 2018 to earn up to a 40 percent interest in the joint venture; through December 31, 2016, Royal Alaska has earned a 20.6 percent interest (Athey and Werdon, 2017).

With a budget of $11 million aimed at expanding the gold- and copper-rich skarn deposits in the Tetlin project area, Peak Gold conducted Alaska’s largest exploration program for 2016. Peak Gold completed a three-phase drilling program: 19 core holes drilled in Phase I, 62 holes in Phase II, and 37 holes in Phase III, for a total of 20,522.8 m. The 2016 drilling traced a roughly 2,000-meter-long arc of contiguous, high-grade skarn mineralization, which is about three times the footprint of the Peak deposit described in Contango’s 2013 initial resource. One hole drilled in the 2016 expansion area cut three gold-rich intercepts, including 38.88 meters averaging 51.62 grams of gold per tonne from a depth of 14.5 m, which was the best intercept

at Tetlin in terms of high grades over broad widths. The North Peak area remains open to expansion on the northwest and southeast portions, as the last holes drilled were still in gold bearing skarn (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

A resource estimate was completed in 2013 for the Peak zone. The resource came from 78 of 140 holes, totaling 16,010 meters of drill core. An indicated resource with a 0.5 gram of gold per tonne equivalent cut-off yielded 5,970,000 tonnes at 3.46 grams of gold per tonne, 11.8 grams of silver per tonne, 0.25 percent copper, and a gold equivalent at 4.08 grams per tonne. The inferred resource also used a 0.5 gram of gold per tonne equivalent cut-off and yielded 3,850,000 tonnes at 2.07 grams of gold per tonne, 14.28 grams of silver per tonne, 0.23 percent copper, and 2.69 grams of gold per tonne equivalent (Freeman, 2014).

Contango’s December 2013 Tetlin project area report states an indicated resource of 5.97 million tonnes at a grade of 3.46 grams of gold per tonne (664,000 ounces of gold), 11.8 grams of silver per tonne, and 0.25 percent copper. In addition, there is an inferred resource of 3.85 million tonnes at a grade of 2.07 grams of gold per tonne (256,000 ounces of gold), 14.28 grams of silver per tonne, and 0.23 percent copper. These estimated resources are based on 16,010 meters of core in 78 of 130 holes, assuming prices of $1,318 per ounce of gold, $21.55 per ounce of silver, and $3.25 per pound of copper (Athey and Werdon, 2017). An updated resource is planned for release in 2017.

Additional comments:

This prospect is on Tetlin Native lands and Contango Ore Inc. is operating under a 10-year lease with the Tetlin Village Council that begin in July 2008.

Gold equivalent was calculated using gold at 1,318 US dollars per ounce, copper at 3.25 US dollars per pound, and silver at 21.55 US dollars per ounce (Freeman, 2014).

Last report date: 2017-08-26

Site name(s): Chief Danny: Saddle Zone

Site type: Prospect

ARDF no.: TC041

Latitude: 63.2042 **Quadrangle:** TC A-4

Longitude: 142.8983

Location description and accuracy:

The Saddle Zone prospect is about 1.5 miles north of VABM 3345 'Tetlin' and about 9 miles northwest of the center of Tetlin Lake. The prospect is centered about 0.5 mile south of the center of section 34, T. 17 N., R. 13 E., of the Copper River Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Au, Cu

Other: As

Ore minerals: Chalcopyrite?, gold

Gangue minerals: Quartz?

Geologic description:

There is little specific information about the Saddle Zone prospect other than it was discovered and drilled in conjunction with the Peak Zone prospect (TC040), about 2 miles to the south-southwest (Contango Ore Inc., 2012). Both of these zones are considered part of the Chief Danny prospect. It is assumed that they share the same geology and style of mineralization, although they are offset vertically by a fault.

The Saddle Zone prospect was first identified in 2009 in the search for the source of anomalous panned-concentrate, stream-sediment samples (Contango Ore Inc., 2012). Soil augering and geochemical surveys in 2010 and 2011 expanded the potential area of mineralization. Three holes were drilled on the Saddle Zone prospect in 2011; only 'weak mineralization' was found.

There is little detailed mapping in the area. Foster (1970) indicates that the rocks in the area are mainly Paleozoic or Precambrian biotite gneiss and schist or Paleozoic phyllite and schist. A cross-section through the drill holes at the nearby Chief Danny prospect indicates that the rocks are mainly greenstone and schist (Contango Ore Inc., 2012). The Saddle Zone prospect is associated with a strong magnetic low.

District and regional scale northeast and northwest trending faults are present on the project and are often associated with gold and copper mineralization in this terrane (Avalon Development Corporation, 2014).

As of 2014, the prospect is described as a diatreme polymictic breccia that is gold and arsenic rich, and copper poor. This diatreme is interpreted to be an ignimbrite filling a magmatic diatreme vent and is periphery to a prospective gold-silver target (Freeman, 2014).

Alteration:

Not described.

Age of mineralization:

Only that it is younger than the Paleozoic or Precambrian host rocks (Foster, 1970).

Generic deposit model:

Deposit model:

Insufficient data to assign.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Site type: Prospect

ARDF no.: TC042

Latitude: 63.1482 **Quadrangle:** TC A-6

Longitude: 143.9618

Location description and accuracy:

The Shalosky prospect is about 8.4 miles west of the junction of the Tok and Dry Tok Rivers. It is about 1.6 miles south-southwest of VABM 7302 'White'; about 0.5 mile southeast of the center of section 19, T. 16 N., R. 8 E., of the Copper River Meridian. The location is accurate within 1/4 mile.

Commodities:

Main: Au, Au, Sb

Other: As, Bi, Cu, Pb, Sb, Te, Zn

Ore minerals: Gold

Gangue minerals: Quartz

Geologic description:

The rocks in the area are part of the Tok Schist and consists mainly of quartz-muscovite schist with a thick layer of quartz-chlorite schist (Rhyolite Resources Ltd., 2012a). The Tok Schist is cut by several steep to vertical faults, one of which control the trend of the mineralization at the Shalosky prospect. To the north across a north-dipping thrust fault, the rocks are a folded sequence of argillaceous sediments, felsic-sulphidic schist, chlorite schist, feldspar-quartz schist, banded sedimentary rocks, and gabbro. The age of the rocks is uncertain; Foster (1970) only indicates that they are Paleozoic or Mesozoic.

The mineralization in the area is sediment hosted and controlled by structure; it is associated with zones of silicification and quartz-vein stockwork (Rhyolite Resources Ltd., 2012b). Sulfides vary from 1 to more than 20 percent of the mineralization. There is a strong geochemical association of the gold with arsenic and antimony; copper, lead, zinc, bismuth, tellurium, and silver are low.

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored the area (Rhyolite Resources Ltd., 2012a; 2012b). They collected many rock and geochemical samples, trenched, and drilled 12 holes totaling 1,174 meters, but the data are not publicly available. In 2009, Rhyolite Resources acquired the property and identified 3 high-priority areas that included the Shalosky prospect.

Placer Dome drilled at least two holes at the Shalosky prospect (Rhyolite Resources Ltd., 2012a; 2012b). Some notable intercepts were 38.2 meters with 0.8 gram of gold per tonne, including 1.3 meters with 17.8 grams of gold per tonne; and 17.5 meters with 1.2 grams of gold per tonne, including 7.0 meters with 2.2 grams of gold per tonne.

Rhyolite Resources Ltd. (2012a; 2012b) diamond drilled eight holes totaling 1,388 meters, along about 600 meters of the Shalosky zone. The zone is associated with a regional east-northeast striking, steeply dipping, mineralized structure up about 35 meters wide that appears to widen at depth. Seven of the eight holes cut significant gold mineralization. Some notable intercepts are 23.1 meters with 3.5 grams of gold per tonne, and 69.0 meters with 1.7 grams of gold per tonne. The mineralization occurs in two styles. The highest-grade mineralization with values of 5 to 23 grams of gold per tonne is associated with quartz veins and several periods of brecciation. Lower grade mineralization with values from 0.2 to 4 grams of gold per tonne is associated with pervasive hydrothermal alteration characterized by intense clay alteration and local silicification.

Alteration:

Lower grade mineralization is characterized by intense clay alteration and local silicification (Rhyolite Resources Ltd., 2012b).

Age of mineralization:

Unknown other than that it is younger than the Paleozoic or Mesozoic host rocks (Foster, 1970).

Generic deposit model:

Deposit model:

Gold-quartz in veins and brecciated zones; lower grade disseminated mineralization? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

The earliest documented samples of gold mineralization from Shalosky Prospect were collected in 1995 by geologist Bill Shalosky exploring on behalf of American Copper & Nickel Company, Inc. (S. Dashevsky, written communication, 2014).

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored the area (Rhyolite Resources Ltd., 2012a). They collected many rock and geochemical samples, trenched, and drilled 12 holes totaling 1,174 meters in the area but the data are not publicly available. Placer Dome drilled at least two holes at the Shalosky prospect (Rhyolite Resources Ltd., 2012b). In 2009, Rhyolite Resources acquired the property and identified 3 high-priority areas that included the Shalosky prospect. Rhyolite diamond drilled 8 holes totaling 1,388 meters, along about 600 meters of the Shalosky zone (Rhyolite Resources Ltd., 2012a; 2012b).

The Hunter prospect is about 8.0 miles west-southwest of the junction of the Tok and Dry Tok Rivers. It is about 2.0 miles south of VABM 7302 'White'; about 0.2 mile west of the center of section 29, T. 16 N., R. 8 E., of the Copper River Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Sb, W

Other: As, Bi, Cu, Pb, Te, Zn

Ore minerals:

Gangue minerals: Quartz

Geologic description:

The rocks in the area are part of the Tok Schist and consists mainly of quartz-muscovite schist with a thick layer of quartz-chlorite schist (Rhyolite Resources Ltd., 2012a). The Tok Schist is cut by several steep to vertical faults, one of which control the trend of the mineralization at the nearby Shalosky prospect (TC042). To the north across a north-dipping thrust fault, the rocks are a folded sequence of argillaceous sediments, felsic-sulphidic schist, chlorite schist, feldspar-quartz schist, banded sedimentary rocks, and gabbro. The age of the rocks is uncertain; Foster (1970) only indicates that they are Paleozoic or Mesozoic.

The mineralization in the area is sediment hosted and controlled by structure; it is associated with zones of silicification and quartz-vein stockwork (Rhyolite Resources Ltd., 2012b). Sulfides vary from 1 to more than 20 percent of the mineralization. There is a strong geochemical association of the gold with arsenic and antimony; copper, lead, zinc, bismuth, tellurium, and silver are low.

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored the area (Rhyolite Resources Ltd., 2012a); Rhyolite Resources Ltd., 2012b). They collected many rock and geochemical samples, trenched, and drilled 12 holes in the area totaling 1,174 meters in the area, but the data are not publicly available. It is likely that they discovered the Hunter prospect and drilled at least one hole. In 2009, Rhyolite Resources acquired the property and identified 3 high-priority areas that included the Hunter prospect.

The one Placer Dome hole cut 4.4 meters with 0.8 gram of gold per tonne. Rhyolite Resources Ltd. (2011; 2012a; 2012b) drilled two holes totaling 323 meters at the Hunter prospect in 2011 and collected surface samples. A trench 6.3 meters long averaged 9.6 grams of gold per tonne and they drilled where surface samples contained up to 50.8 grams of gold per tonne. Neither of the Rhyolite holes cut significant gold values. One hole cut 3.9 meters with 256.1 grams of silver per tonne; this included 0.9 meter that contained 963 grams of silver per tonne and 6,230 parts per million tungsten. The mineralization is associated with highly fractured and altered metasedimentary rocks that hindered core recovery.

Alteration:

The mineralization is associated with highly fractured and altered metasedimentary rocks (Rhyolite Resources Ltd., 2012b).

Age of mineralization:

Unknown other than that it is younger than the Paleozoic or Mesozoic host rocks (Foster, 1970).

Generic deposit model:

Deposit model:

Gold-quartz in veins and brecciated zones; lower grade disseminated mineralization? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

Gold mineralized schist with quartz-sulfide veining and alteration was discovered in outcrop by geologist Ed Hunter in 1996 exploring on behalf of American Copper & Nickel Company, Inc. (S. Dashevsky, President, Northern Associates Inc., written communication, 2014).

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored in the area (Rhyolite Resources Ltd., 2012a; 2012b). They collected many rock and geochemical samples, trenched, and drilled 12 holes totaling 1,174 meters,but the data is not publicly available. It is likely that they discovered the Hunter prospect and drilled at least one hole.

In 2001, a 50 meter long trench was sampled for Grayd Resources Inc. with a reported 6.3 meter section returning 9.6 grams of gold per tonne. A 2001 diamond drill hole collared approximately 50 meters east of the Hunter trench reportedly returned a best interval of 0.8 gram of gold per tonne over 4.4 meters. Field indications suggest that the mineralized target was not adequately tested by the orientation of that single drill hole (Rhyolite Resources Ltd., 2014).

In 2009, Rhyolite Resources acquired the property and identified 3 high-priority areas that included the Hunter prospect. Rhyolite Resources Inc. (2012a; 2012b) drilled two holes totaling 323 meters at the Hunter prospect in 2011 and collected surface samples (S. Dashevsky, President, Northern Associates Inc., written communication, 2014).

During the 2010 field season, Northern Associates, Inc. geologists working on behalf of Rhyolite Resources Ltd. collected confirmation grab samples from the collapsed trench that returned 5.37 grams of gold per tonne and 50.80 grams of gold per tonne, while a 2.5 meter channel sample returned 1.0 gram of gold per tonne (S. Dashevsky, President, Northern Associates Inc., written communication, 2014).

In 2011, Rhyolite Resources again attempted to test the Hunter prospect with two core holes, comprising 323 meters collared at the Hunter showing, by drilling at an opposing azimuth to the 2001 hole drilled by Grayd & Placer-Dome (S. Dashevsky, President, Northern Associates Inc., written communication, 2014). Neither hole encountered significant gold mineralization, but highly anomalous silver/tungsten values were found in highly broken and altered metasediments at the interface of overburden and bedrock. The mineralized interval had very poor core recovery - less than 50 percent. The very high silver value was 963 grams of silver per tonne (Rhyolite Resources Ltd., 2014).

Latitude: 63.1478 **Quadrangle:** TC A-6

Longitude: 143.9024

Location description and accuracy:

The Low prospect is about 6.7 miles west of the junction of the Tok and Dry Tok Rivers. It is about 2.0 miles south-southeast of VABM 7302 'White' and about 0.4 mile south-southeast of the center of section 16, T. 16 N., R. 8 E., of the Copper River Meridian. The location is accurate within 1/4 mile.

Commodities:

Main: Au

Other: Ag, As, Bi, Cu, Pb, Te, Sb, Zn

Ore minerals: Arsenopyrite, gold

Gangue minerals: Muscovite, quartz

Geologic description:

The rocks in the area are part of the Tok Schist and consists mainly of quartz-muscovite schist with a thick layer of quartz-chlorite schist (Rhyolite Resources Ltd., 2012a). The Tok Schist is cut by several steep to vertical faults, one of which controls the trend of the mineralization at the nearby Shalosky prospect (TC042). To the north across a north-dipping thrust fault, the rocks are a folded sequence of argillaceous sediments, felsic-sulphidic schist, chlorite schist, feldspar-quartz schist, banded sedimentary rocks, and gabbro. The age of the rocks is uncertain; Foster (1970) only indicates that they are Paleozoic or Mesozoic.

The mineralization in the area is sediment hosted and controlled by structure; it is associated with zones of silicification and quartz-vein stockwork (Rhyolite Resources Ltd., 2012b). (Unstated) sulfides vary from 1 to more than 20 percent of the mineralization. There is a strong geochemical association of the gold with arsenic and antimony; copper, lead, zinc, bismuth, tellurium, and silver are low.

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored the area (Rhyolite Resources Ltd., 2012a; 2012b). They collected many rock and geochemical samples, trenched, and drilled 12 holes in the area totaling 1,174 meters, but the data are not publicly available. It is likely that they discovered the Low prospect. In 2009, Rhyolite Resources acquired the property and identified 3 high-priority areas that included the Low prospect.

Rhyolite Resources Ltd. (2011a; 2011b; 2012a; 2012b) drilled four holes totaling 537 meters at the Low prospect in 2011 and collected surface samples. The Tok Schist in the vicinity consists of highly altered, oxidized, calcareous metasedimentary rocks intruded by mafic/intermediate dikes. Samples of a trench 26.2 meters long contained up to 15.74 grams of gold per tonne. Two of the holes cut mineralization; notable intercepts were 13.6 meters with 3.4 grams of gold per tonne and 5.5 meters with 4.2 grams of gold per tonne. The Low prospect is associated with a steeply dipping shear zone with quartz veining, brecciation, and fault gouge. The mineralized structure has been traced for 150 meters on the surface.

Alteration:

Hydrothermal-silica and muscovite (Rhyolite Resources Ltd., 2014). Mineralization is associated with highly altered, oxidized calcareous metasedimentary rocks intruded by mafic/intermediate dikes (Rhyolite Resources Ltd., 2011b).

Age of mineralization:

Unknown other than that it is younger than the Paleozoic or Mesozoic host rocks (Foster, 1970).

Generic deposit model:

Deposit model:

Gold-quartz in veins and brecciated zones; lower grade disseminated mineralization? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

The earliest documented samples of gold mineralization from Low Prospect were collected in 1996 by prospector Adam Low who found quartz-stibnite boulders and arsenopyrite bearing float while exploring on behalf of American Copper & Nickel Company, Inc (ACNC). Subsequent work by ACNC and Grayd Resources located and trenched a source area shedding the gold-arsenopyrite mineralization in talus, but not the stibnite style of mineralization. (S. Dashevsky, President, Northern Associates Inc., oral communication, 2014).

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored in the area (Rhyolite Resources Ltd., 2012a; 2012b). They collected many rock and geochemical samples, trenched, and drilled 12 holes in the area totaling 1,174 meters, but the data are not publicly available. It is likely that they discovered the Low prospect and may have drilled it. In 2009, Rhyolite Resources acquired the property and identified 3 high-priority areas that included the Low prospect.

In 2010 geologists from Northern Associates, Inc. collected a series of three contiguous one meter long samples from sub-talus bedrock on behalf of Rhyolite Resources Ltd., which returned gold assays of 8.75 grams per tonne, 18.95 grams per tonne, and 12.4 grams per tonne . Five meters to the west, two contiguous one meter samples returned 3.51 grams of gold per tonne and 3.03 grams of gold per tonne. A further 150 meters to the west, channel sampling returned a weighted average of 3.76 grams of gold per tonne over 4 meters with a perpendicular channel sample yielding 6.23 grams of gold per tonne over 0.5 meter. Individual rock samples collected along the Low zone returned from 0.01 gram of gold per tonne to 18.95 grams of gold per tonne (Rhyolite Resources Inc., 2014).

Rhyolite Resources Ltd. completed a four hole diamond drill program, totaling 537 meters, in 2011 and collected surface samples. Two holes targeting the Hi-Low Showing encountered significant gold values within oxidized, carbonaceous fragmented schists and, silica and muscovite alteration that is associated with intermediate and mafic dikes (WG11-05: 27.4 meters at 1.9 grams of gold per tonne including 2.8 meters of 14.2 grams of gold per tonne). The dikes appear to have utilized the same structures as the mineralizing fluids, and they are themselves altered and locally auriferous (WG11-06: 2.2 meters at 8.6 grams of gold per tonne). In other cases, dikes are barren. Thus the relationship between dikes and the auriferous hydrothermal system remains poorly constrained (Rhyolite Resources Inc., 2014).

To the north across a north-dipping thrust fault, the rocks are a folded sequence of argillaceous sediments, felsic-sulphidic schist, chlorite schist, feldspar-quartz schist, banded sedimentary rocks, and gabbro. The age of the rocks is uncertain; Foster (1970) only indicates that they are Paleozoic or Mesozoic.

The mineralization in the area is sediment hosted and controlled by structure; it is associated with zones of silicification and quartz-vein stockwork (Rhyolite Resources Inc., 2012 [February 23]). (Unstated) sulfides vary from 1 to more than 20 percent of the mineralization. There is a strong geochemical association of the gold with arsenic and antimony; copper, lead, zinc, bismuth, tellurium, and silver are low.

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored the area (Rhyolite Resources Inc., 2012 [February 18]; 2012 [February 23]). They collected many rock and geochemical samples, trenched, and drilled 12 holes in the area totaling 1,174 meters but the data are not publicly available. It is likely they examined and sampled the HD Saddle prospect and they may have discovered it.

In 2009, Rhyolite Resources Inc. (2012 [February 23])acquired a large block of claims that covered the HD Saddle prospect. They drilled two holes; the best intercept was 10.9 meters that contained 0.05 gram of gold per ton. They also note that a (rock?) sample contained 6.2 grams of gold per tonne. The HD Saddle prospect is probably similar to several other gold projects in the area, the best known of which the Shalosky prospect (TC042).

Alteration:

Age of mineralization:

Unknown other than that it is younger than the Paleozoic or Mesozoic host rocks.

Generic deposit model:

Deposit model:

Gold-quartz in veins and brecciated zones; lower grade disseminated mineralization (Cox and Singer, 1986; model 22c?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

From 1998 through 2001, Grayd Resources and Placer Dome Inc. explored the area (Rhyolite Resources Inc., 2012 [February 18]; 2012 [February 23]). Site name(s): MM

Site type: Occurrence

ARDF no.: TC053

Latitude: 63.13 **Quadrangle:** TC A-4

Longitude: 143.0027

Location description and accuracy:

The MM prospect is about 5.0 miles southeast of VABM 3345 'Tetlin' and about 9.4 miles west-northwest of the center of Tetlin Lake. The prospect is centered about 0.5 mile northwest of the center of section 32, T. 16 N., R. 13 E., of the Copper River Meridian. The location is accurate to within one mile or less from the center of the deposit.

Commodities:

Main: Au, Cu

Other:

Ore minerals: Chalcopyrite?, gold

Gangue minerals: Quartz?

Geologic description:

There is little published specific information about the MM prospect other than it is a prospect composed of phyllite and schist, located at the Tetlin Project, currently operated by Contango ORE Inc. The prospect contains multiple magnetic and conductivity highs corresponding to anomalous surface geochemistry (Freeman, 2014).

The Tetlin project is located in Precambrian to Paleozoic greenschist to amphibolite-grade metamorphic rocks of the Yukon Tanana Terrane intruded by Cretaceous to Tertiary felsic and intermediate plutonic bodies. District and regional scale northeast and northwest trending faults are present on the project and are often associated with gold and copper mineralization in this terrane (Illig, 2014).

The Tetlin project is located within the prolific Tintina Gold Belt (+200 million ounces of resource) and is prospective for mid-Cretaceous intrusive-related gold deposits. The project also is cut by a younger, northeast striking belt of porphyry copper–gold deposits which have remained virtually unexplored since their discovery in the early 1970s (Illig, 2014).

Alteration:

Not described.

Age of mineralization:

Undetermined, but proximal to the Peak deposit, a massive sulfide distal skarn mineralization, which has been dated to 70 million years old (Illig, 2014).

Generic deposit model:

Deposit model:

Insufficient data to assign.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 2008, Contango ORE Inc. signed the lease with Tetlin Village, also acquiring and analyzing remote sensing data. In 2009, the first reconnaissance program was conducted, followed by soil sampling and trenching. In 2010, the field program entailed prospecting, stream sediment, and a pan concentrate program, and a focused basal soil sampling and IP surveys. In 2011, the basal soil sampling was continued, in addition to airborne magnetic and resistivity surveying (Freeman, 2014).

MM was identified through pan-stream sampling, soil sampling, and airborne geophysics. The prospect contains multiple magnetic and conductivity highs that correspond to anomalous surface geochemistry (Freeman, 2014).

Production notes:

None.

Reserves:

None.

Last report date: 2014-12-15

Site name(s): McElfish

Site type: Prospect

ARDF no.: TC054

Latitude: 63.7368 **Quadrangle:** TC C-1

Longitude: 141.0321

Location description and accuracy:

The McElfish prospect is located next to the Alaska-Canada border on a north-south trending ridge at the headwaters of a northeast branch of McElfish Creek that drains into the Ladue River. The site location is based on where strongly altered augen gneiss was mapped near the center of a 1.1 by 1.5 kilometer soil grid located in the northwest corner of section 31, T. 23 N., R. 23 E. of the Copper River Meridian.

Commodities:

Main: Au

Other: Ag, Cu, Mo, Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, molybdenite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

McElfish is located within the Yukon-Tanana Terrane between the Denali and Tintina faults. The basement rock is comprised of amphibolite- to greenschist-facies metamorphic rocks intruded by Jurassic, Cretaceous, and Tertiary mostly felsic units. The amphibolite-facies rocks consist of schist, gneiss including augen gneiss, amphibolite, quartzite, and minor marble. The greenschist-facies rocks consist of schist and minor phyllite and metavolcanic rocks. These two packages represent an autochthonous continental-margin of Late Devonian to Early Mississippian age (Dusel-Bacon and others, 2006).

The bedrock geology at McElfish, from north to south, consists of weakly foliated metamorphosed gabbro that is in an east-west trending thrust contact with a metamorphic assemblage of megacrystic augen gneiss and quartz-feldspar-sericite gneiss to schist. The augen gneiss contains very large potassium feldspar porphyroblasts that range up to 3 inches in diameter. A feldspar-quartz porphyry is found intruding the augen gneiss along a northwest trending fault on the south side of the main ridge. The porphyry and the augen gneiss along the northwest trending fault have strong quartz-sericite-pyrite alteration. To the south of the prospect area, biotite-garnet amphibolite and biotite schist overlie the augen gneiss and define a general east-west thrust fault contact (King and Tedeschi, 2012).

Mineralization at McElfish is mostly stockwork quartz veinlets up to 2 mm wide cross cutting foliation at high angles and the veinlets commonly exhibit strong jarosite staining and minor disseminated gossanous blebs after weathering of sulfide minerals along vein selvages (Siron and Grady, 2011).

Alteration:

The augen gneiss and feldspar-quartz porphyry have strong quartz-sericite-pyrite alteration along a northwest trending fault (King and Tedeschi, 2012).

Age of mineralization:

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz veins? (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a?

Production Status: None

Site Status: Inactive

Workings/exploration:

In the mid-1970s Cities Service Minerals Corporation (CSMC) conducted regional reconnaissance exploration in the Tanacross quadrangle area. Several ridge and spur soil samples and rock samples were collected over the McElfish prospect area at this time (Hedderly-Smith, 2009).

Full Metal Minerals (FMM), in a joint venture with BHP Billington, conducted a 31,000 line-kilometer high-resolution airborne magnetic survey covering 1.05 million hectares of the Tanacross quadrangle encompassing the McElfish prospect and collected rock and soil samples within the headwaters of McElfish Creek during 2008 (Hedderly-Smith, 2009). This work identified weakly anomalous gold-in-soils (up to 10 parts per billion (ppb) gold) and highly altered rocks consisting of an assemblage of clay and silica within quartz-sericite schist and augen gneiss. Samples of the stockwork quartz veining that contain disseminated trace pyrite returned values up to 185 ppb gold (Siron and Grady, 2011).

In 2010 FMM completed a 50 by 100 meter soil grid within a larger 1 by 1.3 kilometer area of intense and pervasive silicification and clay alteration of augen gneiss and quartz-sericite schist. The sampling showed a soil geochemical anomaly with strong gold, silver, molybdenum, lead, and zinc. Baseline gold-in-soil observations display weakly anomalous gold, around 13 ppb gold, but have shown values as high as 7,160 ppb gold. Silver distribution is much broader and ranges from 300 ppb and up to 1,900 ppb silver over the same area as anomalous gold mineralization. A strong molybdenum anomaly occurs to the east and downslope of anomalous gold-in-soils and ranges from 5 to 30 parts per million (ppm) molybdenum. Lead (50 to 180 ppm) and zinc (80 to 170 ppm) also occur with gold and silver (Siron and Grady, 2011).

The soil grid was expanded to the south by FMM in 2011 collecting 207 more soil samples. Results from the grid showed a silver and gold anomaly with gold showing potentially two northeast-trending zones of mineralization. There were no significant silver and gold values in the rock samples collected as most of the samples were gathered on the ridge top where the silver and gold anomaly was weakest. A copper and molybdenum soil anomaly trends northwest-southeast with up to 48 ppm molybdenum and up to 463 ppm copper. A rock sample of strongly oxidized augen gneiss with magnetite veins was collected in this same area and contained 551 ppm copper and 113 ppm molybdenum. This mineralized trend is parallel to foliaion of the strongly quartz-sericite-pyrite-altered augen gneiss observed on the ridge (King and Tedeschi, 2012).

Production notes:

Site name(s): Road Metal

Site type: Prospect

ARDF no.: TC055

Latitude: 63.0152 **Quadrangle:** TC A-2

Longitude: 141.7895

Location description and accuracy:

The Road Metal prospect is a 1.5 mile-long northeast trend of silver-gold-base metal mineralization on Doyon, Limited conveyed land near the Northway Junction along the Alaska Highway near the Canadian border. The prospect site is centered on a 500 square meter area of drilling in the gold geochemical anomaly near an intrusion breccia along the northern edge of section 10, T. 14 N., R. 19 E. of the Copper River Meridian.

Commodities:

Main: Ag, Au, Cu, Pb

Other: Bi, Sb

Ore minerals: Bismuthinite, chalcopyrite, galena, gold, pyrite, silver sulfosalts, stibnite

Gangue minerals: Quartz

Geologic description:

The Road Metal prospect lies within the Yukon-Tanana terrane between the Tintina fault to the north and the Denali fault to the south. The region is comprised mostly of greenschist to amphibolite grade Paleozoic metasedimentary rocks and some mafic to felsic meta-igneous rocks. These Paleozoic rocks were extensively intruded by Mesozoic and Cenozoic granitic rocks and minor intermediate and mafic rocks. The area north of the Road Metal prospect contains abundant Cretaceous and Tertiary volcanic rocks. The Road Metal prospect lies within what has been mapped as a poorly exposed, coarse- to fine-grained Cretaceous batholith that ranges in composition from felsic to mafic (Foster, 1970, 1992).

Drilling completed on the gold geochemical anomaly at Road Metal has shown mineralization to be intrusion-hosted. An intrusion breccia, which contains granite and aplite clasts in a porphyritic granite matrix, has been mapped in the vicinity of drilling (North Star Exploration, 2001).

22c?

Production Status: None

Site Status: Active?

Workings/exploration:

At the Road Metal prospect grid soil sampling completed by North Star Exploration, Inc. between 1997 to 2002 identified an open-ended, 1.5 mile-long trend of silver-gold-base metal mineralization. Twelve line kilometers of ground geophysics (magnetics and induced polarization) completed shows an anomaly which is adjacent to the mineralized trend (North Star Exploration, 2001; North Star Exploration, 2002; North Star Exploration, 2003).

Core drilling between 2000 to 2002 totaling 17,984 feet in 22 holes at the Road Metal prospect intersected intrusion-hosted, base metal mineralization that has silver grades of up to 135 ounces per ton (oz/ton) and gold grades of up to 2.51 oz/ton (North Star Exploration, 2002; North Star Exploration, 2003). Five of the drill holes completed by North Star Exploration, Inc. in 2000 intersected high-grade intercepts including three very significant intervals of silver-gold bearing sulfide and sulfosalt mineralization: 17.8 feet assaying 0.263 oz/ton gold and 14.7 oz/ton silver, 15.7 feet grading 0.03 oz/ton gold and 48.5 oz/ton silver, and 73.8 feet grading 0.045 oz/ton gold and 0.35 oz/ton silver. Corresponding base-metal assays for the intersections range up to 0.86 percent copper, 3.22 percent lead, 0.92 percent bismuth, and 2.80 percent antimony (Doyon Limited, 2015; North Star Exploration, 2001).

Site name(s): Peak Zone

Site type: Prospect

ARDF no.: TC056

Latitude: 63.1776 **Quadrangle:** TC A-4

Longitude: 142.8984

Location description and accuracy:

The Saddle Zone prospect is about 0.3 mile northeast of VABM 3345 'Tetlin' and about 7.9 miles northwest of the center of Tetlin Lake. The prospect is centered about 0.2 mile east-northeast of the center of section 11, T. 16 N., R. 13 E., of the Copper River Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu

Other: As, Bi, Co, Cd, Mo, Ni, Sb, Sn, Te, W, Zn

Ore minerals: Arsenopyrite, chalcopyrite, bismuth, galena, gold, magnetite, malachite, native copper, pyrargyrite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Amphiboles, calcite, chlorite, garnet?

Geologic description:

The Peak Zone is a ‘gold skarn’ prospect at the Tetlin Project that lies within the Yukon-Tanana Terrane. The host rock is a deformed marble lens (Illig, 2014). An inferred related intrusive is quartz monzonite. The main prograde metamorphism mineral is pyroxene while the main retrograde metamorphism minerals are amphibole and chlorite (Freeman, 2014a). The mineralization is characterized by gold hosted in skarn-altered carbonates, pyrrhotite dominant, with chalcopyrite, arsenopyrite, and lesser pyrite with anomalous silver, bismuth, cobalt, and sporadic anomalous molybdenum and tin. The mineralization is within an amphibole and chlorite alteration envelope (Freeman, 2014a). There is also green to black hornblende-chlorite and calcite alteration. Malachite and native copper are present in fractures below weathered sulfide mineralization. Quartz monzonite porphyry contains barren quartz magnetite veins (Van Treeck, 2013). Metal is zoned around the prospect as copper + gold proximal to mineralized center, and arsenic + lead + zinc distal to mineralized center. The indicated tonnage is 6 million tonnes with a gold grade of 3.46 grams per tonne, 11.87 grams of silver per tonne, and 25 percent copper (Freeman, 2014a).

The geophysical signature of the Peak zone is high relative magnetic susceptibility and a high relative conductivity/low relative resistivity associated with mineralization. Airborne magnetic and resistivity surveys have outlined the Peak Zone mineralization in the upper 150 meters of crust. Areas with a similar geophysical signature located near the Peak Zone are along inferred stratigraphic horizons and share geochemical signatures (Van Treeck, 2013).

This prospect is part of the Tetlin Project; it is hosted in Precambrian to Paleozoic greenschist to amphibolite-grade metamorphic rocks of the Yukon-Tanana Terrane intruded by Cretaceous to Tertiary felsic and intermediate plutonic bodies (Foster, 1970). District and regional scale northeast and northwest trending faults are present on the project and are often associated with gold and copper mineralization in this terrane (Freeman, 2014b). The project area is interpreted to be located in overlapping mineral belts of the Tintina gold belt with the Carmacks Porphyry Belt (Freeman, 2014a).

Metallurgical test results were reported in 2014 by Contango ORE, Inc.. These results from three samples indicate that all samples achieved consistently high metallurgical recovery across the primary grind sizes that ranged from 49 to 115 microns. The proportion of contained gold recovered by gravity methods ranged from 8 percent to 30 percent with the lowest gravity recovery in a high copper bearing sample with

progressively higher percentages of gold in the gravity concentrate as gold grade increased in the other samples. Primary sulfides identified in the analysis were pyrrhotite and chalcopyrite with lesser amounts of arsenopyrite, silver-bearing minerals, sphalerite and native gold. Primary silicate minerals include quartz, calcite, chlorite, potassium feldspar, amphibole and pyroxene. Abundant visible gold was observed in two of the three samples (Contango ORE, Inc., 2014b).

Alteration:

Chlorite and amphibole alteration is associated with gold and silver mineralization (Illig, 2014).

Age of mineralization:

70 million years old, Cretaceous, according to U/Pb radioisotope dating techniques (Illig, 2014).

Generic deposit model:

Deposit model:

Skarn? (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b?

Production Status: None

Site Status: Active

Workings/exploration:

There has been no recorded past placer or lode mining or exploration drilling conducted on any prospect on the Tetlin Project until Contango Ore, Inc. completed its first reconnaissance exploration program in 2009 (Contango Ore Inc., 2012).

In 2008, Contango ORE, Inc. began acquiring and analyzing remote sensing data in the area of Peak Zone to begin exploration work targeting in the area. In 2009, the first reconnaissance program was conducted, followed by soil sampling and trenching (Freeman, 2014a). The first indication of mineralization was a linear gold-copper soil anomaly with a small induced polarization (IP) resistivity low (Illig, 2014). In 2010, the field program entailed prospecting, stream sediment sampling, and pan concentrate sampling, and focused basal soil sampling and IP surveys. In 2011, the basal soil sampling was continued, in addition to an airborne magnetic and resistivity survey and 11 holes (2,456 meters) of core drilling. The 2012 field program continued the basal soil sampling, along with a 50 hole (10,974 meters) core drilling program. The 2012 exploration work is what led to the discovery of Peak (Freeman, 2014b). Multiple drill intercepts with gold in excess of 10 parts per million (ppm) over 10 feet were reported. Gold is accompanied by variable silver of up to 500 ppm and copper of up to 1 percent over 100 feet The highest gold grade is associated with highly magnetic sulfide-bearing host rocks and also conductive sulfide-bearing host rocks. In 2013, Contango conducted an airborne magnetic and resistivity survey, and continued a basal soil sampling, stream sediment and pan concentrate sampling program, in addition to a 69 hole (14,625 meters) oriented core drilling program (Van Treeck, 2013).

In 2014, Contango reported the following resource estimate with a cut-off grade of 0.5 gram per tonne: 1) indicated resources of 5,970,000 tonnes grading 3.46 grams of gold per tonne, 11.00 grams of silver per tonne and 0.25 percent copper, and 2) inferred resources 3,850,000 tonnes grading 2.07 grams of gold per tonne, 14.28 grams of silver per tonne and 0.23 percent copper (Contango ORE, Inc., 2014a). They also reported results from metallurgical testing that indicated that all samples achieved consistently high metallurgical recovery across the primary grind sizes that ranged from 49 to 115 microns (Contango ORE Inc., 2014b).

Production notes:

None.

Reserves:

Indicated resources for the Peak Zone are reported, with a cutoff of 0.5 gram of gold per tonne equivalent and cut-off of 5,970,000 tonnes, to be 3.46 grams of gold per tonne, 11.00 grams of silver per tonne, 0.25 percent copper, 4.08 grams of gold per tonne equivalent, with total grams being 24,357,600 and total ounces of 783,115 (Contango Ore, Inc., 2014a).

Inferred resources for the Peak Zone are reported, with a cutoff of 0.5 gram of gold per tonne equivalent and cut-off of 3,850,000 tonnes, to be 2.07 grams of gold per tonne, 14.28 grams of silver per tonne, 0.23 percent copper, 2.69 grams of gold per tonne equivalent, with total grams being 10,356,500 and total ounces of 332,969 (Contango ORE, Inc., 2014a).

Resource from 78 of 130 holes, 16,010 meters of core. Seven gold values were capped at 75.0 grams per tonne, 13 silver values at 252.0 grams per tonne and 7 copper values at 5.40 percent. Resource blocks are 10 by 10 by 5 meters, ore specific gravity is 3.15, waste specific gravity is 2.81. Grades for gold, silver, copper were interpolated using ordinary kriging. For gold equivalent calculation: gold = US$1318 per ounce, copper = $3.25 per pound, silver = $21.55 per ounce (Freeman, 2014a).

Additional comments:

In 2008, Contango ORE, Inc. signed a lease with Tetlin Village to control mineral rights on about 675,000 acres of fee simple land leased from the Tetlin Village(Freeman, 2014b).

Location description and accuracy:

Eagle is a prospect about 3.5 miles north-northwest of the peak named 'Eagle' and about 19.7 miles northwest of the center of Tetlin Lake. The prospect is centered about 0.4 mile north-northwest of the center of section 12, T. 17 N., R. 11 E., of the Copper River Meridian. The location is accurate to within a mile.

Commodities:

Main: Ag, Au, Cu

Other: Bi, Co, Cd, Mo, Ni, Sb, Sn, Te, W, Zn

Ore minerals:

Gangue minerals: Amphiboles, calcite, chlorite

Geologic description:

The Eagle prospect is part of the Tetlin Project, which is located in Precambrian to Paleozoic greenschist to amphibolite-grade metamorphic rocks of the Yukon-Tanana Terrane intruded by Cretaceous to Tertiary felsic and intermediate plutonic bodies (Foster, 1970). District and regional scale northeast and northwest trending faults are present on the project and are often associated with gold and copper mineralization in this terrane. Eagle is within a granitic rock unit (Freeman, 2014a).

The Eagle prospect is located within the Tintina Gold Belt (+200 million ounces of resource) and is prospective for mid-Cretaceous intrusive-related gold deposits. The area is also cut by a younger, northeast striking belt of porphyry copper–gold deposits, which have remained virtually unexplored since their discovery in the early 1970s (Freeman, 2014a).

Eagle exploration potential is characterized by multiple streams with visible gold or gold +/- copper anomalies (Freeman, 2014a).

Deposit model:

Skarn? (Cox and Singer, 1986; model 18b).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

18b?

Production Status: None

Site Status: Active

Workings/exploration:

In 2008, Contango ORE Inc. signed the lease with Tetlin Village, and began acquiring and analyzing remote sensing data in the area. Contango ORE, Inc. worked in the area of the Eagle prospect starting with surface geochemistry work and geophysics. In 2013, based on similar geology to the Peak Zone, pan concentrate stream sediment sampling and prospecting work were conducted (Van Treeck, C.J., Senior Geologist, Avalon Development Corp., written communication, 2014). The Eagle prospect contains multiple streams with visible gold or gold +/- copper anomalies (Freeman, 2014a).

Production notes:

None.

Reserves:

None.

Additional comments:

In 2008, Contango ORE, Inc. signed a lease with Tetlin Village to control mineral rights on about 675,000 acres of fee simple land leased from the Tetlin Village(Freeman, 2014b).

Site name(s): Goodrich Porphyry

Site type: Prospect

ARDF no.: TC060

Latitude: 63.0569

Quadrangle: TC A-1

Longitude: 141.091

Location description and accuracy:

Goodrich Porphyry is a prospect located 3.7 miles east of VABM 3385 'Flat', 0.4 mile north from the center of section 29, T. 15 N., R. 23 E., of the Copper River Meridian This location is accurate to within 500 feet of the center of the prospect.

Commodities:

Main: Au, Cu, Mo

Other: Ag, As, Ba, Bi, Mn, Pb, Sb, W, Zn

Ore minerals: Arsenopyrite, bismuthite, boulangerite, chalcopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Barium, quartz

Geologic description:

Goodrich Porphyry is part of the Blue Moose Exploration, Inc. (BME) project located in the Moosehorn Range on the Alaska-Yukon border. The Moosehorn Range is located in the Tintina Gold Belt, in the Dawson Range Batholith of the Yukon-Tanana Terrane (Joyce, 2002). The BME project geology consists of regional gneiss and schist intruded by a Mid-Cretaceous granodiorite and a quartz-rich mineralized porphyry. The area is unglaciated, and Moosehorn Range outcrop exposures are limited (Handverger, 2015).

The principal Moosehorn host rock is hornblende-biotite granodiorite. The mineralogy is 20 to 30 percent quartz, 25 to 45 percent plagioclase, 10 to 20 percent potassium-feldspar, 10 to 15 percent biotite, 10 percent hornblende, and titanite, pyrite, magnetite, allanite, epidote, and chlorite. The hornblende may be altered to biotite +/- sericite and chlorite. Feldspars may be sericitized (Joyce, 2002).

Using geochemical sampling, BME discovered and staked the Goodrich Porphyry, a quartz-rich mineralized intrusive underlying almost two square miles. Soil and rock geochemistry, trench sampling and mapping and 31 short (under 22 feet) churn drill holes have established anomalous values of gold, silver, arsenic, copper, molybdenum, antimony, strongly anomalous barium, zinc and manganese (Handverger, 2015).

The geology from a 4,600 foot-long trench excavated by BME in 2001 consists predominantly of altered quartz-rich rocks including quartz (+/-feldspar) porphyries and totally silicified units. Unaltered Moosehorn granodiorite and small intermediate dikes make up less than ten percent of the rocks exposed in the trench. Some of the silicic units indicate total quartz flooding showing ghosts of former feldspar crystals . Intense fracturing followed by silica invasion was observed. Limonitic veinlets with gossan boxworks after sulfides were identified and one tiny specimen of chalcopyrite was identified. A quartz-eye unit hosted limonitic veinlets and locally intense fracturing approaching a breccia (Handverger, 2015).

The 2014 pit sampling program of bedrock of the Goodrich Porphyry established evidence of a highly fractured, altered, supergene, leached capping of a mineralized copper porphyry system (Handverger, 2015).

Alteration:

Quartz-flooding of quartz-feldspar porphyries (Handverger, 2015).

Age of mineralization:

Site Status: Active

Workings/exploration:

The initial discovery of gold in the Moosehorn Range occurred in 1970 during a Quintana Minerals Corp. porphyry copper exploration program. The first placer gold claims were staked shortly after, and the Moosehorn Range has been the site of placer operations since then. The placer and limited hard rock mining production in the Moosehorn Range exceeds 100,000 ounces of gold (Handverger, 2015), largely in Canada.

In 1975, Great Bear Mining Ltd. conducted the first significant gold exploration project in the Canadian portion of the Moosehorn Range. In 1990, Canada Tungsten conducted a placer gold exploration program on the Alaskan side of the border (Handverger, 2015).

Blue Moose Exploration, Inc. (BME) first staked claims on the Alaska side of the Moosehorn Range in 1993. In 1999, BME conducted a widespread soil geochemical survey program of 111 samples in Alaska along the west side of the Moosehorn Range. This was followed up in 2000 by a 420-sample program over fifteen square miles in the same area. In 2010, Millrock Resources staked claims around the BME property and conducted an additional 252 soil sampling geochemical program on and around BME claims (Handverger, 2015).

In 2001, following up on anomalous soil geochemical results, BME personnel excavated a 4,600 foot-long trench cross-cutting the Goodrich Porphyry. Forty-five rock samples were collected and assayed from this trench. The highest trench rock sample contained 0.021ppm gold, 6.4 ppm silver, 540 ppm copper, 616 ppm molybdenum, 3677 ppm lead, 693 ppm zinc, 213 ppm antimony, 54 ppm bismuth, and 2.59 ppm mercury (Handverger, 2015).

During the summer field season of 2011, Blue Moose completed 33 shallow drill holes on the Goodrich Porphyry target to sample the bedrock below the frozen soil horizons. A total of 416 holes were drilled using a down-hole hammer with a 4.5-inch bit. The depth of the holes ranged from 4.0 to 22.5 feet with a median depth of 12.5 feet; 128 samples were assayed. The dimensions of the area drilled are 8,000 feet by 2,000 feet (Handverger, 2015).

The 2014 pit sampling program of bedrock on the Goodrich Porphyry established evidence of a highly fractured, altered, supergene, leached capping of a mineralized copper porphyry system (Handverger, 2015).

Production notes:

Site name(s): Honks

Site type: Prospect

ARDF no.: TC061

Latitude: 63.0731 **Quadrangle:** TC A-1

Longitude: 141.008

Location description and accuracy:

Honks is a prospect located a quarter mile southwest of Monument 150 in the northwest corner of section 23, T. 15 N., R. 23 E., of the Copper River Meridian. This location is accurate to within 500 feet.

Commodities:

Main: Au

Other: As, Sb, U

Ore minerals: Arsenopyrite, gold

Gangue minerals: Quartz

Geologic description:

The Honks prospect is part of Blue Moose Exploration, Inc. (BME) project located in the Moosehorn Range on the Alaska-Yukon border. The Moosehorn Range is located in the Tintina Gold Belt, in the Dawson Range Batholith of the Yukon-Tanana Terrane (Joyce, 2002). The BME project geology consists of regional gneiss and schist intruded by a Mid-Cretaceous granodiorite and a quartz-rich mineralized porphyry. The area is unglaciated, and Moosehorn Range outcrop exposures are limited (Handverger, 2015).

This prospect is characterized by gold-arsenopyrite-quartz veins with anomalous elevated values of gold, arsenic, anitmony, and uranium. Secondary indicator elements are copper, lead, and bismuth (Handverger, 2015).

In 2010, Millrock Resources Inc. collected rock samples from 1,060 feet of trenches in this area with these gold values: 45 feet of 0.221 part per million (ppm), 15 feet of 0.378 ppm, and 70 feet of 0.230 ppm and within the latter, 10 feet of 0.481 ppm. Anomalous arsenic values are associated with the higher levels of gold (Handverger and Gibler, 2014).

Alteration:

Age of mineralization:

Mineralization at Honks is likely a similar age as gold vein mineralization on the Yukon side of the Moosehorn Range which has been dated between 93 and 88 million years old, and the age of the Moosehorn intrusive is 96 to 99 million years, dated using K/Ar, Ar/Ar, and U/Pb methods (Joyce, 2002).

Generic deposit model:

Deposit model:

Polymetallic veins? (Cox and Singer, 1986; model 22c).

Workings/exploration:

The initial discovery of gold in the Moosehorn Range occurred in 1970 during a Quintana Minerals Corp. porphyry copper exploration program. The first placer gold claims were staked shortly after, and the Moosehorn Range has been the site of placer operations since then. The placer and limited hard rock mining production in the Moosehorn Range exceeds 100,000 ounces of gold (Handverger, 2015).

In 1975, Great Bear Mining Ltd. conducted the first significant gold exploration project in the Canadian portion of the Moosehorn Range. In 1990, Canada Tungsten conducted a placer gold exploration program on the Alaskan side of the border. Blue Moose Exploration, Inc. (BME) first staked claims on the Alaska side of the mountain range in 1993 (Handverger, 2015).

In 2010, Millrock Resources Inc. collected rock samples from 1,060 feet of trenches in this area with these gold values: 45 feet of 0.221 part per million (ppm), 15 feet of 0.378 ppm, and 70 feet of 0.230 ppm and within the latter, 10 feet of 0.481 ppm. Anomalous arsenic values are associated with the higher levels of gold (Handverger and Gibler, 2014).

Production notes:

None.

Reserves:

None.

Additional comments:

Exploration for placer gold has occured downstream of the Honks prospect on Honks Creek. In 1990, Canada Tungsten conducted a placer gold exploration drill hole program consisting of twenty-nine 3.5 inch air-trac holes in six lines on Honks Creek near Blue Moose Exploration, Inc. (BME) claims. Five of the lines intersected pay gravels. The program defined resources of 325,784 cubic yards containing 5,880 ounces gold; this was too small to be of further consideration by Canada Tungsten. In 2010, a small placer operation commenced stripping and sluicing the Honks Creek gravels (Handverger, 2015).

Site name(s): Kelly Creek

Site type: Prospect

ARDF no.: TE069

Latitude: 65.7706 **Quadrangle:** TE D-2

Longitude: 165.8962

Location description and accuracy:

Kelly Creek, unofficially named in 1982 after film actress Grace Kelly, is a north tributary to the American River. Kelly Creek is the largest tributary entering from the north in the area where the direction of American River changes from north to south. The prospect is about 14.3 miles southeast of Ear Mountain. The 2011 drilling by Cedar Mountain Exploration and the earlier drilling by Anaconda Minerals was 1) aligned northwest to both sides of the saddle centered about 0.5 mile southwest of section 2, T. 4 N., R. 35 W., and 2) in a area about 0.5 mile to the northwest. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Hg, Sb

Ore minerals: Arsenopyrite?, gold, pyrite

Gangue minerals: Calcite, quartz

Geologic description:

The Kelly Creek prospect is in mica-quartz schist and graphitic quartz schist intercalated in a metasedimentary sequence that includes schistose, micaceous, dolomitic marble; mica-calcite schist; and minor micaceous quartzite (Cedar Mountain, 2011 [project]). The sequence is interpreted as a limestone-shale assemblage with facies variations. It is highly deformed and perhaps isoclinally folded. Schistosity dips moderately in various directions. Steeply-dipping marble-schist contacts and other strong linear features may indicate normal faults. In the headwaters of Fox Creek, 3 miles north of the Kelly Creek prospect, the rocks consist of a mafic to intermediate(?) metavolcanic and metasedimentary assemblage which consist of various greenschist and amphibolite units regionally intercalated with some calcareous quartzite and marble. The relation of the metavolcanic assemblage to the pelitic schist/marble assemblage that hosts the Kelly Creek prospect is not known. All of the metavolcanic and metasedimentary rocks in area were probably Paleozoic originally and have been metamorphosed in the Cretaceous; Sainsbury (1972) however mapped them as Precambrian.

The Kelly Creek prospect is primarily tundra-mantled metapelitic rocks in saddles and slopes between rubble uplands of schistose marble; bedrock outcrops are only locally present on the marble uplands. The metapelitic rocks have lineated quartz segregations along their foliation; disseminated euhedral pyrite crystals are common.

The Kelly Creek prospect is one of several similar deposits that define a district-level, west-northwest trending belt of gold mineralization about 11 miles long and 2 miles wide. This is the best known and most extensively explored of the deposits in the belt; other are the Wolf (TE107), North Fox (TE109), South Fox (TE108), Wolverine (TE110), Moose (TE111), and Jaeger (TE112) prospects.

The Kelly Creek prospect was discovered by following up gold and arsenic anomalies in soils and stream sediments from the west headwaters of Kelly Creek (Hudson and Wyman, 1983; Hudson, 1984; Cedar Mountain, 2011 [assay]). The soil geochemical surveys defined an irregularly shaped area about 3,000 by 4,00 feet in size with gold values up to 1.4 parts per million (ppm), arsenic up to 1,000 ppm, antimony up to 62 ppm, mercury up to 5 ppm, and silver up to 0.9 ppm. The gold, arsenic, and antimony values define

strong, coherent, multi-element anomalies. Mercury is commonly elevated in the soils, but its distribution and concentration are more erratic and it is more widely dispersed at anomalous levels than the other three elements.

Rock samples from frost boils and surface pits 3 to 4 feet deep show that the stronger anomalies are associated with silicified breccia and quartz-stockwork veins in sooty, black carbonaceous quartz schist. The quartz stockwork veins are less than 0.5 inch wide, and locally are broken and recemented by fine-grained, dark siliceous matrix. Two small-diameter diamond drill holes drilled by Anaconda Minerals cut mineralization at shallow depths (Marrs and Ivey, 1984). The holes were oriented N 45 E, were inclined 45 and 60 degrees, and reached depths of 140 and 154 feet. One penetrated 77 feet with 0.032 ounce of gold per ton, and the other 44 feet with 0.035 ounce of gold per ton. The higher gold values seem to be in a zone that dips gently west. All the rocks in these holes had highly anomalous metal contents; gold values are commonly in the several-hundred parts-per-billion range.

In 2011, Cedar Mountain Exploration drilled 18 holes totaling 1820.5 meters (Cedar Mountain Exploration, 2011 [Sept. 26, news release]. Twelve holes were aligned northwest across the saddle centered about 0.5 mile southwest of the center of section 2, T. 4 N., R. 35 W. The best intercepts in the saddle zone were: 1) 16.5 meters that contained 0.85 gram of gold per tonne, this included 7.5 meters with 1.34 grams of gold per tonne; and 2) 26.8 meters with 1.04 grams of gold per tonne, this included 10.1 meters with 2.07 grams of gold per tonne. Another 6 holes were drilled on a strong geochemical anomaly at the head of Kelly Creek about a half mile to the northwest of the saddle. These holes only cut one strong, narrow intercept of 6.10 meters with 1.31 grams of gold per tonne. The drilling indicates that the best grades are associated with zones of quartz veining and stockworks within fractured and sheared carbonaceous schist.

Clay is locally present in fractures and as part of the matrix in breccia. Dolomite and calcite reportedly accompany quartz in the veins in some drill core (Marrs and Ivey, 1984). Pyrite is disseminated in pelitic schist and is present in all mineralized rocks; in part, it is probably of sedimentary origin. Quartz segregations along the foliation in pelitic schist are recrystallized, sugary textured, and vuggy in mineralized rocks. The controls on the mineralization have not been fully identified nor has the distribution of gold; large geochemical anomalies in gold have not been drilled.

Alteration:

Brecciation, silicification, and quartz stockwork veining is common in pelitic schist. Some quartz veins contain carbonate minerals. Clay and limonite are present in some mineralized rocks.

Age of mineralization:

Unknown but probably mid-to Late Cretaceous as the mineralization postdates regional metamorphism.

Generic deposit model:

Deposit model:

Disseminated and stockwork quartz and gold mineralization in metapelitic rocks. Possibly carbonate-hosted Au-Ag and/or low sulfide Au-quartz vein (Cox and Singer, 1986; models 26a or 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

26a or 36a?

Production Status: None

Site Status: Active

Workings/exploration:

Exploration includes regional stream sediment geochemistry; a soil geochemical survey on a grid covering a 3,000 by 6,000 foot area; several shallow surface pits; and four small-diameter diamond drill holes. In 2011, Cedar Mountain Exploration drilled 18 holes totaling 1820.5 meters (Cedar Mountain Exploration, 2011 [Sept. 26, news release]. Twelve holes were aligned northwest across the saddle centered about 0.5 mile southwest of the center of section 2, T. 4 N., R. 35 W. Another 6 holes were drilled on a strong

geochemical anomaly at the head of Kelly Creek about a half mile northwest of the saddle.

Production notes:

None.

Reserves:

None.

Site type: Prospect

ARDF no.: TE072

Latitude: 65.7103 **Quadrangle:** TE C-1

Longitude: 165.2289

Location description and accuracy:

The Kougarok prospect is a 1.5 square mile area centered 2 miles north of the summit of Kougarok Mountain (2,870 feet elevation), the highest area in the Teller quadrangle outside the York Mountains. The prospect area is on the west flank of the north-south trending ridge crest from near the Kougarok Mountain summit downslope to elevations of about 1,000 feet in the southeast headwaters of Star Creek. Star Creek is a north-flowing headwater tributary to the south fork of the Serpentine River.

Commodities:

Main: Nb, Sn, Ta

Other:

Ore minerals: Arsenopyrite, cassiterite, columbite-tantalite, pyrrhotite

Gangue minerals: Fluorite, quartz, topaz, tourmaline, white mica

Geologic description:

A Late Cretaceous composite granite complex intrudes metapelitic schist in the Kougarok prospect area. The metapelitic schist is a highly deformed mica-quartz schist characterized by isoclinally folded quartz boudins and segregations that may be Precambrian in age (Gardner and Hudson, 1984). It is thermally metamorphosed to biotite-bearing hornfels within several hundred feet of the granite contact. Boron-rich metasomatism has altered metapelitic schist and hornfels to tourmaline-axinite-sulfide rocks throughout the main prospect area.

Most of the granite complex is only present in the subsurface but a few granite dikes and a highly altered plug are exposed at the surface. Diamond drilling shows the subsurface granite to have porphyritic and equigranular phases (Puchner, 1986). Equigranular leucocratic phases were intruded later than the porphyritic phases and are associated with extensive alteration of the country rocks, exogreisen development in peripheral dikes and plug, and roof greisen development in the subsurface pluton. Local and regional gravity surveys (Puchner, 1986; Barnes and Hudson, 1977) show that the Kougarok granites are part of a much larger batholithic complex at depth. Puchner (1986) reports Rb/Sr and K/Ar data that indicate that the granite and associated mineralized rocks are Late Cretaceous in age (72 +/- 2 and 70.2 +/- 2.2 Ma respectively). These ages are consistent with that of other tin granite complexes on the western Seward Peninsula (Hudson and Arth, 1983).

A greisen-altered granite dike, Chuck's dike, and the Main plug are the principal exogreisen deposits (Puchner, 1984; Apel, 1984). The equigranular zinnwaldite granite dike is offset locally by normal faults and is almost 3,000 feet long in the prospect area (Puchner, 1986, figure 3). This dike dips steeply east, and varies in thickness from one to 15 feet although it commonly is 6 to 8 feet thick. It is variably altered over most of its length but complete greisenization is present at five places at the surface (Puchner, 1986, p. 1787). The longest exposed greisen segment is 500 feet in strike length and greisen development in it continues down dip in the subsurface about 500 feet where it merges with a roof greisen in the subsurface pluton (Puchner, 1986, p. 1786). Tin grades in the Chuck's dike greisen are commonly 1 percent. Two surface trenches and 9 diamond drill holes in this part of the dike indicate a resource of 240,000 tons of 1.3 percent tin (with a 0.1 percent tin cutoff grade (Puchner, 1984). This resource includes a higher grade

portion of 110,000 tons averaging 2.3 percent tin. The Main plug area that is exposed up slope to the east of Chuck's dike at an elevation of about 2,100 feet is a nearly vertical composite intrusive center that is extensively altered and contains two greisen pipes. These pipes, each about 100 feet across at the surface, appear to merge at depth and extend to deep levels in the intrusive center (Puchner, 1986, p. 1786). The Main plug is a complex body but surface trenches and diamond drilling suggest a combined resource of 1.4 million tons averaging 0.45 percent (no cutoff); tantalum and niobium are each present in the 0.1 to 0.03 percent range (Puchner, 1984). A high grade resource within this plug (0.5 percent tin cutoff) is estimated to contain 100,000 tons averaging 2.1 percent tin.

The zinnwaldite granite that forms Chuck's dike at the surface becomes a subhorizontal granite intrusion at depth whose irregular upper part is a greisen (Puchner, 1986, p. 1786). Alteration throughout this intrusion increases upward to quartz-tourmaline-topaz greisen in which tin grades can exceed 1 percent. Limited diamond drilling suggests a resource of 1.3 million tons or more averaging 0.36 percent tin (0.1 percent cutoff) including a portion where 140,000 tons averages 1.0 percent tin (0.5 percent cutoff) (Puchner, 1984). One of the diamond drill intercepts in the roof greisen was 53 feet of 0.23 percent tin (0.1 percent cutoff) including 13 feet of 0.93 percent tin (0.5 percent cutoff). In general, tin grade increases to as much as 3.4 percent upwards through the altered zinnwaldite intrusion to the roof greisen. Upward from the base to the roof greisen, silver increases to 17 parts per million (ppm) and lead to 1,340 ppm; tantalum increases from 20 ppm to as high as 845 ppm from the base to the roof greisen. The zinnwaldite granite contains 1 to 2 percent fluorite and arsenic may be as high as 1,000 ppm locally in the upper part of the intrusion (Puchner, 1986, p. 1791).

Kougarok is a boron-rich tin system characterized by abundant tourmaline and axinite replacement in the host schist and by tourmaline disseminations in altered granite. Its elevated tantalum and niobium, present in discrete tantalite/columbite grains, is also notable.

Anaconda's 1980s exploration showed that parts of the roof greisen and main plug zones contained elevated tantalum contents in the few to several hundred ppm range. (The following information has not previously been made public; it comes from the personal involvement in the work by the compiler, Travis Hudson.) Navigator Exploration Corp. and Chapleau Resources, Ltd. optioned this prospect from Greatland Exploration Ltd. in 2001 and 2002 to evaluate its tantalum potential. This exploration included surface prospecting and sampling, examination and sampling of core from Anaconda's 1980s drilling, analysis of gravity and magnetic data, and drilling of 7 vertical diamond drill holes totaling 2,438.2 m (8,000 feet). Their descriptions follow:

1) Drill hole 2002-1 was located near the summit of Kougarok Mountain (489457 mE, 7284312 mN). This 237.6 m (813 foot) hole encountered a few felsic dikes intruding Kougarok Schist. The highest tantalum value was 32 ppm and the highest tin value was 310 ppm; 2) Drill hole 2002-2 was located near the north end of Chuck's dike and about 650 meters northwest of the main plug (489222 mE, 7287955 mN). This 237.6 meter (780 feet) hole encountered 70.8 meters (232 feet) of zinnwaldite granite with tantalum values to 87 ppm and tin values to 337 ppm; 3) Drill hole 2002-3 was located between 2002-2 and the main plug (489494 mE, 7287718 mN). Its total length was 368.4 meters (1,209 feet) and it encountered 114.4 meters (375 feet) of zinnwaldite granite and related intrusive breccias. The highest tantalum value was 57 ppm and the highest tin value was 408 ppm; 4) Drill hole 2002-4 was located about 40 meters east of the main plug (489683 mE, 7287497 mN). This 328.6 meter (1,078 feet) hole encountered 198 meters (649 feet) of variously altered zinnwaldite granite and related intrusive breccias. Tantalum values reached 353 ppm; one 31.5 meter (103 feet) interval averaged 233 ppm Ta. Tin values reached 3.6 percent.; 5) Drill hole 2002-5 was located about 250 meters east of 2002-4 (389916 mE, 7287460 mN). This 408.6 meter (1,340 foot) hole encountered 172 meters (564 feet) of Kougarok Schist above 237 meters (778 feet) of Paleozoic quartzite and marble. No samples were submitted for assay from this hole.; 6) Drill hole 2002-6 was located on Tourmaline Ridge about 1,200 meters southwest of the main plug and near the south end of Chuck's dike (489453 mE, 7826435 mN). This 473.1 meter (1,552 foot) hole encountered a zone of zinnwaldite granite intrusives between 393 and 470 meters (1,289 and 1,542 feet). The hole bottomed in porphyritic biotite granite. The highest Ta value in the hole was 13 ppm and the highest Sn value was 59 ppm; 7) Drill hole 2002-7 was located about 900 meters (2,950 feet) north of the main plug (489700 mE, 7288447 mN) This 264.6 meter (868 foot) hole encountered several felsic dikes and brecciated intrusives in Kougarok Schist. One dike contained 119 ppm tantalum.

Alteration:

Hydrothermal alteration is extensive in the Kougarok prospect area. The country rock metapelitic schist and hornfels is extensively veined and replaced by tourmaline, axinite, and sulfide minerals (dominantly pyrrhotite but including arsenopyrite and chalcopyrite) over a roughly circular area with a diameter of 3,700 feet at the surface and to a depth of almost 800 feet in the area above the zinnwaldite granite and between Chuck's dike and the Main plug (Puchner, 1986). Tin is commonly anomalous in these rocks and in places exceeds 0.1%. Sericite and tourmaline development is ubiquitous in granite intrusions of the prospect area. Puchner (1986) recognizes increasing degrees of alteration from weak sericite-tourmaline replacement to assemblages with increasing zinnwaldite contents to quartz-tourmaline-topaz greisen. Zinnwaldite-rich alteration zones peripheral to roof greisen are common.

Age of mineralization:

Late Cretaceous; the radiometric ages referenced by Puchner (1986) include an Rb/Sr age of 72 +/- 2 Ma for porphyritic biotite granite and a K/Ar age of 70.2 +/- 2.6 Ma for zinnwaldite granite from the Main plug.

Generic deposit model:

Deposit model:

Tin greisen including exogreisen and endogreisen (roof) deposits (Cox and Singer, 1986, model 15c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

15c

Production Status: None

Site Status: Active

Workings/exploration:

Surface dozer trenching has been completed on a part of Chuck's dike and in the Main plug area. Twenty nine larger diameter diamond drill holes and 32 smaller diamond drill (Winkie) holes were done in the early 1980s (Puchner, 1984). Most of these have been in the north Chuck's dike and Main plug area.

Anaconda's 1980s exploration showed that parts of the roof greisen and main plug zones contained elevated tantalum contents in the few to several hundred ppm range. Navigator Exploration Corp. and Chapleau Resources, Ltd. optioned this prospect from Greatland Exploration Ltd. in 2001 and 2002 to evaluate its tantalum potential. This exploration included surface prospecting and sampling, examination and sampling of core from Anaconda's 1980s drilling, analysis of gravity and magnetic data, and drilling of 7 vertical diamond drill holes totaling 2,438.2 meters (8,000 feet).

Production notes:

None.

Reserves:

Preliminary resource estimates have been made for a part of the exogreisen deposit in Chuck's dike, the exogreisen deposit in the Main plug, and the roof greisen in buried zinnwaldite granite (Puchner, 1984). The resource estimate for exogreisen in Chuck's dike is 240,000 tons averaging 1.3 percent tin (including a part that is 110,00 tons averaging 2.3 percent tin). The Main plug exogreisen resource estimate is 1.4 million tons averaging 0.45 percent tin and 0.1 to 0.3 percent of both tantalum and niobium; this includes a part that has 100,000 tons of 2.1 percent tin. The roof greisen estimate is 1.3 million tons of 0.36 percent tin including a part that is 140,000 tons of 1.0 percent tin. Puchner (1984) emphasized that these estimates are preliminary and that more exploration is needed to constrain them. (No reserves have been published from the drilling in 2001 and 2002).

Reporter(s): Travis L. Hudson (Applied Geology, Inc.)

Last report date: 2005-10-10

Site name(s): Christophosen Creek

Site type: Prospect

ARDF no.: TE103

Latitude: 65.026 **Quadrangle:** TE A-2

Longitude: 165.629

Location description and accuracy:

Christophosen Creek is a stream on the north flank of the Kigluaik Mountains whose mouth is on Windy Cove of Imuruk Basin. This creek is not identified by name on USGS topographic maps; its name comes from a location map made by Coats (1944). It is located 0.2 mile east from the center of section 30, T. 5 S., R. 35 W., of the Kateel River Meridian. The graphite deposit at this locality is 1.75 miles southeast of the mouth of the creek and 8.5 miles due east of the White River. It is at the abrupt break in slope on the north side of the mountain front, just upslope of the surface trace of the active Kigluaik normal fault. The graphite-bearing rocks are in the footwall of this fault. This location was not shown by Cobb and Sainsbury (1972), but Cobb (1975) summarized relevant references under the name 'Christophosen Cr.' Location is accurate within 500 feet.

Commodities:

Main: Graphite

Other:

Ore minerals: Graphite, pyrrhotite

Gangue minerals: Amphibole, biotite, garnet, muscovite, plagioclase, quartz, sillimanite, sphene, zircon

Geologic description:

Christophosen Creek is now encompassed as part of the Graphite Creek record (TE105).

Flake graphite occurs as disseminations and high-grade tabular lenses within amphibolite facies metasedimentary rocks (Coats, 1944). The metamorphic rocks are primarily biotite-quartz schist with some sillimanite and garnet (Sainsbury, 1972). Small granitic plugs, dikes, and sills locally intrude the metamorphic rocks. The graphite-bearing schists are sharply bound to the north by the recently active Kigluaik fault, the principal fault along which late Cenozoic uplift of the Kigluaik Mountains has taken place (Hudson and Plafker, 1978). The graphite-bearing schists strike approximately parallel to the mountain front and dip north between 25 and 65 degrees. They form a zone along the mountain front that is 200 to 400 feet thick and possibly 20,000 feet long (Hudson, 1981; also see Ruby Creek (TE104) and Graphite Creek (TE105) localities to the east). To the south, the graphite-bearing schists are in conformable contact with other amphibolite facies metasedimentary rocks. The latter appear to be feldspathic and contain much less graphite. The graphite-bearing schists make up two general sequences; (1) a heterogeneous sequence of garnet-sillimanite-biotite-quartz schist with disseminated graphite and graphite-rich lenses, and (2) a more evenly layered biotite-quartz schist with disseminated graphite. The latter contains disseminated pyrrhotite and commonly weathers orange.

Claims were first staked on this deposit in 1900 but most of the work appears to have taken place between 1912 and 1917 (Cobb, 1975). Coats (1944) describes 25-foot thick schist units containing 10 percent disseminated graphite. Lenses in these schists, a few inches to 18 inches thick, can contain 50 to 90 percent coarse graphite by volume. The length of the lenses appears to be 10 to 15 times their width. The graphite flakes are commonly 0.004 to 0.04 inches in diameter although some are greater than 0.1 inch across. Two samples (Coats, 1944) contained 24.9 percent and 56.6 percent graphite of which 76 percent and 82 percent was coarser than 30 mesh per inch. Samples of schist with disseminated graphite from this locality appeared

to have a few to 15 percent graphite in thin section but laboratory analyses indicated only 4 to 6 percent (Wolgemuth, 1982).

During 2011 and 2012, Graphite One conducted exploration work at the Graphite Creek Property. The majority of the exploration work was completed during the summer 2012 including: a time-domain helicopter-borne electromagnetic survey; geological mapping; surface grab, channel and bulk pit sampling; and an 18 drillhole program to test the graphitic units at depth (Duplessis and others, 2013). In 2013, a 10 drillhole program expanded the area of mineralization both easterly and westerly, more than doubling the length of the graphite zone, which was about 2.2 kilometers in 2012, and became 4.8 kilometers in 2013 (Eccles and Nicholls, 2014).

Alteration:

Some shearing and deformation of graphite-rich lenses has accompanied faulting and oxidation of disseminated pyrrhotite has led to orange-staining of graphite-bearing rocks but other types of alteration are not identified.

Age of mineralization:

The metamorphism that has developed coarse graphite in these rocks is Late Jurassic to Early Cretaceous in age.

Generic deposit model:

Deposit model:

Disseminated flake graphite (Orris and Bliss, 1992; model 37f).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

37f

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Small surface pits are the principal workings here. Exploration activity in the general area took place in 1994 (Swainbank and others, 1995) as well as in 2011 to 2013 (Duplessis and others, 2013; Graphite One Resources, 2014).

During 2011 and 2012, Graphite One conducted exploration work at the Graphite Creek Property. The majority of the exploration work was completed during the summer 2012 including: a time-domain helicopter-borne electromagnetic survey; geological mapping; surface grab, channel and bulk pit sampling; and an 18 drillhole program to test the graphitic units at depth (Duplessis and others, 2013). In 2013, a 10 drillhole program expanded the area of mineralization both easterly and westerly, more than doubling the length of the graphite zone, which was about 2.2 kilometers in 2012, and became 4.8 kilometers in 2013 (Eccles and Nicholls, 2014).

Production notes:

About 130 tons of hand-sorted high-grade material were shipped in 1916 (Mertie, 1918) and other small shipments of similar material may have occurred.

Reserves:

A stock pile of hand-sorted material is estimated to contain 50 tons and the few miles of strike between the area of the Christophosen Creek deposit and the Graphite Creek deposit to the east has been estimated to contain 65,000 tons averaging about 60 percent graphite (Coats, 1944). This zone has also been estimated to contain, overall, more than 10 million tons of 10 percent or more graphite (Weiss, 1973).

The first mineral resource estimate for Graphite Creek (TE105), which also includes Christophosen Creek and Ruby Creek (TE104), was prepared by Claude Duplessis, Eng., senior consultant for SGS Canada Inc.

(SGS), and an independent Qualified Person under National Instrument (NI) 43-101, using the Canadian Institute of Mining, Metallurgy and Petroleum (CIM) Standards on Mineral Resources and Reserves, Definitions and Guidelines (Duplessis and others, 2013), which was updated the following year to include 2013 drill program results (Eccles and Nicholls, 2014).

They report an inferred resource of 186.86 million tonnes of schist containing 5.5 percent graphite with a recommended cut-off grade of 3 percent graphitic carbon (by LECO CR-412 Carbon Analyzer) and an inferred resource in-situ graphite of 10.34 million tonnes. For the list of other cut-off grades, refer to Eccles and Nicholls, 2014.

Additional comments:

In January 2012, Graphite One Resources entered an option agreement to earn 100 percent interest in claims encompassing known graphite showings over a three year period through exploration work totaling approximately $1.525 million, which Graphite One has completed with its 2012 summer exploration program. The total Graphite Creek Property land package comprises 129 claims totaling 16,801 acres (6,799 hectares), essentially controlling all prospective lands of known graphite mineralization in the region (Duplessis and others, 2013). The historically-named Christophosen Creek prospect is part of the overall Graphite Creek Project (Eccles and Nicholls, 2014).

Site name(s): Ruby Creek

Site type: Prospect

ARDF no.: TE104

Latitude: 65.037

Quadrangle: TE A-2

Longitude: 165.552

Location description and accuracy:

Ruby Creek is a small east headwater tributary to Glacier Canyon Creek that flows northward across the Kigluaik Mountain front 0.4 mile northeast of Glacier Canyon Creek. It is located 0.5 mile east-southeast from the center of section 21, T. 5 S., R. 34. W., of the Kateel River Meridian. This creek is not identified by name on USGS topographic maps; its name comes from a location map made by Coats (1944). Ruby Creek is now encompassed as part of Graphite Creek Property (TE105, 2014). This location is 11.8 miles due east of White River and 2.4 miles northeast of the Christophosen mine (TE103) at elevations of 550 to 650 feet. It is at the abrupt break in slope on the north side of the mountain front, just upslope of the surface trace of the active Kigluaik normal fault. The graphite-bearing rocks are in the footwall of this fault. This location was not shown by Cobb and Sainsbury (1972), but Cobb (1975) summarized relevant references under the name 'Ruby Cr.' Location is accurate within 500 feet.

Commodities:

Main: Graphite

Other:

Ore minerals:

Gangue minerals: Amphibole, biotite, garnet, muscovite, plagioclase, quartz, sillimanite, sphene, zircon

Geologic description:

Ruby Creek is now encompassed as part of the Graphite Creek record (TE105, 2014).

Flake graphite occurs as disseminations and high-grade tabular lenses within amphibolite facies metasedimentary rocks (Coats, 1944). The metamorphic rocks are primarily biotite-quartz schist with some sillimanite and garnet (Sainsbury, 1972). Small granitic plugs, dikes, and sills locally intrude the metamorphic rocks. The graphite-bearing schists are sharply bound to the north by the recently active Kigluaik fault, the principal fault along which late Cenozoic uplift of the Kigluaik Mountains has taken place (Hudson and Plafker, 1978). The graphite-bearing schists strike approximately parallel to the mountain front and dip north between 25 and 65 degrees. They form a zone along the mountain front that is 200 to 400 feet thick and possibly 20,000 feet long (Hudson, 1981; also see Christophosen Creek (TE103) locality to the west and Graphite Creek (TE105) locality to the east). To the south, the graphite-bearing schists are in conformable contact with other amphibolite facies metasedimentary rocks. The latter appear to be feldspathic and contain much less graphite. The graphite-bearing schists make up two general sequences; (1) a heterogeneous sequence of garnet-sillimanite-biotite-quartz schist with disseminated graphite and graphite-rich lenses, and (2) a more evenly layered biotite-quartz schist with disseminated graphite. The latter contains disseminated pyrrhotite and commonly weathers orange.

To the west of Ruby Creek, a 50-foot trench along strike exposes lenses up to 1 foot wide that are estimated to contain 70 percent graphite by volume. This zone of high-grade lenses has been traced along strike for 500 feet and is exposed over a vertical extent of 175 feet. The width of the graphite-rich zone was not recorded. A sample from this exposure contained 60 percent graphite of which 65 percent was coarser than 30 mesh to the inch (Coats, 1944). Other graphite-rich zones are present along Ruby Creek including a faulted section 4 feet wide with 1 to 6 inch wide graphite stringers and a 12 foot wide section with several 4

to 12 inch thick graphite-rich lenses. Individual lenses are not more than 20 feet long and seem to be about 12 times their width in length. The lenses overlap one another and come and go through the graphite-rich section (Coats, 1944). A sample of schist (plagioclase-biotite-quartz schist) with disseminated graphite from this locality was thought to have 5 to 10 percent graphite in thin section but laboratory analysis indicated a graphite content of 3 percent (Wolgemuth, 1982).

During 2011 and 2012, Graphite One conducted exploration work at the Graphite Creek Property. The majority of the exploration work was completed during the summer 2012 including: a time-domain helicopter-borne electromagnetic survey; geological mapping; surface grab, channel and bulk pit sampling; and an 18 drillhole program to test the graphitic units at depth (Duplessis and others, 2013). In 2013, a 10 drillhole program expanded the area of mineralization both easterly and westerly, more than doubling the length of the graphite zone, which was about 2.2 kilometers in 2012, and became 4.8 kilometers in 2013 (Eccles and Nicholls, 2014).

Alteration:

Age of mineralization:

The metamorphism that has developed coarse graphite in these rocks is Late Jurassic to Early Cretaceous in age.

Generic deposit model:

Deposit model:

Disseminated flake graphite (Orris and Bliss, 1992; model 37f).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

37f

Production Status: Yes; small

Site Status: Active

Workings/exploration:

A 50 foot-long surface trench and a 20 foot-long drift were noted by Coats (1944) and other small surface workings (pits) are probably present. Exploration activity in the general area took place in 1994 (Swainbank and others, 1995) as well as in 2011 to 2013 (Duplessis and others, 2013; Graphite One Resources, 2014).

During 2011 and 2012, Graphite One conducted exploration work at the Graphite Creek Property. The majority of the exploration work was completed during the summer 2012 including: a time-domain helicopter-borne electromagnetic survey; geological mapping; surface grab, channel and bulk pit sampling; and an 18 drillhole program to test the graphitic units at depth (Duplessis and others, 2013). In 2013, a 10 drillhole program expanded the area of mineralization both easterly and westerly, more than doubling the length of the graphite zone, which was about 2.2 kilometers in 2012, and became 4.8 kilometers in 2013 (Eccles and Nicholls, 2014).

Production notes:

Some of the graphite shipments reported for the Alaska Graphite Company may have come from this locality. These shipments include 35 tons (1907) and 100 tons (1916 or 1917) of hand-sorted, high-grade material (Mertie, 1918; Harrington, 1919; Coats, 1944).

Reserves:

The few miles along strike between the area of the Christophosen Creek (TE103)deposit and the Graphite Creek (TE105) deposit to the east has been estimated to contain 65,000 tons averaging about 60 percent graphite (Coats, 1944). This zone has also been estimated to contain, overall, more than 10 million tons of 10 percent or more graphite (Weiss, 1973).

The first mineral resource estimate for Graphite Creek (TE105), which also includes Christophosen Creek (TE103) and Ruby Creek, was prepared by Claude Duplessis, Eng., senior consultant for SGS Canada Inc. (SGS), and an independent Qualified Person under National Instrument (NI) 43-101, using the Canadian Institute of Mining, Metallurgy and Petroleum (CIM) Standards on Mineral Resources and Reserves, Definitions and Guidelines (Duplessis and others, 2013), which was updated the following year to include 2013 drill program results (Eccles and Nicholls, 2014).

They report an inferred resource of 186.86 million tonnes of schist containing 5.5 percent graphite with a recommended cut-off grade of 3 percent graphitic carbon (by LECO CR-412 Carbon Analyzer) and an inferred resource of in-situ graphite of 10.34 million tonnes. For the list of other cut-off grades, refer to Eccles and Nicholls, 2014.

Additional comments:

In January 2012, Graphite One Resources entered an option agreement to earn 100 percent interest in claims encompassing known graphite showings over a three year period through exploration work totaling approximately $1.525 million, which Graphite One has completed with its 2012 summer exploration program. The total Graphite Creek Property land package comprises 129 claims totaling 16,801 acres (6,799 hectares), essentially controlling all prospective lands of known graphite mineralization in the region (Duplessis and others, 2013). The historically-named Ruby Creek prospect is part of the overall Graphite Creek Project (Eccles and Nicholls, 2014).

Last report date: 2016-02-25

Site name(s): Graphite Creek

Site type: Prospect

ARDF no.: TE105

Latitude: 65.04 **Quadrangle:** TE A-2

Longitude: 165.535

Location description and accuracy:

The Graphite Creek Prospect is located near the center of section 22, T. 5 S., R. 34 W., of the Kateel River Meridian. Graphite Creek flows northward across the Kigluaik Mountain front 0.9 mile northeast of Glacier Canyon Creek and 0.5 mile northeast of Ruby Creek. This creek is not identified by name on USGS topographic maps; its name comes from a location map made by Coats (1944). Its mouth is on the east shore of Windy Cove on Imuruk Basin, 0.75 mile northeast of the mouth of Glacier Canyon Creek. The graphite deposits are at about 750 feet elevation at the abrupt break in slope on the north side of the mountain front, just upslope of the surface trace of the active Kigluaik normal fault. The graphite-bearing rocks are in the footwall of this fault. This location was not shown by Cobb and Sainsbury (1972), but Cobb (1975) summarized relevant references under the name 'Graphite Cr.' Location is accurate within 500 feet.

Commodities:

Main: Graphite

Other:

Ore minerals:

Gangue minerals: Amphibole, biotite, garnet, muscovite, plagioclase, quartz, sillimanite, sphene, zircon

Geologic description:

Flake graphite occurs as disseminations and high-grade tabular lenses within amphibolite facies metasedimentary rocks (Coats, 1944). The metamorphic rocks are primarily biotite-quartz schist with some sillimanite and garnet (Sainsbury, 1972). Small granitic plugs, dikes, and sills locally intrude the metamorphic rocks. The graphite-bearing schists are sharply bound to the north by the recently active Kigluaik fault, the principal fault along which late Cenozoic uplift of the Kigluaik Mountains has taken place (Hudson and Plafker, 1978). The graphite-bearing schists strike approximately parallel to the mountain front and dip north between 25 and 65 degrees. They form a zone along the mountain front that is 200 to 400 feet thick and possibly 20,000 feet long (Hudson, 1981; also see Christophosen Creek (TE103) to the west). To the south, the graphite-bearing schists are in conformable contact with other amphibolite facies metasedimentary rocks. The latter appear to be feldspathic and contain much less graphite. The graphite-bearing schists make up two general sequences; (1) a heterogeneous sequence of garnet-sillimanite-biotite-quartz schist with disseminated graphite and graphite-rich lenses, and (2) a more evenly layered biotite-quartz schist with disseminated graphite. The latter contains disseminated pyrrhotite and commonly weathers orange.

West of Graphite Creek a 30 foot-long pit exposes a garnet-bearing schist with disseminated graphite and graphite-rich lenses. A 13-foot section here contained 3 feet of garnet -bearing schist with graphite and a 3.5 foot thick high-grade graphite lense with quartz stringers. A sample of the garnet-bearing schist contained 12 percent graphite of which 80 percent was coarser than 30 mesh per inch and a sample of the graphite-rich material contained 59 percent graphite of which 83 percent was coarser than 30 mesh per inch (Coats, 1944). A 25-foot thick zone containing disseminated graphite and a 3-foot wide high-grade lens is exposed on the east side of Graphite Creek. Twenty feet of this section is estimated to contain 10 percent disseminated graphite. This zone has been traced eastward on the surface for a distance of 480 feet and

where it is well exposed, a 3- to 4-foot wide high-grade lens is present (Coats, 1944).

In 2016, Graphite One Resources conducted a comprehensive product-development program for graphite from their Graphite Creek deposit. Significant results include: test work exceeded graphite-purity threshold requirements; produced premiumgrade spherical graphite (SPG) from purified graphite; achieved almost 75 percent conversion of STAX graphite (Spheroidal, Thin, Aggregate, and eXpanded naturallyoccurring morphologies present in graphite sourced from the Graphite Creek deposit) to SPG in the size range suitable for electric-vehicle applications compared to typical industry yields of 30 to 40 percent; successful, near-theoretical-limit discharge-capacity tests on coated and uncoated spherical graphite; nearing completion of preliminary test work on mineral-processing circuit for producing high-grade graphite concentrate; and, demonstrated potential to produce products that will effectively compete in the high-end battery market (for both electric vehicles and power storage) as well as other markets for purified graphite and graphite byproducts (Athey and Werdon, 2017).

Alteration:

The graphite occurs as massive to semi-massive segregations and disseminations in amphibolite grade biotite-quartz schist with zones of sillimanite-garnet-biotite-quartz schist with high-grade graphite within 1 km of a fault zone (Eccles and Nicholls, 2014).

Age of mineralization:

The metamorphism that has developed coarse graphite in these rocks is Late Cretaceous, based on K/Ar and Ar/Ar dating which is immediately preceding or coincident with the intrusion of the Kigluaik Pluton (Eccles and Nicholls, 2014).

Generic deposit model:

Deposit model:

Disseminated flake graphite (Orris and Bliss, 1992; model 37f).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

37f

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Surface pits, including one 30 feet long from which 50 tons of high-grade material were recovered, are present. Exploration activity in the general area took place in 1994 (Swainbank and others, 1995).

In January 2012, Graphite One Resources (Graphite One) entered an option agreement to earn 100 percent interest in claims encompassing known graphite showings over a three year period. The total Graphite Creek Property land package comprises 129 claims totaling 16,801 acres (6,799 hectares) (Duplessis and others, 2013).

During 2011 and 2012, Graphite One conducted exploration work at the Graphite Creek Property. The majority of the exploration work was completed during the summer 2012 including: a time-domain helicopter-borne electromagnetic survey; geological mapping; surface grab, channel and bulk pit sampling; and an 18 drillhole program to test the graphitic units at depth (Duplessis and others, 2013). In 2013, a 10 drillhole program expanded the area of mineralization both easterly and westerly, more than doubling the length of the graphite zone, which was about 2.2 kilometers in 2012, and became 4.8 kilometers in 2013 (Eccles and Nicholls, 2014).

In 2014 infill drilling along a 730 meter strike length at Graphite Creek was completed by Graphite One. Twenty-two holes were drilled for a total of 2313 meters. Two of these drill holes were for metallurgical work. The other 20 drill holes, along with drill holes from previous years, provided enough drill coverage and confidence to estimate an indicated and inferred resource at Graphite Creek. Highlights from the 2014 drilling include 23.43 meters of 8.66 percent graphitic carbon (Cg), 38.87 meters of 10.50 percent Cg, 42.81

meters of 6.27 percent Cg, 38.80 meters of 7.80 percent Cg, and 24.56 meters of 6.76 Cg (Eccles and others, 2015).

Production notes:

Most of the graphite shipments reported for the Alaska Graphite Company may have come from this locality. These shipments include 35 tons (1907) and 100 tons (1916 or 1917) of hand-sorted, high-grade material (Mertie, 1918; Harrington, 1919; Coats, 1944). Coats (1944) reports that about 50 tons were recovered in 1916 from the 30-foot long pit on the west side of Graphite Creek.

Reserves:

The few miles along strike between the area of the Christophosen Creek (TE103) deposit and the Graphite Creek deposit to the east has been estimated to contain 65,000 tons averaging about 60 percent graphite (Coats, 1944). This zone has also been estimated to contain, overall, more than 10 million tons of 10 percent or more graphite (Weiss, 1973).

The first mineral resource estimate for Graphite Creek, which includes Christophosen Creek (TE103) and Ruby Creek (TE104), calculated according to modern standards was by Duplessis and others in 2013. Eccles and Nicholls (2014) updated this estimate with an inferred resource of 186.86 million tonnes of 5.5 percent graphitic carbon with a recommended cut-off grade of 3 percent graphitic carbon and in-situ graphite of 10,346,000 tonnes.

With more infill drilling completed, in 2015 an indicated resource at Graphite Creek was finally able to be estimated by Eccles and others (2015). The indicated resource at a 3 percent cut-off grade is 17.95 million tonnes at 6.3 percent graphitic carbon and 1,133,000 tonnes in-situ graphite. The inferred resource was updated at a 3 percent cut-off grade to 154.36 million tonnes at 5.7 percent graphitic carbon and 8,764,000 tonnes of in-situ graphite (Eccles and others, 2015).

Graphite One Resources plans to release Graphite Creek’s inaugural Preliminary Economic Assessment, including a refined resource estimate, in February 2017. As of April 2015, Graphite Creek’s indicated resources include 17.95 million tonnes grading 6.3 percent carbon-as-graphite (Cg) for an in situ 1.13 million tonnes of graphite, and inferred resources of 154.36 million tonnes grading 5.7 percent Cg for an in situ 8.76 million tonnes of graphite (Graphite One Resources, 2015). Resources are based on 48 drill holes, using a cut-off grade of 3 percent. The deposit remains open along strike in both the east and west directions, as well as down dip.

Last report date: 2017-08-26

Site name(s): Wolf

Site type: Prospect

ARDF no.: TE107

Latitude: 65.7624 **Quadrangle:** TE D-2

Longitude: 165.9036

Location description and accuracy:

The Wolf prospect is about 15.1 miles southeast of Ear Mountain, about 0.3 mile southeast of hill 1095, and about 0.4 mile south-southeast of the center of section 11, T. 4 N., R. 35 W. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Hg, Sb

Ore minerals: Arsenopyrite?, gold, pyrite

Gangue minerals: Calcite, quartz

Geologic description:

The Wolf prospect is in mica-quartz schist and graphitic quartz schist intercalated in a metasedimentary sequence that includes schistose, micaceous, dolomitic marble; mica-calcite schist; and minor micaceous quartzite (Cedar Mountain, 2011 [project]). The sequence is interpreted as a limestone-shale assemblage with facies variations. It is highly deformed and perhaps isoclinally folded. Schistosity dips moderately in various directions. Steeply-dipping marble-schist contacts and other strong linear features may indicate normal faults. The Wolf prospect is along a northwest-trending, regional fault that marks the contact between schist to the southwest and marble to the northeast. All of the metavolcanic and metasedimentary rocks in area were probably Paleozoic originally and have been metamorphosed in the Cretaceous; Sainsbury (1972) however mapped them as Precambrian.

The Wolf prospect is one of several similar deposits that define a district-level, west-northwest-trending belt of gold mineralization about 11 miles long and 2 miles wide. The best known and most extensively explored of these is the Kelly Creek prospect (TE069) about a half mile to the north; other are the North Fox (TE109), South Fox (TE108), Wolverine (TE110), Moose (TE111), and Jaeger (TE112) prospects.

The Wolf prospect was discovered by following up gold and arsenic anomalies in soils and stream sediments from the west headwaters of Kelly Creek (Hudson and Wyman, 1983; Hudson, 1984; Cedar Mountain, 2011 [assay]). The gold, arsenic, and antimony values define strong, coherent, multi-element anomalies. Mercury is commonly elevated in the soils, but its distribution and concentration are more erratic and it is more widely dispersed at anomalous levels than the other three elements. Rock samples from frost boils show that the stronger anomalies are associated with silicified breccia and quartz-stockworks in sooty, black carbonaceous quartz schist.

Clay is locally present in fractures and as part of the matrix in breccia. Dolomite and calcite reportedly accompany quartz in the veins in some drill core (Marrs and Ivey, 1984). Pyrite is disseminated in pelitic schist and is present in all mineralized rocks; in part, it is probably of sedimentary origin. Quartz segregations along the foliation in pelitic schist are recrystallized, sugary textured, and vuggy in mineralized rocks.

Cedar Mountain Exploration Inc. acquired the property in March 2010 and began aggressive exploration (Cedar Mountain Exploration Inc., 2011 [Kelly Creek]). In 2011, they drilled four holes totaling 473.8 meters along a high-angle fault; three holes were directed across the trace of the fault (Cedar Mountain, 2011 [November 2, news release]. One hole had to be abandoned before it reached the target zone but the

three holes that were completed all cut intervals with at least 0.1 gram of gold per tonne. The best intercepts were four, 1.5-meter-thick zones with 0.12 to 0.48 gram of gold per tonne, a 1.5 meter interval with 0.17 gram of gold per ton, and a 1.5-meter thick zone with 0.28 gram of gold per tonne. The gold-bearing intercepts are in sheared and quartz-veined, partly calcareous, mica-graphite-quartz schist.

Alteration:

Brecciation, silicification, and quartz stockwork veining is common in pelitic schist. Some quartz veins contain carbonate minerals. Clay and limonite are present in some mineralized rocks.

Age of mineralization:

Unknown but probably mid-to Late Cretaceous as the mineralization postdates regional metamorphism.

Generic deposit model:

Deposit model:

Disseminated and stockwork quartz and gold mineralization in metapelitic rocks. Possibly carbonate-hosted Au-Ag and/or low sulfide Au-quartz vein (Cox and Singer, 1986; models 26a or 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

26a or 36a

Production Status: None

Site Status: Active

Workings/exploration:

Site name(s): South Fox

Site type: Prospect

ARDF no.: TE108

Latitude: 65.7864 **Quadrangle:** TE D-2

Longitude: 165.9999

Location description and accuracy:

The South Fox prospect is about 11.9 miles southeast of Ear Mountain. It is centered about 0.5 mile west of hill 1180 and about 0.6 mile southwest of the center of section 35, T. 5 N., R. 35 W. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Hg, Sb

Ore minerals:

Gangue minerals: Calcite, quartz

Geologic description:

The South Fox prospect is in mica-quartz schist and graphitic quartz schist intercalated in a metasedimentary sequence that includes schistose, micaceous, dolomitic marble; mica-calcite schist; and minor micaceous quartzite (Cedar Mountain, 2011 [project]). The sequence is interpreted as a limestone-shale assemblage with facies variations. It is highly deformed and perhaps isoclinally folded. Schistosity dips moderately in various directions. Steeply-dipping marble-schist contacts and other strong linear features may indicate normal faults. The South Fox prospect is along a northwest-trending, regional fault that marks the contact between schist to the southwest and marble to the northeast. All of the metavolcanic and metasedimentary rocks in area were probably Paleozoic originally and have probably been metamorphosed in the Cretaceous; Sainsbury (1972) however mapped them as Precambrian.

The South Fox prospect is one of several similar deposits that define a district-level, west-northwest trending belt of gold mineralization about 11 miles long and 2 miles wide. The best known and most extensively explored of these is the Kelly Creek prospect (TE069) about a half mile to the north; other are the North Fox (TE109), Wolf (TE107), Wolverine (TE110), Moose (TE111), and Jaeger (TE112) prospects.

The prospect was discovered by following up gold and arsenic anomalies in soils and stream sediments collected in the west headwaters of Kelly Creek (Hudson and Wyman, 1983; Hudson, 1984; Cedar Mountain, 2011 [assay]) The gold, arsenic, and antimony values define strong, coherent, multi-element anomalies. Mercury is commonly elevated in the soils, but its distribution and concentration are more erratic and it is more widely dispersed at anomalous levels than the other three elements. Rock samples from frost boils show that the stronger anomalies are associated with silicified breccia and quartz-stockworks in sooty, black carbonaceous quartz schist.

Clay is locally present in fractures and as part of the matrix in breccia. Dolomite and calcite reportedly accompany quartz in the veins in some drill core (Marrs and Ivey, 1984). Pyrite is disseminated in pelitic schist and is present in all mineralized rocks; in part, it is probably of sedimentary origin. Quartz segregations along the foliation in pelitic schist are recrystallized, sugary textured, and vuggy in mineralized rocks.

Cedar Mountain Exploration Inc. acquired the property in March 2010 and began aggressive exploration (Cedar Mountain Exploration Inc., 2011 [Kelly Creek]). In 2011, Cedar Mountain drilled 10 holes that totaled 1,102 meters (Cedar Mountain Exploration, 2011 [November 18]). Four holes in the northern part of

the prospect cut significant intervals with gold values along a strike length of about 250 meters. The best intercepts were 0.45 gram of gold per ton along 28.40 meters and 0.76 gram of gold per tonne along 24.00 meters. The mineralization is associated with faulted and sheared quartz-veinlets and stockworks in mica-quartz schist and calcareous, graphite-quartz schist. The other holes in the south portion of the prospect did not cut significant mineralization, possibly due to faulting that offset the mineralized zone.

Alteration:

Age of mineralization:

Unknown but probably mid-to Late Cretaceous as the mineralization postdates regional metamorphism.

Generic deposit model:

Deposit model:

Disseminated and stockwork quartz and gold mineralization in metapelitic rocks. Possibly carbonate-hosted Au-Ag and/or low sulfide Au-quartz vein (Cox and Singer, 1986; models 26a or 36a).

Primary Reference: Cedar Mountain Exploration, 2011 [November 18 news release]

Reporter(s): D.J. Grybeck (Contractor, USGS)

Last report date: 2012-04-01

Site name(s): North Fox

Site type: Prospect

ARDF no.: TE109

Latitude: 65.7957 **Quadrangle:** TE D-2

Longitude: 165.9691

Location description and accuracy:

The North Fox prospect is about 12.1 miles southeast of Ear Mountain. It is about 0.7 mile north-northeast of hill 1180 and about 0.6 mile northeast of the center of section 35, T 5. N., R. 35 W. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Hg, Sb

Ore minerals:

Gangue minerals: Calcite, quartz

Geologic description:

The North Fox prospect is in mica-quartz schist and graphitic quartz schist intercalated in a metasedimentary sequence that includes schistose, micaceous, dolomitic marble; mica-calcite schist; and minor micaceous quartzite (Cedar Mountain, 2011 [project]). The sequence is interpreted as a limestone-shale assemblage with facies variations. It is highly deformed and perhaps isoclinally folded. Schistosity dips moderately in various directions. Steeply-dipping marble-schist contacts and other strong linear features may indicate normal faults. The North Fox prospect is along a northwest-trending, regional fault that marks the contact between schist to the southwest and marble to the northeast. All of the metavolcanic and metasedimentary rocks in area were probably Paleozoic originally and have been metamorphosed in the Cretaceous; Sainsbury (1972) however mapped them as Precambrian.

The North Fox prospect is one of several similar deposits that define a district-level, west-northwest trending belt of gold mineralization about 11 miles long and 2 miles wide. The best known and most extensively explored of these is the Kelly Creek prospect (TE069) about 2.6 miles to the southeast; other are the South Fox (TE108), Wolf (TE107), Wolverine (TE110), Moose (TE111), and Jaeger (TE112) prospects.

The prospect was discovered by following up gold and arsenic anomalies in soils and stream sediments from the west headwaters of Kelly Creek (Hudson and Wyman, 1983; Hudson, 1984; Cedar Mountain, 2011 [assay]; Cedar Mountain, 2011 [November 2, news release], Cedar Mountain, 2011 [November 2 map]) The gold, arsenic, and antimony values define strong, coherent, multi-element anomalies. Mercury is commonly elevated in the soils, but its distribution and concentration are more erratic and it is more widely dispersed at anomalous levels than the other three elements. Rock samples from frost boils show that the stronger anomalies are associated with silicified breccia and quartz-stocks in sooty, black carbonaceous quartz schist.

Clay is locally present in fractures and as part of the matrix in breccia. Dolomite and calcite reportedly accompany quartz in the veins in some drill core (Marrs and Ivey, 1984). Pyrite is disseminated in pelitic schist and is present in all mineralized rocks; in part, it is probably of sedimentary origin. Quartz segregations along the foliation in pelitic schist are recrystallized, sugary textured, and vuggy in the mineralized rocks.

Cedar Mountain Exploration Inc. acquired the property in March 2010 and began aggressive exploration

(Cedar Mountain Exploration Inc., 2011 [Kelly Creek]). In 2011, they drilled six holes at North Fox that totaled 668.5 meters on a geochemical anomaly in carbonaceous schist (Cedar Mountain, 2011 [November 2, news release], Cedar Mountain, 2011 [November 2 map]). All the holes cut intervals with more than 0.1 gram of gold per tonne. The gold intersects are relatively narrow and low grade. Some notable intercepts are 4.5 meters with 0.32 gram of gold per tonne, 4.5 meters with 0.42 gram of gold per tonne, 4.5 meters with 0.50 gram of gold per tonne, and 4.5 meters with 0.70 gram of gold per tonne. However the grade increase systematically toward the eastern end of the gold-in-soil geochemical anomaly that extends beyond the drilling. The gold-bearing zones are in sheared and quartz-veined, partly calcareous, mica-graphite-quartz schist.

Alteration:

Age of mineralization:

Unknown but probably mid-to Late Cretaceous as the mineralization postdates regional metamorphism.

Generic deposit model:

Deposit model:

Disseminated and stockwork quartz and gold mineralization in metapelitic rocks. Possibly carbonate-hosted Au-Ag and/or low sulfide Au-quartz vein (Cox and Singer, 1986; models 26a or 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

26a or 36a?

Production Status: None

Site Status: Active

Workings/exploration:

The North Fox prospect was discovered by following up gold and arsenic anomalies in soils and stream sediments from the west headwaters of Kelly Creek (Hudson and Wyman, 1983; Hudson, 1984; Cedar Mountain, 2011 [assay]; Cedar Mountain, 2011 [November 2, news release], Cedar Mountain, 2011 [November 2 map]) Cedar Mountain Exploration Inc. acquired the property in March 2010 and began aggressive exploration (Cedar Mountain Exploration Inc., 2011 [Kelly Creek]). In 2011, they drilled six holes at North Fox that totaled 668.5 meters on a geochemical anomaly in carbonaceous schist (Cedar Mountain, 2011 [November 2, news release], Cedar Mountain, 2011 [November 2 map]). All the holes cut intervals with more than 0.1 grams of gold per tonne. The gold intersects are relatively narrow and low grade. Last report date: 2012-04-01

Site name(s): Wolverine

Site type: Prospect

ARDF no.: TE110

Latitude: 65.7822 **Quadrangle:** TE D-2

Longitude: 165.7776

Location description and accuracy:

The Wolverine prospect is about 16.3 miles southeast of Ear Mountain. It is centered along the ridge top about 1.2 mile south of peak 1610 and about 0.5 mile north-northeast of the center of section 5, T. 4 N., R. 34 W. The location is accurate.

Commodities:

Main: Au

Other: Ag, As, Hg, Sb

Ore minerals:

Gangue minerals: Calcite, quartz

Geologic description:

The Wolverine prospect is in mica-quartz schist and graphitic quartz schist intercalated in a metasedimentary sequence that includes schistose, micaceous, dolomitic marble; mica-calcite schist; and minor micaceous quartzite (Cedar Mountain, 2011 [project]). The sequence is interpreted as a limestone-shale assemblage with facies variations. It is highly deformed and perhaps isoclinally folded. Schistosity dips moderately in various directions. All of the metavolcanic and metasedimentary rocks in area were probably Paleozoic originally and have been metamorphosed in the Cretaceous; Sainsbury (1972) however mapped them as Precambrian.

The Wolverine prospect is in mica-quartz schist and graphitic quartz schist intercalated in a metasedimentary sequence that includes schistose, micaceous, partly dolomitic marble, mica-calcite schist, and minor micaceous quartzite (Cedar Mountain, 2011 [project]). The metasedimentary sequence is interpreted to represent a limestone-shale assemblage with facies variations. It is highly deformed and perhaps isoclinally folded. Schistosity dips moderately in various directions. All of the metavolcanic and metasedimentary rocks in the area are of unknown but probable Paleozoic age; however, Sainsbury (1972) mapped them as Precambrian.

The Wolverine prospect is one of several similar deposits that define a district-level, west-northwest-trending belt of gold mineralization about 11 miles long and 2 miles wide. The best known and most extensively explored of these is the Kelly Creek prospect (TE069) about 3.5 miles to the west-southwest; other are the South Fox (TE108), North Fox (TE109), Wolf (TE107), Moose (TE111), and Jaeger (TE112) prospects.

The Wolverine prospect was discovered by following up gold and arsenic anomalies in soils and stream sediments (Hudson and Wyman, 1983; Hudson, 1984; Cedar Mountain, 2011 [assay]; Cedar Mountain, 2011 [November 2, news release], Cedar Mountain, 2011 [November 2 map]). The gold, arsenic, and antimony values define strong, coherent, multi-element anomalies. Mercury is commonly elevated in the soils, but its distribution and concentration are more erratic and it is more widely dispersed at anomalous levels than the other three elements. Rock samples from frost boils show that the stronger anomalies are associated with silicified breccia and quartz-stockworks in sooty, black carbonaceous quartz schist.

Clay is locally present in fractures and as part of the matrix in breccia. Dolomite and calcite reportedly accompany quartz in the veins in some drill core (Marrs and Ivey, 1984). Pyrite is disseminated in pelitic

schist and is present in all mineralized rocks; in part, it is probably of sedimentary origin. Quartz segregations along the foliation in pelitic schist are recrystallized, sugary textured, and vuggy in mineralized rocks.

Cedar Mountain Exploration Inc. acquired the property in March 2010 and began aggressive exploration (Cedar Mountain Exploration Inc., 2011 [November 2]). In 2011, Cedar Mountain drilled seven hole totaling 755.5 meters on a large, linear gold-in-soil anomaly. All of the drill holes cut least one mineralized interval 1 to 5.5 meters wide with 0.1 grams or more of gold per tonne. Two of the holes cut five such intervals. The best was 4.5 meters with 0.44 gram of gold per tonne. The gold-bearing zones are predominantly associated with sheared and quartz veined, partly calcareous, mica quartz schist and graphite quartz schist.

Alteration:

Age of mineralization:

Unknown but probably mid-to Late Cretaceous as the mineralization postdates regional metamorphism.

Last report date: 2012-04-01

Site name(s): Coal Creek

Site type: Prospect

ARDF no.: TK005

Latitude: 62.9909 **Quadrangle:** TK D-6

Longitude: 149.8633

Location description and accuracy:

The Coal Creek prospect is at an elevation of about 2,800 feet, approximately 2 miles east of lower Eldridge Glacier and about 0.4 mile northwest of hill 2650. It is near the head of an unnamed, small south-flowing tributary of Coal Creek in the SW1/4 sec. 21, T. 22 S., R. 12 W., Fairbanks Meridian. The location is accurate and it is approximately at the center of 15 claims staked on the prospect in 2005.

Commodities:

Main: Ag, Sn, W

Other: Bi, Cu, Mo, W, Zn

Ore minerals: Arsenopyrite, bismuthinite, cassiterite, chalcopyrite, galena, loellingite, marcasite, pyrite, pyrrhotite, sphalerite, stannite, wolframite

Gangue minerals: Fluorite, quartz, sericite, topaz, tourmaline

Geologic description:

Tin-silver mineralization was discovered at Coal Creek in 1972 by C. C. Hawley (Clark and others, 1972). The deposit was staked by Houston Oil and Minerals in 1980 and they explored the deposit until 1985. Their work included geologic mapping, trenching, surface sampling, and airborne and ground geophysics; they also drilled 42 holes totaling 17,193 feet. The U.S. Bureau of Mines examined the deposit in 1984 and 1988 (Parker, 1991, Kurtak and others, 1992). In 2005, Brett Resources staked 15 State of Alaska claims over the deposit and commissioned a NI 43-101 report (Ellis, 2006) on the property. The report relied heavily on the previous studies, drill hole information, and analytical data, but also involved relogging of the old core, analysis of old core that had not previously been analyzed, and reanalysis of selected portions of the old core with more modern methods to get a better definition of its metal content. In the late summer of of 2006, Brett drilled 4 holes to confirm historic values; their results were 'significantly lower than from earlier work' (Brett Resources, Inc., 2006).

The Coal Creek silver-tin deposit is a barely eroded, sheeted tin greisen (Reed, 1978; Thurow, 1983; Parker, 1991; Ellis, 2006). The deposit is at the top of a multiphase, 50-55 Ma granitic body made up of seriate granite porphyry that is intruded at depth by fine-grained equigranular porphyritic granite. The granite intrudes Devonian clastic sedimentary rocks and limestone that is altered to skarn near the granite. The mineralization is in steeply dipping, tabular sheeted greisen bodies in the granite that are characterized by quartz, tourmaline, topaz, sericite, and minor fluorite.

The mineralization consists mainly of coarse-grained sphalerite, cassiterite, arsenopyrite, and pyrrhotite in quartz veins in the greisen; disseminated ore minerals also are in the silicified margin of the granite and in the hornfels. The veins vary in width from hairline to 1 cm, are nearly vertical, and reach a density of 10 veins per meter in the most intensely fractured zones. The veins form a stockwork along a fracture zone in granite in an area of about 4,000 square meters (Thurow, 1983). The mineralization extends to the bottom of the drill holes, about 700 feet. In addition to the primary minerals, bismuthinite, chalcopyrite, galena, loellingite, marcasite, pyrite, stannite, and wolframite also occur and samples collected by Reed (1978) contained up to 4.3 ounces of silver per ton. Selected samples collected by Balen (1990) have up to 65 ppm silver, 0.5 ppm gold, 328 ppm lead, 720 ppm tungsten, and 4.86 percent zinc. In the limited drilling in the

late summer of 2006 (Brett Resources Inc., 2006), the best intercepts were were: 1) 9.4 meters with 18.21 ppm silver, 0.41 percent tin, and 0.81 percent zinc; and 2) 9.3 meters with 11.95 ppm silver, 0.45 percent tin, and 0.29 percent zinc.

Thurlow (1982) estimated that the deposit as drilled by Houston Oil and Minerals contain 4.85 million tons of mineralized greisen with an average grade of 0.27 percent tin. However Ellis (2006) emphasized that these figures are more conceptual than adhering to modern standards for defining mineral resources.

Alteration:

Sericitization and greisenization of the granite host rock; hornfels developed at the borders of the granite.

Age of mineralization:

Probably genetically related to the 50-55 Ma granite that hosts the deposit.

Generic deposit model:

Deposit model:

Tin greisen (Cox and Singer, 1986; model 15c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

15c

Production Status: None

Site Status: Active

Workings/exploration:

Tin-silver mineralization was discovered at Coal Creek in 1972 by C. C. Hawley (Clark and others, 1972). The deposit was staked by Houston Oil and Minerals in 1980 and they explored the deposit until 1985. Their work included geologic mapping, trenching, surface sampling, and airborne and ground geophysics; they also drilled 42 holes totaling 17,193 feet. The U.S. Bureau of Mines examined the deposit in 1984 and 1988 (Parker, 1991, Kurtak and others, 1992). In 2005, Brett Resources staked 15 Alaska claims over the deposit and commissioned a NI 43-101 report on the property (Ellis, 2006). The report relied heavily on the previous studies, drill hole information, and analytical data, but also involved relogging of the old core, analysis of old core that had not previously been analyzed, and reanalysis of selected portions of the old core with more modern methods to get a better definition of its metal content. In the late summer of of 2006, Brett drilled 4 holes to confirm historic values; the results were 'significantly lower than from earlier work' (Brett Resources, Inc., 2006).

Production notes:

None.

Reserves:

Thurlow (1982) estimated that the deposit as drilled by Houston Oil and Minerals contain 4.85 million tons of mineralized greisen with an average grade of 0.27 percent tin. However Ellis (2006) emphasized that these figures are more conceptual than adhering to modern standards for defining mineral resources.

Site name(s): Grizzly Bear; Grizzly Butte

Site type: Prospect

ARDF no.: TK032

Latitude: 62.9749 **Quadrangle:** TK D-2

Longitude: 147.873

Location description and accuracy:
The center of the Grizzly Butte prospect is at an elevation of about 4,000 feet about 1 mile northwest of VABM 5608 'Watana' and about 15 miles southwest of the bridge on the Denali Highway over the Susitna River near the community of Denali. The prospect is near the northeast corner of section 35, T. 22 S., R. 2 W. The location is accurate.

Commodities:

Main: Au, Cu

Other: Ag, W

Ore minerals: Bornite, chalcopyrite, magnetite, pyrite, pyrrhotite

Gangue minerals:

Geologic description:
The rocks in the area are mainly Triassic and/or Jurassic basalt flows with minor argillite, limestone, and tuff, intruded by gabbroic sills (Csejtey and others, 1978 [geologic map]; Full Metal Minerals, 2011). These rocks are intruded by an intrusive complex that consists of plugs and dikes of hornblende diorite and a porphyritic diorite to syenite stock. The intrusive complex is exposed for about 1.2 square kilometers but extends under surficial material to the west; the aeromagnetic data suggest it is much larger. The intrusive complex and surrounding rocks are cut by trachyte, felsic, diorite, and andesite dikes. In their regional mapping, Csejtey, Nelson and others (1978 [geologic map]) did not map an intrusive at this prospect although Tertiary granodiorite and a Cretaceous or Tertiary granite are several miles away.
As described by Csejtey and others (1978 [mineral deposits]), a sulfide-bearing felsic dike cuts Triassic metabasalt at the Grizzly Butte prospect. The sulfide minerals are bornite, chalcopyrite, pyrite, and pyrrhotite. Low-grade sulfide veins and disseminated sulfides also occur in silicified metabasalt. A U.S. Geological Survey sample of mineralized volcanic rock contained 0.5 part per million (ppm) gold; a sample of felsic intrusive rock contained 3 ppm silver and 350 ppm copper (Miller and others, 1978). A U.S. Bureau of Mines grab sample of limonitic metabasalt contains 5.17 percent copper, 0.4 parts per million gold, and 550 parts per million tungsten (Kurtak and others, 1992).
Cities Service Minerals Company held 96 claims over the prospect in 1972 and 1973 and Northland Mines held 18 claims in 1974. Kennecott Exploration staked claims in 1998, carried out rock and stream-sediment geochemical surveys, and flew an aeromagnetic survey over the area. Full Metals Minerals optioned the property from Kennecott in 2010 and staked additional claims (Full Metal Minerals, 2011). They began drilling in August 2010.
A zone of strong potassic alteration about 1,000 by 2,000 meters in area is centered on the intrusive complex (Full Metals Minerals, 2011). Disseminated and fracture-controlled chalcopyrite and bornite(?) coincide with the southwest portion of the altered zone; to the northeast, magnetite-biotite-flooded stockworks are more common. One or more zones of sericitic alteration are along the east side of the potassic alteration and epidote-magnetite alteration is along the west side. Pyrite, pyrrhotite, and magnetite occur along fracture zones in the rocks around the intrusive; sparse disseminated chalcopyrite is widespread in the diorite-syenite intrusive. The mineralization is accompanied by strong geochemical soil anomalies in

gold, silver, and copper. Rock samples contain up to 17,900 ppm copper 1,680 ppm molybdenum, and 2,660 parts per billion gold.

Alteration:

A zone of strong potassic alteration about 1,000 by 2,000 meters in size is centered on the mineralized intrusive complex. One or more zones of sericitic alteration are along the west side of the potassic alteration and epidote-magnetite alteration is along the west side.

Age of mineralization:

Probably related to an intrusive complex of uncertain age; possibly Cretaceous or Tertiary.

Generic deposit model:

Deposit model:

Unclear.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Surface sampling by U.S. Geological Survey and U.S. Bureau of Mines (Miller and others, 1977; Kurtak and others, 1992). Cities Service Minerals Company held 96 claims in 1972-73 and Northland Mines held 18 claims in 1974. Kennecott Exploration staked claims in 1998, carried out rock and stream-sediment geochemical surveys, and flew an aeromagnetic survey over the area. Site name(s): Lichen; Rush

Site type: Prospect

ARDF no.: TK045

Latitude: 62.8893 **Quadrangle:** TK D-1

Longitude: 147.3355

Location description and accuracy:

The Lichen prospect is at an elevation of about 3,150 feet, about 6 miles west of the Susitna River and 4.0 miles southeast of the center of Coal Lake. The prospect is about 0.15 mile west of the center of sec. 2, T. 32 N., R. 11 E., Seward Meridian. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Bornite, chalcopyrite, covellite, digenite, malachite

Gangue minerals: Epidote, feldspar, quartz

Geologic description:

The Lichen prospect is a stratabound copper deposit in Triassic(?) metavolcanic rocks. Veins and disseminated sulfides occur in a mafic, volcanic flow (Smith and others, 1975; Schmidt and others, 2002). The ore minerals are confined to a single flow, and consist of disseminations and veinlets of bornite, chalcopyrite, covellite, digenite, and malachite. The veinlets average less than 0.4 inch thick and contain quartz, feldspar, and epidote as well as sulfides. The mineralized zone is about 6 feet wide and 3,000 feet long. it strikes N60W and dips nearly vertically. The host rock has undergone greenschist-grade regional metamorphism and is coated with secondary iron and copper minerals. Samples of mineralized rock contained up to 4.5 percent copper, 16 parts per million (ppm) gold, and 68 ppm silver (Smith and others, 1975).

The prospect was explored in the 1970s by Cities Service Minerals using soil geochemical sampling, ground magnetic and EM surveys, and excavation of 2 trenches. Seraphim Engineering and Cities Service Minerals Company staked 145 claims in 1975-1976. The Amphitheater 1-25 claims were staked by Cominco American in 1988.

Alaska Ventures, Inc. (Bundtzen, 2008) began work on the Lichen deposit in 2005. They describe the prospect as a basaltic copper deposit that consists mainly of bornite and chalcopyrite in quartz veinlets in weakly metamorphosed, sub-alkaline basalt of Permian or Carboniferous age. The quartz veinlets are associated with epidote flooding in the basalt; other base metals are lacking although samples contain significant gold and silver values. In addition to the original discovery, work in 2007 located at least 6 other occurrences of similar mineralization spread over an area of several square miles. In the discovery zone, they defined an area about 360 meters long by 160 meters wide where the average value for the sulfide-quartz veinlets is about 1.75 percent copper, 30.5 grams of silver per tonne and 0.475 gram of gold per ton. Placer gold, probably of local origin, can be panned from most of the streams that drain the ridge on which the mineralization occurs. A soil geochemical survey outlined three, northwest-trending copper-silver-gold anomalies, the best of which coincided with the Lichen discovery but several were in areas covered by thick glacial cover. A ground IP survey covered an area about 1,600 meters by 2,600 meters in size and outlined several anomalies that suggest mineralization. The sampling and the geophysical and geochemical surveys indicate that the mineralization is along a northwest-striking zone about 4.0 kilometers long and 200 meters wide.

Alteration:

The volcanic host rock is altered to chlorite and epidote and stained with secondary iron and copper minerals.

Age of mineralization:

Early work suggests the deposit occurs in Triassic(?) metabasalt; later work suggests the basalt is Permian to Carboniferous.

Generic deposit model:

Deposit model:

Basaltic copper (Cox and Singer, 1986; model 23).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

23

Production Status: None

Site Status: Active

Workings/exploration:

The prospect was explored in the 1970s by Cities Service Minerals using soil geochemical sampling, ground magnetic and EM surveys, and excavation of 2 trenches. Seraphim Engineering and Cities Service Minerals Company staked 145 claims in 1975-1976. The Amphitheater 1-25 claims were staked by Cominco American in 1988. As of January 1, 2000 a large block of state mining claims and prospecting sites covered the prospect (Northern Associates Inc., written communication, 2001). In 2005-2007, Alaska Ventures, Inc. explored the deposit by surface sampling, soil geochemistry, and ground IP geophysical surveys.

Site name(s): King and Queen; Golddigger

Site type: Prospect

ARDF no.: TK088

Latitude: 62.4851 **Quadrangle:** TK B-4

Longitude: 148.7927

Location description and accuracy:
The King and Queen prospect is at an elevation of about 3,400 feet on northwest end of a ridge; it is about 2 miles south of the Talkeetna River in the SW1/4 sec. 30, T. 28 N., R. 4 E., Seward Meridian. The location is accurate to within 1/4 mile.

Commodities:

Main: Ag, Au

Other: Hg

Ore minerals: Gold, iron oxides, pyrite, silver tellurides?

Gangue minerals: Calcite, chalcedony, clay

Geologic description:
The rocks in the vicinity of this prospect are interbedded felsic and mafic volcanic rocks (Ben Porterfield, written communication, 2001). In part, the felsic rocks form a dome that consists of flow-banded rhyodacite, volcanic breccia, and possibly hot-springs sinter. Hydrobreccia occurs in float. Argillic alteration is dominant, with some propylitic alteration and silicification. Minor fine-grained pyrite and silver tellurides(?) occur in the matrix of the volcanic breccia, which weathers to conspicuous iron oxides. Based on air photos, the dome appears to be 2,000 feet long by 1,600 feet wide.
The following data are provided by Ben Porterfield (written communication, 2001), who owned the property in 2002. The prospect was discovered in 1918 by Sinclair and Foster. An old shaft is on top of the volcanic dome. The prospect was explored by Kennecott in 1919, when L.W. Storm reported that gold could be panned from almost any material selected at random. Trench samples contained 0.24 ounce of gold per ton from 'seams'; a 25-foot channel sample had 0.08 ounce of gold per ton and 1.76 ounces of silver per ton. A 6-inch-wide seam in an outcrop of felsic rock assayed 6.8 ounces of gold per ton and 15.9 ounces of silver per ton. Samples across 58 feet of trench averaged 1.82 parts per million gold. Grab samples every three feet along 190 feet of an old dump averaged 490 parts per billion gold. A grab sample of typical volcanic breccia from the shaft dump contained 1 part per million gold. Samples from the margins of the dome contained 12 parts per million mercury. Seven samples collected from a 38-foot-long northern trench contained 1 to 5.7 parts per million gold, and averaged 2.2 parts per million gold. Stream-sediment samples contained up to 870 parts per billion gold, 1.4 parts per million silver, and 5 parts per million mercury.
In 2006, Full Metal Minerals acquired the King and Queen prospect under an agreement with Ben Porterfield (Full Metal, 2007, Gold Digger). They reported that in recent years samples over a felsic dome contained 1.8 grams of gold per ton across 17.7 meters and samples from a trench vary from 0.7 to 5.7 grams of gold per ton. Full Metals also staked several other prospects nearby(?), the Toklat and Talkeetna prospects. (One or both of these may be among the unnamed prospects that have been listed in ARDF as TK049 to TK058, TK089 to TK092, and TK125). The Toklat prospect was explored by Anaconda Exploration in the 1980s and consists of silicified material with visible cinnabar in altered volcanic rocks and limestone. Samples contained 0.3 to 2.2 grams of gold per ton, 10 to 30 grams of silver per ton and 0.5 percent mercury. The Talkeetna prospect is associated with a shear zone and a 2.3-meter-long chip sample

averaged 2.5 percent copper and 5.4 grams of silver per ton.

Alteration:

Float samples on the rhyodacite dome show strong argillic alteration, mainly illite and smectite. Local propylitic alteration, with calcite veining and opaline silica is associated with mafic agglomerate north of the dome (Ben Porterfield, written communication, 2001). Conspicuous iron staining.

Age of mineralization:

A preliminary whole-rock age date on the basalt is 45±3 Ma (P. Oswald, oral commun., 2002).

Generic deposit model:

Deposit model:

Hot spring Au-Ag (Cox and Singer, 1986; model 25a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

25a

Production Status: None

Site Status: Active?

Workings/exploration:

An old shaft is on top of the dome. The prospect was explored by Kennecott in 1919, when L.W. Storm reported that gold could be panned from almost any material selected at random. As of January 1, 2000, a block of 4 prospecting sites covered this prospect (Northern Associates Inc., written communication, 2001). In 2006, Full Metal Minerals acquired the property and did some surface sampling and mapping.

Production notes:

None.

Last report date: 2008-03-04

Site name(s): Round Mountain

Site type: Prospect

ARDF no.: TL064

Latitude: 62.0619 **Quadrangle:** TL A-6

Longitude: 152.6943

Location description and accuracy:

The Round Mountain prospect is on Round Mountain about 2 miles southeast of Puntilla Lake; it is near the southeast corner of section 23, T. 22 N., R. 19 W., of the Seward Meridian. The location is generally accurate but the size of the deposit is unclear.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: As, Sb

Ore minerals: Arsenopyrite, chalcopyrite, galena, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Quartz, sericite

Geologic description:

In early 2010, the Round Mountain prospect was part of the Whistler project of Kiska Metals Corporation and was actively being explored (Wahl and others, 2008; Kiska Metals Corporation, 2010a).

Cominco Alaska began mineral exploration in the area in 1986; they found this deposit but ended their work in 1989. The work by Cominco included sampling silt, soil, and rocks, magnetic and VLF geophysical surveys, and mapping at 1:12,000 scale. From 2004 to 2006, Kennecott Exploration Company carried out major exploration in the area including, geologic mapping; soil, stream sediment, and rock geochemistry; and geophysical surveys. They staked several large blocks of ground that included the Round Mountain prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott in 2007, and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation. Six holes were drilled on Round Mountain or nearby, probably by Cominco or Kennecott.

The rocks in the area are Jurassic and Cretaceous sedimentary rocks and Tertiary volcanic rocks (Reed and Nelson, 1980; Wilson and others, 2009) that are intruded by intermediate to mafic sills, dikes and small plugs (Cominco American Incorporated, unpublished report). The intrusive rocks are overprinted by quartz-sericite-pyrite and magnetite-carbonate alteration. Auriferous veins, pods and stockwork, that contain variable amounts of quartz, pyrite, pyrrhotite, sphalerite, galena, chalcopyrite, stibnite and arsenopyrite are concentrated along intrusive contacts and faults (Cominco American Incorporated, unpublished report). Geochemical values in rock chip samples range from several hundred parts per billion gold to just under an ounce of gold per ton in selected high-grade samples. Some samples contain up to about an ounce of silver per ton.

Round Mountain has been identified by its anomalous geochemistry, alteration, and anomalous geophysical features (Roberts, 2014).

Alteration:

Quartz-sericite-pyrite, quartz-pyrite, carbonate, and magnetite alteration (Kiska Metals Corporation, 2010a).

Age of mineralization:

Early or middle Tertiary. The mineralization is interpreted to be coeval with or younger than Tertiary

volcanic and intrusive country rocks that Reed and Nelson (1980) correlated with plutonism of the same age in this part of the Alaska Range.

Generic deposit model:

Deposit model:

Gold-copper porphyry (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

In early 2010, the Round Mountain prospect was part of the Whistler project of Kiska Metals Corporation and was actively being explored (Wahl and others, 2008; Kiska Metals Corporation, 2010a). Cominco Alaska began mineral exploration in the area in 1986; they found this deposit but ended their work in 1989. The work by Cominco included sampling silt, soil, and rocks, magnetic and VLF geophysical surveys, and mapping at 1:12,000 scale. From 2004 to 2006, Kennecott Exploration Company carried out major exploration in the area including, geologic mapping; soil, stream sediment, and rock geochemistry; and geophysical surveys. They staked several large blocks of ground that included the Round Mountain prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott in 2007, and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation. Six holes were drilled on Round Mountain or nearby, probably by Cominco or Kennecott.

In 2010, Kiska drilled two core holes to complete Kiska's requirements for their partnership with Kennecott. The two holes did not return any significant results (Kiska Metals Corp., 2010b). Kiska's 2014 Executive Summary characterizes Round Mountain as an early stage prospect (Roberts, 2014).

Production notes:

None.

Reserves:

None.

Site name(s): Oxide Ridge

Site type: Prospect

ARDF no.: TL077

Latitude: 62.0112 **Quadrangle:** TL A-6

Longitude: 152.9043

Location description and accuracy:

The Oxide Ridge prospect is about 3.3 miles northeast of Portage Pass and about 0.5 mile west of the center of section 11, T. 22 N., R. 20 W., of the Seward Meridian. The location is accurate to within 100 feet to the center of the prospect.

Commodities:

Main: Au, Cu, Mo

Other: As

Ore minerals: Arsenopyrite, chalcopyrite, gold, molybdenite, pyrite

Gangue minerals:

Geologic description:

The rocks in the area are Jurassic and Cretaceous marine sedimentary rocks that are intruded by the 65-66 Ma granodiorite of Mount Estelle (Reed and Nelson, 1980). The granodiorite at this prospect has a leucocratic equigranular phase and a porphyritic phase with potassium feldspar phenocrysts up to 10 millimeters in size (Cominco American Incorporated, unpublished report).

As described by Cominco American, chalcopyrite, pyrrhotite, arsenopyrite, molybdenite and pyrite occur as joint coatings, in veins, and as disseminations adjacent to northwest-striking mineralized joint sets. Sulfide-bearing rock samples from this site contain from 60 parts per billion (ppb) gold to more than 1 ounce of gold per ton. Silver is generally below the detection limit of 0.4 parts per million (ppm) but some samples contain as much as 11 ppm silver.

Altered granodiorite float about 2 miles to the southwest contains gold-bearing veinlets of arsenopyrite and pyrite (TL063). Curtin and others (1978) report panned-concentrate samples with visible gold from Quaternary gravels about one mile downstream from this locality (TL052).

In 2011, Millrock Resources Inc. on behalf of Teck America Inc. drilled a 457.9-meter hole. The entire hole was invariably-altered, fractured intrusive rocks cut by porphyritic dikes. The mineralization occurs in quartz veins and stockworks; gold is associated with arsenopyrite and chalcopyrite. Over 350 meters of the hole averaged 0.43 gram of gold per tonne. Some notable intercepts were: 15.73 meters that contained 0.98 gram of gold per tonne; 31.03 meters that contained 0.79 gram of gold per tonne; and 4.48 meters that contained 0.84 gram of gold per tonne.

In 2012, Millrock Resources Inc. drilled one drill hole. Mineralized intercepts include 10.7 meters of 0.51 gram of gold per tonne, and 7.6 meters of 0.75 gram of gold per tonne (Millrock Resources Inc., 2012).

Alteration:

Most of the 2011 hole was in variably-altered intrusive rocks (Millrock Resources Inc., 2011).

Age of mineralization:

Late Cretaceous/early Tertiary?; mineralization in the area is thought to be related to the 65-66 Ma, granodiorite of Mount Estelle (Cominco American Incorporated, unpublished report).

Generic deposit model:

Deposit model:

Intrusion-related gold (Millrock Resources Inc., 2011).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Cominco American Inc. mapped and collected rock-chip samples in the late 1980s. A 457.8-meter hole was drilled by Millrock Resources Inc. in 2011. Another hole was drilled in 2012. Mineralized intercepts include 10.7 meters of 0.51 gram of gold per tonne, and 7.6 meters of 0.75 gram of gold per tonne (Millrock Resources Inc., 2012).

Production notes:

None.

Reserves:

None.

Site name(s): Shulin Lake

Site type: Prospect

ARDF no.: TL078

Latitude: 62.2017 **Quadrangle:** TL A-2

Longitude: 150.84

Location description and accuracy:
The Shulin Lake diamond prospect is about 2 miles northeast of the junction of Peters Creek and the Kahiltna River. Several holes were drilled on the prospect; their exact location is unknown but they are probably in or near section 1, T. T. 24 N., R. 9 W. The location is accurate to within a mile.

Commodities:

Main: Diamond

Other:

Ore minerals: Diamond

Gangue minerals:

Geologic description:
The rocks in the vicinity of the prospect near junction of Peters Creek and the Kahiltna River consist of scattered exposures of continental sandstone and siltstone of the Tertiary Tyonek Formation (Alex Geosciences Ltd., 2002). These rocks are underlain by Jurassic or Cretaceous marine sedimentary rocks that are isoclinally folded and consist of graywacke, phyllite, and shale with lenses of quartz-chert conglomerate Several miles from the prospect, several small Tertiary or Cretaceous intrusions are exposed near the contacts of the sedimentary rocks. There is a well-defined, strong, almost circular, magnetic high about 10 miles in diameter that covers much of the area between Peters Creek and Bear Creek, just west of the Kahiltna River; it may reflect a gabbroic intrusion at depth.

In 1999, several independent studies of placer concentrates collected near the junction of Peters Creek and the Kahiltna River revealed that they contained several diamond-indicator minerals, including chromite; low-iron, low-chromium clinopyroxene; high-magnesium orthopyroxene; and olivine. In 2000, Apex Geoscience Ltd. collected six samples for more detailed work and they identified 9 possible chrome diopsides, 5 possible eclogitic garnets, and 6 possible chrome grains (Apex Geoscience Ltd., 2000).

In 2001, a joint program by Golconda Resources Ltd., Shulin Lake Mining Company, and Shear Minerals Ltd. began work on a large block of claims. A detailed airborne geophysical survey showed numerous smaller anomalies in addition to the large circular anomaly (Golconda Resources Ltd., 2008; Shear Minerals, 2004, 2005). This was followed up by a ground magnetic survey that identified three targets that were drilled in 2002. Most of the holes were in sandy tuff but the northernmost two showed an increasing amount of olivine and pyroxene at depth. A sample from one hole taken at a depth of from 574 to 609 feet contained 15 microdiamonds and one macrodiamond as well as peridotite nodules. By the end of 2004, a total of 22 holes had been drilled and 20 diamonds were recovered from two holes.

Alteration:
None specifically noted.

Age of mineralization:
Insufficient data.

Generic deposit model:

Deposit model:

Diamonds associated with buried kimberlite pipe?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Several square miles east of the Kahilta River between the mouths of Bear Creek and Peters Creeks were explored for diamonds from 1999 to at least 2004. Twenty-two holes were drilled on geophysical anomalies and 20 microdiamonds and macrodiamonds were recovered from two drill holes.

Production notes:

None.

Reserves:

None.

Site name(s): Snow Ridge

Site type: Prospect

ARDF no.: TL079

Latitude: 62.0151 **Quadrangle:** TL A-6

Longitude: 152.7102

Location description and accuracy:

Only a general location is known for this prospect. But it is probably within a half mile of VABM 4804, which is about 5.2 miles south of the middle of Puntilla Lake and about 0.3 mile north of the center of section 11, T. 22 N., R 18 W.

Commodities:

Main: Au?, Cu?

Other:

Ore minerals: Chalcopyrite?, gold?

Gangue minerals: Quartz

Geologic description:

Cominco Alaska began mineral exploration in the area in 1986 and may have identified this deposit before they ended their work in 1989. From 2004 to 2006, Kennecott Exploration Company was active in the area and staked several large blocks of ground that included the Snow Ridge prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott, and in 2009, Kiska Metals Corporation, the current holder of the claims, was formed by a merger of Geoinformatics and Rimfire Minerals Corporation.

Little is known about this property other that it is one of the centers of mineralization being explored by Kiska Metals Incorporated in early 2010 (Wahl and others, 2008; Kiska Metals Incorporated, 2010). The regional geologic maps of the area indicates it is near a swarm of andesite dikes that intrude Jurassic to Cretaceous graywacke (Wahl and others, 2008, Wilson and others, 2009). Several gold-copper porphyry deposits are nearby, notably the Whistler prospect (TY022), that may have similar mineralization.

Alteration:

Unknown.

Age of mineralization:

Younger than the Jurassic and Cretaceous host rocks.

Generic deposit model:

Deposit model:

Gold-copper porphyry (Cox and Singer, 1986; model 20c).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

Little is known about the history of this prospect other than it being cited as one of the centers of mineralization in a large block of ground being explored by Kiska Metals Corporation (2010).

Production notes:

None.

Reserves:

None.

Site name(s): Oxide Valley

Site type: Prospect

ARDF no.: TL080

Latitude: 62.0082 **Quadrangle:** TL A-6

Longitude: 152.9019

Location description and accuracy:

The Oxide Valley prospect is located about 2.6 miles north-northeast from Portage Pass; about 0.3 mile west of the center of section 11, T. 22 N., R. 20 W., of the Seward Meridian. The location is accurate to within 100 feet to the center of the prospect.

Commodities:

Main: Au, Cu

Other: Bi, Te

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

Gold mineralization at Oxide Valley is associated with an elongate, northerly trending composite plutonic complex intruding a Jurassic to Early Cretaceous flysch sequence. The intrusives consist of ultramafic to felsic plutons of Late Cretaceous/Early Tertiary age (69.7 Ma) and are centrally located in a region of arc-magmatic related gold deposits. Gold mineralization is correlated with arsenic, bismuth, and tellurium anomalies (Millrock Resources Inc., 2014).

The Oxide Valley prospect was identified by Millrock Resource Inc. in 2008 when multiple vein zones containing arsenopyrite, pyrite and chalcopyrite were discovered. Since then, geologic mapping and rock chip sampling has resulted in the definition of multiple mineralized zones returning anomalous gold values including chip sample results of 0.91 gram of gold per tonne over 46 meters (151 feet) in Oxide Valley (Millrock Resources Inc., 2014).

In 2010, an induced polarization (IP) survey in Oxide Valley defined multiple chargeability anomalies, which appeared to align along a northwest trend similar to the trend of mineralized, extensional vein sets (Millrock Resources Inc., 2014).

During 2011, one core hole (SE11-001) was drilled in Oxide Valley targeting the IP anomaly. Encouraging results were obtained with an average grade of 0.375 gram of gold per tonne over the entire 461 meters (1,512 feet) length of the hole leading to further exploration and drilling in 2012, mainly northwest and southeast of drill hole SE11-001. Elevated gold values were returned from two of the four follow-up holes, both located southeast of SE11-001. Core hole SE12-002 averaged 0.368 gram of gold per tonne over the entire 188 meters (617 feet) length and core hole SE12-004 intersected 41.45 meters (136 feet) averaging 1.14 grams of gold per tonne (Millrock Resources Inc., 2014).

A wide-spaced Reconnaissance Induced Polarization (RIP) survey was conducted in Oxide Valley during 2012 with a follow-up tighter spaced survey done in 2013. Multiple chargeability anomalies were defined by the surveys with the majority untested by drilling. Geologic mapping in 2012 and 2013 defined several mineral trends all of which remain open along trend and down dip. Of particular interest is the Oxide Valley 'corridor' which hosts several zones of close spaced gold-bearing extensional quartz veining (Millrock Resources Inc., 2014).

Alteration:

Carbonate, chlorite, sericite, and quartz are commonly associated with the sulfide and gold mineralization (Millholland,1995; Crowe and others, 1991).

Age of mineralization:

Relative correlation of gold with arsenic, bismuth, and tellurium at Oxide Valley is similar to other deposits in the Tintina Gold Province such as Golden Zone and Shotgun in Alaska and Casino and Mt. Nansen in the Yukon suggesting a possible large scale, age-related mineralizing event. Age dating of intrusives at Oxide Valley of 69.7 Ma indicate mineralization is no older than Late Cretaceous/Early Tertiary (Millrock Resources Inc., 2014).

Generic deposit model:

Deposit model:

Intrusion-related gold (Millrock Resources Inc., 2014).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

The Oxide Valley prospect was identified by Millrock Resource Inc. in 2008 when multiple vein zones containing arsenopyrite, pyrite and chalcopyrite were discovered. Since then, geologic mapping and rock chip sampling has resulted in the definition of multiple mineralized zones returning anomalous gold values including chip sample results of 0.91 gram of gold per tonne over 46 meters (151 feet) in Oxide Valley (Millrock Resources Inc., 2014). In 2010, an induced polarization (IP) survey in Oxide Valley defined multiple chargeability anomalies, which appeared to align along a northwest trend similar to the trend of mineralized, extensional vein sets (Millrock Resources Inc., 2014). Drill holes were completed in 2011 and 2012. A wide-spaced Reconnaissance Induced Polarization (RIP) survey was conducted in Oxide Valley during 2012 with a follow-up tighter spaced survey done in 2013. Geologic mapping in 2012 and 2013 defined several mineral trends all of which remain open along trend and down dip (Millrock Resources Inc., 2014).

Site name(s): Oxide North

Site type: Prospect

ARDF no.: TL081

Latitude: 62.0266 **Quadrangle:** TL A-6

Longitude: 152.8983

Location description and accuracy:

The prospect is located about 3.8 miles north-northeast of Portage Pass, and about 0.32 miles west-northwest of the center of section 2, T. 23 N., R. 20 W., of the Seward Meridian. This location is accurate to within 1/2 mile.

Commodities:

Main: Au

Other: As

Ore minerals: Gold

Gangue minerals: Arsenopyrite, tourmaline

Geologic description:

This site is a mineralized zone within Oxide, the northernmost prospect at Estelle (TY019), and is about 2.5 km north of the original Oxide Ridge showing (TL077). Oxide North lies within a plutonic complex intruding a Jurassic to Early Cretaceous flysch sequence. This zone is characterized by disseminated arsenopyrite and tourmaline returned anomalous values in talus fines sampling. Soil geochemical surveys in the valley have returned widespread arsenic anomalies with gold (Millrock Resource, Inc., 2014).

Alteration:

Not indicated.

Age of mineralization:

Late Cretaceous of younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Porphyry Cu-Au? or intrusion-related gold? (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c?

Production Status: None

Site Status: Active

Workings/exploration:

Gold mineralization was initially discovered in 2008 when multiple vein zones containing arsenopyrite,

pyrite and chalcopyrite were noted along nearby Oxide Ridge, a north-south trending ridge located in the southern part of the prospect. Extensive geologic mapping helped define the target.

In summer, 2012, Millrock Resources, Inc., executed a chip sampling of mineralized outcrops, in addition to an induced polarization geophysical survey to test for disseminated sulfides. Soil geochemical surveys in the valley have returned widespread arsenic anomalies with gold (Millrock Resource, Inc., 2014).

Production notes:

None.

Reserves:

None.

Site name(s): Kohlsaat

Site type: Occurrence

ARDF no.: TL082

Latitude: 62.285 **Quadrangle:** TL B-6

Longitude: 152.7352

Location description and accuracy:

The occurrence is in a drainage located about 3.9 miles west-northwest of the fork of the Kichatna River with Moose Creek and about 4.2 miles north-northeast of Kohlsaat Peak in section 2, T. 12 N., R. 19 W., of the Seward Meridian. Accurate to within about 0.25 miles.

Commodities:

Main: Ag, Au

Other: Cu, Pb

Ore minerals: Chalcopyrite, galena

Gangue minerals: Calcite, muscovite, quartz

Geologic description:

The Kohlsaat occurrence is defined by quartz carbonate vein and vein breccia with steeply dipping 3-10 foot (1-3 meters) thick vein zone cutting monzodiorite (William Ellis, Alaska Earth Sciences, personal communication, 2014).

The local geology is composed of Jurassic to Early Cretaceous flysch sequence with local composite plutonic complexes intruding the host rock (Wilson and others, 2012).

Alteration:

Quartz carbonate.

Age of mineralization:

Late Cretaceous.

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

Mapping and sampling program executed in 2013 by Alaska Earth Resource, Inc., and Millrock

Resources, Inc.; no drilling has been performed. Over 100 samples were taken and assayed. One grab sample assayed at 4.25 ppm gold and 50 ppm silver (William Ellis, Alaska Earth Sciences, personal communication, 2014).

Production notes:

None.

Reserves:

None.

Additional comments:

Site name(s): West Tanana; Ring Hill-Monday Creek

Site type: Prospect

ARDF no.: TN018

Latitude: 65.2474 **Quadrangle:** TN B-6

Longitude: 152.8676

Location description and accuracy:

The West Tanana prospect covers much of the western half of section 23, the northeast one-quarter of section 22, and the SE1/4 of section 15, T. 5 N., R. 26 W., of the Fairbanks Meridian. The coordinates are at about the center of this prospect which is about 1 mile north-northwest of the junction of Monday and Grant Creek.

Commodities:

Main: Ag, Au, Bi, Te

Other: As, Ba, Cu, Mo, Pb, Pd, Pt, Sb, Zn

Ore minerals: Gold, pyrite

Gangue minerals: Quartz

Geologic description:

The West Tanana prospect is on the southwest flank of Grant Dome in a broad divide that separates Monday and Lynx creeks. The bedrock in the area is black graphitic schist, quartz-muscovite schist, chert, and quartzite (WGM, Inc., 1998). The closest intrusive rock known in the area is the Cretaceous Melozitna pluton, which crops out about 8 miles northwest of the prospect (Chapman and others, 1982). Boulders of a diorite dike are in gravel at the American Creek placer mine, about 2 miles to the northwest (TN015) (WGM, Inc., 1998).

Although placer gold was mined in the early 1900s from nearby Grant Creek (TN071), more recent work has focused on exploring the area for lode deposits. DiMarchi (1991) postulated that concentric rings identified in air photos of Lynx Dome may represent a granitic cupola associated with mineralization. Anomalous values of 1-3 parts per million (ppm) molybdenum in geochemical samples support this possibility. Concentric circular features and intersecting lineaments at Ring Hill also suggest a buried pluton there.

During the 1990 season, 121 soil, 12 rock, and 5 stream-sediment samples were collected by Central Alaska Gold Company (DiMarchi, 1991). The sampling program delineated an area up to 5,000 feet wide of anomalous gold and arsenic values, including 15 samples with gold values between 30 and 910 parts per billion (ppb) and arsenic as high as 1,510 ppm.

Trenches dug by Central Alaska Gold Company in 1991 intersected several gold-bearing shear zones that trend N10E and dip 20W. Samples show high arsenic, barium, iron, strontium and phosphorus values. Platinum and palladium values are also elevated, but silver and base metal values are low.

Ventures Resource Corporation (1997) reported that west of Monday Creek there is a broad area of gold geochemical anomalies, quartz veins, and altered zones of silification, iron oxide and clay. Of 64 samples, 16 contained gold ranging from 50 to 580 ppb. These samples average twice background levels of arsenic and contain weakly anomalous phosphorus.

WGM, Inc., explored the Ring Hill-Monday Creek area in 1997. Their work confirmed that several large, northeast-trending, as well as smaller, northwest-trending, faults cut the prospect area (WGM, Inc., 1998). These faults may be conjugate sets associated with the east-west trending, right-lateral Kaltag fault. The northeasterly structures are traceable for up to 12 miles, and cut across Lynx Creek and Grant Creek.

Silicification appears to have occurred along all of the faults; silicified country rocks up to 1,000 feet from the faults contain up to 5 percent sulfides, mostly pyrite.

In 2006, International Tower Hill Mines, Ltd. (2007, Drilling; 2008, West Tanana) began geochemical soil surveys and mapping in this area under a exploration agreement with Doyon, Ltd. They defined a geochemical anomaly in gold, bismuth, and tellurium, about 1 kilometer in diameter. Samples from old trenches and outcrops contained 5.7 to 17.6 ppm gold, up to 11.8 ppm silver, less than 5 ppm to 1 percent arsenic, less than 2 to 96 ppm bismuth, less than 0.05 to 3.95 ppm tellurium, and minor copper, lead, zinc, and antimony. Drilling in 2007 defined a shallow, east-dipping zone of gold mineralization about 30 meters wide. Notable intercepts include 0.3 meters with 15.6 grams of gold per ton and a 4.3 meter breccia zone with 2.5 grams of gold per ton. The mineralization seems to be associated with a series of north-northeast-trending structures. The prospect is considered to be a stacked Pogo-type vein system.

Alteration:

Silicification and pyritization; iron oxide and clay.

Age of mineralization:

Mineralization may be Cretaceous based on the age of the nearby Melozitna Pluton.

Generic deposit model:

Deposit model:

Pogo-type Au-Bi-Te-quartz veins?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Although placer gold was first mined in the early 1900s from nearby Grant Creek (TN071), more recent work has focused on exploring the area for lode deposits and trenches were dug by Central Alaska Gold Co. in 1991 (DiMarchi, 1991) that intersected several gold-bearing shear zones. In 1996 Dighem Surveys of Toronto Canada flew magnetic and electromagnetic surveys, and Ventures Resource Corporation worked in the area. WGM, Inc. worked in on the prospect in 1997 and carried out a soil geochemical survey over an area of about 2 square miles (WGM, Inc., 1998). In 2006, International Tower Hill Mines, Ltd. (2007, Drilling; 2008, West Tanana) began soil geochemical surveys and surface mapping under a exploration agreement with Doyon, Ltd. Drilling in 2007 defined a shallow, east-dipping zone of gold mineralization about 30 metes wide.

Production notes:

None.

Reserves:

None.

Additional comments:

The prospect lies on land leased or owned by Doyon, Ltd.

Last report date: 2008-03-04

Site name(s): Elephant Mountain

Site type: Prospect

ARDF no.: TN067

Latitude: 65.2742

Quadrangle: TN B-1

Longitude: 150.0279

Location description and accuracy:

The Elephant Mountain lode prospect is at an elevation of about 3,500 feet on Elephant Mountain at the head of Aloha Creek. It is just east of the center of section 9, T. 5 N., R. 12 W., of the Fairbanks Meridian. The site is the location of drilling from 1999 to 2001. The location is accurate within 1000 feet.

Commodities:

Main: Au

Other: As, Bi, Mo, Sb

Ore minerals: Arsenopyrite, bismuth, gold, molybdenite, stibnite

Gangue minerals: Quartz

Geologic description:

Elephant Mountain is underlain by a Cretaceous pluton that intrudes Jurassic or Cretaceous quartzite, sandstone, siltstone, and shale (Chapman and others, 1982; Reifenstuhl and others, 1997). The pluton is one of several 90 Ma alkalic plutons in the eastern Tanana, central Livengood, and western Circle quadrangles. Contacts of the Elephant Mountain pluton indicate that it is a northeast-trending, dike-like body about a mile wide and 5 miles long, cut off by high-angle faults at the northeastern and southwestern ends (Reifenstuhl and others, 1997). Its composition ranges from diorite to granite, but it mostly is trachytoidal, quartz-free syenite and subequigranular quartz syenite. The pluton is zoned, and has a core of altered, equigranular quartz syenite, granite, and granite pegmatite (Reifenstuhl and others, 1997).

Soil sampling completed by Placer Dome, Inc. defined an open-ended linear zone of gold and arsenic geochemical anomalies that extends for over 6,000 feet and is up to 1,500 feet wide. Gold contents in soil samples ranged up to 1,540 parts per billion (ppb) (North Star Exploration, Inc., 2000). The mineralized zone is structurally controlled, with prominent northeast- and northwest-trending, and weaker north-trending, patterns. Soil sampling completed by North Star Exploration, Inc., in 1999 indicated that the anomalous zone continues northeast for at least another 2,000 feet (North Star Exploration, Inc., 2000).

Observations from drill holes indicate that higher gold values are associated with fractured and crushed zones, which often become stockwork in nature (North Star Exploration, Inc., 2000). Visible gold also occurs in drill core. Gold is primarily associated with pervasive silicification and quartz veinlets. Arsenopyrite, molybdenite, and stibnite occur in the silicified zones, and there is a strong gold-arsenic correlation. Gold is associated in some drill holes with bismuth (North Star Exploration, Inc., 2000).

The results from a helicopter-borne magnetic-electromagnetic-radiometric survey show that the Elephant Mountain pluton is a nearly featureless, low-magnetic plateau that has coincident high resistivity. Resistivity data at higher frequencies show lineaments that are inferred by North Star to be the effects of surface weathering of fault and fracture zones in the pluton. Some of the soil geochemical anomalies coincide with these lineaments (North Star Exploration, Inc., 2000).

In 2016, Endurance Gold Corporation drill-tested soil anomalies with greater than 100 ppb gold; three holes were drilled in the South Zone and one hole in the North Zone, for a total of 598 m. The South Zone is associated with 1-kilometer-long by 0.25-kilometer-wide gold-arsenic-antimony soil anomaly. The North Zone is associated with a 1-square-kilometer surface-alteration zone with disseminated pyrite and

arsenopyrite in a pervasively silica, sericite, clay altered granodiorite and a gold-arsenic soil anomaly. Endurance Gold Corporation’s follow-up plans for 2017 include ground-based geophysical surveys, geochemical sampling, and drilling (Athey and Werdon, 2017).

Alteration:

Pervasive silicification (North Star Exploration, Inc., 2000).

Age of mineralization:

Cretaceous, assumed to be contemporaneous with the 89 +/- 1 Ma age of the Elephant Mountain pluton (Reifenstuhl and others, 1997).

Generic deposit model:

Deposit model:

Alaskan plutonic-related gold deposit (McCoy and others, 1997).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Placer Dome, Inc. discovered visible gold in an outcrop of altered granite on Elephant Mountain in 1991 (North Star Exploration, Inc., 2000). Their soil sampling defined an open-ended linear zone of gold and arsenic geochemical anomalies that extends for over 6,000 feet and is up to 1,500 feet wide. Gold contents in soil samples ranged up to 1,540 parts per billion (ppb) (North Star Exploration, Inc., 2000). Soil sampling by North Star Exploration, Inc. in 1999 indicated that the anomalous zone continues northeast for at least another 2,000 feet (North Star Exploration, Inc., 2000).

Placer Dome, Inc. conducted ground geophysical surveys over portions of Elephant Mountain after a gold-sulfide association was identified while logging drill core (North Star Exploration, Inc., 2000). Their geophysical surveys included magnetics, very low frequency (VLF) gradient induced polarization (IP), resistivity, and limited dipole-dipole IP. A large chargeable zone (1,500 feet wide and 4,500 feet long) was detected between the drilled areas, which Placer Dome, Inc.'s geophysicists attributed to a large volume of material containing a relatively low concentration of sulfides with a small increase in sulfide content at depth.

In 1992, Placer Dome, Inc. dug 6,000 feet of trenches and diamond drilled 10 diamond core holes totaling 4,000 feet (Swainbank and others, 1993). The drill logs indicate that higher gold values are associated with fractured and crushed zones, which often become stockwork in nature (North Star Exploration, Inc., 2000).

Visible gold also occurs in the drill core. Gold is primarily associated with pervasive silicification and quartz veinlets. Arsenopyrite, molybdenite, and stibnite occur in the silicified zones, and there is a strong gold-arsenic correlation. Gold is associated in some drill holes with bismuth (North Star Exploration, Inc., 2000). Placer Dome, Inc.'s best hole was DDH-2, grading an average of 0.015 ounce per ton (oz/t) gold over 326 feet that bottomed in mineralization. Other drill results include 334 feet grading 0.010 oz/t gold in hole DDH-8, 340 feet grading 0.008 oz/t gold in hole DDH-1, and 225 feet grading 0.005 oz/t gold in hole DDH-4 (North Star Exploration, Inc., 2000). The highest drill core sample contained 1,740 ppb gold and several thousand parts per million (ppm) arsenic (Harry Noyes, oral communication, 1996).

A rock sample of altered granite (sample number 96RN185) collected in 1996 by the Alaska Division of Geological and Geophysical Surveys contained 164 ppb gold, 2211 ppm arsenic, and 61 ppm antimony (Liss and others, 1997). Aeromagnetic surveys of the area completed by the Alaska Division of Geological and Geophysical Surveys indicate that the plutonic rocks have fairly low magnetic signatures, whereas the surrounding rocks are more variable (Staff and others, 1997).

North Star Exploration, Inc. conducted a helicopter-borne, magnetic-electromagnetic-radiometric survey

over Elephant Mountain (North Star Exploration, Inc., 2000). The results show that the Elephant Mountain pluton is a nearly featureless, low-magnetic plateau that has coincident high resistivity. Resistivity data at higher frequencies show lineaments that are inferred by North Star Exploration, Inc. to be the effects of surface weathering of fault and fracture zones in the pluton. Some of the soil geochemical anomalies coincide with these lineaments. In 2000, North Star Exploration, Inc. drilled two core holes totaling 631 feet at Elephant Mountain and encountered arsenopyrite with geochemically anomalous gold in silicified granite (North Star Exploration, Inc., 2001; Szumigala and others, 2001).

A 2007 prospecting and sampling program resulted in the discovery of gold values in grab samples of quartz vein material from the intrusive including 12.98 grams per tonne (g/t), 5.21 g/t, 3.02 g/t, 2.59 g/t and 2.18 g/t gold. These high gold values were collected where Placer Dome, Inc. collected a grab sample in 1991 that assayed 12 oz/t gold (411.4 g/t gold). This quartz vein is approximately one kilometer south of the best Placer Dome, Inc. drill hole and is defined by a greater than 100 ppb gold-in-soil anomaly within a 150 by 800 meter area (Endurance Gold Corporation, 2015b).

In 2013 Endurance Gold Corporation completed a reconnaissance prospecting rock and soil sampling program collecting 61 rock grab samples with the best gold values associated with altered intrusive and quartz vein stock-work material including 4,440 ppb gold, as well as 1920 ppb, and 1880 ppb gold (Endurance Gold Corporation, 2014). In 2014 Endurance Gold Corporation completed an orientation survey of 36 power-assisted auger soil samples at recovery depths of between 0.81 and 1.52 meters. These deep soil samples, with peak values up to 320 ppb gold at 1.52 meters (5 feet) depth, together with shallower soil samples collected in 2013, have confirmed a strong and continuous 600 meter long soil anomaly which exceeds 100 ppb gold (Endurance Gold Corporation, 2015a).

In 2016, Endurance Gold Corporation drill-tested soil anomalies with greater than 100 ppb gold; three holes were drilled in the South Zone and one hole in the North Zone, for a total of 598 m. Highlights of South Zone drilling include 4.09 grams of gold per tonne over 4.6 m, including 20.4 grams of gold per tonne over 0.67 meter spatially associated with 1-kilometer-long by 0.25-kilometer-wide gold-arsenic-antimony soil anomaly. Highlights of North Zone drilling include 0.40 gram of gold per tonne over 147.1 m, including 0.63 gram of gold per tonne over 48.2 meters spatially associated with a 1-square-kilometer surface-alteration zone with disseminated pyrite and arsenopyrite in a pervasively silica, sericite, clay altered granodiorite and a gold-arsenic soil anomaly. Endurance Gold Corporation’s follow-up plans for 2017 include ground-based geophysical surveys, geochemical sampling, and drilling (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (near Kilo Hot Spring)

Site type: Occurrence

ARDF no.: TN140

Latitude: 65.8511 **Quadrangle:** TN D-3

Longitude: 151.2172

Location description and accuracy:

This placer occurrence is about 3 miles downstream from the Kilo Hot Spring on the Kanula Kilolitna River. It is near the center of section 24, T. 12 N., R. 18 W.

Commodities:

Main: Au, Sn

Other: W

Ore minerals: Cassiterite, gold

Gangue minerals:

Geologic description:

Upstream from this site, the Kanuti Kilolitna River cuts through the Ray Mountains batholith, a Cretaceous, coarse-grained, porphyritic, biotite quartz monzonite pluton. The contact of the quartz monzonite with chlorite-quartz schist and biotite gneiss is exposed near the site.

Panned concentrate samples collected from bars on the river contained flour gold (Kurtak and others, 2002) . One panned concentrate sample assayed 6,976 parts per billion (ppb) gold, 506 parts per million (ppm) tungsten, and 90 ppm tin. Several other samples collected upstream contained 504 to 3,289 ppm tin, 310 ppm tungsten, and small amounts of gold. The source of the tin and gold was not located and none of the rock samples contained anomalous metals.

In addition to the work by the Bureau of Land Management (Kurtak and others, 2002), claims were staked on this site in 1959 and 1960, but no production is documented.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Tin placer (Cox and Singer, 1986; model 39e).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39e

Production Status: None

Site Status: Undetermined

Workings/exploration:

Only a limited amount of work by the Bureau of Land Management in about 2000 to asses the mineral potential of the area.

Production notes:

None.

Reserves:

None.

Longitude: 150.5712

Location description and accuracy:

This site represents an approximately 30-mile-long area of placer tin-REE on the Ray River drainage basin. The prospect area is accessible from the Dalton Highway only on the extreme eastern extent, or otherwise requires helicopter or winter trail access. This placer prospect is on and follows much of the Ray River and several tributaries and numerous terraces (Barker, 1991a,b). For this record, the site is at the confluence of an unnamed tributary from the north located at the east edge of NW¼NW¼ Section 5, T. 13 N., R. 14 W., of the Fairbanks Meridian. The site is about mid-way across the area of the prospect and accurate to less than 1,000 feet.

Commodities:

Main: Sn

Other: Au, Nb, REE, Ti, W, Zr

Ore minerals: Cassiterite, gold, ilmenite, monazite, wolframite, xenotime, zircon

Gangue minerals:

Geologic description:

The Ray River drainage is underlain at the headwaters by the Sithylemenkat pluton and flows eastward approximately 30 miles, dissecting the Ray River pluton and ultimately encountering the Ft. Hamlin Hills pluton on the east where it is forced by topography to flow south to join the Yukon River. Placer tin and REE occur along the entire length of the river within the Tanana Quadrangle. The granitic rocks are all considered part of the broad northeast-trending peraluminous Ruby Batholith of central Alaska (Chapman and others, 1982; Barker and Foley, 1986: Herreid, 1969). Generally the granitic rocks are coarse-grained equigranular to porphyritic K-spar-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been recognized locally. The granitic rocks cut Paleozoic schist, phyllite, quartzite, and lesser greenstone and limestone. The granitic plutons, especially the Sithylemenkat pluton, feature alteration zones including chloritic greisen veins/bodies that are the apparent source of at least some of the detrital cassiterite and REE minerals. Minor placer gold is also consistently present in heavy mineral samples and though minor commodity it would constitute an additional value.

The Ruby batholith region is within the glacial ice-free Quaternary province of Beringia, defined as the non-glaciated intermontane region extending from eastern Siberia and eastward across a then-dry Bering Sea-floor, thence transecting interior Alaska, and extending into northwestern Canada. Across the Beringia region, the fluvial processes have generally continued since the Tertiary and consequently the region is historically known for the Pleistocene mammals that survived there, as well as a multitude of placer gold camps; districts such as the Klondike and Fairbanks. In the Ruby batholith region, the on-going erosional and mineral concentration processes that can concentrate valuable heavy minerals, have apparently remained un-interrupted since the late Tertiary.

The heavy mineral concentration processes are further enhanced by multiple-stages of fluvial activity within the principal drainages that have subsequently reworked sediments in each drainage basin. Each episode of channel down-cutting leads to yet another phase of re-deposition at continually lower elevations;

the process continues locally to rework the alluvial sheet deposits at several documented locations on the Ray River (Barker, 1991b). Each repeated down-cutting event removes and transport more of the lighter aggregate downstream, thus potentially up-grading the residual heavy mineral concentrations left behind. This is best exemplified along the middle and upper Ray River. Strikingly evident, the middle Ray River alluvium-filled basin is beginning yet another episode of down-cutting due to recent breaching of barrier highland topography by the Ray River in Section 1 and 2, T. 13 N., R. 14 W. Further downstream the basin-filling of a graben-type feature(s) continues and forms at least two, lower Ray River basins (Barker, 1991b).

Remnant terraces are evidence of ancient (late Tertiary?) alluvial gravel deposition that predictably contain REE and tin in heavy mineral fractions are now perched as high as 150m (500 ft) above present-day channels of the lower Ray River. Along the northern and western Fort Hamlin Hills the tin- and REE-bearing terrace deposits have been developed for construction aggregate for the Trans-Alaska Pipeline. Predictably the grade of contained tin and REE in the high terrace deposits is lower than the re-worked and re-concentrated active basin sediments.

Alteration:

Thermal alteration from the batholith is widespread. Locally extensive, tourmalization, potassic, carbonate, and argillic styles of advanced alteration can be mapped and generally are associated with regional-scale northeast trending faults. Such zones of altered and weakened rock give rise to locally intense large-scale disintegration of the bedrock granite which has released the contained heavy minerals. Source of the placer tin- and REE- minerals appears to be local areas of argillic alteration and greisen vein-like occurrences that are particularly evident in the better exposed Sithylemenkat; a few typically dark green colored greisen fragments can generally be found in creek float at any location throughout the region (Barker and Foley, 1986). Greisen samples will generally contain 100 ppm to as much as 2500 ppm Sn and contain elevated REE. Cassiterite has also been found associated with quartz veins at a few locations. The older fluvial deposits also exhibit a degree of residual (in-place) concentration that are characterized by feldspar grains altered variably to white clayey quartz-rich sediment that are seen to grade upward into unaltered cross-bedded fluvial gravel.

Age of mineralization:

In the Ruby batholith region, the on-going erosional and mineral concentration processes that can concentrate valuable heavy minerals, have apparently remained un-interrupted since the late Tertiary (Barker, 1991b).

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Sn (Cox and Singer, 1986; model 39e).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39e

Production Status: None

Site Status: Active

Workings/exploration:

The Ray River has been explored by the U.S. Bureau of Mines as part of the Critical and Strategic Minerals Program in the 1970s-1980s (Barker, 1983, 1991a, 1991b; Barker and Foley, 1986). Gravel samples have been collected and processed from 37 locations along the Ray River and from a series of 7 auger drill holes randomly located on river gravel bars of the Ray River. All samples were processed by gravity methods for the analysis of the heavy mineral content (Barker, 1991a).

Ucore Rare Metals, Inc., through their Alaska subsidiary Landmark Alaska, acquired the property in 2011 and in 2012 announced additional sample results for 98 samples which included Ray River drainage, No Name Creek, and some sites along the Kilolitna and its tributaries (Ucore Rare Metals Inc., 2012). Follow

link to Excel data table.
Auger drill holes demonstrated higher heavy mineral values are encountered beginning about 5 to 7 ft. below the surface where gravel is more permanently clayey sand-bound as compared to the seasonally active gravel exposed in gravel bars near or at the surface. Holes were drilled to 15 to 21 ft deep. The sand fraction from a single hole in west-central area of the basin (Section 4), T. 13 N., R. 15 W., contained 897g/m3 REE+Sn while a second hole central in the basin in Section 6, T. 14 N., R. 14 W., reported 2,174g/m3 REE+Sn in the sand fraction. Surface samples from both a mile above and a mile below this location were mostly above the threshold value of 150g/m3 REE+Sn. Three auger drill holes on the east of and several miles beyond the upper basin reported similar threshold values (Barker, 1991a, Ucore, 2012).

Production notes:

None.

Reserves:

A 'very preliminary' resource estimate of the tin resource was made by the U.S. Bureau of Mines 'for the purpose of land-use management and planning purposes' consisting of between 62- to as much as -172 million pounds-tin in 300 million cubic yards of gravel (Barker, 1991). Grade is estimated between 0.2 and 0.5 pounds-tin per cubic yard; higher grade values are mostly from No Name Creek, the northern fork of the Ray River (see ARDF number BT021). No estimate was made for the REE, gold, or other possible placer minerals.

Additional comments:

The Ray River flows through lands on which the State of Alaska has filed ‘Priority Selection’ requests under the land entitlement provision of the 1959 Statehood Act. To date only a very small portion of the drainage (T. 13 N., R. 13 W.) has been transferred as ‘Tentatively Approved’ to the State from the federal government, Bureau of Land Management (BLM). The BLM will not issue any permits for surface disturbance activities including exploration under State Selection status.
Splits of most samples collected by the U.S. Bureau of Mines and referenced in this report have been archived at the Alaska Geologic Materials Center, Anchorage, Alaska and are available for review.

ARDF no.: TN142

Latitude: 65.9526 **Quadrangle:** TN D-3

Longitude: 151.204

Location description and accuracy:

This record represents occurrences of anomalous heavy minerals in samples from the Kilolitna River basin and several unnamed tributaries (Barker, 1983, 1991a, 2012; Barker and Foley, 1986; Ucore, Incorporated, 2012, 2014; Freeman, et al., 2014). For this record, the site is a gravel bar where two bulk samples of surface river bar gravel were collected in 2014 by Ucore subsidiary Landmark Alaska, LLP. The site location is accurate within 500 feet and is located in T. 13 N., R. 17 W., section 17 NW¼SW¼, Fairbanks Meridian. The general subject area of this report is a distinct lowland about 3 to 5 miles wide and up to 10 miles north-south on the north side of the Ray Mountains. The site, as described extends into the adjacent Bettles quadrangle.

Commodities:

Main: Sn

Other: Nb, REE, Ta, Ti, W, Zr

Gangue minerals:

Geologic description:

The Kilolitna River basin is a prominent, north trending and gently north-sloping basin feature about 10 miles long and up to 5 miles wide. The basin developed at the margin of the northern foothills of the Ray Mountains, and has been in-filled by sedimentation off the Ray Mountains pluton. Granitic rocks border the basin on the south, east, and north. The Kilolitna River basin lies between the Sithylemenkat pluton to the north-northeast and the Ray Mountains pluton to the south. The granitic rocks are all considered part of the broad northeast-trending peraluminous Ruby Batholith of central Alaska (Chapman and others, 1982; Barker and Foley, 1986; Herreid, 1969; Patton and Miller, 1970, 1973; Tuzzolino and others, 2013). Generally the granitic rocks are coarse-grained, equigranular to porphyritic orthoclase-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been recognized locally. The granitic rocks cut Paleozoic schist, phyllite, quartzite, and lesser greenstone and limestone. The granitic plutons, especially the Sithylemenkat pluton, are multi-phased intrusions with trace element signatures comparable to tin-rare earth element granites elsewhere (Patton and Miller, 1973; Barker and Foley, 1986). Placer gold is not present in heavy mineral samples as it is in the Ray River alluvium to the east suggesting the gold-bearing source rocks are farther east (Barker, 1991a) of the Kilolitna drainage.

Schist and quartzite, generally silicified due to the regional plutonic intrusions, outcrop and abut the basin on the west. Satellite imagery indicates the river has progressively occupied and later successively abandoned a series of northeast-flowing channels beginning on the west and progressing to the east across the basin. The present Kilolitna River occupies the eastern-most channel along the east margin of the basin. Regional tilting due to the Porcupine-Kaltag fault system is suspected to be the cause. Consequently there is little evidence of basin downcutting; however, the present river is reworking the flood plains created by the earlier river channels along the east of the basin (T. 13 N., R. 17 W., sections 17-21, 27-33). This area

appears to be associated with the better heavy mineral concentrations, ranging from 100 up to 333 grams per cubic meter (rare earth elements plus tin), (Ucore Rare Metals Inc., 2012). The area of higher grade rare earth elements plus tin is also in agreement with heavy mineral sample results reported by Freeman and others, 2014, in a sampling campaign by the Alaska Division of Geological and Geophysical Surveys [ADGGS] (Bachmann, and others, 2013). Depth of the unconsolidated sediments in the basin is unknown and both the river gravel bed and the cut banks are particularly poorly consolidated and mostly covered by transient silt and vegetation.

In 2011 to 2013, ADGGS collected rock, stream sediment, as well as heavy mineral concentrates from the Kilolitna Basin area and reported numerous samples were anomalous for rare earth elements, tin and tungsten in rock and stream sediments. The work was part of a mineral resource evaluation of rare metals on State lands and land selections (Bachmann, et. al., 2013).

Alteration:

Thermal alteration from the Ruby Batholith is widespread. Locally extensive, tourmalization, potassic, carbonate, and argillic styles of advanced alteration can be mapped and generally are associated with regional-scale northeast trending faults. Such zones of altered and weakened rock give rise to locally intense large-scale disintegration of the bedrock granite, which has released the contained interstitial heavy minerals. Local sources of the placer tin and rare earth element minerals also include areas of argillic alteration, and chloritic greisen vein-like occurrences apparently from source areas in the Ray Mountains pluton to the south and east. Such alteration is also particularly evident in the better exposed Sithylemenkat pluton to the north (Barker and Foley, 1986). Greisen samples will generally contain 100 to as much as 2500 ppm tin and contain elevated rare earth elements. Cassiterite has also been found associated with quartz veins at a few locations, for example, the high ridge to the east of the Kilolitna basin (Bachmann, et. al., 2013).

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Alluvial tin placer (Cox and Singer, 1986; model 39e).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Sample results from field investigations in the 1970s (Barker, 1983); in the 1980s (Barker and Foley, 1986); Ucore, (Ucore Rare Metals Inc., 2012; 2014); and 2014, by ADGGS (Bachmann, et. al., 2013) indicate potential economic-grade alluvial concentrations of rare earth elements and tin in the upper Kilolitna River basin. Sampling of the large area remains relatively sparse; however, as many areas are covered by soil and vegetation. Surface exposures of alluvial gravel and sand containing a threshold value of about 0.15 kilograms per cubic meter (0.25 pounds per cubic yard) of combined rare earth elements and/or tin are found along the present channel of the river. Mineral concentrates also contain by-product concentrations of tungsten, zirconium, niobium, and tantalum. Samples containing near or exceeding this threshold value are mostly concentrated in the east and southeast of the Kilolitna basin where the lower segments of older channels of the Kilolitna are being reworked by the modern river channel. Sample details for 15 heavy mineral sample sites by Landmark Alaska, LLP, including original volumes, the recovered weight of heavy mineral, rare metal analyses, and the calculated grams of total rare earth elements and tin per cubic meter can be accessed at http://ucore.com/projects/ray-mountains-alaska. Details for 10 heavy

mineral sites by ADGGS are in Bachmann and others, 2013, and data for 12 Kilolitna basin area samples by USBM are in Barker, 1983. All samples after 2010 were analyzed by ALS Minerals, Incorporated, in Vancouver, British Columbia, using lithium metaborate fusion followed by ICP-MS analyses.

Most samples were one standard gold pan in volume. Samples by Landmark Alaska, Ltd., consisted of one or more 5-gallon buckets (0.0133 cubic meter per 5-gallon bucket) of material that was later concentrated on a standard shaking table or processed by hand panning. Either procedure achieves an estimated 75 to 85 percent recovery of the heavy mineral suite, including rare earth element-bearing minerals such as monazite and xenotime, thus demonstrates amenability to physical separation in a full scale mine plant. This simple gravity separation method uses only water as the separation medium. Furthermore, extraction technology for rare earth elements from a monazite-xenotime matrix and tin from cassiterite in concentrates is well known and does not present new metallurgical challenges. Cassiterite, monazite, xenotime, wolframite (ferberite end-member), scheelite, ilmenite, and zircon have been identified in heavy mineral concentrates. A few grains of yttroflourite were reported by Barker and Foley, 1986. The total rare earth element composition includes 15 to 20 percent heavy rare earth elements gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, and yttrium in the majority of samples.

Production notes:

None.

Reserves:

None.

Additional comments:

The land in the Kilolitna Basin is held by the U.S. Bureau of Land Management. The State of Alaska has selected the area under provisions of the 1959 Statehood Act and nominated it as a priority selection. Ucore, through its local subsidiary Landmark Alaska, LLP, has located State mining claims according to the provisions provided by Alaska for locating claims on State Selected land. No surface disturbance activities, including ground-transported drilling equipment, can be permitted until Alaska receives tentative approval of the land transfer from the BLM. Ucore's subsidiary (Landmark Alaska, LLP) is planning expanded exploration once title transfer is tentatively approved by the federal government.

Site name(s): Ray River Metalliferous Coal

Site type: Occurrence

ARDF no.: TN143

Latitude: 65.9843 **Quadrangle:** TN D-2

Longitude: 150.589

Location description and accuracy:

The site location is along the Ray River located immediately downstream of a prominent unnamed hot spring. The occurrence is in a topographic basin of the mid- to upper Ray River valley. Accuracy of the site and sample locations presented here is about 1,500 feet. The site location is in the SW¼, NE ¼ Section 6, T. 13 N., R. 14 W., of the Fairbanks Meridian. Similar mineral occurrence locations are reported approximately 10 miles farther downstream of this site and are described in the Bettles quadrangle ARDF site records.

Commodities:

Main: Ge, Pb, W

Other: Ag, Au, Cu, Ga, Mo, REE, Sb, U, Zr

Ore minerals:

Gangue minerals: Coal, coal ash

Geologic description:

This site is similar to other metalliferous coal sites farther down river that also occur in small, semi-closed basins along the Ray River immediately west of the Fort Hamlin Hills pluton (Barker, 2006). Both plutons are considered part of the broad northeast-trending peraluminous Ruby Batholith of central Alaska (Patton and Miller, 1973; Barker and Foley, 1986). Generally the granitic rocks are coarse-grained, equigranular to porphyritic, orthoclase-biotite-quartz monzonite varying to granite with subordinate phases of aplite, biotite aplite, tourmaline aplite, and fine-grained quartz monzonite. Tourmaline pegmatite phases have been locally recognized. The granitic rocks cut Paleozoic schist, phyllite, quartzite, and lesser greenstone and limestone. The Ray River coal-bearing basins are part of a regional series of Tertiary basins that occur intermittently along the southeast margin of the Ruby Batholith.

Along the Ray River these small, semi-closed basins are mapped as graben features, and range from several square miles in area to as little as 200 acres (Barker, 1991b, 2006). Metals are found highly concentrated in the calcium-rich coal ash derived from the coal. When prepared according to American Society for Testing Materials (ASTM, 1979) standards, ash samples will generally contain 0.01 to in excess of 1.0 percent each of germanium, lead, and tungsten. Ash samples also contain up to 0.5 percent total rare earth elements, and up to 0.1 percent antimony, copper, gallium, molybdenum, uranium, and zirconium. Gold and silver values are also present. All samples are variably mineralized within these limits (Barker, 2006).

The coal beds occur in soft sedimentary rock that is rarely found exposed; exposed coal beds are subject to destruction by forest fires. Sampling has relied on the fact that during high water events the Ray River will rip coal fragments from the coal beds within the mudstone and conglomerate section that comprise the bedrock under the river bed gravel in this region. Following high water events, random chips of fresh coal may be found on gravel bars, where they eventually oxidize and destruct.

Alteration:

Metal values in the coal at this site appears related to a 65-mile-long, northeast-trending series of

geothermal springs that likely altered and mineralized the organic material during and/or after the coal-forming period, possibly accentuated by overlying fissure basalt flows. An unnamed hot spring occurs about 200 meters upstream of the site, warm springs were found a few miles down river. Known geothermal springs extend about N 60 E from Ishtalitna Creek on the southwest to the Dall River on the northeast and are assumed to correlate to a splay of the Porcupine-Kaltag fault.

Age of mineralization:

A sample of tephra from the Coal Creek-Dall River section (about 30 miles to the northeast of this site) described above was dated at 38.6±1.6 Ma (Barker, 1981). Albanese, 1987, reported an age of 30.59±0.92 Ma for the basalt flows at a location nearer the Dalton Highway and immediately east of the Ray River. Coal mapped nearby is overlain by the basalt flows and therefore judged to be Eocene in age.

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

The site was explored by the U.S. Bureau of Mines as part of the Critical and Strategic Minerals Program in the 1970s-1980s (Barker, 1981, 1991b, 2006; Barker and Foley, 1986). Coal from this site was sampled, ash was prepared and analyzed as part of a group of metalliferous coal occurrences found at locations farther down river in the Bettles Quadrangle. Coal ash from this site contained 0.082 percent Ga, 1.22 percent Ge, 0.309 percent U, and 0.23 percent W. Ash constituted 14.68 percent of the coal.

All coal rank analyses and preparation of coal ash samples were done by the University of Alaska, Mineral Industry Research Laboratory. Metal values were determined by commercial laboratories.

Coal in the Ray River-Fort Hamlin Hills area, when fresh, will break with a conchoidal fracture and will have an apparent rank of high-volatile, lignite A to subbituminous B, generally with a 6-10 weight percent ash yield. Maceral composition is dominated by vitrinite. Ray River coal consistently contains higher sulfur (>1.4 percent) as compared to non-mineralized low-sulfur coal in the Dall River valley to the northeast and most other coal in central Alaska, an apparent affiliation of the Ray River coal and elevated metal content. The stratigraphic relationship of mudstone overlying coal beds in the Ray River occurrence is similar to the Dall River occurrence, but at the Dall site coal does not contain the elevated metal values, though the mudstone beds do (see ARDF number BV005) (Barker, 1981, 2006).

Microprobe studies suggest the finely disseminated mineralization found in coal of the Ray River valley mostly occurred in peat bogs prior to, or concurrent with, diagenesis and coal formation (Barker, 2006). Mineralization is likely related to geothermal activity associated with rifting in a granitic terrane and volcanism. Water samples from six of the seven known nearby hot springs/warm springs, including the spring immediately upstream of this site, were tested and determined to contain anomalous levels of tungsten. Mineralization processes affecting the original peat accumulations, or within coal beds, and were likely accentuated due to Oligocene fissure basalts that entrapped the geothermal waters in the coal-forming section. The mudstones in the Dall River-Coal Creek area contain elevated tungsten assumed concentrated during formation of lacustrine deposits in shallow lakes fed by the similar geothermal water and intermittently covered by ash falls (Barker, 1981, 2006).

None.

Additional comments:

The Ray River coal occurrences are on lands on which the State of Alaska has filed ‘Priority Selection’ under the land entitlement provision of the 1959 Statehood Act. Various temporary land withdrawals remain to be lifted by the Bureau of Land Management (BLM) before these selections can be processed. The BLM will not issue any permits for surface disturbance activities including exploration until then.

Site name(s): St. Eugene

Site type: Prospect

ARDF no.: TY016

Latitude: 61.7092 **Quadrangle:** TY C-7

Longitude: 152.5571

Location description and accuracy:

The center of the St. Eugene prospect is about 9.8 miles north-northwest of Mount Gerdine in the Tordrillo Mountains. It is about 1.1 mile north-northeast of peak 8545, near the center of section 28, T. 19 N., R. 18 W.

Commodities:

Main: Au, Cu, Mo

Other:

Ore minerals: Azurite, chalcopyrite, chrysocolla, malachite, molybdenite, pyrite, pyrrhotite

Gangue minerals: Carbonate, quartz

Geologic description:

Lode claims were staked at this prospect in the 1970s but no information is available on that work (MacKevett and Holloway, 1977). There was no other work until 2009, when Millrock Resources Inc. restaked the property (Eden, 2010). In 2009 and 2010, Millrock did a geochemical survey over the area and collected numerous rock samples. In 2010 Brixton Metals Corp. optioned the property (Brixton Metals Corp., 2010). Their exploration is in the early stages.

The mineralization at the St. Eugene prospect covers an area about 5.3 by 6.5 kilometers (Eden, 2010). Three separate zones of mineralization have been found in hornfels adjacent to a Tertiary diorite intrusion. The largest extends about 700 meters along strike. Rock samples contained up to 1 percent copper and 2.1 grams of gold per tonne; quartz-carbonate veins are common. Chalcopyrite, molybdenite, pyrite, and pyrrhotite have been identified in the mineralized area. The rocks locally show strong silicification, quartz stockworks with quartz-sericite alteration, and chlorite-epidote alteration. The area is prominently stained with azurite, malachite, chrysocolla, hematite, jarosite after pyrite, and limonite. The areas of greatest interest are marked with deep red hematite staining. Eden (2010) suggests that the mineralization may represent a copper-gold-molybdenum porphyry system.

Alteration:

The rocks locally show strong silicification, quartz stockworks with quartz-sericite alteration, and chlorite-epidote alteration. The area is prominently stained with azurite, malachite, chrysocolla, hematite, jarosite after pyrite, and limonite.

Age of mineralization:

Probably related to an adjacent Tertiary diorite intrusion.

ARDF no.: TY018

Latitude: 61.7748 **Quadrangle:** TY D-8

Longitude: 152.7594

Location description and accuracy:

The center of the Island Mountain prospect is about 3.2 miles south-southwest of the mouth of Emerald Creek on the Skwentna River. It is about 0.5 mile west of the center of section 33, T. 20 N., R. 19 W., of the Seward Meridian. The prospect occupies much of the prominent mountain between Emerald Creek and the Skwentna River. The location is accurate to within 500 feet.

Commodities:

Main: Au, Cu, Mo, Zn

Other: Ag, As, Fe

Ore minerals: Arsenopyrite, chalcopyrite, gold, magnetite, molybdenite, pyrite, pyrrhotite, sphalerite

Gangue minerals: Quartz

Geologic description:

The rocks in the area are Jurassic and Cretaceous sediments of the Kahlitna terrane that are intruded by a small body of Cretaceous or Tertiary granite and quartz monzonite (Reed and Elliott, 1970; Wilson and others, 2009). As studied by Cominco American (unpublished reports, 1987 and 1988), the Island Mountain deposit consists of pyrite-chalcopyrite-quartz veins; disseminated pyrite and chalcopyrite; and arsenopyrite-gold and stockwork quartz veins with magnetite and trace molybdenite. The mineralization is in fine- to medium- grained plagioclase-hornblende porphyritic andesite and medium-grained monzonite that are probably related to the mineralization. Carbonate-rich beds in the sedimentary country rocks are locally replaced with pyrrhotite, pyrite, and sphalerite.

As mapped by Kiska Metals (2010b), the Island Mountain prospect covers an area about 3 by 4 kilometers in size. Monzonite porphyry, diorite, and monzonite intrude argillite and hornfels at the prospect. Kiska Metals drilled two holes in 2006 and two holes in 2009. The first hole in 2009 targeted a hydrothermal breccia zone 150 meters in diameter. Surface samples from the breccia zone contained actinolite, magnetite, pyrrhotite, pyrite, and chalcopyrite, and assayed up to 1.19 gram of gold per tonne, 5.2 grams of silver per tonne, and 0.2 percent copper. The hole intersected two zones of gold mineralization. A 150-meter intercept averaged 0.72 gram of gold per tonne; a 106.9 intercept averaged 1.22 grams of gold per tonne. The hole was almost entirely in diorite. The second hole averaged 0.13 gram of gold per tonne over 202.3 meters. Kiska Metals considers the deposit to be a gold-copper porphyry similar to the Whistler deposit (TY022) to the north.

The Island Mountain area has extensive gold-copper soil geochemical anomalies and significant porphyry-related mineralization, alteration and brecciation. Porphyry centers, as defined by central zones of potassic alteration associated with gold-copper mineralization and airborne magnetic high anomalies have been confirmed at four zones: the Breccia Zone, Cirque Zone, Howell Zone and Gilligan Zone. In addition, the Super Conductor is a 1 kilometer by 1.8 kilometers area defined by a strong airborne EM conductor associated with disseminated pyrrhotite and local gold mineralization (Roberts, 2014).

Roberts (2014) describes mineralization as gold-copper porphyry mineralization typical of the 'reduced'-type porphyry systems where pyrrhotite is a dominant sulfide (e.g. Catface deposit, BC). Gold-copper porphyry mineralization has been intersected in drilling at two separate centers at Island Mountain (Breccia

Zone and Cirque Zone). In contrast to the Whistler porphyry systems, which are 22 kilometers south, Island Mountain has significantly different alteration, veining, brecciation and sulfide assemblages associated with mineralization, principally the occurrence of pyrrhotite associated with gold-copper mineralization, core zones of mineralization hosted by magmatic-hydrothermal breccias, strong sodic-calcic alteration, lack of significant sulfates, very minor hydrothermal quartz and weak to insignificant phyllic alteration. For these reasons, the porphyry systems at Island Mountain may belong to the 'reduced' subclass of porphyry copper-gold deposits. In addition to these known occurrences, there are multiple zones with similar features (e.g. Howell Zone, Super Conductor). At the southern end of the Breccia Zone, the Discovery Breccia is comprised of intermingled intrusive and hydrothermal matrix breccias dominated by sodic-calcic alteration. This breccia complex records early pervasive biotite alteration, local k-feldspar alteration with disseminated followed by strong actinolite-albite alteration. Assays returned several significant intercepts of predominantly gold mineralization including a deep, strongly silicic/possibly potassic zone containing massive pyrite-dominant sulfide veins (IM11-030), a style not seen previously at Island Mountain (Roberts, 2014).

One target outside of the Breccia Zone at Island Mountain is the Howell Zone, which occurs 2 kilometers to the northeast. The Howell Zone is defined by very strong gold, copper, and molybdenum soil anomalies over significant widths. In addition, a 2011 airborne electro-magnetic (EM) survey identified a significant 1800 meters by 1000 meters conductor to the east of the Breccia Zone, which is largely hidden by colluvial and alluvial cover. This EM anomaly is interpreted to potentially represent a large zone of disseminated or net-textured pyrrhotite, which may be similar to the pyrrhotite-gold zone located east of the Discovery Breccia (Roberts, 2014).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

The Island Mountain area was discovered by Cominco Alaska, who worked in the area from 1986 to 1989

(Wahl and others, 2008). Kennecott Exploration Company was active in the area from 2004 to 2006 and staked a large block of claims that covered the Island Mountain prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott in 2007 and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation. In early 2010, Kiska Metals (2010a) was exploring their claim blocks as the Whistler project and they drilled the Island Mountain prospect in 2009.

Historic exploration included silt sampling, mapping, rock and contour soil sampling, soil grid geochemical surveys, magnetic and VLF geophysical surveys and diamond drilling by Cominco America in the mid-1980s. Similar work continued to 2009 by Kennecott and Kiska Metals. Kiska Metals drilled two holes in 2006 and 2 holes in 2009 (Kiska Metals Corporation, 2009).

During the 2009 to 2010 field seasons, Kiska completed 8,660 meters of diamond drilling in 23 drill holes, 224 line-kilometers of 3D induced polarization (IP) geophysics, 40 line-kilometers of 2D IP geophysics, geological mapping, geochemical sampling and metallurgical testing of mineralization from the Breccia Zone at Island Mountain (Roberts, 2014).

Kiska continued to drill and explore Island Mountain for the duration of the 2010 and 2011 field seasons, including step-out drilling at the Island Mountain Breccia Zone, an airborne EM survey of the Island Mountain area (Roberts, 2014).

The Island Mountain area has extensive gold-copper soil geochemical anomalies and significant porphyry-related mineralization, alteration and brecciation. Porphyry centers, as defined by central zones of potassic alteration associated with gold-copper mineralization and airborne magnetic high anomalies have been confirmed at four zones: the Breccia Zone, Cirque Zone, Howell Zone and Gilligan Zone. In addition, the Super Conductor is a 1 kilometer by 1.8 kilometers area defined by a strong airborne EM conductor associated with disseminated pyrrhotite and local gold mineralization (Roberts, 2014).

Kiska drilled the first drill hole in the Breccia Zone in 2009 (IM09-001), in which 150 meters averaged 0.72 gram of gold per tonne and 0.16 percent copper primarily in actinolite-magnetite breccia, and 106.9 meters averaged 1.22 grams of gold per tonne and 0.05 percent copper in a deeper pyrrhotite-gold zone. Kiska has conducted a total of 15,572 meters of exploration drilling at Island Mountain from 40 diamond drill holes, with the majority of those holes targeting the Breccia Zone (34 drill holes). At the southern end of the Breccia Zone, the Discovery Breccia is comprised of intermingled intrusive and hydrothermal matrix breccias dominated by sodic-calcic alteration. Assays returned several significant intercepts of predominantly gold mineralization including a deep, strongly silicic/possibly potassic zone containing massive pyrite-dominant sulfide veins (IM11-030), a style not seen previously at Island Mountain. This zone returned 73.9 meters averaging 0.72 gram of gold per tonne, 2.24 grams of silver per tonne and 0.09 percent copper (Roberts, 2014).

One target outside of the Breccia Zone at Island Mountain is the Howell Zone, which occurs 2 kilometers to the northeast. The Howell Zone is defined by very strong gold, copper, and molybdenum soil anomalies over significant widths. The core of the zone is defined by a semicircular 650 meters diameter zone with greater than 90th percentile gold-in-soil values (greater than 0.362 part per million (ppm) gold) with coincident greater than 90th percentile copper (greater than 498 ppm copper) and molybdenum (greater than 17 ppm molybdenum) soil anomalies extending a further 250 meters to the southwest. The core of this anomaly is coincident with a very strong, sub-circular magnetic high anomaly (Roberts, 2014).

In addition, a 2011 airborne electro-magnetic (EM) survey identified a significant 1800 meters by 1000 meters conductor to the east of the Breccia Zone, which is largely hidden by colluvial and alluvial cover. This EM anomaly is interpreted to potentially represent a large zone of disseminated or net-textured pyrrhotite, which may be similar to the pyrrhotite-gold zone located east of the Discovery Breccia. Kiska subsequently tested this anomaly with three widely spaced diamond drill holes for a total of 602 meters. Only one of these holes adequately tested this anomaly, and returned two gold-bearing intervals associated with net-textured pyrrhotite that averaged 0.61 gram of gold per tonne equivalent over 21 meters and another averaging 0.45 gram of gold per tonne equivalent over 30.0 meters (Roberts, 2014).

Production notes:

None.

Reserves:

In 2016, Brazil Resources Inc. (now Gold Mining Inc.) is evaluating prospects it acquired from Kiska Metals Corporation in 2015. Although no on-site work was performed in 2016 at the Whistler (TY022),

Raintree West (TY038), and Island Mountain porphyry copper–gold–silver prospects, in May of 2016, Brazil Resources Inc. released a new technical report announcing the first resource estimates for the Raintree West (TY038) and Island Mountain deposits, largely based on drilling by Kiska Metals Corporation between 2009 and 2011 (Giroux, 2016; Athey and Werdon, 2017).

The Island Mountain deposit contains an indicated resource of 31.08 million tonnes averaging 0.49 gram of gold per tonne (490,000 ounces of gold), 1.10 grams of silver per tonne (1.1 million ounces of silver), and 0.06 percent copper (41.12 million pounds of copper). Additionally, Island Mountain contains an inferred resource of 82.02 million tonnes averaging 0.47 gram of gold per tonne (1.24 million ounces of gold), 1.02 grams of silver per tonne (2.69 million ounces of silver), and 0.05 percent copper (90.43 million pounds of copper). The resource is based on 12,668 meters of drilling in 34 holes on the southwest slope of Island Mountain and a cut-off grade of 0.3 gram gold equivalent per tonne (Giroux, 2016).

Additional comments:

The 2009 to 2010 field program was operated by Kiska under the direction of a Technical Committee comprised of two Kennecott and two Kiska employees. In August of 2010, Kiska delivered a Technical Report to Kennecott summarizing the results of the completed 'Trigger Program'. In September of 2010, Kennecott informed Kiska that it would not exercise its back-in right on the project and hence retained a 2 percent Net Smelter Royalty on the property (Kiska Metals Corporation, 2010a).

Site name(s): Unnamed (Near Mount Estelle)

Site type: Prospects

ARDF no.: TY019

Latitude: 61.8497 **Quadrangle:** TY D-8

Longitude: 152.8928

Location description and accuracy:

This records includes numerous prospects are in a 10-mile-square area near Mt. Estelle. The coordinates are at about the center of this area that includes parts of T. 20 N., R. 20 W., T. 21 N., R., 19 W., and T. 21 N., R. 20 W.

Commodities:

Main: Au, Cu

Other: As, Mo, Pb, Sb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, galena, malachite, molybdenite, native gold, pentlandite, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Carbonate, chlorite, limonite, quartz, sericite

Geologic description:

Note: This is an early ARDF record that describes work in the general area of Mount Estelle. Exploration work from 2000 to 2008 (Hidefield Gold, Plc., 2008; International Tower Hill Mines, Ltd., 2007; Millrock Resources Inc., 2008) has defined several specific prospects in or near this area within this area or nearby that are described separately, e.g., the Train (T031) and Shoeshine (TY032) prospects. This record is retained for its general geologic information on the geology and mineralization in the area.

The Mount Estelle pluton, dated at 65 to 66 Ma by Reed and Lanphere (1972), is the southern-most Late Cretaceous/early Tertiary composite pluton in the Yentna trend. This trend is described by Reed and Nelson (1980) as a 65-km-long, curvilinear belt extending from Mount Estelle in the south to Cascade Creek in the northeast. These plutons primarily intrude Mesozoic marine sedimentary rocks of the Kahiltna terrane. The Mount Estelle pluton (Reed and Elliott, 1970) is zoned from a granite core to marginal phases of quartz monzonite, quartz monzodiorite, augite monzodiorite, diorite and lamprophyric mafic and ultramafic rocks (Millholland, 1995; Crowe and others, 1991; Crowe and Millholland, 1990). Xenoliths of the country rocks and of the various intrusive phases occur throughout the pluton. Sheeted joint sets and unusual spherical, onion-skin-like features occur in the core of the pluton. Sparse tourmaline and beryl occur in and adjacent to the pluton. Foley and others (1997) note that the composite plutons at the southwestern end of the Yentna trend are more granitic in composition and probably have not been as deeply eroded as the more mafic and ultramafic bodies to the northeast in the Talkeetna quadrangle. Adjacent to the Mount Estelle pluton, the country rock is hornfelsed and locally exhibits red staining and sericite-clay alteration, and pyrite in disseminations and along fractures.

Float and stream-sediment samples taken in the vicinity of the Mount Estelle pluton suggest widespread polymetallic mineralization. Stream sediments consistently contain anomalous gold, copper, arsenic, and silver. Mineralized rock samples typically give high values for gold and copper, and some contain anomalous amounts of silver, arsenic, molybdenum, bismuth, boron, lead, antimony, tin, zinc and manganese. Cominco American Incorporated's work (unpublished reports, 1985-1989) shows gold values. Native gold occurs with chalcopyrite, pyrite, arsenopyrite, and pyrrhotite associated with sericite, carbonate and chlorite alteration in sheeted joints, stockwork veinlets, and circular structures that range from 1 inch to more than 15 feet in diameter (Millholland, 1995; Crowe and others, 1991; Crowe and Millholland, 1990).

These structures are in the felsic and intermediate phases of the pluton. Gold associated with pyrrhotite, chalcopyrite, pentlandite and molybdenite also occurs in ultramafic rocks on the south side of the pluton. Mineralization is less common in the sedimentary rocks. In Muddy Creek, one zone of coarse galena, pyrrhotite, sphalerite and chalcopyrite replaces carbonate-rich horizons in the hornfelsed sedimentary rocks.

Anomalous gold, platinum-group elements, copper, chrome, nickel and arsenic are reported from many of the composite plutons of the Yentna trend (Reed and others, 1978; Reed and Nelson, 1980; Nelson and others 1992). Gold and platinum-group-element placers have been worked at several sites downstream from the plutons (Mertie, 1919; Cobb, 1973; ARDF records TL001, TL 002, TL003, TL020, TL023, TL051, TL052, and TL053).

There are notable similarities between the Mount Estelle pluton and the Kohlsaat pluton described by Reiners, Nelson, and Nelson (1996). The Kohsaat pluton is a concentrically-zoned body with a biotite-granite-porphyry core that intrudes seriate and porphyritic, intermediate composition rocks. The latter include olivine-, pyroxene-, and biotite-bearing quartz syenite, quartz monzonite, and monzonite. Lamprophyric mafic and ultramafic rocks that range in composition from peridotite to alkali gabbro and monzonite form large xenoliths at the northeastern margin of the pluton. The granite-porphyry core is altered to sericite, quartz, carbonate and tourmaline assemblages, with minor enrichments of copper, gold, lead, molybdenum, and zinc. The composite Kohlsaat pluton may have formed from depleted mantle melts that were contaminated by crustal components during several stages of mafic magma generation. Also see ARDF record TL052.

Alteration:

Alteration is weak and restricted to vein and joint selvages. Carbonate, chlorite, sericite, and quartz are commonly associated with the sulfide and gold mineralization (Millholland, 1995; Crowe and others, 1991; Crowe and Millholland, 1990; Cominco American Incorporated, unpublished reports, 1985 through 1989).

Age of mineralization:

Late Cretaceous to Early Tertiary based on 65 to 66 Ma. intrusions that are probably related to the mineralization (Reed and Lanphere, 1972).

Generic deposit model:

Deposit model:

Intrusive-hosted gold-copper deposits.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Prospecting in the area has been conducted by several private companies since the 1970s. From 1980 to 1985, many of the claims were held for their placer potential; however, they were never mined to any great extent because the large glacial boulders in the stream gravels hampered recovery. Work in the area included: silt and rock geochemistry, mapping, magnetic, VLF, IP and radar geophysical surveys, and diamond drilling. To evaluate the steep, glaciated terrain, technical climbers from Dihedral Exploration were employed.

This is an early ARDF record that describes work in the general area of Mount Estelle and has been retained for its regional geologic and mineral information. Exploration work from 2000 to 2008 (Hidefield Gold, Plc., 2008; International Tower Hill Mines, Ltd., 2007; Millrock Resources Inc., 2008) has defined several prospects in or near that are described separately, e.g., the Train (TY031) and Shoeshine (TY032) prospects.

Production notes:

None.

Site type:

Prospects

ARDF no.: TY020

Latitude: 61.9115 **Quadrangle:** TY D-8

Longitude: 152.9159

Location description and accuracy:

The Stoney prospect area is a locally discontinuous 6.8 mile north-northeast trending gold-silver-copper anomaly. The location point is centered on the Stoney Vein about 0.5 mile northwest of Mount Stoney, in the NE1/4 section 15, T. 21 N., R. 20 W., of the Seward Meridian. The location is accurate to within about a half mile.

Commodities:

Main: Ag, Au, Cu, Pb

Other: As, Sb, Zn

Ore minerals: Arsenopyrite, chalcocite, chalcopyrite, native copper, galena, gold, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Calcite, dolomite, epidote, graphite, quartz, siderite, tourmaline

Geologic description:

The Stoney prospect and others in the vicinity are on the Yentna trend of Late Cretaceous/early Tertiary composite plutons described by Reed and Nelson (1980). The Mount Estelle pluton (Reed and Elliott, 1970) extends from Timber Creek on the south to the Portage Creek area in the north. In the central part of the pluton, a biotite-hornblende-quartz monzonite intrudes Mesozoic marine sedimentary rocks of the Kahiltna terrane.

Two veins follow dilatant zones in the pluton along its west side (Cominco American Incorporated, unpublished reports, 1986-1987). The main Stoney mineralized zone dips steeply and has been traced for more than 3 miles. It is 14 to 60 feet wide and has a vertical relief of at least 1000 feet. The quartz-calcite-dolomite-siderite-tourmaline veins alternate with altered intrusive rocks and the veins contain pyrrhotite, chalcopyrite, arsenopyrite, pyrite, stibnite, and, locally, sphalerite and galena. The North Stoney vein is a sub-parallel feature just west of the northern end of the main Stoney vein. It is up to 35 feet wide and has similar mineralogy to the main Stoney vein. A third vein is one mile to the west.

There was considerable work in the area by government and industry as far back as the 1970's that identified widespread mineralization in the Mount Estelle area (see TY019). From 2005 to 2008, several companies (Hidefield Gold Plc. (2008), International Tower Hill Mines Ltd. (2007) and Millrock Resources Inc. (2008)) have worked in the area and identified several specific prospects. Millrock began exploring the area in 2008 as part of the Estelle project that covers a large block of claims north and south of Mount Estelle. The Stoney vein is within that block and Millrock has sampled it. Hidefield (2008) shows several other veins to the north and south; the Trundle vein and another unnamed vein are about two miles to the north, the Tomahawk vein is about 4 miles to the north, and the Kid vein is about 4 miles the south. All are in the Mount Estelle pluton and are probably similar to the Stoney, Shoeshine (TY032), and Train (TY031) prospects to the south.

Millrock Resources Inc. (2014) reports the Stoney prospect area contains locally discontinuous north-northeast trending gold-silver-copper anomalies defined by both soil and rock samples. The anomalies are all greater than 2.5 kilometers in length with the longest greater than 8 kilometers. The distance from the

northernmost to southernmost anomaly is about 11 kilometers. None of the anomalies have been drill tested (Millrock Resources Inc., 2014).

One such anomaly hosts the Stoney vein system, a series of high angle, east-dipping, north-northeast-trending shear-hosted massive sulfide veins. The main Stoney vein varies in width from 1 meter to 3 meters and has a vertical relief greater than 300 meters. The vein follows a greater than 5 kilometer long north-trending dilational shear zone in highly alkaline biotite-hornblende-quartz monzonite. In this location, an intersection of strong northwest-southeast and east-west trending magnetic lineaments coincides with veins of quartz-calcite-dolomite-siderite-tourmaline-pyrrhotite-chalcopyrite-arsenopyrite-pyrite-stibnite ± graphite, chalcocite, native copper, sphalerite and galena. Samples of vein material have returned results up to 11.05 parts per million (ppm) gold. Samples from the nearby T-5 prospect show increased silver and copper values with assays as high as 1,140 ppm silver and 7.43 percent copper (Millrock Resources Inc., 2014).

Alteration:

Calcite, epidote, sericite, tourmaline, quartz (Millrock Resources Inc., 2014).

Age of mineralization:

Late Cretaceous/early Tertiary?; mineralization in the area is thought to be related to the 65-66 Ma, granodiorite of Mount Estelle (Millrock Resources Inc., 2014).

Generic deposit model:

Deposit model:

Polymetallic vein (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Workings/exploration:

There was considerable work in the area by government and industry as far back as the 1970s that identified widespread mineralization in the Mount Estelle area (see TY019). From 2005 to 2008, several companies (Hidefield Gold Plc. (2008), International Tower Hill Mines Ltd. (2007) and Millrock Resources Inc. (2008)) have worked in the area and defined several specific prospects Millrock began exploring the area in 2008 as part of its Estelle project, which covers a large block of claims north and south of Mount Estelle. The Stoney vein is in that block and Millrock has sampled it.

Millrock Resources Inc. (2014) reports the Stoney prospect area contains locally discontinuous north-northeast trending gold-silver-copper defined by both soil and rock samples. The anomalies are all greater than 2.5 kilometers in length with the longest greater than 8 kilometers. The distance from the northernmost to southernmost anomalies is about 11 kilometers. Site type: Prospect

ARDF no.: TY022

Latitude: 61.9638 **Quadrangle:** TY D-8

Longitude: 152.6799

Location description and accuracy:

The center of the Whistler prospect is about 3.8 miles west of the junction of Portage Creek and the Skwentna River, near the center of section 29, T. 22 N., R. 18 W., of the Seward Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Ba, Cu, Pb, Zn

Other: Fe

Ore minerals: Chalcopyrite, galena, gold, magnetite, pyrite, sphalerite

Gangue minerals: Carbonate, chlorite, gypsum, quartz

Geologic description:

In early 2010, the Whistler prospect was the most developed property of the Whistler project of Kiska Metals Corporation and was aggressively being explored (Kiska Metals Corporation, 2010). Cominco Alaska began mineral exploration in the area in 1986; they drilled 15 short holes on the Whistler prospect but dropped it in 1989. It was restaked in 1999 and leased to Kennecott Exploration Company in late 2002. From 2004 through 2006, Kennecott carried out major exploration in the area, including geologic mapping; soil, stream sediment, and rock geochemistry; ground induced-polarization and airborne magnetic geophysical surveys; and they drilled 15 core holes in the Whistler prospect that totaled 7,948 meters. In 2007, Geoinformatics Exploration Inc. optioned the property from Kennecott. As of 2008, the Whistler prospect is on a block of 732 State of Alaska mining claims (Wahl and others, 2008). In 2009, Kiska Metals Corporation, was formed through a merger of Geoinformatics and Rimfire Minerals Corporation (Morris, 2011).

The Whistler prospect is a porphyry copper-gold deposit that in 2010 extended over an area at least 1,000 meters in diameter (Kiska Metals Corporation, 2010; Wahl and others, 2008). It is closely associated with a [Cretaceous-]Tertiary extrusive igneous complex that overlays and intrudes feldspathic sandstone of Jurassic-Cretaceous age (Wilson and others, 2009). At least three diorite porphyry intrusive phases intrude the feldspathic sandstone unit and are associated with the sulfide mineralization event at Whistler, although strong phyllic alteration has obliterated primary textures, making it difficult to differentiate lithologies and determine intrusive contacts. The oldest intrusive phase (‘main stage’) exhibits the best gold-copper mineralization; the second oldest phase (‘inter-mineral stage’) is strongly altered and carries weak gold-copper mineralization, while the third and youngest is altered but typically barren. Most of the complex consists of 'inter-mineral stage' and 'main stage' diorite porphyry; the best mineralization is in the main-stage porphyry. The complex is cut by dikes of 'late stage' diorite porphyry and porphyritic andesite. The structure is not well constrained because of the wide spacing of the drill holes but there is at least one major fault and several breccia zones (Wahl and others, 2008). Roberts (2014) reported diorite porphyry bodies at the Whistler deposit occur as batholiths, stocks, and dikes and generally have a northwest-oriented elongation that is sub-parallel to significant regional-scale faults, such as the Alger Peak fault and the Timber Creek fault.

The paragenesis of the mineralization is: 1) early barren, quartz-magnetite veins associated with secondary

biotite alteration; 2) 'main' stage, quartz-magnetite-chalcopyrite veins, associated with secondary biotite, quartz-pyrite and pyrite veins, and pervasive quartz-sericite-pyrite alteration, and 3) late calcite veins with sphalerite and galena. Gypsum is common. Near the complex, the original textures of the sedimentary rocks are almost obliterated by strong phyllitic alteration that makes it hard to distinguish them from the igneous rocks (Wahl and others, 2008).

In January of 2011, Kiska announced a new estimate of the resources of the Whistler deposit that incorporated the drilling through 2010 (Kiska Metals Corporation, 2011; Morris, 2011). They estimate it has 79.2 million tonnes of 'indicated resource' with a grade of 0.51 gram of gold per tonne, 1.97 grams of silver per tonne, and 0.17 percent copper, and an 'inferred resource' of 145.8 million tonnes with an average grade of 0.40 gram of gold per tonne, 1.75 grams of silver per tonne, and 0.15 percent copper (Morris, 2011).

Alteration:

Early secondary biotite alteration in the porphyry; intense quartz-sericite-pyrite alteration during the main stage of mineralization in the porphyry; and strong phyllitic alteration in the sandstone around the intrusion (Wahl and others, 2008).

Age of mineralization:

Younger than or related to a Cretaceous-Tertiary diorite porphyry, intrusive-extrusive complex (Morris, 2011).

Generic deposit model:

Deposit model:

Gold-copper porphyry (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

In early 2010, the Whistler prospect was the most developed property of the Whistler project of Kiska Metals Corporation and was aggressively being explored (Kiska Metals Corporation, 2010). Cominco Alaska began mineral exploration in the area in 1986; they drilled 16 diamond drillholes (1,677 meters) and completed 8.4 line-kilometers of 2D Induced Polarization (IP) geophysics for the Whistler deposit, but dropped it in 1989 (Morris, 2011). It was restaked in 1999 and leased to Kennecott Exploration Company in late 2002. From 2004 through 2006, Kennecott carried out major exploration in the area, including geologic mapping; soil, stream sediment, and rock geochemistry; ground induced-polarization and airborne magnetic geophysical surveys; and they drilled 15 core holes in the Whistler prospect that totaled 7,948 meters. In 2007, Geoinformatics Exploration Inc. optioned the property from Kennecott. As of 2008, the Whistler prospect is on a block of 732 State of Alaska mining claims (Wahl and others, 2008). From 2007 through 2008, Geoinformatics drilled 12 holes for 5,784 meters in order to infill the Whistler deposit to sections spaced at 75 meters and to test for the extent of the deposit to the north and south (Morris, 2011).

Results from airborne magnetic surveys (using 50-meter spacing) by Kennecott in 2004 showed that the Whistler deposit displays a strong 900 meter by 700 meter positive magnetic anomaly attributed to the Whistler Diorite intrusive complex, secondary magnetite alteration and veining associated with gold-copper mineralization. Additionally, two IP lines run over the deposit magnetic anomaly showed that mineralization is coincident with a strong chargeability anomaly. Soil grids over the deposit showed anomalous gold-copper results that were also coincident with the magnetic high (Morris, 2011).

In 2009, Kiska Metals Corporation, was formed through a merger of Geoinformatics and Rimfire Minerals Corporation. In 2010, Kiska drilled 5 holes in the Whistler deposit totaling 4,456 meters in order to infill

gaps from previous drilling and to test the edges and depth of the intrusive complex that hosts the deposit (Morris, 2011). In 2011, Kiska performed minor infill drilling at the Whistler Deposit, followed by publication of an updated 43-101 compliant resource estimate (Roberts, 2014).

Production notes:

None.

Reserves:

In 2011, Kiska announced a new estimate of the resources of the Whistler deposit that incorporated the drilling through 2010 (Morris, 2011). The pit delineated resource has 79.2 million tonnes of 'indicated resource' with a grade of 0.51 gram of gold per tonne, 1.97 grams of silver per tonne, and 0.17 percent copper, and an 'inferred resource' of 145.8 million tonnes with an average grade of 0.40 gram of gold per tonne, 1.75 grams of silver per tonne, and 0.15 percent copper (Morris, 2011).

In 2016, Brazil Resources Inc. (now Gold Mining Inc.) is evaluating prospects it acquired from Kiska Metals Corporation in 2015. Although no on-site work was performed in 2016 at the Whistler, Raintree West (TY038), and Island Mountain (TY018) porphyry copper–gold–silver prospects, in May of 2016, Brazil Resources Inc. released a new technical report announcing the first resource estimates for the Raintree West (TY038) and Island Mountain (TY018) deposits, largely based on drilling by Kiska Metals Corporation between 2009 and 2011 (Giroux, 2016). Their report also re-states the resource estimate for the Whistler gold-copper deposit (initially released in 2015), based largely on the historic resource estimate completed by Kiska Metals Corporation in March 2011 (Athey and Werdon, 2017).

The Whistler deposit contains an indicated resource of 79.2 million tonnes, averaging 0.51 gram of gold per tonne (1.28 million ounces of gold), 1.97 grams of silver per tonne (5.03 million ounces of silver), and 0.17 percent copper (302 million pounds of copper). Additionally, Whistler contains an inferred resource of 145.8 million tonnes grading 0.40 gram of gold per tonne (1.85 million ounces gold), 1.75 grams of silver per tonne (8.21 million ounces silver), and 0.15 percent copper (467 million pounds copper). Metal recoveries reported for the Whistler deposit resource estimate include 85 percent for copper, 75 percent for gold, and 75 percent for silver (Giroux, 2016).

Site name(s): Old Man Breccia

Site type: Prospect

ARDF no.: TY025

Latitude: 61.9398 **Quadrangle:** TY D-7

Longitude: 152.3248

Location description and accuracy:

The Old Man Breccia prospect is about 3.8 miles west-southwest of the junction of Old Man Creek and Happy River. It is about 0.5 mile west of the center of section 1, T. 21 N., R. 17 W. The location is accurate.

Commodities:

Main: Au, Cu

Other: Fe

Ore minerals: Chalcopyrite, gold, pyrite, pyrrhotite

Gangue minerals: Carbonate, quartz

Geologic description:

In early 2010, the Old Man Breccia prospect was part of the Whistler project of Kiska Metals Corporation and was is actively being explored (Kiska Metals Corporation, 2010a). Cominco Alaska began mineral exploration in the area in 1986; they found the deposit but ended their work in 1989. From 2004 to 2006 Kennecott Exploration Company carried out major exploration in the area, including geologic mapping; soil, stream sediment, and rock geochemistry; and geophysical surveys. They staked several large blocks of ground that included the Old Man Breccia prospect. In 2005, Geoinformatics Exploration Inc. acquired the property from Kennecott, and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation.

A float sample of quartz with pyrrhotite, chalcopyrite, and pyrite, that assayed contained several ounces of gold per ton led to the discovery of the deposit. It consists of breccia in siltstone of Upper Jurassic and Lower Cretaceous flysch (KJs) of the Kahiltna terrane (Cominco American Incorporated, unpublished reports, 1986-1988; Wilson and others, 2009). The breccia is exposed over an area approximately 105 feet by 90 feet. It consists of angular clasts of argillite from less than one inch to a few inches cemented by milky quartz and lesser carbonate. The quartz-argillite breccia forms sinuous, sub-vertical zones around large argillite blocks. Sulfides in the breccia are sparse (generally less than 1 percent) and consist of pyrrhotite, pyrite, chalcopyrite, and rare coarse-grained arsenopyrite. Quartz veins with pyrrhotite, pyrite, and chalcopyrite that crosscut the breccia zone vary from a few inches to 2 feet thick; they contain occasional specks of visible gold. There is no obvious alteration.

In 2009, three trenches showed substantial gold values in an area of breccia about 30 meters in diameter (Kiska Metals Corporation, 2010b). Channel samples included: 0.74 gram of gold per tonne along 16 meters; 1.94 grams of gold per tonne along 24 meters; 3.34 grams of gold per tonne along 28 meters; and 7.12 grams of gold per tonne along 10 meters. Only small sections of the trenches had gold values below 0.30 gram of gold per tonne.

Alteration:

Iron-oxide.

Age of mineralization:

The breccia is younger than the Jurassic-Cretaceous host rock.

Generic deposit model:

Deposit model:

Gold-bearing sulfide breccia.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Discovered by Cominco in the early 1980s. Exploration work included mapping, rock chip geochemistry, soil sampling, magnetic and VLF geophysical surveys, and diamond drilling. Kennecott Exploration Company probably did some work from 2004 to 2006. Trenched and sampled by Kiska Metals Exploration in 2009.

Production notes:

None.

Reserves:

None.

Primary Reference: Kiska Metals Corporation, 2010a and 2010b

Reporter(s): Madelyn A. Millholland (Anchorage); D.J. Grybeck (Contractor, U.S. Geological Survey)

Last report date: 2010-04-02

Site name(s): Train

Site type: Prospect

ARDF no.: TY031

Latitude: 61.8314 **Quadrangle:** TY D-8

Longitude: 152.9157

Location description and accuracy:

The center of the Train prospect is about 1.5 miles south of Mount Estelle; it is about 0.5 mile south of the center of section 9, T 20 N., R. 20 W. The location is accurate.

Commodities:

Main: Ag, Au

Other: Cu, Pb, Zn

Ore minerals: Arsenopyrite, pyrite (and probably others)

Gangue minerals: Quartz, tourmaline

Geologic description:

The Train prospect is near the periphery of the Cretaceous (65-66 Ma) Mount Estelle pluton, which is zoned from a granite core to marginal phases of quartz monzonite, quartz monzodiorite, augite monzodiorite, diorite and lamprophyric mafic and ultramafic rocks (Reed and Elliott, 1970; Millholland, 1995; Crowe and others, 1991; Crowe and Millholland, 1990). The pluton intrudes Jurassic and Cretaceous sedimentary rocks that are hornfelsed adjacent to the pluton, are locally stained red, and have been altered to sericite and clay. Pyrite occurs as disseminations and along fractures.

There was considerable work in the area by government and industry as far back as the 1970s that identified mineralization, but the work was more general than prospect specific (see TY019). From 2005 to 2008, several companies, Hidefield Gold Plc. (2008), International Tower Hill Mines Ltd. (2007) and Millrock Resources Inc. (2008), have defined several specific prospects in the area, including the Train prospect and the nearby Shoeshine prospect (TY032). Millrock is currently (2008) exploring the deposit as part of its Estelle project that covers a large block of claims north and south of Mount Estelle.

International Tower Hills collected a sample of a quartz-sulfide vein at the Train prospect that contained 57 parts per million (ppm) gold, 212 ppm silver, 3.6 ppm copper, and 0.3 ppm lead. The vein trends north and dips steeply. Millrock collected numerous samples along a north- to north-northeast trending zone about 1.5 miles long; many of the samples contained more than 2 grams of gold per ton. Of the 83 samples they collected, the average gold content was 7.61 grams per tonne; the minimum was 0.01 gram per ton, and the highest was 56.9 grams per tonne. The possible porphyry-style mineralization consists mainly of quartz-arsenopyrite veins; auriferous quartz stockworks; and breccia zones cemented by quartz, oxidized sulfides, and tourmaline.

Alteration:

The alteration associated with the quartz veins, stockworks, and breccia is not specifically noted.

Age of mineralization:

Later than the 65-66 Ma Mount Estelle pluton that hosts the mineralization; may be genetically related to the pluton.

Generic deposit model:

Deposit model:
Gold-arsenopyrite-quartz veins, stockworks, and breccias.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:
Limited sampling by a succession of companies since the 1970s.

Production notes:
None.

Reserves:
None.

Last report date: 2008-06-05

Site name(s): Shoeshine

Site type: Prospect

ARDF no.: TY032

Latitude: 61.8278 **Quadrangle:** TY D-8

Longitude: 152.8869

Location description and accuracy:

The Shoeshine prospect is on the east-facing slopes of peak 6952, about 2.0 miles southeast of Mount Estelle. It is about 0.4 mile northwest of the center of section 15, T. 20 N., R. 20 W., of the Seward Meridian. The center of the prospect location is accurate to within 500 feet.

Commodities:

Main: Ag, Au

Other: As, Cu, Pb, Zn

Ore minerals: Arsenopyrite, chalcopyrite, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

The Shoeshine prospect is in the Cretaceous (65-66 Ma) Mount Estelle pluton, which is zoned from a granite core to marginal phases of quartz monzonite, quartz monzodiorite, augite monzodiorite, diorite, and lamprophyric mafic and ultramafic rocks. The pluton intrudes Jurassic and Cretaceous sedimentary rocks that are hornfelsed adjacent to the pluton, are locally stained red, and have been altered to sericite and clay. Pyrite occurs as disseminations and along fractures (Reed and Elliott, 1970; Millholland, 1995; Crowe and others, 1991; Crowe and Millholland, 1990).

The highest grades of mineralization and the most significant alteration in the Shoeshine area occur in the leucocratic phase of the composite pluton, one of five igneous phases mapped at this prospect. Intrusion-hosted mineralization is represented by multi-episodic quartz vein arrays. In one location, a 300 meter wide sheeted vein swarm has been traced for a strike length of more than 1 kilometer and through a vertical range of up to 200 meters. Individual veins, ranging from several millimeters to 20 centimeters thick, have assayed greater than 200 grams of gold per tonne (Millrock Resources Inc., 2014).

There was considerable work in the area by government and industry as far back as the 1970's that identified mineralization, but the work was more general than prospect specific (see TY019). From 2005 to 2008, several companies (Hidefield Gold Plc. (2008), International Tower Hill Mines Ltd. (2007), and Millrock Resources Inc. (2008)) have defined several specific prospects in the area, including the Shoeshine prospect. In 2011, Millrock explored the Shoeshine prospect as part of their Estelle project, which covers a large block of claims north and south of Mount Estelle (Millrock Resources Inc., 2011).

International Tower Hill (2007) collected 3 samples of quartz-sulfide veins at the Shoeshine prospect that contained 63 to 238 parts per million (ppm) gold, 14 to 389 ppm silver, 0.3 to 1.0 ppm copper, and 0.0 to 2.0 ppm lead. The veins trend north-northwest and dip steeply to the northeast or southwest. Millrock collected numerous samples in an area about 3,500 feet by 2,500 feet in size on the east slope of peak 6952; many of the samples contained more than 2.0 grams of gold per ton. Of the 58 samples they collected, the average gold content was 5.29 grams per tonne; the minimum was 0.09 gram of gold per tonne, and the highest value was 238.0 grams of gold per tonne. The porphyry-style(?) mineralization consists mainly of quartz-arsenopyrite veins; auriferous quartz stockworks; and breccia zones cemented by quartz, oxidized sulfides, and tourmaline.

In 2011, Millrock drilled a 388.8-meter hole that went through altered, mineralized rock for most of its

length. The mineralization consists of narrow quartz veins and disseminated sulfides. Gold is associated with arsenopyrite and minor chalcopyrite. The best intercept was 241.8 meters that averaged 0.24 gram of gold per tonne; this included 8.32 meters that averaged 1.18 grams of gold per tonne and 5.82 meters that average 1.62 grams of gold per tonne (Millrock Resources Inc., 2011).

Alteration:

Plutons have hornfelsed adjacent sedimentary rocks, which may be locally stained red and altered to sericite and clay (Reed and Elliott, 1970; Millholland, 1995; Crowe and others, 1991; Crowe and Millholland, 1990). Quartz + gold in multi-episodic quartz vein arrays are present in intrusion-hosted mineralization. Extensive but otherwise undefined (Millrock Resources Inc., 2014).

Age of mineralization:

Late Cretaceous/early Tertiary?; mineralization in the area is thought to be related to the 65 to 66 Ma granodiorite of Mount Estelle (Millrock Resources Inc., 2014).

Generic deposit model:

Deposit model:

Auriferous, arsenopyrite-quartz veins and stockworks (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: None

Site Status: Active

Site name(s): Rainmaker

Site type: Prospect

ARDF no.: TY033

Latitude: 61.9557 **Quadrangle:** TY D-7

Longitude: 152.6082

Location description and accuracy:

The center of the Rainmaker prospect is about 1.6 miles southwest of the mouth of Portage Creek on the Skwentna River and about 0.3 mile northeast of the center of section 32, T. 22 N., R. 18 W., of the Seward Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena, gold, sphalerite

Gangue minerals: Carbonates, quartz

Geologic description:

The Rainmaker prospect is situated in a Cretaceous to Tertiary continental margin arc. It is underlain by flysch sediments of the Kahiltna assemblage and is one of several gold-copper porphyry deposits that form a belt that trends north-northwest for at least 9 miles (Wahl and others, 2008; Kiska Metals Corporation, 2010). The best known is the Whistler deposit (TY022), about 3 kilometers to the west-northwest of Rainmaker. As of early 2010, relatively little detail is available on the Rainmaker prospect; it is largely covered by surficial material, but it is probably similar to the Whistler deposit.

The Rainmaker prospect occurs in a low-lying, glacial-till covered valley floor (Morris, 2011). Rainmaker is hosted by diorite porphyry dikes cutting porphyritic andesite centers within a volcanic basin. A large, semi-circular induced polarity (IP) chargeability high anomaly at Rainmaker has been confirmed by mapping and drilling to be related to extensive phyllic alteration of quartz-sericite-pyrite indicative of porphyry potential. An intense circular aeromagnetic high also exists (Roberts, 2014).

The style of alteration, mineralization, veining and cross-cutting relationships displayed is generally typical of porphyry systems associated with relatively oxidized magma series (quartz vein stockwork, chalcopyrite-pyrite ore assemblage, presence of sulfates, and core of potassic alteration with well-developed peripheral phyllic alteration zones). Mineralization occurs at bedrock surfaces immediately below till cover (Roberts, 2014).

Alteration:

Typical of porphyry systems associated with relatively oxidized magma series (quartz vein stockwork, chalcopyrite-pyrite ore assemblage, presence of sulfates, core of potassic alteration with well-developed peripheral phyllic alteration zones) (Morris, 2011).

Age of mineralization:

Paleocene to Late Cretaceous based on age of host diorite, monzonite and granite (Roberts, 2014).

Generic deposit model:

Deposit model:

Gold-copper porphyry (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

The prospect is at the southern end of a belt of porphyry gold-copper mineralization that has been extensively explored by several companies since the early 1980s.

Cominco Alaska began mineral exploration in the area in 1986 but they ended their work in 1989. From 2004 to 2006, Kennecott Exploration Company was active in the area and staked several large blocks of claims that included the Raintree prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott (Wahl and others, 2008). In 2009, Kiska Metals Corporation, the current (2010) holder of the claims, was formed by a merger of Geoinformatics and Rimfire Minerals Corporation (Morris, 2011).

Rainmaker was discovered during the 2004 to 2006 exploration period by Kennecott Exploration Company. In that time, Kennecott conducted extensive exploration of the region, including geological, geochemical, and ground induced polarization surveys, and drilling (Roberts, 2014).

There were at least 7 holes drilled on the Raintree prospect by 2008. In 2008, Geoinformatics drilled at least one hole on Raintree. A 184-meter intercept contained 0.44 grams of gold per tonne and 0.16 percent copper (Wahl and others, 2008).

Since 2010, it was being actively explored by Kiska Metals Corporation. Kiska's work has included detailed mapping, geochemical and geophysical surveys, sampling, and at least seven drill holes between 2008 and 2011. Significant drilling intercepts include hole 05-DD-WH-REC-08, which returned 168.5 meters of 0.47 gram of gold per tonne, 2.25 grams of silver per tonne, 0.17 percent copper. As of 2014, drilling suggests that this prospect resembles approximately 100 meters diameter, steeply-dipping 'pencil'-shaped porphyries (Roberts, 2014).

Five drill holes were drilled in 2011 by Kiska. Hole WH11-049 returned 104.4 meters that averaged 0.59 gram of gold per tonne and 0.20 percent copper (1.04 grams of gold per tonne equivalent) indicating improving grades with depth. Hole WH11-047 was successful in extending the Rainmaker zone 110 meters to the southeast, returning 58 meters of 0.35 gram of gold per tonne and 0.14 percent copper (0.69 gram of gold per tonne equivalent). Three holes stepping-out 350 meters to the southeast (holes WH11-043 and WH11-045) and 150 meters to the northwest (hole WH11-051) tested geophysical anomalies and shallow grid-drilling results and intersected strongly altered volcanic rocks with anomalous gold and copper values and local high grade silver-lead-zinc values (WH11-043: 34 meters averaging 44 grams of silver per tonne, 0.35 percent zinc, 0.27 percent lead) that may indicate stronger gold-copper porphyry mineralization in the vicinity (Kiska Metals Corporation, 2011).

Production notes:

None.

Reserves:

None.

Additional comments:

The Whistler Deposit (TY022), which is within 3 kilometers of the Rainmaker prospect, has an existing 43-101 compliant resource: 2.25 million ounces of gold equivalent (Indicated category) and 3.35 million ounces of gold equivalent (Inferred category) (Morris, 2011).

Site name(s): Muddy Creek West

Site type: Prospect

ARDF no.: TY034

Latitude: 61.8521 **Quadrangle:** TY D-8

Longitude: 152.8623

Location description and accuracy:

The center of the Muddy Creek West prospect is about 1.8 miles east of Mount Estelle and about 0.4 mile west of the center of section 2, T. 20 N., R. 20 W. The location is accurate.

Commodities:

Main: Ag, Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

The date of the discovery of the Muddy Creek West prospect is uncertain; it probably was sometime between 1986 to 1989 when Cominco Alaska worked in the area (Wahl and others, 2008). Kennecott Exploration Company was active from 2004 to 2006 and staked a large block of claims that covered the Muddy Creek West prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott in 2007, and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation. In early 2010, Kiska Metals (2010a) was actively exploring their claim block as part of their Whistler project.

The Muddy Creek West prospect covers a north-northwest trending area about 1 kilometer by 4 kilometers in size (Kiska Metals Corporation, 2010b). Numerous rock samples were collected at the prospect. A high percentage of them contained more than 1 gram of gold per tonne, 10 contained more than 5 grams of gold per tonne, and the best sample contained 56.60 grams of gold per tonne. There is little information on the prospect other than that it and the other prospects in the Muddy Creek area have 'high-grade gold-silver and base metals' and that the host rocks in the area are monzonite, monzonite porphyry, and biotite monzonite. These are probably part of the Mount Estelle pluton to the east (Wilson and others, 2009) that Reed and Lanphere (1972) dated at 65 to 66 Ma. See ARDF record TY019 for a general description of the mineralization associated with the Mount Estelle pluton.

Alteration:

Not mentioned.

Age of mineralization:

Probably coeval with or younger than the 65 to 66 Ma Mount Estelle pluton.

Generic deposit model:

Deposit model:

'... high-grade gold-silver and base metals...' mineralization.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Apparently only surface sampling.

Production notes:

None.

Reserves:

None.

The center of the Muddy Creek Central prospect is about 2.2 miles east-southeast of Mount Estelle and about 0.4 mile southwest of elevation 4785. It is 0.5 mile south of the center of section 2, T. 20 N., R. 20 W., of the Seward Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au

Other: As, Bi

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, pyrrhotite

Gangue minerals: Feldspar, quartz, tourmaline

Geologic description:

The date of the original discovery of the Muddy Creek Central prospect is uncertain; it probably was discovered when Cominco Alaska worked in the area from 1986 to 1989 (Wahl and others, 2008). Kennecott Exploration Company was active in the area from 2004 to 2006 and staked a large block of claims that covered the Muddy Creek Central prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott in 2007, and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation. As of early 2010, Kiska Metals (2010a) was actively exploring their claim blocks, which they named the Whistler project.

The Muddy Creek Central prospect covers a north-northwest trending area about 1 kilometer by 2 kilometers in size (Kiska Metals Corporation, 2010b). Numerous rock samples were collected in the area. A high percentage of them contained more than 1 gram of gold per tonne, eight contained more than 5 grams of gold per tonne, and the two best samples contained 81.1 and 111.5 grams of gold per tonne. Muddy Creek and other nearby prospects have 'high-grade gold-silver and base metals' and the rocks in the area consist of monzonite and biotite monzonite. These are probably part of the Mount Estelle pluton to the east (Wilson and others, 2009) that Reed and Lanphere (1972) dated at 65 to 66 Ma. See ARDF record TY019 for a general description of the mineralization associated with the Mount Estelle pluton in this area.

Gold mineralization is restricted to systematic sheeted vein zones with narrow millimeter-scale veinlets and pegmatitic veinlets of quartz, feldspar, tourmaline and sulfides that include arsenopyrite, minor chalcopyrite and pyrite-pyrrhotite. Gold mineralization is largely confined to the minute veinlets whereas the intervening intrusive rocks are largely unaltered and unmineralized (Roberts, 2014).

In 2011, Kiska's exploration program at Muddy Creek that focused on drilling three diamond drill holes totaling 955 meters. The first two holes tested the southwestern edge of the Phoenix Creek anomaly. The northeast directed hole, MC11-001, returned significant gold-bearing intersections including 38.8 meters averaging 0.51 gram of gold per tonne equivalent within a broader interval of 138.8 meters averaging 0.29 gram of gold per tonne equivalent. The southwest directed hole MC11-002 also had significant intersections with 45.0 meters averaging 0.52 gram of gold per tonne equivalent and 44.2 meters average 0.51 gram of gold per tonne equivalent within a broad 338.1 meters interval averaging 0.30 gram of gold per tonne equivalent. Hole MC11-003 did not reach target depth due to difficult drilling. These are the first holes at Muddy Creek and have tested a small portion of the surface geochemical anomalies (Roberts, 2014).

Alteration:

Systematic sheeted vein zones with narrow millimeter-scale veinlets and pegmatitic veinlets of quartz, feldspar, tourmaline and sulphides that include arsenopyrite, minor chalcopyrite and pyrite-pyrrhotite (Roberts, 2014).

Age of mineralization:

Probably coeval with or younger than the 65 to 66 Ma Mount Estelle pluton (Wilson and others, 2009; Reed and Lanphere, 1972).

Generic deposit model:

Deposit model:

Intrusion related gold (intrusion related gold-arsenic-bismuth-type associated with reduced plutons).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

In 2011, Kiska's exploration program at Muddy Creek that focused on drilling three diamond drill holes totaling 955 meters. The first two holes tested the southwestern edge of the Phoenix Creek anomaly. The northeast directed hole, MC11-001, returned significant gold-bearing intersections including 38.8 meters averaging 0.51 gram of gold per tonne equivalent within a broader interval of 138.8 meters averaging 0.29 gram of gold per tonne equivalent. The southwest directed hole MC11-002 also had significant intersections with 45.0 meters averaging 0.52 gram of gold per tonne equivalent and 44.2 meters average 0.51 gram of gold per tonne equivalent within a broad 338.1 meters interval averaging 0.30 gram of gold per tonne equivalent. Hole MC11-003 did not reach target depth due to difficult drilling. These are the first holes at Muddy Creek and have tested a small portion of the surface geochemical anomalies (Roberts, 2014).

Production notes:

None.

Reserves:

None.

Additional comments:

The Whistler Deposit (TY022), which is part of the Whistler project area (as is Muddy Creek), has an existing 43-101 compliant resource: 2.25 million ounces of Au equivalent (Indicated category) and 3.35 million ounces of Au equivalent (Inferred category) (Morris, 2011). However, Muddy Creek is over 16 kilometers from the Whistler Deposit and is part of a different intrusive suite than the Whistler Deposit (Roberts, 2014).

Site name(s): Bonanza

Site type: Prospect

ARDF no.: TY036

Latitude: 61.8346 **Quadrangle:** TY D-8

Longitude: 152.83

Location description and accuracy:

The Bonanza prospect is about 3.2 miles east-southeast of Mount Estelle and about 0.5 mile southwest of the center of section 12, T. 20 N., R. 20 W. The location is accurate.

Commodities:

Main: Ag, Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

The date of the original discovery of the Bonanza prospect is uncertain; it probably was discovered when Cominco Alaska worked in the area from 1986 to 1989 (Wahl and others, 2008). Kennecott Exploration Company was active in the area from 2004 to 2006 and staked a large block of claims that covered the Bonanza prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott in 2007, and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation. As of early 2010, Kiska Metals (2010a) was actively exploring their claim blocks as the Whistler project.

The Bonanza prospect is along about 600 meters of the contact of diorite with hornfelsed sediments (Kiska Metals Corporation, 2010b). Twenty samples were collected. Eleven contained more than 1 gram of gold per tonne and the best contained 69.12 grams of gold per tonne. There is little more information on the prospect other than it and their other prospects in the Muddy Creek area have 'high-grade gold-silver and base metals' and the rocks in the general area consist of monzonite porphyry and hornfels. The plutonic rocks are probably part of the Mount Estelle pluton to the east (Wilson and others, 2009) that Reed and Lanphere (1972) dated at 65 to 66 Ma. See ARDF record TY019 for a general description of the mineralization associated with the Mount Estelle pluton in this area.

Alteration:

Not mentioned.

Age of mineralization:

Probably coeval with or younger than the 65 to 66 Ma Mount Estelle pluton.

Generic deposit model:

Deposit model:

'... high-grade gold-silver and base metals...' mineralization.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:
Apparently only surface sampling.

Production notes:
None.

Reserves:
None.

Site name(s): Raintree (West, North, and South); Raintree

Site type: Prospects

ARDF no.: TY038

Latitude: 61.9769 **Quadrangle:** TY D-7

Longitude: 152.6072

Location description and accuracy:

The Raintree prospect is about 1.6 miles northwest of the mouth of Portage Creek on the Skwentna River and about 0.6 mile southeast of the center of section 20, T. 22 N., R. 18 W., of the Seward Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Au, Cu

Other: Pb, Zn

Ore minerals: Chalcopyrite, galena, gold, magnetite, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

The Raintree (West, North, and South) prospect is one of several gold-copper porphyry deposits that form a belt that trends north-northwest for at least 9 miles (Wahl and others, 2008; Kiska Metals Corporation, 2010). The best known is the Whistler deposit (TY022) about two and half miles to the west-southwest. Relatively little detail is available for the Raintree prospect. It is largely covered by surficial material but it is probably similar to the adjacent Whistler prospect (TY022). The rocks in the vicinity are mainly extrusive porphyritic andesite cut by porphyritic diorite dikes.

Cominco Alaska began mineral exploration in the area in 1986 but they ended their work in 1989. From 2004 to 2006, Kennecott Exploration Company was active in the area and staked several large blocks of claims, which included the Raintree prospect. Geoinformatics Exploration Inc. acquired the property from Kennecott, and in 2009, Kiska Metals Corporation was formed by a merger of Geoinformatics and Rimfire Minerals Corporation.

There are two significant zones of gold-copper porphyry mineralization at Raintree West, a near surface zone on the east side of the Alger Peak fault and a deeper zone on the west side of the fault. The near surface porphyry mineralization is coincident with a northwest-elongate aeromagnetic (AMAG) high anomaly that measures 250 meters long and 150 meters wide, which pinches out to the northwest and southeast. The host rock to mineralization in both zones (diorite porphyry) and the general style of gold-copper mineralization and alteration (disseminated chalcopyrite and quartz-chalcopyrite veins associated with magnetite and potassic alteration) is almost identical to the Whistler Deposit. In contrast, there is a significant component of gold-silver-lead-zinc mineralization overprinting both the gold-copper porphyry mineralization and the adjacent volcanic wall-rocks associated with quartz-carbonate veins that contain sphalerite + galena + pyrite ± chalcopyrite. These veins are interpreted as intermediate sulphidation epithermal veins that typically overlie and commonly telescope onto the core of porphyry systems. The near surface zone of porphyry mineralization has a defined strike length of 200 meters, remains open to the south, and occurs from surface down to a maximum depth of approximately 170 meters, where it is truncated by post-mineral diorite porphyry intrusions and/or faulting (Roberts, 2014).

There were several (shallow?) holes drilled at the Raintree prospect before 2008. In 2008, Geoinformatics drilled two holes, including the first at Raintree West (Kiska Metals Corporation, 2008). The area is covered by up to 5 meters of gravel and the holes were sited using proprietary targeting techniques. The first hole cut

160 meters that contained 0.59 gram of gold per tonne, 6.02 grams of silver per tonne, and 0.1 percent copper, and was entirely in porphyritic diorite. In 2009, Kiska drilled a 471.6-meter hole that cut porphyritic andesite, porphyritic diorite, and trachyandesite; it bottomed in mineralization (Kiska Metals Corporation, 2009 and 2010). The best intervals were 128.7 meters that contained 0.56 gram of gold per tonne, and 6.7 grams of silver per tonne; and 97.2 meters that contained 0.61 gram of gold per tonne, 6.94 grams of silver per tonne, 0.16 percent copper, 0.25 percent lead, and 0.59 percent zinc. The entire hole averaged 0.38 gram of gold per tonne, 4.67 grams of silver per tonne, 0.09 percent copper, 0.15 percent lead, and 0.35 percent zinc. The presence of late-stage lead- and zinc-bearing quartz-carbonate veins suggests that the drilling ended at the top of a gold-porphyry system distinct from the Whistler deposit (TY022).

Alteration:

Phyllic alteration is noted widely around the prospect at the surface. Alteration is typical of porphyry systems associated with relatively oxidized magma series (quartz vein stockwork, chalcopyrite-pyrite ore assemblage, presence of sulfates, core of potassic alteration with well-developed peripheral phyllic alteration zones) (Morris, 2011).

Age of mineralization:

Early or middle Tertiary; mineralization is interpreted to be coeval with or younger than the Tertiary volcanic, host rocks (Wahl and others, 2008).

Generic deposit model:

Deposit model:

Gold-copper porphyry (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c

Production Status: None

Site Status: Active

Workings/exploration:

The area has been explored by several companies since the early 1980s and has been one of the principal interests of Kiska Metals Corporation's Whistler project. Their work has included detailed mapping, geochemical and geophysical surveys, sampling, and at least 6 drill holes, including two in 2008 and another in 2009.

There were several (shallow?) holes drilled at the Raintree prospect before 2008. In 2008, Geoinformatics drilled two holes, including the first at Raintree West (Kiska Metals Corporation, 2008). The area is covered by up to 5 meters of gravel and the holes were sited using proprietary targeting techniques. The first hole cut 160 meters that contained 0.59 gram of gold per tonne, 6.02 grams of silver per tonne, and 0.1 percent copper, and was entirely in porphyritic diorite. In 2009, Kiska drilled a 471.6-meter hole that cut porphyritic andesite, porphyritic diorite, and trachyandesite; it bottomed in mineralization (Kiska Metals Corporation, 2009 and 2010). The best intervals were 128.7 meters that contained 0.56 gram of gold per tonne, and 6.7 grams of silver per tonne; and 97.2 meters that contained 0.61 gram of gold per tonne, 6.94 grams of silver per tonne, 0.16 percent copper, 0.25 percent lead, and 0.59 percent zinc. The entire hole averaged 0.38 gram of gold per tonne, 4.67 grams of silver per tonne, 0.09 percent copper, 0.15 percent lead, and 0.35 percent zinc. The late-stage lead- and zinc-bearing quartz-carbonate veins suggests that the drilling ended at the top of a gold-porphyry system distinct from the Whistler deposit (TY022).

Kennecott Exploration Company carried out systematic exploration of the Whistler project area between 2003 and 2006, which included reconnaissance mapping and prospecting; airborne geophysical and radiometric surveying; rock, soil and stream sediments sampling; detailed mapping over selected areas and ground induced polarization (IP) surveying (Wahl and others, 2008).

Since the first hole that discovered mineralization at the Raintree West prospect (Hole RN08-06, drilled

by Geoinformatics in 2008) there has been a total of 8,538 meters drilled (Roberts, 2014). Five holes were drilled by Kiska in 2009 and 2010 (Morris, 2011).

The near surface porphyry mineralization is coincident with a northwest-elongate aeromagnetic (AMAG) high anomaly that measures 250 meters long and 150 meters wide, which pinches out to the northwest and southeast. Drilling has intersected porphyry mineralization on two 100 meter-spaced east-west AMAG cross-sections (6,871,350 millinewtons and 6,871,450 millinewtons). Hole WH09-002 (drilled at an opposing azimuth to hole RN08-06) confirmed the near surface zone of mineralization discovered in hole RN08-06, returning 128.7 meters of 0.56 gram of gold per tonne and 0.16 percent copper from 59.0 meters downhole. In addition, this hole crossed to the west of the Algers Peak fault and intersected the deeper zone of porphyry mineralization returning 40 meters of 0.98 gram of gold per tonne and 0.21 percent copper from 429.0 meters downhole (Roberts, 2014).

The deep zone of mineralization on the west side of the fault has been drilled along a northwest-trending strike length of 325 meters and is open to the north, west and to depth. The AMAG and 3D IP data could not resolve the mineralization due to the limited depth penetration of these surveys and a masking effect caused by the presence of narrow, but strongly magnetic, dykes in the near subsurface. A cross-section of the AMAG anomaly at 6,871,650 millinewtons shows significant grades and widths of porphyry mineralization, and demonstrates that this strong system remains open to depth. Significant intercepts include 172.0 meters averaging 1.13 grams of gold per tonne and 0.18 percent copper from 619.0 meters in hole WH10-030 and 218.0 meters averaging 0.53 gram of gold per tonne and 0.11 percent copper from 480.1 meters in hole WH11-033 (Roberts, 2014).

Drilling at Raintree North and Raintree South has confirmed that porphyry stocks in these areas host gold-copper porphyry mineralization, with alteration and veining remarkably similar to that characteristic of the Whistler Deposit and Raintree West. Gold-copper mineralization in all three prospects occurs immediately below till cover at the top of bedrock. Significant drilling intercepts include: Raintree North: WH11-034 returned 77.3 meters averaging 0.58 gram of gold per tonne, 1.6 grams of silver per tonne and 0.19 percent copper (0.99 gram of gold per tonne equivalent) within a larger interval averaging 0.40 gram of gold per tonne, 1.53 grams of silver per tonne and 0.14 percent copper over 148.5 meters (Roberts, 2014).

In 2016, Brazil Resources Inc. (now Gold Mining Inc.) is evaluating prospects it acquired from Kiska Metals Corporation in 2015. Although no on-site work was performed in 2016 at the Whistler (TY022), Raintree West, and Island Mountain (TY018) porphyry copper–gold–silver prospects, in May of 2016, Brazil Resources Inc. released a new technical report (Giroux, 2016) announcing the first resource estimates for the Raintree West and Island Mountain (TY018) deposits, largely based on drilling by Kiska Metals Corporation between 2009 and 2011. Metal recoveries reported for the Whistler deposit (TY022) resource estimate, and assumed for the Raintree West deposit, include 85 percent for copper, 75 percent for gold, and 75 percent for silver (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

At a 0.6 gram of gold-equivalent per tonne cut-off grade below the 100-m elevation level, the new resource estimate for Raintree West includes an inferred resource of 51.76 million tonnes grading 0.68 gram of gold per tonne (1.13 million ounces of gold), 3.74 grams of silver per tonne (6.22 million ounces of silver), and 0.10 percent copper (114.13 million pounds of copper). At a 0.3 gram gold-equivalent per tonne cut-off above the 250-m elevation level, Raintree West also contains an inferred resource of 31.68 million tonnes grading 0.40 gram of gold per tonne (410,000 ounces of gold), 5.39 grams of silver per tonne (5.49 million ounces of silver), and 0.06 percent copper (41.91 million pounds of copper). The Raintree West resource is based on 7,078 meters of drilling in 14 holes (Giroux, 2016).

Additional comments:

The Whistler Deposit (TY022), which is within 3 kilometers of the Raintree prospect, has an existing 43-101 compliant resource: 2.25 million ounces of gold equivalent (Indicated category) and 3.35 million ounces of gold equivalent (Inferred category) (Morris, 2011). However, Raintree seems to be a different system from Whistler based on the presence of late-stage lead- and zinc-bearing quartz-carbonate veins (Kiska Metals Corporation, 2010).

Site name(s): Monte Cristo

Site type: Prospect

ARDF no.: TY039

Latitude: 61.7649 **Quadrangle:** TY D-7

Longitude: 152.4617

Location description and accuracy:

The center of the Monte Cristo prospect is about 13 miles north of Mount Gerdine in the Tordrillo Mountains. It is about 1.5 miles north of lake 2885 on the 1:63,360-scale topographic map, near the center of section 1, T. 19 N., R. 18 W., of the Seward Meridian. This location is accurate to within 500 feet.

Commodities:

Main: Au

Other: Fe

Ore minerals: Arsenopyrite, pyrite, pyrrhotite

Gangue minerals: Quartz, sericite

Geologic description:

The Monte Cristo prospect was first identified by Millrock Resources Inc. in 2009 and was optioned to Brixton Metals Corp. in 2010 (Eden, 2010). This prospect is located in the Kahlitna Terrain. There has been little past exploration in this area due to the challenges posed by the mountainous terrain and alpine glaciers. However, the glacial retreat of recent years has improved exposure and access (Millrock Resources Inc., 2014).

The rocks in the vicinity of the Monte Cristo prospect are highly altered Jurassic and Cretaceous volcaniclastic rocks and Tertiary granitic rocks (Wilson and others, 2009). There is little iron-staining, but carbonate alteration covers an area about 3.5 by 4.5 kilometers in size. Eden (2010) suggests that the mineralization is part of a gold porphyry system.

In 2009 and 2010, Millrock did a geochemical survey over the area consisting of 213 soil samples, and collected 80 rock samples. This exploration work showed that the gold mineralization at Monte Cristo is hosted in zones of highly hydrothermally altered volcaniclastic and porphyritic intrusive rocks. Mineralized zones occur on two parallel ridge-backs separated by about 300 m of shallow glacial debris cover. Rock samples assayed up to 4.2 grams per tonne gold and soil samples (talus fines) assayed up to grams per tonne gold. Alteration is dominated by carbonate with quartz-sericite assemblages (Millrock Resources Inc., 2014).

In 2011, Brixton (2011) collected rock samples and carried out soil and stream-sediment geochemical surveys over the area. Samples they collected typically included 1-3 percent pyrite, pyrrhotite, and arsenopyrite that occurs along fractures and disseminated. Brixton terminated their agreement with Millrock in January, 2012.

Alteration:

Widespread carbonate alteration (Eden, 2010) with quartz and sericite (Millrock Resources Inc., 2014).

Age of mineralization:

May be related to a nearby Tertiary granitic intrusion (Eden, 2010).

Generic deposit model:

Deposit model:

Polymetallic vein? (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Active

Workings/exploration:

The Monte Cristo prospect was first identified by Millrock Resources Inc. in 2009 and was optioned to Brixton Metals Corp. in 2010 (Eden, 2010). In 2009 and 2010, Millrock did a geochemical survey over the area and collected numerous rock samples (Millrock Resource Inc., 2012). Brixton Metals sampled the property in 2011 and carried out soil and stream-sediment surveys (Brixton Metals, 2011).

Site name(s): El-10

Site type: Prospect

ARDF no.: TY040

Latitude: 61.541 **Quadrangle:** TY C-5

Longitude: 151.8393

Location description and accuracy:

This prospect is located about equidistant between Strandine Lake and Coal Creek; NW1/4 of section 29, T. 17 N., R. 14 W., of the Seward Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, pyrite, sphalerite

Gangue minerals: Chlorite, quartz

Geologic description:

El-10 is a prospect in the Beluga Project area. This area has been intruded by younger 62 million year old felsic intrusive volcanic and sedimentary package with that exhibit porphyry style alteration and lead-zinc-silver mineralization. This area is thought to be part of the Jurassic Talkeetna Formation. Numerous color anomalies were noted in the lower parts of the stream valleys within the felsic package and semi-massive float boulders were also discovered (Ellis, 1994).

The showing at El-10 is characterized by chlorite-sulfide stock work, gossanous breccias, and vein breccias. Pyrite, chalcopyrite, and sphalerite are found in dark chlorite and silica. The breccias and veins crosscut rhyolite crystal tuffs in a 1-200 foot area. The style of mineralization and alteration resembles footwall stringers of a VMS-type system. The alteration type is chloritic (Ellis, 1994).

Exploration by American Copper and Nickel Company in 1994 focused on mapping, sampling and prospecting. Eight rock samples and four stream and pan samples from El-10 were collected and analyzed. Average results were 12 parts per million (ppm) silver, 0.03 percent copper,0.6 percent lead, and 3.8 percent with a high of 10.0 percent zinc (Ellis, 1994).

Analysis from a fine-grained porphyry returned an age of 62 million years using argon-argon dating analyzed by the University of British Columbia petrology lab (Ellis, 1994).

Alteration:

Chloritic (Ellis, 1994).

Age of mineralization:

Analysis from a fine-grained porphyry returned an age of 62 million years using argon-argon dating analyzed by the University of British Columbia petrology lab (Ellis, 1994).

Site type: Prospect

ARDF no.: TY041

Latitude: 61.5308 **Quadrangle:** TY C-5

Longitude: 151.8643

Location description and accuracy:

This prospect is located about 1.8 miles east of Strandine Lake; about 0.27 miles north-northeast from the southwest corner of section 29, T. 17 N., R. 14 W., of the Seward Meridian. The location is accurate to within 500 feet.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: Ba

Ore minerals: Barite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals: Chlorite, fluorite, quartz

Geologic description:

Squirrel Head is a prospect in the Beluga Project area. This area has been intruded by younger 62 million year old felsic intrusive volcanic and sedimentary package with that exhibit porphyry style alteration and lead-zinc-silver mineralization. This area is thought to be part of the Jurassic Talkeetna Formation. Numerous color anomalies were noted in the lower parts of the stream valleys within the felsic package and semi-massive float boulders were also discovered (Ellis, 1994).

The showings at Squirrel Head and Squirrel Head East are characterized by mineralized silica-sulfide breccias. Variable amounts of pyrite-pyrrhotite + galena and sphalerite plus trace chalcopyrite mineralization within intensely silicified and banded to stockworked occur in zones up to 50 feet by 300 feet. Gangue minerals are barite, quartz, chlorite, and rare fluorite. This area exhibits footwall stockwork VMS feeder zones. The alteration is baritic, silicification, and sericitization barite, quartz, and sericite (Ellis, 1994).

Analysis from a fine-grained porphyry returned an age of 62 million years using argon-argon dating analyzed by the University of British Columbia petrology lab (Ellis, 1994).

Alteration:

Barite, sericite, and quartz alteration (Ellis, 1994).

Age of mineralization:

Site name(s): West Wing

Site type: Prospect

ARDF no.: TY042

Latitude: 61.9151 **Quadrangle:** TY D-8

Longitude: 152.9557

Location description and accuracy:

West Wing is located about 2.7 miles south of Cathedral Mountain; about 0.3 mile north-northeast of the center of section 16, T. 21 N., R. 20 W., of the Seward Meridian. This location is accurate to within 500 feet from the center of the prospect.

Commodities:

Main: Au, Cu

Other: As, Bi, Fe, Te

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, pyrrhotite

Gangue minerals: Quartz

Geologic description:

West Wing is a mineralized prospect that is part of the Estelle gold property (TY019). West Wing lies within a plutonic complex intruding a Jurassic to Early Cretaceous flysch sequence (Reed and Nelson, 1980). The intrusive complex consists of ultramafic to felsic plutons of Late Cretaceous/Early Tertiary age (69.7 Ma) and are centrally located in a region of arc-magmatic related gold deposits (Millrock Resources Inc., 2014).

West Wing is characterized by roof pendants of hornfels that are cut by biotite-rich diorite. Hydrothermal breccia, quartz sulfide veins and carbonate veins cut all lithologies. Mineralization occurs as disseminated sulfides and as sulfides associated with veins. The highest sulfide content is associated with a diorite sill containing 1 to 3 percent disseminated arsenopyrite ± pyrite ± chalcopyrite ± pyrrhotite. This unit and the hornfels unit are cut by high density quartz ± pyrite ± chalcopyrite ± arsenopyrite ± pyrrhotite veinlets also containing 1 to 3 percent sulfide, and appears to increase in intensity toward the lower contact of the sill (Millrock Resources Inc., 2014).

Alteration:

Hornfelsed sedimentary rocks cut by biotite-rich diorite are cross-cut by hydrothermal breccia, quartz-sulfide veins and carbonate veins (Millrock Resources Inc., 2014).

Age of mineralization:

Late Cretaceous/early Tertiary?; mineralization in the area is thought to be related to the 65 to 66 Ma granodiorite of Mount Estelle (Reed and Lanphere,1972).

Generic deposit model:

Deposit model:

Porphyry Cu-Au or intrusion-related gold? (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c?

Production Status: None

Site Status: Active

Workings/exploration:

Geologic mapping in 2012 defined a zone of strong hydrothermal alteration surrounding a diorite sill. At surface, copper, iron and arsenic sulfide mineralization with gold in quartz veins and veinlets appears to increase in intensity toward the lower contact of the sill (Millrock Resources Inc., 2012).

In 2012, soil and rock sampling at West Wing defined multiple surface gold and copper anomalies with individual sample results as high as 18 parts per million (ppm) gold in soil and 108 ppm gold in rock. Composited chip sample results, collected near the site of the 2012 drilling, included 20 meters (66 feet) averaging 0.94 ppm gold and 4050 ppm copper (Millrock Resources Inc., 2014).

Drill results from hole SE12-007 are 0.68 gram of gold per tonne from 50.29 to 61.87 meters, including 1.01 grams of gold per tonne from 50.29 to 57.30 meters. Results from hole SE12-007 are 1.20 grams of gold per tonne from 75.29 to 76.51 meters. Results from SE12-009 are 0.52 gram of gold per tonne from 48.77 to 52.43 meters. Note: Listed composites are those averaging greater than 0.50 gram of gold per tonne calculated using a 0.20 gram of gold per tonne cutoff with a maximum 3 meters internal dilution. Elevated copper values are also present in core from this prospect and range between 1000 and 4580 ppm copper. This newly discovered mineralization appears to be hosted by a shallow dipping diorite dike or sill (Millrock Resources Inc., 2012).

Production notes:

None.

Reserves:

None.

Site name(s): RPM

Site type: Prospect

ARDF no.: TY043

Latitude: 61.7759

Quadrangle: TY D-8

Longitude: 152.9555

Location description and accuracy:

The RPM prospect is located about 2.0 miles northwest of Emerald Creek; about 0.2 mile from the southwest corner of section 32, T. 29 N., R. 20 W., of the Seward Meridian. This location is accurate to within 500 feet from the center of the prospect.

Commodities:

Main: Au, Cu

Other: As, Bi, Te

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite

Gangue minerals: Quartz, tourmaline

Geologic description:

RPM is a mineralized prospect that is part of the Estelle gold property. RPM lies within a plutonic complex intruding a Jurassic to Early Cretaceous flysch sequence (Reed and Nelson, 1980). The intrusive complex consist of ultramafic to felsic plutons of Late Cretaceous/Early Tertiary age (69.7 Ma) and are centrally located in a region of arc-magmatic related gold deposits. Though mineralization at Estelle is generally restricted to the intrusive rocks, mineralization at RPM occurs in both intrusive and hornfels (Millrock Resources Inc., 2014).

At RPM roof pendants of hornfels occur overlying multiple intrusive units. Fingers of fine grained aplite, monzonite and biotite-rich diorite cut the hornfels. All of the lithologic units are in turn cut by stockwork and/or sheeted veins. Veins range in size and character from meter wide quartz ± sulfide to millimeter scale quartz-arsenopyrite veins and centimeter scale quartz-tourmaline-sulfide veins. A granitic intrusive body, which underlies the hornfels and crops out in the southern part of the prospect area appears to be potentially related to mineralization (Millrock Resources Inc., 2014).

The RPM prospect is contained in a 3,500 meter long, northwest trending gold anomaly defined by soils assaying over 0.010 part per million (ppm) gold including individual samples containing up to 13.25 ppm gold. Copper values are also elevated with the majority of samples returning assays over 200 ppm copper. The copper values outline a broader, more dispersed anomaly. In addition to soil sampling, extensive rock chip sampling has been done returning composited sample results up to 90 meters (295 feet) averaging 0.54 gram of gold per tonne (Millrock Resources Inc., 2014).

Alteration:

Hornfelsed sedimentary rock roof pendants overlying multiplie intrusive units are cut by aplite, monzonite, and biotite-rich diorite dikes. All of these units are cut by stockwork and/or sheeted quartz +/- sulfide veins (Millrock Resources Inc., 2014).

Age of mineralization:

Late Cretaceous/early Tertiary?; mineralization in the area is thought to be related to the 66 to 67 Ma granodiorite of Mount Estelle (Reed and Lanphere,1972).

Generic deposit model:

Deposit model:

Porphyry Cu-Au or intrusion-related gold? (Cox and Singer, 1986; model 20c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

20c?

Production Status: None

Site Status: Active

Workings/exploration:

Millrock Resources Inc. conducted a 2012 exploration program consisting of prospecting, soil sampling, rock sampling, and drilling at RPM prospect. RPM is contained in a 3,500 meter long, northwest trending gold anomaly defined by soils assaying greater than 0.010 part per million (ppm) gold including individual samples containing up to 13.25 ppm copper. Copper values are also elevated with the majority of samples returning assays greater than 200 ppm copper. The copper values outline a broader, more dispersed anomaly. In addition to soil sampling, extensive rock chip sampling has been done returning composited sample results up to 90 meters (295 feet) averaging 0.54 gram of gold per tonne (Millrock Resources Inc., 2014).

One drillhole completed in 2012 targeted a mineralized monzonite plug cut by sheeted and stockwork quartz veins. The hole encountered significant gold mineralization returning an intercept of 2.07 grams of gold per tonne over 21.94 meters (72 feet) within a 102.11 meters (335 feet) interval averaging 1.04 grams of gold per tonne with mineralization open in all directions (Millrock Resources Inc., 2012).

Site type: Occurrence

ARDF no.: TY044

Latitude: 61.7083 **Quadrangle:** TY C-5

Longitude: 151.7876

Location description and accuracy:

T-Bird is located about 3.5 miles southeast of Hayes River Pass; about 0.2 mile east of the center of section 27, T. 19 N., R. 14 W., of the Seward Meridian. The location is accurate to within 100 feet of the center of the occurrence (Ellis, 1994).

Commodities:

Main: Ag, Au, Cu, Mo, Pb, Zn

Other: Ba

Ore minerals: Barite, chalcopyrite, galena, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

T-bird is an occurrence in the Beluga Project Area. This area is made of Cretaceous sedimentary units that have been intruded by 62 Ma felsic hypabyssal rocks and exhibits porphyry style alteration and lead-zinc-silver mineralization. Numerous color anomalies were noted in the lower parts of the stream valleys within the felsic package and massive sulfide float boulders were also discovered (Ellis, 1994). The Cook Inlet region geologic map (Wilson and others, 2012) shows that this occurrence occurs in an area of intermediate composition Cretaceous volcanic and sedimentary rocks overlain by Tertiary or Cretaceous age felsic tuff.

The T-bird occurrence is characterized by a fault-controlled massive sulfide vein consisting of massive pyrite-pyrrhotite + chalcopyrite, galena and sphalerite in a silica-rich matrix. This vein is 1-2 feet thick and can be traced about 50 feet. It trends north, is near vertical and is hosted by rhyolite. High-grade base metal samples carried up to 4 ounces of silver per ton and up to 0.68 percent molybdenum. Drainages below and to the north of T-bird contained from 20 to 73 parts per million (ppm) molybdenum and 50 to 356 ppm copper. Copper and molybdenum anomalies have been identified in stream sediment samples (Ellis, 1994).

Alteration:

Silicification (Ellis, 1994).

Age of mineralization:

Analysis from a fine-grained porphyry returned an age of 62 million years using argon-argon dating analyzed by the University of British Columbia petrology lab (Ellis, 1994).

Generic deposit model:

Longitude: 151.7752

Location description and accuracy:

Lucky Bear is located about 4.2 miles southeast of Hayes River Pass; about 0.5 mile west-northwest of the center of section 2, T. 18 N., R. 14 W., of the Seward Meridian. The location is accurate to within about 500 feet from the center of the occurrence (Ellis, 1994).

Commodities:

Main: Ag, Au, Cu, Mo, Pb, Zn

Other: Ba

Ore minerals: Galena, molybdenite, pyrite, pyrrhotite, sphalerite

Gangue minerals:

Geologic description:

Lucky Bear is an occurrence in the Beluga Project Area. This area is made of Cretaceous sedimentary units that have been intruded by 62 Ma felsic hypabyssal rocks and exhibits porphyry style alteration and lead-zinc-silver mineralization. Numerous color anomalies were noted in the lower parts of the stream valleys within the felsic package and massive sulfide float boulders were also discovered (Ellis, 1994). The Cook Inlet region geologic map (Wilson and others, 2012) shows that this occurrence occurs in an area of intermediate composition Cretacous volcanic and sedimentary rocks.

This area has been intruded by younger 62 million year old felsic intrusive volcanic and sedimentary packages that exhibit porphyry style alteration and lead-zinc-silver mineralization. Lucky Bear is characterized by veins and breccias with sphalerite and galena and stratiform massive sulfide pods and lenses of pyrrhotite and sphalerite up to 2 feet thick and 20 feet long. They are intermittently exposed within a 1 to 200 foot thick interval of thin-bedded siltstone, fine-grained tuff and chert. Mineralization can be traced a few thousand feet along strike. Quartz-calcite gangue is locally recrystallized and epidote-altered. Mineralization is either exhalative volcanic massive sulfides (VMS) or replacement (Ellis, 1994).

Alteration:

Quartz-calcite gangue is locally recrystallized and epidote-altered (Ellis, 1994).

Age of mineralization:

A fine-grained porphyry returned an age of 62 million years using argon-argon dating analyzed by the University of British Columbia petrology lab (Ellis, 1994).

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Workings/exploration:

In 1993, a reconnaissance effort was carried out by American Copper and Nickel Company's 'Alaska Task Force' to identify targets for future work (Ellis, 1994).

Exploration by American Copper and Nickel Company in 1994 focused on mapping, sampling and prospecting. Twenty rock samples and five stream and pan samples from Lucky Bear were collected and analyzed. Average results were 470 parts per billion (ppb) gold, 3 parts per million (ppm) silver, 0.2 percent copper, 8.6 percent zinc (Ellis, 1994).

Production notes:

None.

Reserves:

None.

Last report date: 2016-03-15

Site name(s): Opal; Tiger Mining Co.

Site type: Mine

ARDF no.: VA021

Latitude: 61.5371 **Quadrangle:** VA C-2

Longitude: 144.6462

Location description and accuracy:

This prospect is located in the cirque at the southwest head of Liberty Creek. It is in the southeast headwall of this cirque, about nine-tenths of a mile north of elevation 5,285. It is at an elevation of 4,400 feet in the NW1/4 section 11, T. 4 S, R. 4 E., of the Copper River Meridian. This prospect is approximately located, perhaps to within one-half mile. It is locality 54 of of Cobb and Matson (1972) and locality 45 of Winkler and others (1981 [OFR 80-892-B]). The location used in this report is that shown by Winkler and others (1981 [OFR 80-892-B]); it is nine-tenths of a mile north of the location shown by Cobb and Matson (1972).

Commodities:

Main: Au

Other: Ag, Pb, Zn

Ore minerals: Arsenopyrite, galena, gold, pyrite, sphalerite

Gangue minerals: Quartz

Geologic description:

Widely spaced quartz veins as much as 1 meter wide cut the schist of both the Liberty Creek terrane and Eocene tonalite (Winkler and others, 1981 [OFR 80-892-B]; Winkler and others, 1981 [OFR 80-892-A]). The veins contain arsenopyrite, pyrite, galena, and sphalerite.

The Opal prospect, being evaluated by Ben Porterfield, contains gold-bearing, polymetallic quartz veins hosted in a white mica-altered, 52 million-year-old tonalite sill. In 2016, exploration was conducted on high-angle shear zones cutting the sill and on pods at the wall-rock contact at the top of the sill (Athey and Werdon, 2017).

Alteration:

Age of mineralization:

Tertiary; the quartz veins cut tonalite with a K/Ar age of 52.4 +/- 2.6 m.y. (Winkler and others, 1981 [OFR 80-892-A]).

Generic deposit model:

Deposit model:

Polymetallic veins (Cox and Singer, 1986; model 22c)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

The Opal prospect, being evaluated by Ben Porterfield, contains gold-bearing, polymetallic quartz veins hosted in a white mica-altered, 52 million-year-old tonalite sill. High gold grades, up to 4 ounces of gold per ton, are present, visible gold is common, and it is associated with galena, sphalerite, pyrite, and arsenopyrite. In 2016, exploration was conducted on high-angle shear zones cutting the sill and on pods at the wall-rock contact at the top of the sill (Athey and Werdon, 2017).

Production notes:

None.

Reserves:

None.

Last report date: 2017-08-26

Site name(s): Unnamed (on lower Walkaround Creek)

Site type: Occurrence

ARDF no.: WI002

Latitude: 67.858 **Quadrangle:** WI D-6

Longitude: 152.5947

Location description and accuracy:

Following Brosge and Reiser (1960), this occurrence is on Walkaround Creek at an elevation of about 430 meters; it is about 0.3 mile west of the center of section 17, T. 35 N., R. 22 W. The location is accurate within 1 mile. Early reports by Berg and Cobb (1967), Cobb (1972), and Grybeck (1977) commonly refer to both this site and WI001 as 'Hunt Fork'.

Commodities:

Main: Cu, Pb

Other:

Ore minerals: Chalcopyrite, galena

Gangue minerals: Quartz

Geologic description:

This occurrence is a galena-bearing quartz vein (Brosge and Reiser, 1960). The country rocks are black slate and phyllite of the Upper Devonian Hunt Fork Shale. The area was re-examined by Kurtak and others (2002) who found no more than phyllite with quartz lenses parallel to the foliation. The quartz contained only trace amounts of galena and chalcopyrite; on analysis, a sample did not contain anomalous lead or copper. (The Kurtak and others (2002) work also probably included an examination of a nearby site with similar mineralization (WI001).

Alteration:

None noted.

Age of mineralization:

Upper Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Quartz veins.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Examined by several parties of government geologists.

Production notes:

None.

Reserves:

None.

Additional comments:

The site is in Gates of the Arctic National Park.

Site name(s): John River

Site type: Occurrence

ARDF no.: WI003

Latitude: 67.7596 **Quadrangle:** WI D-5

Longitude: 152.3832

Location description and accuracy:

The original reference for this occurrence only describes its location as being on the John River below the mouth of the Hunt Fork (Joesting, 1942). Based on subsequent descriptions (Berg and Cobb, 1967; Cobb, 1972; Maas, 1987), it may be at an elevation of about 1,500 feet on the east side of John River, about 1.5 miles downstream from the mouth of Hunt Fork. y Kurtak and others (2002) searched he area but they found no sign of this occurrence and there is no other evidence of its location other than the brief Joesting reference. The location of this occurrence is suspect.

Commodities:

Main: Sb

Other:

Ore minerals: Stibnite

Gangue minerals:

Geologic description:

Joesting (1942) listed a stibnite lode, a sample of which assayed 42 percent antimony, on an unnamed tributary to the John River about a mile downstream from the mouth of the Hunt Ford. The rocks in the area consists of Upper Devonian, Hunt Fork Shale in fault contact with Middle or Upper Devonian(?) or older(?), black slate, phyllite. and limestone (Dillon and others, 1986). Kurtak and others (2002) searched the area for this occurrence but found no sign of it. The location of this occurrence is suspect.

Alteration:

Not noted.

Age of mineralization:

Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Simple Sb deposit? (Cox and Singer, 1986; model 27d?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

27d?

Production Status: None

Site Status: Inactive

Workings/exploration:

The only evidence of this occurrence is that it is reported by Joesting (1942).

Production notes:

None.

Reserves:

None.

Additional comments:

As best that it can be located, this occurrences is in Gates of the Arctic National Park.

Site name(s): Unnamed (east of VABM Allen)

Site type: Prospect

ARDF no.: WI005

Latitude: 67.5469 **Quadrangle:** WI C-5

Longitude: 152.0431

Location description and accuracy:

This prospect is in a high saddle about 0.8 mile east-northeast of VABM Allen and about 4 miles northeast of the junction of Sheep Creek and John River. The prospect is at an elevation of about 4,000 feet near the southeast corner of section 32, T. 32 N., R. 20 W.. The location is accurate.

Commodities:

Main: Cu

Other: Mo

Ore minerals: Azurite, bornite, chalcocite, chalcopyrite, covellite, malachite

Gangue minerals: Quartz

Geologic description:

Brosge and Reiser (1960) described copper sulfides and malachite at this prospect in fault contact between Devonian Skajit Limestone and a Devonian phyllite and siltstone unit. Dillon and others (1981, sample 284) described disseminated covellite and bornite and malachite stain in pale-green calc-schist and quartz veins. A sample contained up to 5,000 parts per million (ppm) copper and 10 ppm molybdenum. Kurtak and others (2002) analyzed one rock sample of chlorite-quartz schist that contained chalcocite, malachite and azurite. It contained 1,664 ppm copper, 4.8 ppm silver, and 23 parts per billion (ppb) gold. Degenhart and others (1978) reported minor amounts of chalcopyrite, bornite and malachite in metamorphosed, reef limestone near VABM Allen, only a short distance west of this location. Prior to the mid-1970s, at least five companies including Bear Creek Mining Company, General Crude Oil Company, New Jersey Zinc Company, Alvenco Inc., and BP Alaska prospected and sampled in the area as part of their work in a 5-mile-long, northeast-trending belt of mineral occurrences along a thrust fault (Degenhart, and others, 1978).

Alteration:

Local oxidation of copper minerals.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Unclear from the limited information.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Prior to the mid-1970s, at least five companies including Bear Creek Mining Company, General Crude Oil Company, New Jersey Zinc Company, Alvenco Inc., and BP Alaska prospected and sampled in the area as part of their work in a 5-mile-long, northeast-trending belt of mineral occurrences along a thrust fault (Degenhart and others, 1978). Examined and sampled by the U.S. Geological Survey (Brosge and Reiser, 1960), the Alaska Division of Geological and Geophysical Survey (Dillon and others, 1981), and the Bureau of Land Management (Kurtak and others, 2002).

Site name(s): Unnamed (near VABM Pink)

Site type: Prospect

ARDF no.: WI007

Latitude: 67.5142 **Quadrangle:** WI C-5

Longitude: 152.3057

Location description and accuracy:

This prospect is at an elevation of about 3,700 feet , about 0.5 mile northwest of VABM Pink, in the NE1/4 section 18, T. 31 N., R. 21 W. The prospect is the location of sample 518 in Dillon and others (1981). The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Sb

Other:

Ore minerals: Azurite, chalcocite, galena, malachite, tetrahedrite?

Gangue minerals: Quartz

Geologic description:

This rocks in the vicinity of this prospect are marble of the Middle Devonian Skajit Limestone in fault contact with calcareous schist and mudstone of the Upper Devonian Hunt Fork Shale (Dillon and others, 1986). Dillon and others (1981) identified a vein, more than 2 centimeters thick, of azurite, malachite, and chalcocite, in a unit of metamorphosed conglomerate, sandstone and shale, below marble. A sample of the vein contained 66.4 percent copper and 21.7 parts per million (ppm) silver.

Kurtak and others (2002) examined the site as part of a regional mineral resource assessment and collected several samples. Several pieces of quartz float contained minor amounts of tetrahedrite(?), with rims of malachite and galena. A sample contained 1,744 ppm lead, 921 ppm antimony, and 585 ppm copper. Prior to the mid-1970s, at least five companies including Bear Creek Mining Company, General Crude Oil Company, New Jersey Zinc Company, Alvenco Inc., and BP Alaska prospected and sampled in the area as part of their work in a 5-mile-long, northeast-trending belt of mineral occurrences along a thrust fault. (Degenhart, and others, 1978).

Alteration:

Oxidation of copper minerals.

Age of mineralization:

Devonian or younger based on the age of the host rock.

Last report date: 2011-02-01

Site name(s): Surprise Creek; Summit Creek

Site type: Mine

ARDF no.: WI009

Latitude: 67.518 **Quadrangle:** WI C-4

Longitude: 151.5192

Location description and accuracy:

Surprise Creek (named Summit Creek in reports from the 1930s) flows into the east side of Wild Lake about 0.2 mile north of the mouth of Spring Creek. There is evidence of placer mining along a 2-mile stretch of the Surprise Creek, but the mine workings appear to be concentrated along a 500-foot segment about 0.5 mile above the mouth of the creek. This mining is in the NW1/4 section 14, T. 31 N., R 18 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

The rocks in Surprise Creek are described by Reed (1938) as quartzite, greenstone, and graphitic and micaceous schists that are cut by several quartz veins in the lower valley. Quartz also constitutes a substantial portion of the detrital material in the creek. Dillon and others (1986) map the area as Middle Devonian siliceous clastic rocks.

Placer gold was discovered in 1904 in the modern stream bed of Surprise Creek (Summit Creek in old reports) and mining began that year (Reed, 1938). Surprise Creek was sporadically mined from 1904 through about 1937 (Kurtak and others, 2002). There is no record of claims after 1938. There are limited production figures available for Surprise Creek. Kurtak and others (2002) indicate that only 41 ounces of gold were produced from 1932 to 1937 but no figures are available for the mining from 1904 to 1932.

Mining has been sporadic and in many cases the workings failed to reach bedrock. Where it was reached, the depth to bedrock is 12 to 14 feet but the bedrock surface apparently slopes to the north under talus and becomes progressively deeper. The gravel in the creek is not frozen. It is very coarse and angular, and contains many large boulders at the top of the section. Much of the gold was produced in a 500-foot section of the creek by 'booming'. That is the dams ponded water which was then periodically released to wash the gravel over the bedrock. The boulders that remained were stacked to the side and the gold was recovered by hand methods. The gold is coarse and many nuggets accompany the fine gold. The gold occurs in the lower 3 feet of the gravel and on top of the bedrock; it is about 920 fine. Smith (1932) reported that a boulder of quartz float found in Summit (Surprise) Creek was 'liberally spangled with gold'.

Samples collected by Kurtak and others (1999) along Surprise Creek include panned concentrates that contained up to 3,888 ppb gold, limonite-stained quartz-carbonate float that contained 163 ppb gold, and a piece of malachite-stained schist.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes

Site Status: Inactive

Workings/exploration:
Placer gold was discovered in 1904 in the modern stream bed and mining began that year; it continued sporadically to 1937 (Reed, 1938; Kurtak and others, 2002). There is no record of claims after 1938.

Production notes:
There are limited production figures available for Surprise Creek. Kurtak and others (2002) indicate that only 41 ounces of gold were produced from 1932 to 1937 but no figures are available for the mining from 1904 to 1932.

Site name(s): Spring Creek

Site type: Mine

ARDF no.: WI010

Latitude: 67.5114 **Quadrangle:** WI C-4

Longitude: 151.5305

Location description and accuracy:

Spring Creek is a small, west-flowing stream that empties into the east side of the middle of Wild Lake. Mining on Spring Creek has occurred from its mouth to the forks about 1.5 miles upstream. The site is plotted at an elevation of about 1,300 feet, about at the midpoint of the workings and about 0.5 mile east of the center of section 15, T. 31 N., R. 18 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Reed (1938) described the bedrock in Spring Creek as quartzite, and graphitic and greenstone schists. Dillon and others (1986) map the rocks in the Spring Creek area as Middle Devonian(?) siliceous clastic rocks.

Placer gold was discovered on Spring Creek in 1903 and the creek was mined for 22 of the years between 1904 to 1948, mainly by hand mining (Reed, 1938; Kurtak and others, 2002). Several mining operations described by Reed indicate that the depth to bedrock along Spring Creek varied from 5 to 25 feet and occasionally as much as 50 feet. The gravels were frozen, coarse, and waterworn, with numerous boulders on top of the gravel. The gold was coarse and unworn; it was in the lower 3 feet of the gravel and in the upper foot of the bedrock. The gold values determined from mining operations in the 1920s and 1930s were from $0.18 to $0.90 per square foot of bedrock; the fineness ranged from about 920 to 940.

Maddren noted that $7,000 in gold (about 350 ounces) was produced from 1907 to 1909. Reed (1938) estimated that the total production through 1937 had been $59,500 (about 2975 ounces). Kurtak and others (2002) document fairly consistent production from 1904 to 1948 of from 4 to 142 ounces per year; the total production during those years was 1,922 ounces of gold. Brosge and Reiser (1960) reported recent mining and that claims were active from 1969 to 1973 (Kurtak and others, 2002).

Kurtak and others (1999) collected six panned-concentrate samples along a 1.2-mile stretch of Spring Creek. The samples contained no visible gold but assays of the six samples averaged 1,260 parts per billion gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Placer gold was discovered on Spring Creek in 1903 and the creek was mined for 22 of the years between 1904 to 1948, mainly by hand and drift mining (Reed, 1938; Kurtak and others, 2002). Brosge and Reiser (1960) reported recent mining and that claims were active from 1969 to 1973 (Kurtak and others, 2002).

Production notes:

Placer gold was discovered on Spring Creek in 1903 and the creek was mined for 22 of the years between 1904 to 1948, mainly by hand mining (Reed, 1938; Kurtak and others, 2002). Maddren noted that $7,000 in gold (about 350 ounces) was produced from 1907 to 1909. Reed (1938) estimated that the total production through 1937 was $59,500 (about 2975 ounces). Kurtak and other (2002) document fairly consistent production from 1904 to 1948 of 4 to 142 ounces per year; the total production during those years was 1,922 ounces of gold. Brosge and Reiser (1960) reported recent mining but did not indicate the amount of production.

Reserves:

Probably none of substantial size.

Last report date: 2011-02-01

Site name(s): Unnamed (between Sirr Creek and Wild Lake)

Site type: Occurrence

ARDF no.: WI011

Latitude: 67.5217 **Quadrangle:** WI C-4

Longitude: 151.5889

Location description and accuracy:

This occurrence is located on a ridge between Sirr Creek and Wild Lake, about 1.6 miles north of the mouth of Seward Creek on Wild Lake. It is about 0.4 mile south-southwest of the center of section 9, T. 31 N,, R. 18 W. The occurrence is the site of sample 128 of Chipp (1972). Several other samples were collected for about 1.5 miles up the ridge to the north by Chipp (1972), and Kurtak and others (2002) The location is accurate.

Commodities:

Main: Ag, Au, Cu, Sb

Other: Pb, Zn

Ore minerals: Chalcopyrite, galena, malachite, pyrite, tetrahedrite?

Gangue minerals: Ankerite, calcite, quartz

Geologic description:

This occurrence consists of numerous thin quartz veins and lenses in Middle to Lower Devonian chlorite and sericite schist (Dillon and others, 1986). Most are barren quartz although some also contain ankerite(?). Over an area about 200 by 300 feet in size, small amounts of tetrahedrite(?), chalcopyrite, galena, malachite, and pyrite are scattered through the quartz (Chipp, 1972; Kurtak and others, 2002). One sample of altered calcareous schist with vein quartz and unspecified sulfides contains 0.52 parts per million (ppm) gold, 31 ppm silver, 1 percent antimony, 9,700 ppm copper, 2,400 ppm lead, and 1,000 ppm zinc (Chipp, 1972; sample 128).

Alteration:

Chipp (1972) and Dillon and others (1981) describe some of the samples as altered calcareous-schist, but did not describe the alteration.

Age of mineralization:

Unclear other than the veins and lenses are probably younger than the Devonian host rocks.

Generic deposit model:

Deposit model:

Scattered, thin quartz lenses and veins with rare, scattered base and precious-metal minerals.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Briefly examined and sampled by the Alaska Division of Geological and Geophysical Surveys (Chip, 1972, Dillon and others, 1981) and the Bureau of Land Management (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site type: Prospect

ARDF no.: WI014

Latitude: 67.5828 **Quadrangle:** WI C-4

Longitude: 151.9188

Location description and accuracy:

This prospect is at an elevation of about 3,500 feet, about 3.0 miles south of Pet Lake near the center of section 24, T. 32 N., R. 20 W. The location is accurate.

Commodities:

Main: Ag, Cu

Other: Au, Pb?

Ore minerals: Azurite, bornite, chalcopyrite, galena?, malachite

Gangue minerals:

Geologic description:

This prospect is one of several in a northeast-trending zone with minor copper mineralization that extends for about 5 miles northeast of VABM Allen (also see WI005, 006, 012, 013, and 016). Prior to the mid-1970s, at least five companies including Bear Creek Mining Company, General Crude Oil Company, New Jersey Zinc Company, Alvenco Inc., and BP Alaska prospected and sampled along this belt (Degenhart and others, 1978). Most of these prospects consist of malachite, azurite, and chalcopyrite along a thrust-fault contact that separates Devonian, Skajit Limestone from underlying chloritic schist (Dillon and others, 1986).

At this location, a small pod of copper mineralization, no more than 5 feet in diameter, is in marble (Degenhart and others, 1978). A sample, said to represent the mineralization contained 5,700 parts per million (ppm) copper, 3.4 ppm silver, and 10 parts per billion (ppb) gold. Kurtak and others (2002) also described podiform copper mineralization in this area. A sample of schist with bornite, malachite, and possibly galena contained 11 percent copper, 17 ppb gold, and 68.9 ppm silver. A sample of a small quartz vein contained 16.5 percent copper and and 78.6 ppm silver.

Alteration:

None specified.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Insufficient evidence to assign.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Site name(s): Sirr Creek; North Fork Seward Creek

Site type: Mine

ARDF no.: WI019

Latitude: 67.5345 **Quadrangle:** WI C-4

Longitude: 151.6374

Location description and accuracy:

Sirr Creek is a south-flowing tributary of Seward Creek; it is about 2 miles west of Wild Lake. As described by Reed (1938), Sirr Creek was known as the North Fork Seward Creek in the 1930's and only the eastern fork was called Sirr Creek. The location of the workings is uncertain and the mine is arbitrarily plotted on Sirr Creek at an elevation of about 1,750 feet. The mine is near the southeast corner of section 6, T. 31 N., R. 18 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Reed (1938) reported that there was extensive prospecting and a little placer mining on Sirr Creek in the early 1900s. Kurtak and others (2002) found no sign of recent mining although 19 claims were staked along Stirr Creek in 1977. The rocks in the area are Devonian phyllite and schist (Dillon and others, 1986).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Probably inactive

Workings/exploration:

Some prospecting prior to 1938 and some claims were staked in 1977. But no sign of any mining in about

2000 (Kurtak and others, 2002).

Production notes:

Probably none.

Reserves:

None.

Site name(s): Mascot Creek

Site type: Mine

ARDF no.: WI025

Latitude: 67.5087 **Quadrangle:** WI C-2

Longitude: 150.5471

Location description and accuracy:

Mascot Creek flows south about 7 miles to the Glacier River. The coordinates are at about the midpoint of a 3-mile-long stretch of placer mining that extends down the west halves of sections 7, 18, and 19, and the middle of section 30, T. 31 N., R. 13 W. The location is accurate. Kurtak and others (2002) furnish a colored geologic map of the Mascott Creek placer as their Figure I-7.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

According to Reed (1938), the bedrock in Mascot Creek is graphitic and quartz schist. The quartz schist is reddish from iron staining. According to Schrader (1904), mica schist on bedrock contains quartz stringers and a few porphyry dikes. Bliss and others (1988) speculated that the gold might be derived from these quartz stringers. The rocks adjacent to the productive part of Mascot Creek are mainly Cambrian and Silurian siltstone and phyllite and calcareous, chloritic wacke of the Devonian Beaucoup Formation (Dillon and others, 1986).

Since the discovery of gold on Mascot Creek in 1902 (Schrader, 1904), most of the mining has been along a 3-mile stretch of the creek, beginning about 4 miles above its mouth (Maddren, 1913; Reed, 1938; Kurtak and others, 2002). Mining and prospecting above and below this section of the creek has generally proved to be unproductive. The gold occurs in the modern channel but some is along benches. The gravel is waterworn and fine with few boulders; none of the gravel is frozen. The gravel in the modern channel is generally 0.5 to 3 feet thick. The relative ease with which these thin gravels could be mined made Mascot Creek one of the more profitable placer creeks in the district.

The gold in the modern channel is just above and below the bedrock surface; it typically is coarse and well worn. Nuggets with values up to $100 (about 5 ounces) have been recovered (Maddren, 1913). In one location near the upper end of the mined area, the gold was 90% coarse and 10% fine. Fineness ranged from about 942 to 977. Reed (1938) estimated that the value of the ground being mined in the modern channel in 1938 was $1.25 to nearly $7 in gold per square foot of bedrock.

Most mining was by ground sluicing and shoveling in. Placer mining was relatively simple as the gravel over the bedrock is shallow, and there are few boulders and little black sand. Although bedrock beneath the placer gravels in the auriferous portion of the creek was relatively shallow, the thawed gravel hindered sinking shafts in the thicker sections of grave. The last extensive mining on Mascot Creek was in 1984 when Doyon Limited took ownership of the land (Kurtak and others, 2002) In 2000, mining was being done with suction dredges working small pockets left from earlier mining.

Gold also was mined from remnants of a high channel on a bench of Mascot Creek. These remnants typically are along the right limit (west side) of the creek and a few tens of feet above the modern channel. Reed (1938) described one of these remnants as about 100 feet long and 10 feet wide; another was about 30

feet above the modern stream.

The most productive periods of mining were from 1903 to 1905 and in 1954, 1955, 1976, 1977, and 1984. Maddren (1913) reported that the total gold production through 1910 was about $150,000 (approx. 7,900 ounces). Kurtak and others (2002) provide production figures from 1903 to 1984, the last year of extensive mining. The total gold production from Mascot Creek was 11,198 ounces; the most productive years were 1903, when 5,082 ounces of gold was produced, and 1984 when 2,500 ounces were produced.

Mascot Creek is essentially mined out except for perhaps a few small pockets (Kurtak and others, 2002). The conclusion of a validity examination in 1996 by the Bureau of Land Management of the claims on Mascot Creek was that the gold resources left in the creek would not support a large-scale economic placer mine and the title of the land passed to Doyon Limited in 1997 (Keill and Teseneer, 1966). However, Kurtak and others (2002) surmised that small rich pockets remained that might be amenable to small scale mining.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Probably inactive

Workings/exploration:

The Mascot Creek placer was extensively mined and prospected, mostly along a 3-4 mile section of the modern channel beginning about 4 miles above its mouth. Most mining was by ground sluicing and shoveling in. Placer mining was relatively simple as the gravel over the bedrock is shallow, and there are few boulders and black sand. Although bedrock beneath the placer gravels in the auriferous portion of the creek was relatively shallow, generally less than 29 feet deep and often less than 3 feet deep, the thawed gravel hindered sinking shafts. The last extensive mining on Mascot Creek was in 1984 (Kurtak and others, 2002). In 2000, small-scale mining was being done with a suction dredge to recover gold from small pockets left from earlier mining.

Production notes:

The most productive periods of mining were from 1903 to 1905 and in 1954, 1955, 1976, 1977, and 1984. The last extensive mining on Mascot Creek was in 1997 when Doyon Limited took ownership of the land (Kurtak and others, 2002) In 2000, mining was being done with a suction dredge that probably produced a small amount of gold from small pockets left from earlier mining. Maddren reported total gold production through 1910 as about $150,000 (approx. 7,900 oz.). Kurtak and others (2002) provide production figures from 1903 to 1984, the last year of mining. The total gold production was 11,198 ounces; the most productive years were 1903 when 5,082 ounces of gold was produced, and 1984 when 2,500 ounces were produced.

Reserves:

Mascot Creek is essentially mined out except for perhaps a few small pockets (Kurtak and others, 2002). The conclusion of a validity examination in 1996 by the Bureau of Land Management of the claims on

Mascot Creek was that the gold resources left in the creek would not support a large-scale economic placer mine and the title of the land passed to Doyon Limited in 1997 (Keill and Teseneer, 1966). However, they and Kurtak and others (2002) also indicated that small rich pockets probably still remained that might be amenable to small scale mining.

Reporter(s): J.M. Britton (Anchorage); D.J. Grybeck (Contractor, USGS)

Last report date: 2011-02-01

Site name(s): Unnamed (east of head of Bonanza Creek)

Site type: Occurrence

ARDF no.: WI026

Latitude: 67.558 **Quadrangle:** WI C-2

Longitude: 150.8153

Location description and accuracy:

This occurrence is about 2 miles south-southeast of the small lake at the head of Bonanza Creek. It is on the west slope of the ridge between Bonanza and Conglomerate Creeks, about 0.5 mile west-northwest of the center of section 25, T. 32 N., R. 15 W., of the Fairbanks Meridian. The location is accurate.

Commodities:

Main: Pb, Zn

Other: As

Ore minerals: Galena, sphalerite

Gangue minerals: Ankerite?, quartz, siderite?

Geologic description:

Brosge and Reiser (1960) originally describe this occurrence as a galena-bearing quartz vein in Middle(?) Devonian slate, phyllite and siltstone. Kurtak and others (2002) describe a 35-foot-wide by 150-foot-long area of rusty-weathering, intensely fractured and dolomitized metamorphic rock that they tentatively interpret as a northwest-trending shear zone. The rock is cut by numerous quartz veinlets containing traces of galena, sphalerite, and possibly ankerite(?). A sample of quartz float with traces of galena and sphalerite contained 3,510 parts per million (ppm) zinc, 3,438 ppm lead, and 3,772 ppm arsenic.

Alteration:

Rusty weathering, intense fracturing, and dolomitization.

Age of mineralization:

Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Quartz vein? with minor galena and sphalerite.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Only surface sampling by the U.S. Geological Survey and the Bureau of Land Management (Brosge and Reiser, 1960; Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Additional comments:

This occurrence is the Gates of the Arctic National Park.

Site name(s): Vermont Creek; Right Fork

Site type: Mine

ARDF no.: WI027

Latitude: 67.5146 **Quadrangle:** WI C-1

Longitude: 150.1387

Location description and accuracy:

The mouth of Vermont Creek is at an elevation of about 1,800 feet on the Hammond River. The gold placers on Vermont Creek begin at the Hammon River, continue upstream for about a mile and then turn into the Right Fork. Placer gold is not known on Vermont Creek beyond the mouth of Right Fork. The coordinates are at the junction of Vermont Creek and Right Fork about 0.5 mile west-northwest of the center of section 13, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold, pyrite

Gangue minerals:

Geologic description:

Gold was discovered on Vermont Creek in 1901 (Maddren, 1913). It quickly became apparent that the pay streaks on the first mile of Vermont Creek continued up Right Fork and the placers on the two creeks were continuous and often mined together. Especially so since little gold has been found on Vermont Creek beyond the mouth of Right Fork.

Placer gold has been mined in the modern stream channel of Right Fork and lower Vermont Creek and in deep buried channels on lower Vermont Creek (Maddren, 1913; Reed, 1938; Eden, 2000; Kurtak and others, 2002). Shallow auriferous gravels extend continuously along the lower 0.5 to 0.7 mile of Right Fork and then turn east for one or two claim lengths along Vermont Creek. The gravel is about 3 feet thick along Right Fork. and the pay streak is narrow due to the constriction of the valley. The shallow placers that continue from Right Fork into Vermont creek are covered by 6 to 8 feet of muck, and the auriferous gravel is up to 400 feet wide and 4 to 5 feet thick. The pay channel consists of coarse, poorly sorted and subangular gravel, lying on soft micaceous schist (Reed, 1938). The gold in Vermont Creek is on and in the top few inches of, the bedrock. The gold forms few small nuggets and is mostly fine. According to Reed (1938), the value of the ground in these shallow gravels was about $0.13 in gold per square foot of bedrock (gold at $35.00 per ounce). The gravel contains considerable pyrite. Much if not most of the rich shallow gravel was probably mined out by 1909 (Maddren, 1913; Reed, 1938).

On lower Vermont Creek beyond the mouth of Right Fork, the gravel deepens, and Maddren (1913) thought that its lower 0.5 mile of auriferous gravel could, at least in part, be continuous with bench deposits of the Hammond River. Reed (1938) indicated that the deep channel was about 0.2 mile long along the left limit of lower Vermont Creek. The gravels in these deposits are frozen and 30 to 90 feet deep. Reed (1938) noted that gravel on the dumps was fine and waterworn, with few boulders. The gold from the deep channels is rounded and mostly coarse; several nuggets of more than 10 ounces have been recovered. There are unconfirmed reports that the value of the ground in these deep gravels may have run as high a $5 in gold per square foot of bedrock (gold at $35,00 per ounce) (Reed, 1938).

The early mining of the shallow placers was largely by hand and hydraulic methods. In the early days, the deep ground on lower Vermont Creek was drift mined. In recent years, lower Vermont Creek has been

mined with mechanical equipment.

Eden (2000) reports that a total of 9,145 ounces of gold were produced from Vermont Creek between 1904 and 1999. Kurtak and others (2002) estimate that 11,230 ounces of gold were produced between 1901 and 1983. According to Kurtak and others (2002) gold has been mined from Vermont and Right Fork for at least 39 of the years between 1901 and 1983. The most productive period of mining was from 1902 to 1909 when the production was more than 500 ounces year; it reaching 1,451 ounces in 1902. Yearly production was much lower until 1982 and 1983 when 500 ounces was produced each of those years. Mining is reported in 1983 (Bundtzen and others, 1984) and there was some mining in 1992 (Swainbank and others, 1993).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; medium

Site Status: Active?

Workings/exploration:

Placer gold has been mined in the modern stream channel of Right Fork and lower Vermont Creek and in deep buried channels on lower Vermont Creek (Maddren, 1913; Reed, 1938; Eden, 2000; Kurtak and others, 2002). Shallow auriferous gravels extends continuously along the lower 0.5 to 0.7 mile of Right Fork and then turn east for one or two claim lengths along Vermont Creek. On lower Vermont Creek beyond the mouth of Right Fork, the gravels deepen. The early mining of the shallow placers was largely by hand and hydraulic methods. In the early days, the deep ground on lower Vermont Creek was drift mined. In recent years, lower Vermont Creek has been mined with mechanical equipment.

Production notes:

Eden (2000) reports that a total of 9,145 ounces of gold were produced from Vermont Creek between 1904 and 1999. Kurtak and others (2002) estimate that 11,230 ounces of gold were produced between 1901 and 1983. According to Kurtak and others (2002) gold has been mined from Vermont and Right Fork for at least 39 of the years between 1901 and 1983. The most productive period of mining was from 1902 to 1909 when the production was more than 500 ounces year; it reaching 1,451 ounces in 1902. Yearly production was much lower until 1982 and 1983 when 500 ounces was produced each of those years. Mining is reported in 1983 (Bundtzen and others, 1984) and there was some mining in 1992 (Swainbank and others, 1993).

Reserves:

There are apparently no published resource or reserve figures for Vermont Creek and Right Fork. Most of the shallow auriferous gravel has probably l been mined but small remnants of the shallow auriferous gravel may remain. Gold may also remain in the deep channels of lower Vermont Creek or extensions of them below the Hammond River (Kurtak and others, 2002).

Site name(s): Slisco Bench

Site type: Mine

ARDF no.: WI031

Latitude: 67.5105 **Quadrangle:** WI C-1

Longitude: 150.1114

Location description and accuracy:

The Slisco Bench placer mine is located along the west side of Hammond River about 0.2 mile southwest of the mouth of Vermont Creek. The mine is 0.3 mile east-southeast of the center of section 13, T. 31 N., R. 12 W., of the Fairbanks Meridian. It marks the north end of a buried channel on this high bench that may extend a mile to the south. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

The Slisco Bench deposit is one of a number of bench placers in the valley of the Hammond River (Bundtzen, 2008, 2009; Kurtak and others, 2002). The deposit was discovered in the late 1920s; a small amount of mining was done until 1935, and it was mined in 1983 and from 1992 to 1994.

Several companies have drilled a total of 139 holes on the bench over an area about 1,600 feet long and 500 feet wide. Drilling by Silverado Gold Mines Inc. in 1995 intersected gold-bearing gravel in a buried channel beneath 60 to 200 feet of partially frozen gravel (Bundtzen, 2008, 2009). The geology of the gravels is complicated. The gold is in multiple, stacked gold-bearing horizons that are discontinuous along and across the buried channels, and their gold content is erratic. The gravels are also partially thawed making drift mining uncertain. Bundtzen (2008) estimates that the Slisco Bench has a inferred resource of 46,670 cubic yards of gravel with an average grade of 0.045 ounce of gold per cubic yard (about 2,100 ounces of gold).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Probably inactive

Workings/exploration:

The deposit was discovered in the late 1920s; a small amount of mining was done until 1935 and it was mined in 1983 and from 1992 to 1994. As of 2008, 139 exploratory holes had been drilled on the Slisco Bench by several companies (Bundtzen, 2008, 2009).

Production notes:

Some uncertain but probably small production from the late 1920s to 1994.

Reserves:

Bundtzen (2008) estimates that the Slisco Bench has a inferred resource of 46,670 cubic yards of gravel with an average grade of 0.045 ounces of gold per cubic yard (about 2,100 ounces of gold).

Last report date: 2011-02-01

Site name(s): Unnamed (along Right Fork)

Site type: Occurrence

ARDF no.: WI032

Latitude: 67.5109 **Quadrangle:** WI C-1

Longitude: 150.1533

Location description and accuracy:

The best exposed mineralization at this site is just southwest of 'Friday the 13th Pup', an informal name given to the small tributary to Right Fork in the northeast corner of section 14, T. 31 N., R 12 W. The mineralization then continues down Right Fork to Vermont Creek. The location is accurate.

Commodities:

Main: Au

Other: As, Sb

Ore minerals: Arsenopyrite, galena, gold, hematite, marcasite, pyrite, pyrrhotite, sphalerite, stibnite

Gangue minerals: Ankerite, calcite, dolomite, quartz

Geologic description:

Maddren (1913) first identified quartz veins and veinlets along joint surfaces in bedrock on upper Right Fork, noted that at least one of the veins contained sulfides as well as specks and flakes of free gold. The best mineralization exposed at this site is just southwest of 'Friday the 13th Pup', a small tributary to Right Fork in the northeast quarter of section 13, T. 31 N., R 12 W. (Eden, 2000; Kurtak and others, 2002).

Numerous thin quartz veins cut interbedded phyllite and schist of the Upper Devonian Beaucoup Formation (Dillon and others, 1986). Eighteen veins spaced at about 5 foot intervals, occur in one 100-foot-wide exposure of the phyllite near Friday the 13th Pup. The veins average about 0.5 inch thick; they generally strike about N60W and dip 75SW. The veins consist of coarse, white quartz, calcite, ankerite and dolomite, 1-2 percent pyrite, and sparse arsenopyrite, galena, hematite, marcasite, pyrrhotite, sphalerite, and stibnite. Visible gold occurs in some of these veins, mostly along their margins. A sample of a vein with visible gold contained 17.8 parts per million (ppm) gold Other veins contain 415 parts per billion (ppb) to 63.56 ppm gold, 126 to 3,802 ppm arsenic, and 7 to 748 ppm antimony. Samples of phyllite with minor pyrite in the vicinity of the veins contained 13 to 38 ppb gold. The phyllite along Right Fork from Friday the 13th Pup down to Vermont Creek is cut by similar veins that contained up to 815 ppb gold, 1,137 ppm copper, and 1,065 ppm arsenic. A cobble-size boulder of quartz with gold and 1 percent stibnite, presumably from a local source, was found by local placer miners in Right Fork (Dillon, 1982).

Alteration:

The phyllite that hosts the thin quartz veins apparently is not altered.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Undetermined

Workings/exploration:

The thin gold-quartz veins in the bedrock along Right Fork have been recognized since at least 1913 and have repeatedly been sampled, most recently by Kurtak and others (2002).

Production notes:

None.

Reserves:

None.

Site name(s): Ann

Site type: Prospect

ARDF no.: WI034

Latitude: 67.3954 **Quadrangle:** WI B-6

Longitude: 152.8472

Location description and accuracy:

The Ann prospect is located 3.5 miles east-northeast of the east end of Ernie Lake and about 3.5 miles northwest of the junction of Pass Creek and Mettenpherg Creek. The coordinates mark the principal mineral showing; it is on an unnamed creek at an elevation of about 580 meters, near the center of section 26, T. 30 N., R. 24 W. There are other mineral showings up to 500 feet upstream and downstream from the main showing. The location is accurate.

Commodities:

Main: Ag, Cu, Pb, Zn

Other: As, Au

Ore minerals: Arsenopyrite, azurite, chalcopyrite, galena, malachite, pyrite, pyrrhotite?, sphalerite

Gangue minerals: Barite, quartz

Geologic description:

This prospect consists of vein and stratabound(?) Pb-Zn deposits of massive, stringer, and disseminated sulfides in pelitic schist interbeds in the Devonian Skajit Limestone, adjacent to the Ernie Lake granitic plutons (Nokleberg and others, 1996). The principal mineral showing at the Ann prospect is a steeply-dipping lens of massive pyrite, sphalerite, galena and minor chalcopyrite at a contact between graphitic quartz schist and sericite-talc schist (Kurtak and others, 1999). The lens is 4-5 feet thick and is exposed for only about 6 to 7 feet before pinching out in one direction and disappearing under cover in the other. A chip sample across this lens contained 3.34 percent lead, 4.31 percent zinc, 2.64 ounces of silver per ton, and 2.5 parts per million (ppm) gold (Kurtak and others, 2002). Bedded quartz-barite rock occurs a few hundred feet from the main Pb-Zn showing, but it contains no sulfides.

Several similar, but smaller, deposits are within a few hundred feet of the main showing. One of these consists of pyrite, arsenopyrite, pyrrhotite(?), galena, and chalcopyrite in layers and veins in calcareous, quartz-mica schist near the contact of granite gneiss and marble. A sample contained 37.7 ppm silver, 13 percent arsenic, 3.8 percent lead, 1.8 percent zinc, and 315 ppm antimony (Dillon and others, 1981: sample 480). Secondary copper carbonates, malachite and azurite, occur in the marble, calc-schist, and pelitic schist layers.

Claims were staked in 1975 (Grybeck, 1977). Exploration by industry included surface rock sampling, geologic mapping, geochemical soil sampling, hand trenching, and ground geophysics. There was also limited surface rock sampling by government agencies in the 1980s and 1990s (Dillon and others, 1981; Kurtak and others, 1999, 2002).

Alteration:

Oxidation of copper mineral(s).

Age of mineralization:

Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

(Metamorphosed) Polymetallic vein? (Cox and Singer, 1986; model 22c?) or metamorphosed sulfide deposit (Nokleberg and others, 1987).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

22c?

Production Status: None

Site Status: Inactive

Workings/exploration:

Claims were staked in 1975 (Grybeck, 1977). Exploration by industry included surface rock sampling, geologic mapping, geochemical soil sampling, hand trenching, and ground geophysics. There was also limited surface rock sampling by government agencies in the 1980s and the 1990s (Dillon and others, 1981; Kurtak and others, 1999, 2002).

Production notes:

None.

Reserves:

None.

Additional comments:

Site name(s): Colorado Creek

Site type: Mine

ARDF no.: WI035

Latitude: 67.3818 **Quadrangle:** WI B-6

Longitude: 152.7248

Location description and accuracy:

Colorado Creek is a west-northwest-flowing tributary of upper Mettenpherg Creek. There is considerable evidence of placer mining for about 0.3 mile above the mouth of Colorado Creek. The area is centered about 0.3 mile east of the center of section 32, T. 30 N., R. 23 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Smith, 1913 report placer mining on 'Mechlenberg' Creek (probably the modern Mettenpherg Creek) which may have been on or near the mouth of Colorado Creek. Reed (1938) reported mining on Colorado Creek in 1937. Kurtak and others found evidence of extensive mining on the lower 0.3 mile of Colorado Creek that included hand stacked rocks, old pole-riffle sluice boxes, and a suction dredge. They also report that 8 ounces of gold were produced from 1937 to 1939.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Undetermined

Workings/exploration:

Small-scale mining by booming and shoveling in from a small cut in 1937 (Reed, 1938). The presence of

a suction dredge reported by Kurtak and others (2002) indicates at least some modern activity.

Production notes:

Kurtak and others (2002) report that 8 ounces of gold were produced from 1937 to 1939.

Reserves:

None.

Latitude: 67.3978 **Quadrangle:** WI B-6

Longitude: 152.6955

Location description and accuracy:

This occurrence is about 3.2 miles north-northeast of the junction of Pass and Mettenpherg Creeks. The occurrence is at an elevation of about 780 meters, about 0.3 mile northeast of the center of section 28, T. 30 N., R. 23 W. The location is accurate.

Commodities:

Main: Au, Pb, Zn

Other: As

Ore minerals: Fluorite, galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

The rocks in the area consist of Proterozoic(?) granite gneiss and banded schist, and Devonian Skajit Limestone (Dillon and others, 1986) This occurrence was reported to consist of sphalerite and galena in carbonate rocks (Grybeck, 1977). Kurtak and others (2002) investigated the site but only found blocks of limonite-stained schist with up to 2 percent fluorite and stringers of pyrite at a contact of Skajit Limestone and quartz-sericite schist. A select sample contained 67 parts per billion gold and 131 parts per million arsenic. Kurtak and others (2002) reported that 106 lode claims were staked over the property in 1975 but found no evidence of workings.

Alteration:

None noted.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Insufficient evidence to assign.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Site name(s): Midas Creek

Site type: Mine

ARDF no.: WI057

Latitude: 67.3047 **Quadrangle:** WI B-5

Longitude: 152.2285

Location description and accuracy:
Midas Creek is a north-flowing tributary to Sixtymile Creek. The exact location(s) of placer gold prospects on Midas Creek is unknown. The site is plotted near the cabin shown on the Wiseman B-5 topographic map, about 3 miles upstream from the mouth of the creek. It is about 0.5 mile northwest of the center of section 34, T. 29 W., R. 21 N. This locations approximates the location in Cobb (1972).

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:
Maddren (1913) reported that good placer gold prospects had been found on Midas Creek in 1905 although these had not been developed by 1913. A small one-man bulldozer-hydraulic mining operation was underway in 1952 (Holdsworth, 1952). Kurtak and others (2002) found the remains of a cabin (shown on the 1:63,360-scale topographic map) and placer mining equipment about 3 miles above the mouth of the creek, another cabin about 3.5 miles above the mouth, and an old airstrip about 5 miles above the mouth. They noted that there were three placer claims on the creek in 1959 and one claim at the mouth of the creek from 1979 to 1983. They did not find any significant signs of mining along the creek.

Alteration:

Age of mineralization:
Quaternary.

Site name(s): Lake Creek

Site type: Mine

ARDF no.: WI061

Latitude: 67.475 **Quadrangle:** WI B-4

Longitude: 151.5518

Location description and accuracy:

Lake Creek enters the southeast end of Wild Lake about 0.5 mile north of its south end. Lake Creek has mainly been mined from about 0.5 miles to about 1.5 miles above its mouth. The center of the mined area is about 0.6 mile north-northwest of the center of section 34, T. 31 N., R. 18 W. The location is accurate.

Commodities:

Main: Au

Other: As, Bi, Cu, Pt, Sb, W

Ore minerals: Bismuth, bismuthinite, copper, galena, gold, hematite, magnetite, platinum?, pyrite, scheelite, stibnite

Gangue minerals:

Geologic description:

Gold was discovered on Lake Creek in 1903 (Maddren, 1910; 1913) and mining continued intermittently to at least 2001 (Kurtak and others, 2002, Eden, 2004; Brooks Range Exploration, 2012). Most of the gold has been produced near the head of an alluvial fan at the mouth of Lake Creek and in a narrow portion of the creek valley about 1.5 miles from its mouth. Near the head of the alluvial fan, the depth to bedrock is 60 to 95 feet; in the upper valley of the creek, the depth to bedrock is only 3 feet. Reed (1938) reported that production from the mining from 1904 to 1937 was at least $26,000 (about 1,300 ounces of gold) but he speculated that the extent of the workings indicated that the production was many thousands of dollars more. Kurtak and others (2002) report that the creek produced 2,624 ounces of gold in twelve years from 1903 to 1955. Mining before WWII was mainly by hand methods, ground sluicing, and in the upper part of the alluvial fan by drifting. In 1999, a large wash plant was built to mine ground at the upper part of the fan with mechanized equipment. The mining in the late 1990s revealed that there were two distinct bedrock channels underneath the upper portion of the fan and that they they extend upstream from the top of the fan. Incomplete records indicate that at least 1,314 ounces of gold were produced from 1995 to 2001.

The rocks in the area are predominantly Devonian muscovite-chlorite schist that contains numerous quartz lenses and veinlets (Kurtak and others, 1999). Some of the quartz is parallel to the cleavage or schistosity, and transects it. Reed (1938) describes the bedrock about 200 feet above the last of the old workings (about 2 miles from the lake) as alternating micaceous and graphitic schist cut by a 300-foot-wide, greenstone dike. This greenstone dike was not observed by Kurtak and others (1999). Reed (1938) also noted soft reddish schist containing numerous quartz stringers at the head of Lake Creek.

The gravels on Lake Creek are coarse and waterworn with numerous large schist boulders. The upper part of the gravel contains erratics of conglomerate and black chert. The gold occurs as coarse, waterworn nuggets, and also as fine flour gold. Maddren (1913) noted recovery of nuggets valued at $90 to $150 (about 4.7 to 7.9 ounces). A 22-ounce nugget was recovered in 1995 and a 24.25-ounce nugget was recovered in 1996 (Kurtak and others, 2002).

Smith and Mertie (1930) reported that the concentrates from the placers along Lake Creek had a high content of scheelite. Joesting (1943) lists several minerals in the placer concentrates from Lake Creek, including inch-long pieces of stibnite, scheelite, native bismuth, native copper, hematite, pyrite and

magnetite. Sluice concentrates collected by Kurtak and others (1999) contained up to 5,930 parts per billion (ppb) platinum, 976 parts per million (ppm) tungsten, 0.44 percent bismuth, 1,750 ppm arsenic, and 3,043 ppb gold. The sluice concentrates did not contain visible gold. Miners also showed them nuggets of bismuthinite said to come from Lake Creek. Samples of quartz from the placers thought to be from veins contained up to 8,631 ppm copper and 62 ppb gold.

Kurtak and others (2002) and Blakestad (2003) suggest that there is moderate potential for placer gold in the central basin of Lake Creek from the alluvial fan beside Wild Lake upstream to the canyon narrows. The north channel of the creek and possible bench channels to the south of the creek have not been evaluated. Based on an unpublished report by Blakestad (2000), Kurtak and others (2002) give an 'indicated resource' of 10,087 ounces of gold in Lake Creek.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

Intermittent mining by hand methods, sluicing and drifting from 1904 to the the 1990s. In 1999, a large washing plant was built to mine gravels at the top of the alluvial fan above the mouth of Lake Creek with mechanized equipment (Kurtak and others, 2002). Mining continued until at least 2001.

Production notes:

Reed (1938) reported production from early mining from 1904 to 1937 to be at least $26,000 (about 1,300 ounces of gold) but he speculated that the extent of the workings indicated that the production was many thousands of dollars more. Kurtak and others (2002) tabulated the production by year from 1903 to 2001. From 1903 to 1955, the placers on Lake Creek produced 2,624 ounces of gold in 12 years. Another 1,314 ounces of gold was produced from 1955 to 2001 but the records are incomplete. The total production from 1903 to 2001 was thus at least 3,938 ounces of gold.

Reserves:

Kurtak and others (2002) and Blakestad (2003) suggest that there is moderate potential for placer gold in the central basin of Lake Creek from the alluvial fan beside Wild Lake upstream to the canyon narrows. The north channel of the creek and possible bench channels to the south of the creek have not been evaluated. Based on an unpublished report by Blakestad (2000), Kurtak and others (2002) give an 'indicated resource' of 10,087 ounces of gold in Lake Creek.

Site name(s): Crevice Creek

Site type: Mine

ARDF no.: WI064

Latitude: 67.359 **Quadrangle:** WI B-4

Longitude: 151.9028

Location description and accuracy:

Crevice Creek is a west-flowing tributary to John River. The mouth of Crevice Creek is approximately 0.5 mile south of the junction of the John and Allen Rivers. The center of the placer workings is about 3.5 miles upstream from the mouth of Crevice Creek, near the northeast corner of section 12, T. 29 N., R. 20 W. The workings extend for about two miles upstream and downstream. The location is accurate.

Commodities:

Main: Au

Other: Ag

Ore minerals: Gold, magnetite, silver

Gangue minerals:

Geologic description:

About 3.5 miles of Crevice Creek has been placer mined. The most extensive mining was from about 2.0 miles to about 2.5 miles above its mouth. Above and below that section, most of the mining has been with suction dredges working pot holes. Bedrock is exposed or shallow along much of Crevice Creek and consists mainly of Devonian Skajit Limestone (Dillon, 1982; Dillon and others, 1986). Cracks in the weathered bedrock formed numerous natural riffles and potholes up to several feet deep that trapped much of the gold along the creek and were the locus of much of the mining (Reed, 1938; Kurtak and others, 2002). The creek is named for this features.

The concentrates contained abundant magnetite. Occasionally native silver nuggets were recovered with the gold (Kurtak and others, 2002). Bliss and others (1988) speculate that the gold is derived from sulfide-bearing quartz veins in the Devonian Skajit limestone (see WI066). Analyses by Mosier and Lewis (1986) of seven gold samples from Crevice Creek gave median values of 4.2 percent silver, 0.14 percent copper, 0.008 percent lead, and 0.47 percent mercury, and a median fineness of 958. Three of these analyses showed detectable levels (but less than 2 parts per million) palladium.

As documented by Maddren (1910, 1913), Reed (1938), and Kurtak and others (2002), mining began on Crevice Creek in 1904. Production records show that at least 117 ounces of gold was produced in several episodes of mining through 1914. At least another 105 ounces of gold was produced from 1948 to 1953. Most of the production was from 1959 to 1988 by Bill Ficus who recovered at least 2,200 ounces of gold from 1980 to 1998. Suction-dredge mining of the pot holes continued until at least 2000. The total production documented in incomplete records is 2,456 ounces of gold. Kurtak and others (2002) suggest that little gold remains, although the numerous cracks, crevices, and pot holes in the bedrock along the creek probably retain some gold amenable to suction dredging.

Site Status: Active?

Workings/exploration:

About 3.5 miles of Crevice Creek has been placer mined. The most extensive mining was from about 2.0 miles to about 2.5 miles above its mouth. Above and below that section, most of the mining has been with suction dredges working pot holes. As documented by Maddren (1910, 1913) Reed (1938), and Kurtak and others (2002), mining began on Crevice Creek in 1904. Production records show that at least 117 ounces of gold was produced in several episodes of mining through 1914. At least another 105 ounces of gold was produced from 1948 to 1953. Most of the production was from 1959 to 1988 by Bill Ficus who recovered at least 2,200 ounces of gold from 1980 to 1998. Suction-dredge mining of the pot holes continued until at least 2000.

Production notes:

As documented by Maddren (1910, 1913); Reed (1938), and Kurtak and others (2002), mining began on Crevice Creek in 1904. Production records show that at least 117 ounces of gold was produced in several episodes of mining through 1914. At least another 105 ounces of gold was produced from 1948 to 1953. Most of the production was from 1959 to 1988 by Bill Ficus who recovered at least 2,200 ounces of gold from 1980 to 1998. Suction-dredge mining of the pot holes continued until at least 2000. The total production documented in incomplete records is 2,456 ounces of gold.

Reserves:

Kurtak and others (2002) suggest that little gold remains, although the numerous cracks, crevices, and pot holes in the bedrock along the creek probably retain some gold amenable to suction dredging.

Site name(s): Moose Trail

Site type: Prospect

ARDF no.: WI074

Latitude: 67.399 **Quadrangle:** WI B-4

Longitude: 151.9942

Location description and accuracy:

This prospect is about 1 mile north of the junction of McCamant Creek and Allen River. The occurrence is at an elevation of about 1,650 feet, 0.3 mile north-northwest of the center of section 27, T. 30 N., R. 20 W. The location is accurate.

Commodities:

Main: Cu?

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Little information on this prospect is available and none of it suggests significant mineralization. The location of the prospect is given in the U. S. Bureau of Mine's MAS database and is shown by Maas (1987). Dillon and others (1981) indicates that the area contains copper mineralization but did not furnish details. Kurtak and others (2002) examined the prospect but found no indication of mineralization. They reported that BP Exploration Inc. held 28 claims in the area from 1975 to 1977 and did some drilling and trenching. The core of the holes did not show any copper mineralization. The rocks in the area are principally Devonian(?) chloritic and carbonate rocks (Dillon and others, 1986).

Alteration:

None noted.

Age of mineralization:

No mineralization identified.

Generic deposit model:

Deposit model:

No mineralization identified.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

BP Exploration Inc. held 28 claims in the area from 1975 to 1977 and did some drilling and trenching. Examined by the Bureau of Land Management in about 2000 (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Birch Creek

Site type: Mine

ARDF no.: WI076

Latitude: 67.4477 **Quadrangle:** WI B-3

Longitude: 151.345

Location description and accuracy:

Birch Creek is a west-flowing tributary of Flat Creek. Their junction is about 3 miles southeast of Mathews Dome and about 6 miles east-southeast of the south end of Wild Lake. Much of the mining on Birch Creek in the early 1900s occurred along about 1 mile of the stream on either side of the mouth of a south-flowing unnamed tributary locally called Rue Creek. Rue Creek's mouth is about 1.25 miles above the mouth of Birch Creek. The center of mining is near the southeast corner of section 4, T. 30 N., R. 17 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Gold was discovered on Birch Creek in 1904 by Louis Rue (Reed, 1938). He reportedly recovered about $1,800 in gold in 1905 (gold at $20.67 per ounce). The modern channel of Birch Creek has been mined for about 1/2 mile above and below the mouth of Rue Creek (a local name not shown on modern topographic maps) that enters Birch Creek from the north about a mile above its mouth. The gravel is coarse and waterworn in Birch Creek and contains many boulders. An area along the left limit of Birch Creek below Rue Creek was drift mined. The depth of the drift workings is probably about 20 feet, similar to the depth to bedrock in the creek bed (Reed, 1938). Several shafts were also sunk in the alluvial fan where Birch Creek enters the valley of Flat Creek but the results of this work are not known.

In the early 1900s, Birch Creek was mined by shoveling-in and drifting. Reed, (1938) noted that there had been no mining since since 1933 and estimated that the total production from the early 1900s until about 1933 was about $20,000 to $30,000 (gold at $20.67 per ounce). Kurtak and others (2002) document that 1,440 ounces of gold was produced from 1905 to 1933, with the production scattered through those years.

Mining with mechanical equipment began in 1987 and continued to at least 2002 (Kurtak and others, 2002). This mining mainly took place near the mouth of Rue Creek. At least some of the activity was recreational mining. Four to twelve feet of gravel is stripped to bedrock and paying customers used metal detectors search the bedrock surface for gold. A 10.2-ounce nugget was found in 1998. The gold production for these years is not available.

A sample of quartz-mica schist from the ridge on the north side of upper Birch Creek contained 35 parts per billion gold and 1,767 parts per million arsenic (Kurtak and others, 1999).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

Birch Creek was mined by shoveling-in and drifting for scattered years from 1905 to 1933 (Reed, 1938). Mining resumed in 1987 with mechanical equipment and continued to at least 2002. The recent mining included a recreational mining concession. Four to twelve feet of gravel is stripped to bedrock and paying customers using metal detectors search the top of the bedrock for gold.

Production notes:

Reed (1938) estimated that the total production from the early 1900s until about 1933 was about $20,000 to $30,000 (gold at $20.67 per ounce). Kurtak and others (2002) document that 1,440 ounces of gold was produced from 1905 to 1933, with the production intermittent through those years. No production figures are available for the mechanical mining that began in 1987 and continued to at least 2002.

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Unnamed (near the junction of Fall and Michigan Creeks)

Site type: Occurrence

ARDF no.: WI077

Latitude: 67.3051 **Quadrangle:** WI B-3

Longitude: 151.2404

Location description and accuracy:

This occurrence is based on several mineralized rock samples collected in an area about 0.2 mile in diameter (Dillon and others, 1981: Plate 1, samples 467 to 472 and 474 and 475). The area is about 0.2 mile northwest of the junction of Fall and Michigan Creeks. The occurrence is at an elevation of about 1,550 feet, 0.4 mile south-southwest of the center of section 25, T. 29 N., R. 17 W. The location is accurate.

Commodities:

Main: As, Au, Cu

Other: Ag, Co, Pb, Ti, Zn

Ore minerals: Arsenopyrite, cassiterite, chalcopyrite, marcasite, molybdenite?, pyrite, pyrrhotite, rutile, sphalerite

Gangue minerals: Quartz

Geologic description:

Dillon and others (1981) collected mineralized rock samples at several sites in an area about a half mile in diameter. The mineralization consists of layers and veins of massive pyrrhotite, chalcopyrite, sphalerite, arsenopyrite, cassiterite, rutile, pyrite, and possible molybdenite. The pyrrhotite is partly altered to marcasite. Eight samples collected by Dillon and others contained up to 82,000 parts per million (ppm) arsenic, 700 ppm cobalt, 1,360 ppm copper, 8.28 ppm gold, 135 ppm lead, 50 ppm tin, and 329 ppm zinc. The sulfide layers and veins are up to 30 cm. thick in actinolite-biotite felsite interlayered with marble and garnet-quartz-albite-muscovite schist. Hornfelsed calc-silicate rocks along the contact with the felsite contain disseminated pyrite(?). Dillon and others (1986) map the area as Devonian and Devonian(?) interlayered felsic and mafic intrusive and extrusive rocks, locally mixed with clastic sedimentary rocks. They indicate that the upper Devonian felsic schist is regionally associated with copper deposits.

The area was examined by Kurtak and others (2002) as part of a regional mineral assessment . The only sample they collected of a felsitic rock had only 111 ppm copper and 196 parts per billion (ppb) gold; i.e., not nearly the metal values in samples analyzed by Dillon and others (1981).

Alteration:

Alteration of pyrrhotite to marcasite; oxidation of sulfides, development of skarn.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Volcanogenic massive sulfides or skarn?

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Only surface sampling by government agencies (Dillon and others, 1981; Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site name(s): Agnes Creek

Site type: Mine

ARDF no.: WI078

Latitude: 67.485 **Quadrangle:** WI B-3

Longitude: 151.3039

Location description and accuracy:

Agnes Creek is a west-flowing tributary to upper Flat Creek. It is about 6 miles east of Wild Lake and about 5 miles northeast of Mathews Dome. The extent of the placer is unknown and the occurrence is arbitrarily located about a mile upstream from the mouth of Agnes Creek, near the northeast corner of section section 27, T. 31 N., R. 17 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Reed (1938) noted that there had been extensive prospecting and some mining on Agnes Creek in the early 1900s but that records of the mining had been lost. Kurtak and others (2002) note that there were active claims on Agnes Creek from the 1970s to 2002.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Inactive

Workings/exploration:

Prospecting and some mining in the early 1900s. There were active claims from the 1970s to at least 2002.

Production notes:

A small amount of gold was probably produced.

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Unnamed (ridge east of Scofield Creek)

Site type: Occurrence

ARDF no.: WI081

Latitude: 67.3278 **Quadrangle:** WI B-3

Longitude: 151.3112

Location description and accuracy:

This occurrence is between Scofield and Michigan Creeks, about 7.5 miles west of Ipnek Mountain and 2.8 miles northeast of the junction of Scofield Creek and Wild River. The occurrence is at an elevation of about 3,550 feet, about 0.5 mile north-northeast of the center of section 22, T. 29 N., R. 17 W. The location is accurate.

Commodities:

Main: Ag, Pb, Zn

Other: As, Ba, Fe, La

Ore minerals: Sphalerite

Gangue minerals:

Geologic description:

This occurrence is a gossan zone at the contact of calc-schist and marble with granite. A sample of float from the gossan contains up to 20 parts per million (ppm) silver, 1,000 ppm arsenic, 1,500 ppm lead, 1,800 ppm zinc, 20 percent iron, and 0.5 percent barium. (Dillon and others, 1981, sample 380). No sulfides were observed in the sample.

About a mile to the west, Dillon and others (1981, no. 127) collected a sample of quartz-monzonite gneiss in contact with calc-schist and skarn This sample contained about 3 percent unspecified, partly oxidized, sulfides, apparently of replacement origin It also assayed about 200 ppm lanthanum but no other anomalous metal values. The rocks in the area are granite gneiss of the Devonian Wild River Pluton, which intrudes Proterozoic or lower Paleozoic(?) schist of varying types, accompanied by some marble. (Dillon and others, 1986).

Kurtak and others (2002) searched about a mile to the southwest for mineralization described by Bliss and others (1988) as layers or veins of sphalerite and pyrite up to 8 centimeters thick in orange dolomite. They were not successful and none of the samples they collected had significant metal values. Six claims (EPI 1-6) were located by Canevex, Inc. in 1975 (Kurtak and others, 2002).

Alteration:

Not specifically mentioned.

Age of mineralization:

Possibly associated with the emplacement of a Devonian granite and quartz monzonite.

Generic deposit model:

Deposit model:

Several types of unclassified mineralization may be present.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Six claims (EPI 1-6) were located by Canevex, Inc. in 1975 (Kurtak and others, 2002). Field examination and sampling by several government agencies (Dillon and others, 1981; Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site name(s): Jay Creek; Eagle Gulch

Site type: Mine

ARDF no.: WI082

Latitude: 67.4067 **Quadrangle:** WI B-3

Longitude: 151.324

Location description and accuracy:

Jay Creek is a southwest-flowing tributary of Rye Creek; it is about 6 miles southeast of Mathews Dome. Eagle Gulch, which is not named on the Wiseman B-3 topographic map, is a small, right-limit headwater tributary to Jay Creek. Although the exact location of the placer workings on Jay Creek is not known, Reed (1938) noted that the claims extended from No. 1 Below Discovery (which reached about 500 feet into Rye Creek) to No. 5 Above Discovery, and that the creek was mined from the mouth to the lower portion of No. 5 Above. The midpoint of mining is in the lower part of section 22, T. 30 N., R. 17 W. The location is accurate.

Kurtak and others (2002) and possibly others combine Jay Creek and its downstream continuation, Rye Creek (WI084), in their discussion of placer mining in this drainage.

Commodities:

Main: Au

Other: Cu, Sb

Ore minerals: Chalcopyrite, gold, pyrite, stibnite

Gangue minerals: Quartz

Geologic description:

Gold was discovered on Jay Creek in 1904 but mining did not begin until 1912 (Reed, 1938). Jay Creek was once reputed to be the richest creek in the Wild River district. It is in a canyon that averages about 50 feet wide. Brooks (1916) reported that the pay streak was 30 feet wide and 4 feet thick. Reed (1938) reported that the gravel is thawed, very coarse grained, subangular, 3 to 12 feet thick, and that it contains numerous conglomerate boulders. The gold occurs throughout the gravel and in the upper foot of the bedrock. The gold is coarse, unworn, very dark colored, and about 970 fine. Kurtak and others (2002) and possibly others combine Jay Creek and its downstream continuum, Rye Creek (WI084), in discussing placer mining in this drainage.

From 1912 through at least 1935, the creek was mined by booming and shoveling into sluice boxes. Mining took place over 5 or 6 claim lengths from the mouth of the creek to the lower part of No. 5 Above Discovery. A mechanized mining operation was active on Jay Creek in 1998. A little gold was found in Jay Creek near the mouth of Eagle Gulch, a locally named, small, right-limit tributary to Jay Creek (Reed, 1938).

Reed (1938) estimated that the total production from Jay Creek through 1935 is about $200,000 (approximately 10,000 ounces). The ground that was mined had an average value of about $0.505 per square foot of bedrock (gold at $35 per ounce). There is no specific information available about mining specifically on Jay Creek in the 1990s as the same company mined both on Rye Creek (WI084) and Jay Creek (Kurtak and others, 2002). This early 10,000-ounce production figure conflicts with the Kurtak and others (2002) estimate that the combined total production of both the more productive(?) Rye Creek and Jay Creek 'could be as much as 3,537 ounces'.

Dillon (1982) reports a stibnite-quartz vein upstream from the placer, and Bliss and others (1988) speculate that the source of the gold is stibnite(?)-quartz veins in the drainage. The rocks in the vicinity

consist of alternating bands of graphitic schist, micaceous schist, and greenstone schist (Reed, 1938).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Probably inactive

Workings/exploration:

From 1912 through at least 1935, the creek was mined by booming and shoveling into sluice boxes. Mining took place over 5 or 6 claim lengths from the mouth of the creek to the lower part of No. 5 Above Discovery. A mechanized mining operation was active on Jay Creek in 1998 and probably a few years before.

Production notes:

Reed (1938) estimated that the total production from Jay Creek through 1935 is about $200,000 (approximately 10,000 ounces). The ground that was mined had an average value of about $0.505 per square foot of bedrock (gold at $35 per ounce). There is no specific information available about mining specifically on Jay Creek in the 1990s as the same company mined both on Rye Creek (WI084) and Jay Creek (Kurtak and others, 2002). This early 10,000-ounce production figure conflicts with the Kurtak and others (2002) estimate that the combined total production of both the more productive(?) Rye Creek and Jay Creek 'could be as much as 3,537 ounces.'

Site name(s): Silver King

Site type: Prospect

ARDF no.: WI083

Latitude: 67.2891 **Quadrangle:** WI B-3

Longitude: 151.3251

Location description and accuracy:

The Silver King prospect is along the north side of Michigan Creek about 2 miles east of Wild River at an elevation of about 1,100 feet. It is about 0.3 mile west of the top of hill 1370, near the northwest corner of section 34, T. 29 N., R. 17 W. Kurtak and others (2002: fig. I-5 and I-6) provide several excellent maps of the prospect. See figures I-5 and I-6 of Kurtak and others (2002) for a map of the prospect. The location is accurate.

Commodities:

Main: Ag, Au, Cu, Pb, Zn

Other: As, Sb

Ore minerals: Argentiferous galena, chalcopyrite, pyrite

Gangue minerals: Ankerite, quartz, siderite?

Geologic description:

Dillon and others (1986) describe the rocks in the area as Middle Devonian calcareous and chlorite-quartz schist interbedded with quartz-mica schist and marble. This schist unit is overlain by metabasites and felsic volcanic rocks of the Devonian and Mississippian Ambler metavolcanic sequence. The schist is locally deformed into broad, open folds.

Early descriptions of the Silver King prospect, beginning with Schrader (1904) describe it as argentiferous galena-bearing quartz veins in phyllite. Reed (1938) described several poorly exposed outcrops and float of galena-bearing quartz veins about 5 to 6 feet thick. A small adit noted by Reed that apparently did not cut mineralization is now caved. A 20-foot-long trench is about 100 feet north of the adit.

Nokleberg and others (1987 and 1996) characterize the occurrence as a Kuroko massive sulfide deposit. They describe the mineralization as 3- to 4-inch-thick zones of disseminated to massive chalcopyrite and argentiferous galena in felsic schist, with crosscutting pyrite veins. The country rocks are felsic schist, marble and phyllite of the Ambler sequence. Grab samples of the mineralized material contained up to 8.2 percent arsenic, 8.3 grams of gold per tonne, 3.9 grams of silver per tonne, 0.14 percent copper, 0.03 percent zinc, and 0.014 percent lead.

Kurtak and others (2002) mapped and sampled the mineralization . They interpret the deposit as quartz and quartz-carbonate veins 0.5 to 7.0 feet thick that trend northwest to northeast and can be traced for up to 80 feet along strike. The veins contain isolated clots and stringers of galena with minor pyrrhotite and chalcopyrite. A picked sample of galena-bearing quartz contained 121.9 parts per million (ppm) silver and 5.78 percent lead. Another sample from a 7-foot-thick quartz vein contained 64.5 ppm silver, 5.34 percent lead, and 2,000 ppm antimony. Locally, large pieces galena with minor pyrrhotite and chalcopyrite can be found in float; one assayed 583 ppm silver and 168 parts per billion gold.

About a thousand feet upstream from the main prospect in the gorge of Michigan Creek, at least 5 quartz veins 0.5 to 10-feet thick are exposed in the canyon walls. The veins strike about N10W and cut across the schistosity of the wall rocks. A chip sample across a 0.5-foot-wide vein contained 650 ppm silver.

Alteration:

Not specifically noted.

Age of mineralization:

Interpreted as different workers as either epigenetic galena-quartz veins that cut Devonian schist or as a Kuroko massive-sulfide deposit related to the felsic rocks of the Devonian and Mississippian Ambler sequence.

Generic deposit model:

Deposit model:

Galena-quartz veins or Kuroko massive sulfide? (Cox and Singer, 1986; model 28a?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a?

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Before 1938, a 7x7 foot adit, 75 feet long, was driven into the north wall of the canyon of Michigan Creek, probably to undercut a vein exposed in a surface trench about 150 feet north and 100 feet higher than the portal of the adit. This adit was caved in 1999 (Kurtak and others, 2002). Mapped and sampled by several government agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Rye Creek

Site type: Mine

ARDF no.: WI084

Latitude: 67.4092 **Quadrangle:** WI B-3

Longitude: 151.3745

Location description and accuracy:

Rye Creek is a west-flowing tributary to Flat Creek that joins it about 4 miles south-southwest of Mathews Dome. More than a mile of Rye Creek from where it emerges onto the flat valley of Flat Creek to the mouth of Jay Creek (WI082) has been placer mined. The coordinates are at about the midpoint of the mining in the 1980s and 1990s. This location is about 0.2 mile southwest of the center of section 21, T. 30 N., R. 17 W. The location is accurate.

Commodities:

Main: Au

Other: Cu, Pb, REE, W

Ore minerals: Chalcopyrite, galena, gold, ilmenite, monazite, pyrite, scheelite

Gangue minerals:

Geologic description:

Placer gold was found at Rye Creek in 1915 (Brooks, 1916). As described by Reed (1938), gold was found in three environments; along the present channel, along a high channel, and along a deep channel. Beginning in the early history of mining on Rye Creek, the present channel was mined from the mouth of Jay Creek for a short distance out into the alluvial fan where Rye Creek enters the valley of Flat Creek. Most of the mining was by open cut methods but there was some drift mining on the lower part of the creek. A high channel on the north side of the lower valley of Rye Creek was explored by shafts and in the 1990s by mechanical mining with heavy equipment. A deep channel occurs along the right limit of Rye Creek. A shaft was sunk 85 feet to bedrock beside lower Rye Creek and the deep channel was drift mined for a short distance. There was additional drift mining along the deep channel about 0.2 mile below Jay Creek, where the depth to bedrock is about 20 feet. Several deep shafts and drill holes were sunk in the valley of Flat Creek above the lower part of Rye Creek, but a 350-foot drill hole bottomed in muck and ice. Kurtak and others (2002) also found signs of old mining in the upper portion of Rye Creek, locally known as Lucky Creek, above the mouth of Jay Creek (WI082).

Rye Creek was first mined in 1904, then for several years between 1912 and 1916, from 1933 to 1937, and in the late 1960s. There was extensive mining from 1983 to at least 1999 by the Northern Lights Mining Company (Kurtak and others (2002). Reed (1938) reported that total gold production from Rye Creek to 1938 was $55,000 (approximately 1,600 ounces). Nearly half of that was recovered from a short section just below Jay Creek (WI082), where the gold values were about $3.35 per square foot of bedrock (gold at $35 per ounce). The only other documented gold production is 101 ounces in 1938 and 1939. However, Kurtak and others (2002) indicate that the total gold production 'could be as much as 3,537 ounces'.

The gravel in Rye Creek is angular, coarse, and contains numerous small boulders. Miners report that the gold occurs in pockets and that some of it is coarse. Much of the early mining may have concentrated on these pockets. During the mining in the late 1990s, mechanical equipment stripped the gravel over the bedrock and a metal detector was used to check the bedrock for large nuggets. A 7.5 ounce nugget was found this way.

Reed (1938) reports that the bedrock on lower Rye Creek to about 0.5 mile below the mouth of Jay Creek

is blue crystalline limestone; upstream, the bedrock is schist. He suspects a fault contact between these two units. Dillon and others (1986) mapped most of lower Rye Creek as Skajit Limestone; the uppermost part of the creek flows across Devonian chloritic and carbonate rocks. White (1952) reported various accessory minerals in panned samples from Rye Creek; these include ilmenite, andalusite, kyanite, pyrite, zircon, chalcopyrite, monazite, galena, and scheelite.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Probably inactive

Workings/exploration:

Rye Creek was first mined in 1904, then or several years between 1912 and 1916, from 1933 to 1937, and in the late 1960s. There was extensive mining from 1983 to at least 1999 by the Northern Lights Mining Company (Kurtak and others, 2002).

Production notes:

Reed (1938) reported that total gold production from Rye Creek to 1938 was $55,000 (approximately 1,600 ounces). Nearly half of that was recovered from a short section just below Jay Creek (WI082), where the gold values were about $3.35 per square foot of bedrock (gold at $35 per ounce). The only other documented gold production is 101 ounces in 1938 and 1939. However, Kurtak and others (2002) indicate that the total gold production could be as much as 3,537 ounces'.

Reserves:

Unknown but it is likely that at least some gold remains despite several episodes of mining over more than 100 years.

Site name(s): Unnamed (near Mathews Dome)

Site type: Occurrence

ARDF no.: WI086

Latitude: 67.4693 **Quadrangle:** WI B-3

Longitude: 151.4826

Location description and accuracy:

This occurrence consists of rock samples collected by two government parties over a distance of about 2,000 feet immediately north of the summit of Mathews Dome. The occurrence is centered at an elevation of about 4,100 feet on the ridge about 0.2 mile north-northwest of the 4,618-foot peak of Mathews Dome, about 0.3 mile west of the center of section 36, T. 31 N., R. 17 W. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Bornite, malachite, tetrahedrite?

Gangue minerals: Calcite, quartz

Geologic description:

This occurrence consists of bornite, malachite, and possibly tetrahedrite in quartz veins in altered schist (Chipp, 1972). The rocks in the area consist of Devonian phyllite, schist, and subordinate limestone/dolomite (Chipp, 1972). Seven samples contained up to 0.1 part per million (ppm) gold, 14 ppm silver, and 2.1 percent copper. Kurtak and others (2002) reexamined the site and collected several samples. A 3-foot continuous chip sample of calcareous schist collected immediately north of Mathews Dome contained 8,630 ppm copper and a cross-cutting quartz vein at the same locality contained 4,003 ppm copper. Both the quartz veins and calcareous schist are overlain by green chlorite schist with sparse tetrahedrite, bornite(?), and malachite. The copper mineralization along the ridge is limited and discontinuous, extending for a quarter of a mile or less.

Alteration:

Oxidation of copper mineral(s). One sample of calc-schist is described as altered, but there is no description of the alteration.

Age of mineralization:

Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:

Unclear whether epigenetic, syngenetic, remobilized, or a combination of these.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

Examination and sampling by the Alaska Division of Geological and Geophysical Surveys and the Bureau of Land Management. (Chipp, 1972; Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Longitude: 151.2138

Location description and accuracy:

Fall Creek is a west-flowing tributary to Michigan Creek; its mouth is about 6 miles southwest of Ipnek Mountain. The exact locations of placer prospects on Fall Creek are unknown and the site is arbitrarily placed approximately 1 mile upstream from its mouth, near the center of section 31, T. 29 N., R. 16 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Reed (1938) did not visit visit Fall Creek but was told that it flowed entirely over schist and that very good prospects had been found on it in the early 1900s. The area was investigated by Kurtak and others (2002); they found no evidence of mining or prospecting.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

Probably only prospected and no record of that since the early 1900s.

Production notes:

None.

Reserves:

None.

Site name(s): Bourbon Creek

Site type: Mine

ARDF no.: WI090

Latitude: 67.2725 **Quadrangle:** WI B-3

Longitude: 151.1664

Location description and accuracy:

Bourbon Creek is not named on the Wiseman B-3 topographic map. Reed (1938) describes Bourbon Creek as a left-limit tributary of Fall Creek. Later publications (Cobb (1972 [MF469]); Maas, 1987; Bliss and others, 1988) placed the mouth of Bourbon Creek about 2.5 miles upstream from the mouth of Fall Creek although at least two other tributaries farther upstream could correspond to Reed's description. This mine is somewhat arbitrarily located near the mouth of the tributary in the NW1/4 section 6, T. 28 N., R. 16 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Reed (1938) indicated that Bourbon Creek was extensively mined in the early 1900s and was thought to have been mined out by 1937. Kurtak and others (2002 located placer workings that included stacked rocks, a small trench, and the remnants of a small dam on the right limit of the west tributary of the creek about a mile above its mouth. There was no indication of recent workings.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Probably inactive

Workings/exploration:

Reed (1938) indicated that Bourbon Creek was extensively mined in the early 1900s and was thought to have been mined out by 1937. Kurtak and others (2002 located placer workings that included stacked rocks, a small trench, and the remnants of a small dam on the right limit of the west tributary of the creek about a mile above its mouth. There is no other indication of mining nor any record of claims in recent years.

Production notes:

Reed (1938) indicated that Bourbon Creek was extensively mined in the early 1900s and was thought to have been mined out by 1937. There is no record of more recent mining. Production was probably small.

Reserves:

None.

Site name(s): Oregon Creek

Site type: Prospects

ARDF no.: WI093

Latitude: 67.4692 **Quadrangle:** WI B-3

Longitude: 151.3986

Location description and accuracy:

Oregon Creek is not named on the Wiseman B-3 topographic map. It is a small right-limit tributary to Flat Creek. The mouth of Oregon Creek is about 1.5 miles north of the junction of Birch and Flat Creeks. The location of the placer prospects on Oregon Creek is not known and the site is plotted just upstream from the mouth of the creek in about the center of section 32, T. 31 N., R. 17 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Reed (1938) reported that good placer prospects had been found on Oregon Creek but that there had been no mining. Kurtak and others (2002) noted that claims were intermittently active from the 1970s to 2002. Reed described the bedrock on Oregon Creek as schist; Dillon and others (1986) map the area as Upper Devonian(?), Hunt Fork Shale and Middle Devonian(?) siliceous clastic rocks.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Undetermined

Workings/exploration:

There was prospecting on Oregon Creek but apparently no mining. There were active claims on the creek

from the 1970s to at least 2002.

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Minnie Creek

Site type: Mine

ARDF no.: WI096

Latitude: 67.4207 **Quadrangle:** WI B-1

Longitude: 150.0675

Location description and accuracy:

Minnie Creek is a west-flowing tributary to the Middle Fork, Koyukuk River; it joins the Middle Fork about 0.8 mile north of Wiseman. Only the lower three miles of Minnie Creek are in the Wiseman quadrangle; the upper 6 miles is in the Chandalar quadrangle. Although most indications of placer activity are in the Chandalar quadrangle, the exact location of prospecting and/or mining is uncertain. This mine is arbitrarily placed approximately 1 mile upstream from the mouth of Minnie Creek near the southwest corner of section 17, T. 30 N.., R. 11 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Minnie Creek reportedly was heavily prospected and locally drift mined in the early 1900s, but it is unclear where this activity occurred (Reed, 1938). Water problems hindered excavation to bedrock and the early mining efforts were not very successful (Reed, 1938). A shaft to bedrock in 1904 reportedly produced $500 of 'shot' gold from a short drift before it flooded. Drift mining was concentrated in a deep channel. Apparently no gold was produced from the modern channel or from benches, although benches are present. Limited evidence suggests that most mining on Minnie Creek has been on the middle and upper parts of the creek in the Chandalar quadrangle, although it is likely that at least some prospecting has occurred along the lower portion of the creek in the Wiseman quadrangle. Based on incomplete records, Kurtak and others (2002) report that Minnie Creek produced 132 ounces of gold from 1904 to 1916. Claims were active intermittently from the 1970s to the 1990s, but there is no record of production from 1916 to 2000.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Inactive

Workings/exploration:

Considerable prospecting and some drifting was reported in the early 1900s, but underground water impeded mining. Claims were active intermittently from the 1970s to the 1990s, but there is no record of production from 1916 to 2000.

Production notes:

Based on incomplete records, Kurtak and others (2002) report that Minnie Creek produced 132 ounces of gold from 1904 to 1916. Claims were active intermittently from the 1970s to the 1990s, but there is no record of production from 1916 to 2000.

Reserves:

None.

Site name(s): Lofty Gulch

Site type: Mine

ARDF no.: WI097

Latitude: 67.4863 **Quadrangle:** WI B-1

Longitude: 150.0898

Location description and accuracy:

Lofty Gulch is a short, steep, south tributary to the lower Hammond River, between Swift Creek and Gold Bottom Gulch. Placer mining has occurred from near the mouth of Lofty Gulch to about 1,500 feet upstream. The mine is plotted near the mouth of the gulch, about 0.5 mile south of the center of section 30, T., 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Lofty Gulch was mined near its mouth in the early 1900s (Reed, 1938). There has been no mining on the upper part of the creek where it is narrow, steep, and contains only limited amounts of gravel. According to Reed (1938), the creek was mined out. Kurtak and others (2002) examined the creek in about 2000; there was no sign of mining. There is no record of production, but it probably was small.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Site name(s): Union Gulch; Union Creek

Site type: Mine

ARDF no.: WI098

Latitude: 67.4536 **Quadrangle:** WI B-1

Longitude: 150.1039

Location description and accuracy:

Union Gulch flows southeast from Midnight Dome into the Middle Fork Koyukuk River. It is about 3 miles north of Wiseman and about 0.5 mile west of the center of section 6, T. 30 N., R. 11 W. Eden (2000) indicates that the placer gold was mined about 0.8 mile upstream from the mouth of Union Gulch at an elevation of about 1,300 feet.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The placer gold that was mined on Union Gulch came from the modern stream channel (Reed, 1938). The gravel is less than 3 feet thick over bedrock for most of the creek. Gold was discovered in 1901 when a 32-ounce nugget was recovered. Maddren (1913) reported that $35,000 of gold (about 1,850 ounces) was produced from 1900 through 1909, with $30,000 of that in 1902. Kurtak and others (2002) give slightly different figures. They report a total production of 1,633 ounces from 1901 to 1935, with 1,451 ounces of that in 1902. Mining was reported in 1934 and 1937, but Mulligan (1974) indicated that the property was inactive as of 1974. Bliss and others (1986) reported some mining from 1980 to 1982. Kurtak and others (2002) reported that mining was being done with a trommel, sluice box, and suction dredge from the 1990s to the at least 2002. The production since 1935 is not known.

Kurtak and others (2002) examined and sampled the property. They also conducted a ground-penetrating-radar survey along the benches on lower Union Creek to locate buried channels; the results were inconclusive.

ARDF no.: WI100

Latitude: 67.4981 **Quadrangle:** WI B-1

Longitude: 150.1155

Location description and accuracy:

Buckeye Gulch is a short, east-flowing tributary to the lower Hammond River. It is approximately 2 miles northeast of Smith Creek Dome and extends through the middle of section 24, T. 31 N., R. 12 W. Buckeye Gulch has been placer mined for about 2,000 feet above its mouth. The location is accurate.

Commodities:

Main: Au

Ore minerals:

Gangue minerals:

Geologic description:

Gold was first mined on Buckeye Gulch in 1904 (Maddren, 1913). To 1913, the mine produced 0.32 to 0.54 ounce of gold per man day of work. Reed (1938) indicated that the early mining extended for about 2,000 feet above the mouth of the gulch. Reed (1938) noted that a high channel of the Hammond River, which was exposed in Buckeye Gulch just above its mouth, was being explored in 1937. The only evidence of mining found by Kurtak and others (2002) was stacked rocks along the gulch. Buckeye Gulch produced 685 ounces of gold from 1904 to 1935; 612 ounces of that was in 1907 (Kurtak and others, 2002). Dillon (1982) suggested that the gold near the mouth of the gulch probably was derived from bench gravels of the Hammond River.

Site name(s): Nolan Creek

Site type: Mine

ARDF no.: WI101

Latitude: 67.4745 **Quadrangle:** WI B-1

Longitude: 150.2324

Location description and accuracy:

Nolan Creek is a south-southwesterly-flowing tributary of Wiseman Creek; its mouth is about 5 miles northwest of Wiseman. The coordinates are at the old town of Nolan just above the mouth of Smith Creek. The placer deposits extend for about 1 mile below and 1.75 miles above the town. The productive portion of Nolan Creek crosses sections 27, 28, and 33, T. 31 N., R. 12 W. The location is accurate.

Geologic description:

There are three types of gold placers on Nolan Creek: 1) placers in shallow gravel just below the mouth of Fay Creek along the present channel of Nolan Creek; 2) a deep channel roughly under the present course of Nolan Creek from downstream of the mouth of Fay Creek to just below Smith Creek, and 3) bench deposits along the east side of the Nolan Creek valley from just north of Archibald Creek to 0.5 mile south of Smith Creek. The deep channel has been by far the most productive.

The present channel in Nolan Creek was mined just below the mouth of Fay Creek (near the Discovery claim) from 1903 to 1905. This placer and placers in shallow gravels on Smith and Fay Creeks produced a considerable amount of gold. The shallow gravels on Nolan Creek were about 3.5 feet thick and lay on false bedrock in the valley fill. Reed (1938) suggested that the gold in this placer was derived from erosion of gold-bearing gravels in Fay Creek. The auriferous gravel was 20 to 75 feet wide. The deposits were small and mined out in a short time (Reed, 1938).

The most productive of the Nolan Creek placers has been along the deep channel that roughly coincides with the present course of Nolan Creek from near the mouth of Fay Creek to about three-quarters of a mile below the mouth of Smith Creek, i.e., for about 2 miles. At its upper end, bedrock is about 20 feet deep; it gradually deepens to over 200 feet at its lower end. The average gradient of the deep channel is about 2 percent but there are sections with steeper gradients and 'dropoffs' as the deep channel goes down valley. The gravel and overlying fill in Nolan Creek is frozen. It is waterworn and generally fairly fine but large boulders commonly are scattered throughout the gravel. The gold in the deep channel lies directly on bedrock. It is rounded and waterworn and generally coarse grained; nuggets up to 40 ounces have been found. Values, according to Reed (1938), vary from $1.15 to as much as $15 per square foot of bedrock (gold at $35 per ounce). In addition to the principal deep channel, there are sections of other deep channels that have been preserved at levels above the main deep channel. Reed (1938) speculated that these remnants may have been bench deposits formed either when the deep-channel stream was active, or when an aggrading Nolan Creek deposited gold in channels cut in the valley walls as it meandered across the valley floor.

The deep channel was drift mined from before 1913 (Maddren, 1913) to 1938 when it was considered to be mined out (Reed, 1938). In 1989, Silverado Gold Mines Ltd. attempted to reach the deep channel near

the mouth of Acme Creek (WI120) with a decline but was unsuccessful. However, in 1996, Silverado Gold Mines Ltd. began mining the deep channel from a decline and continued drift mining on it in 1998 and 1999 (Bundtzen, 2008).

The bench deposits on Nolan Creek are its east side from just north of Archibald Creek to about a half mile south of Smith Creek. The tops of the bench deposits are 50 to 200 feet above the modern stream channel and bedrock is covered by 40 to 100 feet of overburden. The auriferous gravel varies from 50 to 200 feet wide and extend 300 to 1,000 feet. From north to south, the bench deposits along the east side of Nolan Creek are: the Wooll Bench, the Swede Channel, Mary's Bench, Pingel Bench, and Workman Bench. The gravel in these bench deposits is frozen and coarse but contains few boulders. The gold is coarse; it includes small nuggets and a few large nuggets. The gold fineness varies from 885 to 962. According to Reed (1938) these deposits varied in value from $0.25 to $4.20 per square foot of bedrock (gold at $35 per ounce).

The bench deposits were drift mined in early years with water brought in by ditches but mining was difficult due to the lack of a reliable water supply. In 1991 and 1992, Inside Out Mining drift mined the Nolan Bench. In 1993, Silverado purchased the bench claims (and claims covering many of the streams in the area) and began mining them. In 1988, Silverado mined the Swede Channel and Mary's Bench, and in 1999, the Workman Bench.

Most years between 1979 and 2007, Silverado mined along Nolan Creek and its tributaries Fay Creek (WI112), Archibald Creek (WI113), and Smith Creek (WI116). During that period, the placers produced 23,150 ounces of gold from 271,771 cubic yards of gravel with an average grade of 0.085 ounce of gold per cubic yard. More than two-thirds of the production was by underground drift mining in the winter; the rest was by open-cut mining with heavy equipment in the summer. Some of the mining was to test the gravels east of Nolan Creek or in its tributaries. Most of the gold, probably about 20,000 ounces was produced from the bench deposits east of Nolan Creek. Most of the production took place between 1993 and 1995 but continued at various places along benches on the east side of the creek until 2007.

Nolan Creek has produced gold for at least 63 of the years between 1904 and 2000; the most productive period was 1908 and 1909, when it produced more than 93,000 ounces of gold. Eden (2000) reports that a total of 135,437.70 ounces of gold was produced from it between 1904 and 1999. Kurtak and others (2002) provide (incomplete) production figures year by year from 1904 to 2000 that total 147,045 ounces of gold. Bundtzen (2008) estimates that Nolan Creek and its tributaries, Smith Creek (WI116), Archibald Creek (WI113), and Fay Creek (WI112), have produced about 185,000 ounces of gold from 1901 to 2007.

Bundtzen (2008) estimated that Nolan Creek and its tributaries still had: 1) an 'indicated resource' of 66,800 cubic yards of gravel with an average grade of 0.095 ounce of gold per cubic yard (or 6,250 ounces of gold); and 2) an 'inferred resource' of 103, 500 cubic yards of gravel that contain 3,012 ounces of gold. This gold is in several locations along the Nolan Deep Channel between the mouth of Fay Creek and the mouth of Archibald Creek; in two bench deposits east of Nolan Creek between Fay Creek and Smith Creek; and in shallow gravel along Smith Creek (WI116).

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Nolan Creek has been extensively mined and prospected beginning in 1903 and continuing until until at least 2007, with production in at least 63 of those years (Kurtak and others, 2002; Bundtzen, 2008, 2009). Most mining into the 1960s was by underground drifting. Mining since 1979 has been by a combination of open-pit operation in the summer and underground drift mining in frozen gravel in the winter.

Production notes:

Nolan Creek has produced gold for at least 63 of the years between 1904 and 2000; the most productive period was 1908 and 1909 when it produced more than 93,000 ounces of gold. Eden (2000) reports that a total of 135,437.70 ounces of gold was produced from Nolan Creek between 1904 and 1999. Kurtak and others (2002) provides (incomplete) production figures year by year from 1904 to 2000 that total 147,045 ounces of gold. Bundtzen (2008) estimates that Nolan Creek and its tributaries--Smith Creek (WI116), Archibald Creek (WI113), and Fay Creek (WI112)-- have produced about 185,000 ounces of gold from 1901 to 2007.

Reserves:

Bundtzen (2008) estimated that Nolan Creek and its tributaries still had: 1) an 'indicated resource' of 66,800 cubic yards of gravel with an average grade of 0.095 ounce of gold per cubic yard (or 6,250 ounces of gold); and 2) an 'inferred resource' of 103, 500 cubic yards of gravel that contain 3,012 ounces of gold. This gold is in several locations along the Nolan Deep Channel between the mouth of Fay Creek and the mouth of Archibald Creek; in two bench deposits east of Nolan Creek between Fay Creek and Smith Creek; and in shallow gravel along Smith Creek (WI116).

Geologic description:

Gold was produced from Swift Creek as early as 1901 (Schrader, 1904). The richest placer deposits were near the mouth, although the mines produced only wages and small amounts of coarse gold (Maddren, 1913). The modern stream bed has been mined as was a high channel that coalesced with an eroded high channel of the Hammond River (Reed, 1938). Some of the gold had a white coating similar to that on the gold from Smith Creek (WI116). Mosier and Lewis (1986) report that the gold from the high channel was 880 fine from the high channel and 924 fine from the modern channel. Kurtak and others (2002) report the production by year from 1902 to 1941; gold was recovered in 22 of those years. The total production was 1,396 ounces of gold; the best year was 1916 when 212 ounces were recovered. Claims were active at various times from 1979 to 1996. The rocks in the area are mainly Devonian chlorite-mica schist, quartz-mica schist, and phyllite (Eden, 2000).

Geologic description:

The Hammond River is one of the largest gold producers in the Koyukuk District. Most of the production has come from a three-mile section of the river that extends from the mouth of Jennie Creek (WI169) to the mouth of Vermont Creek (WI027).

Gold was discovered on the Hammond River about 1900 about 2 miles above its mouth (Maddren, 1913). Early work concentrated on mining the shallow gravel along the modern stream channel, notably near the discovery claim about 0.4 mile upstream from the mouth of Jennie Creek and along river meanders as far upstream as Buckeye Gulch (WI100). According to Maddren (1913), mining in the modern channel produced about $8,000 to $10,000 in gold (gold at $20.67 per ounce) by 1913. Most of these deposits were soon mined out although some shallow ground was mined as recently as from 1985 to 1987 near the mouth of Swift Creek and probably elsewhere over the years.

In 1911, drift mining began on the deep channel below the Hammond River and it is the major source of the gold. The deep channel has been mined from near the mouth of Buckeye Gulch to about a mile and a half above the mouth of the river. The lower end of the deep channel extends into the valley of the Middle Fork, Koyukuk River, but is truncated there, presumably by glacial scouring. The deep channel was about 114 feet deep about 0.2 mile above the mouth of Jennie Creek and was thought to be too deep and wet to mine downstream. The deep channel, except for a few areas overlooked by the early miners, was thought to be mined out by 1937 (Reed, 1938). Workings in one of these overlooked areas in 1936 and 1937 found a section 8-10 thick of paying gravel. The channel was 35 feet wide and the depth to bedrock was 115 feet. The gravel consisted of small boulders and large cobbles, separated by sand and fine gravel. The gravel was frozen to bedrock (although this was not always the case at other locations along the deep channel) and the bedrock was described as hard schist (Reed, 1938). The gravel of the deep channel was said to become richer downstream. The gold in the deep channel is on bedrock; it is coarse, rounded, and waterworn. Galena and pyrite locally accompany the gold. Much coarse gold has been produced from the Hammond River. Several 40- and 50-ounce nuggets were found, and one weighed 137 ounces (Maddren, 1913; Dillon, 1982). Mosier and Lewis (1986) reported that gold in 14 samples from Hammond River varied from

from 845 to 929 fine with a median fineness of 900. According to Reed (1938), the ground was valued at about $1.46 per square foot of bedrock (gold at $35 per ounce). At that time, little gold had been found in the deep channel above the mouth of Buckeye Gulch. However, from 1991 to 1995, there was an attempt to mine the deep channel between Buckeye Gulch and Vermont Creek with earth moving equipment. That attempt was unsuccessful due to flooding and silting of the workings.

Gold also occurs in sections of a high channel preserved along the lower Hammond River. These sections appear to be 40-50 feet above the modern river bed and were first encountered where the high channel is cut by tributary streams such as at Buckeye Gulch (WI100). (There are also much higher bench placers that are described separately, notably the Slisco Bench (WI031) southwest of the mouth of Vermont Creek.). In the late 1990s several mines worked these benches between Gold Bottom Gulch and Jennie Creek, but getting water to them was difficult.

An examination in 2011 (by D.J. Grybeck) of the satellite imagery available widely on the internet shows evidence of extensive modern surface placer mining with earth moving equipment at several sites along the Hammond River: 1) opposite the mouth of Jennie Creek; 2) about 2,000 to 3,000 feet upstream; 3) on the opposite side of the river and just upstream from the mouth of Steep Creek; 4) near the mouth of Swift Creek (WI102) , and 5) near the mouth of Buckeye Gulch (WI100).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active?

Workings/exploration:

From 1900 to at least 2001, there have been numerous mines in operation along the Hammond River from the mouth of Jennie Creek to the mouth of Vermont Creek (Kurtak and others, 2002). Early mining concentrated on shallow ground along the modern stream channel but this ground was soon exhausted. In 1911, drift mining began on a deep channel that extended from the mouth of Buckeye Gulch to the mouth of Jennie Creek and most of the gold mined from the Hammond River has come from this deep channel. The deep channel was thought to be mined out by 1938 but various mining operations have continued to mine into the 21st century on remnants of shallow ground and benches along the river, using earth moving equipment and suction dredges. An examination in 2011 (by D.J. Grybeck) of the satellite imagery available widely on the internet shows evidence of extensive modern surface placer mining with earth moving equipment at several sites along the Hammond River: 1) opposite the mouth of Jennie Creek; 2) about 2,000 to 3,000 feet upstream; 3) on the opposite side of the river and just upstream from the mouth of Steep Creek; 4) near the mouth of Swift Creek (WI102); and 5) near the mouth of Buckeye Gulch (WI100).

Production notes:

The total placer gold production from the Hammond River is uncertain, but it has been large. Bliss and others (1988) indicate that total production may be more than 31,746 ounces and as much as 47,620 ounces (but this includes the substantial production from the tributary streams to the Hammond River). Eden (2000) reported that 17,256 ounces of gold was produced from the Hammond River between 1904 and

1999. Kurtak and others (2002) give yearly production figures from 1900 to 1943 that total 19,128 ounces of gold, but they note that the production records are incomplete. The peak of the production was from 1913 to 1916 when 15,705 ounces of gold was mined and most of that probably came from drift mining on the deep channel.

Reserves:

Probably no substantial reserves remain but there may be remnant pockets of unmined auriferous gravel.

Site name(s): Clara Creek

Site type: Mine

ARDF no.: WI105

Latitude: 67.279 **Quadrangle:** WI B-1

Longitude: 150.1094

Location description and accuracy:

Clara Creek is a westward-flowing tributary to the Middle Fork, Koyukuk River; its mouth is about 1 mile north of Coldfoot. The exact location of mining is not known but probably took place in the upper part of the creek between about 1,400 and 1,600 feet in elevation. The site is about 0.5 mile east of the center of section 2, 28 N., R. 12 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Gold was discovered on Clara Creek in 1900 (Schrader, 1904). Mining in 1900 and 1901 produced $3,000 in gold (about 150 ounces), including an 18 ounce nugget (Maddren, 1913). Reed (1938) noted that there was no report of mining on the creek since the early 1900s. From 1953 to 1999, there were several periods of prospecting, trenching, and shaft sinking by several operators and gold was produced at times from 1984 to 1992. Production records are not available after 1901. Kurtak and others (2002) examined the creek and found piles of stacked rocks up to 10 feet high between 1,400 and 1,600 feet in elevation. They also found the remains of shafts at 1,550 feet and 2,000 feet in elevation.

Alteration:

39a

Production Status: Yes

Site Status: Active?

Workings/exploration:

Gold was discovered on Clara Creek in 1900 and it produced about 150 ounces of gold in 1900 and 1901 (Maddren, 1913). There were several periods of prospecting and development from 1953 to 1999. Some gold was produced at times from 1984 to 1992 and perhaps in other years. Kurtak and others (2002) examined the creek and found piles of stacked rocks up to 10 feet high from about 1,400 feet to 1,600 feet in elevation. They also found the remains of shafts at 1,550 feet and 2,000 feet.

Production notes:

Mining in 1900 and 1901 produced $3,000 worth of gold (about 150 ounces), including an 18 ounce nugget. There is no record of the gold production during several periods of prospecting and mining from 1953 to 1999 (Kurtak and others, 2002).

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Ferguson

Site type: Prospect

ARDF no.: WI106

Latitude: 67.4623 **Quadrangle:** WI B-1

Longitude: 150.1473

Location description and accuracy:

This prospect is located just east of the ridge line of Midnight Dome at the head of Union Gulch. It is at an elevation of about 3,500 feet, about 0.7 mile southeast of the center of section 35, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au, Sb

Other: Ag

Ore minerals: Gold, stibnite

Gangue minerals: Quartz

Geologic description:

This deposit was described by Ebbley and Wright (1948) as prospect pits that expose a 6-inch quartz vein containing 'kernels' of stibnite in an earthy yellow matrix of antimony oxides. Samples of vein material contained 0.03 to 0.04 parts per million (ppm) gold, up to 0.15 ppm silver, and more than 1 percent antimony. A sample of bedrock contained 0.05 ppm gold, 0.1 ppm silver, and 0.03 percent antimony (Brosge and Reiser, 1970). Samples of a quartz-stibnite vein collected by Dillon (1982) contain up to 14 ppm gold. A sample of fine- to coarse-grained, crystalline stibnite from dump material assayed 62 percent antimony (Mulligan, 1974). The prospect was examined and sampled by Kurtak and others (2002). They found two trenches about 12 feet long. They analyzed a select sample that contained 33.13 percent antimony and 14 parts per billion gold. About a quarter of a mile south of this prospect, they collected two samples of quartz veins that cut chlorite schist. They averaged 321 ppb gold, 373 ppm lead, 365 ppm arsenic, and 317 ppm antimony. (This occurrence to the south is not the occurrence just west of hill 3860 (WI132) that they describe separately.) The rocks in the area are Middle or Upper Devonian(?) calcareous, chloritic wacke (Dillon and others, 1986).

Alteration:

Oxidation of stibnite to yellow antimony oxides.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Simple stibnite deposit (Cox and Singer, 1986; model 27d).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

27d

Production Status: None

Site Status: Inactive

Workings/exploration:

There are at least two prospect pits and the prospect has been sampled repeatedly by government agencies.

Production notes:

None.

Reserves:

None.

Site name(s): Wiseman Creek

Site type: Prospects

ARDF no.: WI108

Latitude: 67.4523 **Quadrangle:** WI B-1

Longitude: 150.2203

Location description and accuracy:

The mouth of Wiseman Creek is at the town of Wiseman on the Middle Fork, Koyukuk River. There have been several attempts to find and mine placer gold along Wiseman Creek but the only two records of prospecting refer to deep shafts 1 mile and 2 miles below the mouth of Nolan Creek. The coordinates are arbitrarily placed between these two shafts, about 0.5 mile east of the center of section 4, T. 30 N., R. 12 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Schrader (1900) first reported gold on Wiseman Creek but in view of the subsequent mining in the area and the absence of any gold placers that have been found since on Wiseman Creek, he probably was referring to its then-unnamed tributary Nolan Creek (WI101) and its many tributaries. There have been several attempts to find gold on Wiseman Creek below the mouth of Nolan Creek (Maddren, 1910; Kurtak and others, 2002). In 1908, a 260-foot shaft was sunk to bedrock about a mile below the mouth of Nolan Creek. The bottom 30 feet was in washed gravel with only colors of gold, not enough to warrant drift mining. In 1909, another shaft was sunk about 2 miles below the mouth of Nolan Creek but did not reach bedrock at 365 feet. The USGS B-1 topographic map shows a prospect in the Wiseman Creek valley about 3 miles below the mouth of Nolan Creek but there is no record of prospects in this area. In 1928, a company cut two trenches, one 800 feet long and the other 400 feet long, about 1.5 miles north of the town of Wiseman. (The location is shown on figure 1.8 of Kurtak and others, 2002). Only fine flour gold was found in the trenches and the ground contained only 6 to 10 cents per cubic yard (at $20.67 per ounce of gold) (Reed, 1938).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

In 1908, a 260-foot shaft was sunk to bedrock about a mile below the mouth of Nolan Creek. The bottom 30 feet was in washed gravel but not enough gold was found to warrant drift mining. In 1909, another shaft was sunk about 2 miles below the mouth of Nolan Creek but did not reach bedrock at 365 feet. The USGS B-1 topographic map shows a prospect in the Wiseman Creek valley about 3 miles below the mouth of Nolan Creek but there is record of prospects in this area. In 1928, a company cut two trenches, one 800 feet long and the other 400 feet long, about 1.5 miles north of the town of Wiseman. (The location is shown on figure 1.8 of Kurtak and others, 2002). Over the years, placer claims have been staked along the length and width of Wiseman Creek valley but as yet there is no record of workable gold placers anywhere on the creek.

Production notes:

Despite more than 100 years of prospecting along Wiseman Creek and much mining along its tributaries to the north, e.g., Nolan Creek (WI101), there is no record of production on Wiseman Creek.

Reserves:

None.

Site type: Occurrence

ARDF no.: WI109

Latitude: 67.3808 **Quadrangle:** WI B-1

Longitude: 150.162

Location description and accuracy:

This occurrence is on the west side of the Middle Fork, Koyukuk River about 0.5 mile northwest of the mouth of Moose Creek. It is at an elevation of about 1,530 feet, 0.1 mile south of the center of section 35, T. 30 N., R. 12 W., of the Fairbanks Meridian. The name, Roches Moutonnees, is derived from the rounded hummock outcrops in the area, which are said to form a distinctive local feature. The location is accurate within one-half mile.

Commodities:

Main: Cu

Other: Zn

Ore minerals: Bornite

Gangue minerals: Quartz

Geologic description:

This occurrence consists of quartz veinlets in dolomite and limestone (Mulligan, 1974). Analysis of the veinlets show trace amounts of copper and zinc, but the only visible sulfide in freshly broken quartz was a small bleb of bornite. The rocks in the area are Proterozoic or lower Paleozoic(?), calcareous schist, and local marble (Dillon and others, 1986).

Longitude: 150.1997

Location description and accuracy:

The mouth of Fay Creek is about 1.4 miles north-northeast of the old town of Nolan on Nolan Creek. Placer mining extended from near the mouth of Fay Creek to more than 4,000 feet upstream. The coordinates are just upstream from its mouth, about 0.5 mile north of the center of section 27, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Arsenopyrite, boulangerite?, gold, jamesonite?, pyrite, pyrrhotite, stibnite

Gangue minerals: Quartz

Geologic description:

Placer gold in Fay Creek occurs in the modern channel, in a deep channel, and in a high channel. The discovery in 1901 of gold in the shallow gravels near the mouth of the modern channel of Fay Creek sparked the initial interest in the Nolan Creek valley. These shallow gravels were first mined in 1903 but were exhausted within a few years.

Gold in portions of a high channel along the north side of Fay Creek was mined prior to 1930. These high-channel placers begin about 1,000 feet upstream from the mouth of the creek and are about 275 higher in elevation than the modern steam valley (Reed, 1938). A gold-bearing deep channel near the mouth of the creek, which probably was a deep channel of Nolan Creek, was mined out in the early 1900s. This deep channel was about 20 feet below the surface. The high channel was being prospected in 1929 (Reed, 1938) but the modern stream channel and the deep channel were considered to have been mined out by 1937. Brosge and Reiser (1960) noted probable post-World War II mining activity and Dillon (1982) noted reports of recent mining activity.

Maddren (1913) noted that the placer gold in Fay Creek appeared not to have moved very far from its bedrock source inasmuch as it generally occurred in rough and angular grains attached to quartz. There are reports of lode gold occurrences nearby on Smith Creek Dome (WI110 and WI127) near the head of Fay Creek, as well as on on Thompson Pup (WI128), a tributary of Fay Creek. A sample of gold from Fay Creek was 842 fine, and contained 16 percent silver, 94 parts per million (ppm) copper, 16 ppm lead, and 0.625 percent mercury (Mosier and Lewis, 1986).

Most years between 1979 and 2007, Silverado Gold Mining Inc. mined along Nolan Creek (WI101) and its tributaries Fay Creek, Archibald Creek (WI113), and Smith Creek (WI116) (Bundtzen, 2008, 2009). Silverado mined on Fay Creek in 1979 and produced 12 ounces of gold. They continued to mine on Fay Creek and Archibald Creek in 1981, 1984, and 1987, and produced 2,372 ounces of gold from the two creeks. The mining on Fay Creek took place from its mouth to the mouth of Thompson Pup (WI124), probably in open cuts. Silverado did no further work on either Fay Creek or Archibald Creek during their considerable mining in the area until 2007, although they mined on Thompson Pup (WI124), a tributary of Fay Creek, in 1993. In his 2008 estimates of the gold resources of Nolan Creek and its tributaries, Bundtzen (2009) did not include any on Fay Creek.

According to Maddren (1913), Fay Creek produced about $30,000 of gold (about 1,500 ounces) between 1900 and 1909. Eden (2000) reports that a total of about 1,865 ounces of gold were produced from Fay Creek between 1904 and 1999.

Kurtak and others (2002) sampled several quartz veins that cut bedrock on lower Fay Creek. The veins trend northwest and contain sparse pyrite, pyrrhotite, arsenopyrite, chalcopyrite, stibnite, and either boulangerite or jamesonite. Samples contained up to 167 parts per billion gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Active

Workings/exploration:

The modern and deep channels of Fay Creek were mined in the early 1900s, but there is no record of the mining methods. Sections of the high channel were mined in the early 1900s and the high channel was being prospected in 1929 (Reed, 1938). Brosge and Reiser (1960) noted probable post-World War II mining activity and Dillon (1982) noted reports of recent mining activity. Silverado Gold Mining Ltd. mined on Fay Creek in 1979 and produced 12 ounces of gold (Bundtzen, 2008, 2009). They continued to mine on Fay Creek and Archibald Creek in 1981, 1984, and 1987, and produced 2,372 ounces of gold from the two creeks. The mining on Fay Creek took place from its mouth to the mouth of Thompson Pup (WI124), probably in open cuts. Silverado did no further work on either Fay creek or Archibald Creek during their considerable mining in the area until 2007, although they mined on Thompson Pup (WI124), a tributary of Fay Creek, in 1993.

Production notes:

According to Maddren (1913), Fay Creek produced about $30,000 of gold (about 1,500 ounces) between 1900 and 1909. Eden (2000) reports that a total of about 1,865 ounces of gold were produced from Fay Creek between 1904 and 1999. Kurtak and others (2002) indicated that the production was considerably greater, a total of 3,295 ounces from 1903 to 1987, with mining in 14 of the years from 1903 to 1923, and then in 1987.

Reserves:

In his 2008 estimates of the gold resources of Nolan Creek and its tributaries, Bundtzen (2009) did not include any on Fay Creek.

Location description and accuracy:

Archibald Creek is a west-flowing tributary to Nolan Creek. Its mouth is about 1.75 miles above the mouth of Nolan Creek on Wiseman Creek. Most of the mining activity on Archibald Creek has been along the lower 0.5 mile of the creek. The coordinates are about at the midpoint of mining about 0.4 mile west of the center of section 27, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other: Sb

Ore minerals: Gold, stibnite

Gangue minerals:

Geologic description:

Placer gold has been mined both from the modern channel and a deep channel on Archibald Creek. The modern channel was mined near the mouth of the creek in the early 1900s and was being mined about 3/8ths of a mile upstream in 1937. The gravel in the modern channel is coarse and subangular; it contains many boulders. Five to twelve feet of frozen gravel, covered by 3 feet of muck and a foot of moss, overlie soft, schist bedrock. The gold is distributed throughout the gravel and occurs both as fine particles worn flat and smooth, and as coarse particles that are rough and porous. The gold averages 905 fine and the value of the ground was about $0.44 per square foot of bedrock (gold at $35 per ounce) (Reed, 1938).

The deep channel, which is 5 to to 14 feet wide, is on the north side of the creek. It is about 25 feet deep near the mouth of the creek; it rises upstream to coalesce with the modern channel. Seven to nine feet of frozen, coarse, subangular gravel overlies bedrock, which is described as alternating bands of black graphitic and yellow schist (Reed, 1938). The gravel is overlain by 16 to 18 feet of muck and a foot of moss. Unlike the modern channel, the deep channel is free of large boulders. The gold in the deep channel occurs both as coarse, worn, and rounded particles, and as coarse, porous, and unworn particles. Reed (1938) reports values of approximately $2.11 in gold per square foot of bedrock (gold at $35 per ounce). A stibnite vein was reported during drift mining on Archibald Creek (Ebbley and Wright, 1948). The creek and bench placers have been mined by hand and hydraulic methods, and the deep channel by drifting. Mulligan (1974) reported hand mining in 1974.

Most years between 1979 and 2007, Silverado Gold Mining Inc. mined along Nolan Creek (WI101) and its tributaries Fay Creek (WI112), Archibald Creek, and Smith Creek (WI116) (Bundtzen, 2008 and 2009). More than two-thirds of the production was by underground drift mining; the rest was by open-cut mining with heavy equipment. Silverado mined on Fay Creek (WI112) and Archibald Creek in 1981, 1984, and 1987, and produced 2,372 ounces of gold from the two creeks. The mining on Archibald Creek took place from near its mouth upstream for about 1,200 feet. Silverado did no further work on Archibald Creek during their considerable mining in the area from 1988 to 2007. In his 2008 estimates of the gold resources of Nolan Creek and its tributaries, Bundtzen (2009) did not cite any resources on Archibald Creek.

Maddren (1913) reported that $6,000 of gold (about 300 ounces) was produced from 1900 to 1909. Eden (2000) reported that about 5,430 ounces of gold were produced from Archibald Creek between 1904 and

1999. Kurtak and others (2002) give a slightly greater production of 6,577 ounces from 1904 to 1998. A notable year was 1927 when 1,462 ounces of gold was produced, and 1,923 ounces was produced in four years from 1981 to 1998.

Site name(s): Pringle Bench; Jones & Boyle

Site type: Mine

ARDF no.: WI114

Latitude: 67.4746 **Quadrangle:** WI B-1

Longitude: 150.2204

Location description and accuracy:

This mine is on the north side of lower Smith Creek, about 0.5 mile east of Nolan; it is near the northeast corner of section 33, T. 31 N., R. 12 W. The location is accurate. Kurtak and others (2002) include a detailed map of the mine as their figure I-10.

Commodities:

Main: Ag, Au, Sb

Other:

Ore minerals:

Gangue minerals: Quartz

Geologic description:

As the Jones and Boyle, this mine was described prior to 1988 as a series of quartz-stibnite veins that were exposed during placer mining sometime prior to 1943 (Ebbley and Wright, 1948). The veins apparently were still exposed in the old placer cuts as late as 1974. Ebbley and Wright describe six, parallel quartz-stibnite veins, 3-4 inches wide; the stibnite is concentrated in the central 1.5 to 2 inches of the veins. W. W. Patton Jr.'s, U. S. Geological Survey field notes in 1953 indicate that the veins are as wide as 1 foot and that their stibnite core is as wide as 4 inches (Bliss and others, 1988). The veins are in joints and locally are offset by cross faults (Bliss and others, 1988). Six samples of vein material contained 0.02 to 0.06 part per million (ppm) gold and from less than 0.1 ppm to 0.2 ppm silver (Bliss and others, 1988). Two samples of bedrock near the veins contained 0.03 ppm gold. Samples across the veins contained 33.8 to 44.5 percent antimony (Mulligan, 1974).

The host rocks at the Pringle Bench (Jones & Boyle) Mine are Devonian phyllite, schist, and metasiltstone (Dillon and Reifenstuhl, 1990). The gold-stibnite mineralization occurs as distinct veins parallel to and along a structural zone 120 to 350 feet wide that strikes northeast and dips 50 to 85 degrees southeast (Bundtzen, 2008, 2009). Both stibnite (only) and quartz-stibnite veins are present; minor arsenopyrite occurs in them. On the nearby Workman's Bench prospect, there are veins of massive stibnite up 15 inches thick that assayed up to 2.86 ounces of gold per ton. Four major, parallel veins across a width of about 100 feet and a strike length of about 1,100 feet were cut in the 41 drill holes and the underground workings of Workman's Bench (WI115); there were numerous gold-stibnite(-quartz) veinlets between the major veins. When Silverado was working on the Workman's Bench prospects, they drilled 8 holes on Pringle Bench. At the Pringle Bench Mine, two major stibnite-gold(-quartz) veins were intersected that extended for about 600 feet along strike. The mineralization at the Workman's Bench and Pringle Bench only could be followed in the drill holes but the orientation and characteristics of the mineralization at the two sites demonstrate that it is probably continuous over a distance of at least 1,600 feet through the two sites. Soil geochemistry and geophysical data suggest that the mineralization continue further northeast.

Bundtzen (2009) estimated that Pringle Bench has an 'inferred resource' of 6,308 tons with an average grade of 12.78 percent antimony and 0.088 ounce of gold per ton.

Five tons of stibnite ore were recovered from sluice operations somewhere on upper Smith Creek and shipped during World War II (Joesting, 1943). Joesting attributed at least some of this production to this

property, then known as the Jones & Boyle prospect. However, his description of its source on upper Smith Creek contradicts the location of the Jones & Boyle prospect described by Ebbley & Wright (1948). More likely, the source of the stibnite was the unnamed prospect at the head of Smith Creek on Midnight Dome (WI130). The information is so vague however, that the ore may have come ore or more of the stibnite prospects near Smith Creek (WI114, WI115, or WI130). Based on a personal communication from E. Armstrong, about 35 drums of stibnite ore was hand-cobbed from the Pringle Bench Mine in the 1980s and possibly shipped to Texas (Kurtak and others, 2002).

Alteration:

No alteration is mentioned.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Deposit model:

Sb-Au vein (Nokleberg and others, 1987).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: Yes

Site Status: Active

Workings/exploration:

Before 1999, the Pringle Bench Mine apparently was only sampled by government and industry. In 1999, the U.S. Bureau of Land Management began work in the area that included soil sampling and an airborne geophysical survey (Kurtak and others, 2002). Their data encouraged Silverado Gold Mines, Ltd., who was placer mining along Nolan Creek, to more aggressively search for the lode source of the placer gold. They concentrated their work on Pringle Bench and Workman's Bench (WI115), about 1,500 feet to the southwest where auriferous stibnite was also known to occur. Silverado drilled 8 core holes on the Pringle Bench Mine that intersected several auriferous stibnite veins.

Production notes:

Five tons of stibnite ore were recovered from sluice operations somewhere on upper Smith Creek and shipped during World War II (Joesting, 1943). Joesting attributed at least some of this production to this property, then known as the Jones & Boyle prospect. However, his description of its source on upper Smith Creek contradicts the location of the Jones & Boyle prospect described by Ebbley & Wright (1948). More likely, the source of the stibnite was the unnamed prospect at the head of Smith Creek on Midnight Dome (WI130). The information is so vague however, that the ore may have come ore or more of the stibnite prospects near Smith Creek (WI114, WI115, or WI130). Based on a personal communication from E. Armstrong, about 35 drums of stibnite ore was hand-cobbed from the Pringle Bench Mine in the 1980s and possibly shipped to Texas (Kurtak and others, 2002).

Reserves:

Bundtzen (2009) estimated that Pringle Bench Mine has an 'inferred resource' of 6,308 tons with an average grade of 12.78 percent antimony and 0.088 ounce of gold per ton.

Site name(s): Workman's Bench; Wannemaker and Wortman

Site type: Prospect

ARDF no.: WI115

Latitude: 67.4689 **Quadrangle:** WI B-1

Longitude: 150.2241

Location description and accuracy:

This center of the Workman's Bench prospect is about 0.2 mile east of the junction of Smith Creek and Nolan Creek at the mine symbol on the Wiseman B-1 topographic map. The prospect is about 0.3 mile north of the center of section 33, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au, Sb

Other: As, Hg?, Pb?

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Ankerite?, calcite?, dolomite?, quartz

Geologic description:

Before 1999, the Workman's Bench prospect was described as a 3-to-4-inch-wide quartz-stibnite vein exposed in a trench on the south side of Smith Creek. The stibnite fills open spaces between quartz crystals with euhedral terminations deposited along the margins of the vein (Ebbley and Wright, 1948). Mulligan (1974) noted that the vein occupies a vertical fissure that cuts flat-lying, blue-gray phyllite. Selected samples from this prospect contain as much as 12.2 parts per million gold, are anomalous in arsenic (Eden, 2000) and contain up to 58.3 percent antimony (Mulligan, 1974; Eden, 2000). Eden describes auriferous quartz veins containing stibnite and arsenopyrite elsewhere in the general area. Calcite, ankerite and minor dolomite accompany the quartz at the margins of these veins, which strike N44E and dip nearly vertically. The gold is mostly near the margins of the veins and rarely in the stibnite (Eden, 2000).

In 1999, the U.S. Bureau of Land Management began work in the area that included soil sampling and an airborne geophysical survey (Kurtak and others, 2002). Their data encouraged Silverado Gold Mines, Ltd., who was placer mining along Nolan Creek, to more aggressively search for the lode source of the placer gold (Bundtzen, 2008, 2009). They concentrated on Workman's Bench and on Pringle Bench (WI114), about 1500 feet to the northeast where auriferous stibnite also known occurs. From 1994 to 2008 in these two areas, Silverado drilled 15 reverse-circulation holes that totaled 3,230 feet and 58 shallow core holes that totaled 16,152 feet, dug numerous trenches, and drove 570 feet of underground workings on the Workman's Bench prospect that intersected the four stibnite or quartz-stibnite veins in two places along a northeast-trending structure.

The host rocks are Devonian phyllite, schist, and metasiltstone (Dillon and Reifenstuhl, 1990). The gold-stibnite mineralization occurs as distinct veins, four are recognized, parallel to and along a structural zone 120 to 350 feet wide that strikes northeast and dips 50 to 85 degrees southeast (Bundtzen, 2008 and 2009). Both stibnite (only) and quartz-stibnite veins are present; minor arsenopyrite occurs in them. At the Workman's Bench prospect, there are veins of massive stibnite up 15 inches thick that contain up to 2.86 ounces of gold per ton. Four, parallel veins across a distance of about 100 feet and a strike length of about 1,100 feet were cut in the 41 drill holes and in the underground workings of Workman's Bench; there are also numerous gold-stibnite(-quartz) veinlets between the major veins. Coincident with the work on Workman's Bench, Silverado was also working on similar mineralization at the Pringle Bench (WI114). The mineralization between Workman's Bench and Pringle Bench could not be visually followed other than in

the drill core and cuttings but the attitudes and characteristics of the mineralization at the two sites demonstrate that the mineralization is continuous over a distance of at least 1,600 feet between the two prospects. Soil geochemistry and geophysical data suggests that the mineralization continues even further northeast.

Bundtzen, (2009) estimated that Workman's Bench has: 1) a 'probable reserve' of 42,412 tons with an average grade of 28 percent antimony and 0.408 ounce of gold per ton (at a cut-off grade of 4.0 percent antimony); and 2) an 'inferred resource' of 21,389 tons with an average grade of 12.11 percent antimony and 0.272 ounce of gold per ton (at a cut-off grade of 4.0 percent antimony.

Alteration:

Age of mineralization:

The only constraint is the Devonian age of the host rocks.

Generic deposit model:

Deposit model:

Sb-Au vein (Nokleberg and others, 1987).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Active

Workings/exploration:

Before 1999, the Workman's Bench prospect was apparently only sampled by government and industry. In 1999, the U.S. Bureau of Land Management began work in the area that included soil sampling and an airborne geophysical survey (Kurtak and others, 2002). Their data encouraged Silverado Gold Mines, Ltd., who was placer mining along Nolan Creek, to more aggressively search for the lode source of the placer gold (Bundtzen, 2008, 2009). They concentrated on Workman's Bench and on Pringle Bench (WI114), about 1500 feet to the northeast where auriferous stibnite also known occurs. From 1994 to 2008 in these two areas, Silverado drilled 15 reverse-circulation holes that totaled 3,230 feet and 58 shallow core holes that totaled 16,152 feet, dug numerous trenches, and drove 570 feet of underground workings on the Workman's Bench prospect that intersected the four stibnite or quartz-stibnite veins in two places along a northeast-trending structure.

Production notes:

Probably none but see the nearby Pringle Bench (WI114).

Reserves:

Bundtzen, (2009) estimated that Workman's Bench has: 1) a 'probable reserve' of 42,412 tons with an average grade of 28 percent antimony and 0.408 ounce of gold per ton (at a cut-off grade of 4.0 percent antimony); and 2) an 'inferred resource' of 21,389 tons with an average grade of 12.11 percent antimony and 0.272 ounce of gold per ton (at a cut-off grade of 4.0 percent antimony.

Site name(s): Smith Creek; Smith Gulch

Site type: Mine

ARDF no.: WI116

Latitude: 67.4712 **Quadrangle:** WI B-1

Longitude: 150.2126

Location description and accuracy:

Smith Creek is a west-flowing tributary to Nolan Creek; its mouth is near the old town of Nolan on Nolan Creek. The workings extend for approximately 1.5 miles along the creek above its mouth and the coordinates are at about the center of the workings. Smith Creek flows across the northern half of sections 33 and 34, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other: Sb

Ore minerals: Gold, stibnite

Gangue minerals:

Geologic description:

According to Maddren (1913), the placer deposits in the Nolan Creek basin occur in the shallow gravels of the modern channel, as bench deposits, and in deep, frozen gravels. Mining of the shallow gravels began in 1903, two years after their discovery. Maddren (1913) described the gold from upper Smith Creek as mostly rough, angular grains; the gold becomes progressively more rounded and coarser downstream. Some of the gold near the head of Smith Creek is coated by a white substance that Maddren did not identify although he suspected that it might be 'lime' (calcite?). Based on analysis of six gold samples, Eden (2000) concluded that the gold occurs in two different populations, defined by either high or low silver content. The gold in the six samples ranged from 925 to 986 fine. Eden also suggested that the gold in the Nolan-Hammond area has been derived from two gold-bearing vein systems in the area. The rocks in the valley of Smith Creek are micaceous schist, phyllite, and slate (Eden, 2000).

The gravel along the lower 2 miles of the modern channel of Smith Creek was selectively mined in richer spots during the early mining activity in the 1900s, but there is little information about this mining. Gravel in the modern channel that was mined in the 1920s and 1930s was 6 to 20 feet thick (Bundtzen, 2008, 2009). The gravel was frozen, coarse and subangular, and contained a few boulders. The gold was both coarse, rough and pitted, and smooth, rounded and waterworn. The value of the ground was about $0.30 per square foot of bedrock (gold at $20.67 per ounce).

The deep channel on Smith Creek rose from a depth of 135 feet near its mouth to merge upstream with the modern channel. By 1937, this deep channel was considered to be mined out by the methods available at that time. Reed (1938) reported that remnants of the bench channel on Smith Creek had been mined at several locations along the creek. The gravel was frozen and generally coarse and subangular. The gold from one of these locations was mostly coarse, unworn and pitted, but some was smooth, rounded and worn. This gold occurred throughout the gravel but most was in the lower few feet; there were no large nuggets. The gold was about 950 fine.

Most years between 1979 and 2007, Silverado Gold Mining Inc. mined along Nolan Creek (WI101) and its tributaries Fay Creek (WI112) and Archibald Creek (Bundtzen, 2008,2009). Apparently however, Silverado did not mine on Smith Creek. Bundtzen (2008, 2009) estimated an 'inferred resource' of 35,500 cubic yards of gravel about 1,500 feet above the mouth of Smith Creek, with an average grade of 0.030

ounce of gold per cubic yard (or about 1,065 ounces of gold).

Maddren (1913) reported that $208,000 (about 10,400 oz.) in gold was produced from Smith Creek from 1903 to 1909. Eden (2000) reported that a total of about 15,141 ounces of gold were produced from Smith Creek between 1904 and 1999. Kurtak and others (2002) document somewhat different production numbers year by year from 1903 to 1948. Their data indicate that the total production during that period was 17,811 ounces. The most productive period was from 1902 to 1907, when 8,689 ounces of gold was mined.

Cobb (1973) notes that 5 tons of placer and lode stibnite was recovered from somewhere on Smith Creek and shipped during World War II, perhaps from stibnite prospects on Workman's Bench (WI115) or Pringle Bench (WI 114) on the hillsides above lower Smith Creek.

Alteration:

Site name(s): Emma Creek

Site type: Mine

ARDF no.: WI118

Latitude: 67.3219 **Quadrangle:** WI B-1

Longitude: 150.2024

Location description and accuracy:

The mouth of Emma Creek is on the Middle Fork, Koyukuk River, about 4.5 miles north of Coldfoot. The coordinates are about 0.8 mile upstream from its mouth, the site of recent mining near the center of section 22, T. 29 N., R. 12 W.

Commodities:

Main: Au

Other: Cu, Pb, Sb

Ore minerals: Galena, gold, stibnite

Gangue minerals:

Geologic description:

Gold was discovered on Emma Creek in 1900 (Maddren, 1913; Kurtak and others, 2002). The gold occurs in the modern channel and in high bench channels. The productive portion of the modern channel is centered in a steep canyon cut through crystalline limestone. The canyon begins about a mile above the mouth of Emma Creek and extends upstream 1/2 mile or more. Most of the placer gold in Emma Creek was concentrated at the upper end of the canyon and in a gravel fan at its lower end. The richest ground was at the lower end of the canyon.

The high bench channels are on the south side of Emma Creek about a half mile from the mouth. These channels are about 30 feet above the modern creek bed. Recent work indicates that there are at least 4 separate channels on the right limit (Kurtak and others, 2002). The bench gravel is fine-grained and water worn and contains numerous granite and limestone boulders (Reed, 1938). The depth to bedrock varies from 5 to 91 feet. From the top, the section consists of a foot of moss, 0-50 feet of sand and clay, and 4-40 feet of gravel. All of the gravel, except the lower 4-5 feet is frozen. The gold is coarse and angular and commonly attached to quartz (Bliss and others, 1988). The gold on bedrock was in small nuggets valued at $0.25 to $1 (gold at $20.67 per ounce). Bliss and others (1988) suggest that the source of the gold may be quartz veins in the drainage area. Three samples of gold from Emma Creek have a median fineness of 905 and median trace elements contents of 0.047 percent copper, 50 parts per million (ppm) lead, 80 ppm antimony, and 0.31 percent mercury (Mosier and Lewis, 1986). Kurtak and others (2002) note that the gold is in 4 forms: 1) rounded and well-worn 'slugs'; 2) ragged masses with attached calcite and quartz; 3) in sheets; and 4) in rectangular crystalline shapes. The placer concentrates contained abundant galena and stibnite.

Early mining of the modern channel was by sluicing; the high channels were drift mined and open cut. Mining in the modern channel was complicated by numerous large boulders, 3 to 10 feet in diameter, above and below the canyon. From 1957 to at least 2001, Emma Creek was mined using a variety of equipment including heavy mechanized equipment and suction dredges (Kurtak and others, 2002). Some drift mining was done in the high channels of the canyon on both sides of the creek.

The gold production from Emma Creek is uncertain but is substantial. Based on incomplete records, Kurtak and others (2002) report that the production from 1900 to 1928 was 7,861 ounces of gold. Cobb (1976) indicates that the production could have been as much as 9,000 ounces. Production records are not available after 1928 but nuggets weighing up to 8 ounces have been recovered (Kurtak and others, 2002).

Site name(s): Emma Dome

Site type: Occurrence

ARDF no.: WI119

Latitude: 67.3213 **Quadrangle:** WI B-1

Longitude: 150.4104

Location description and accuracy:
This occurrence is at an elevation of about 3,900 feet, in the SE1/4 section 22, T. 29 N., R. 13 W., of the Fairbanks Meridian. It is 0.2 mile south of hill 4465. The location is accurate.

Commodities:

Main: Ag, Au, Cu

Other:

Ore minerals: Malachite, unspecified copper sulfides

Gangue minerals: Quartz

Geologic description:
This occurrence is a quartz vein in Devonian schist and marble (Brosge and Reiser, 1972). A sample contains 0.04 to 0.079 ppm gold and 6.0 to 19 ppm silver. Brosge and Reiser (1960) earlier reported copper sulfides and malachite along the contact between the schist and marble.

Alteration:
Oxidation of copper mineral(s).

Age of mineralization:

Generic deposit model:

Deposit model:

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:
Only surface sampling.

Production notes:
None.

Reserves:

None.

Additional comments:

This occurrence is in Gates of the Arctic National Park and Preserve.

Site name(s): Acme Creek

Site type: Mine

ARDF no.: WI120

Latitude: 67.4839 **Quadrangle:** WI B-1

Longitude: 150.2293

Location description and accuracy:

Acme Creek is a southeast-flowing tributary to lower Nolan Creek. Its mouth is about 0.5 upstream from the old town of Nolan. The site is near the mouth of the creek, about 0.5 mile north of the center of section 33, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Reed (1938) reported that a small amount of fine gold was mined a few hundred feet above the mouth of Acme Creek from a deep channel 70 to 110 feet deep. The deep channel was thought to be related to the deep channel on Nolan Creek (WI101). Reed (1938) noted that gold had not been found in the modern shallow channel of Acme Creek or in high channels along it. In 1989, a decline was started to access the deep channel near the mouth of Acme Creek but was abandoned short of bedrock. (See the record for Nolan Creek (WI101) for the significance and productivity of the deep channel along it.)

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Probably inactive

Workings/exploration:

Some mining on a deep channel just above the mouth of Acme Creek.

Production notes:

Probably some gold production.

Reserves:

None.

Site name(s): Thompson Pup; Thompson Gulch

Site type: Mine

ARDF no.: WI124

Latitude: 67.4892 **Quadrangle:** WI B-1

Longitude: 150.1879

Location description and accuracy:

Thompson Pup is a 0.8-mile-long tributary to Fay Creek. The junction of Fay Creek and and Thompson Pup is about 1 mile northwest of the summit of Smith Creek Dome. Placer gold has been mined along most of Thompson Pup. The coordinates are at the mine symbol on the 1:63,360-scale topographic map, which is a short distance above the mouth of Thompson Pup and about 0.5 mile north of the center of section 27, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Thompson Pup is a tributary of Fay Creek (WI112) and in recent years they may have been mined together. The first record of mining on Thompson Pup was in 1929, when a high channel was mined about 1,000 feet upstream from its mouth on Fay Creek (Reed, 1938). Work on Thompson Pup was noted by Holdsworth (1957) and Williams (1950) who describe a hydraulic and ground sluicing operation on Thompson Gulch. Silverado Gold Mining Inc. mined on Fay Creek in 1993 (Bundtzen, 2008, 2009).

Williams (1950) reported that there were several channels on Thompson Pup and that the fineness of the gold being recovered was unusually high; averaging about 940 fine with nuggets up to 982 fine. Mosier and Lewis (1986), however, indicate that the fineness is generally lower, in the range of 777 to 926. Eden (2000) reports that the gold placer deposits extend up Thompson Pup for approximately a half mile above Fay Creek, and that the gold from Thompson Pup is crystalline. The crystalline nature of the gold distinguishes it from other placer gold in the Nolan Creek area and suggests that it has not traveled far from its source. Kurtak and others (1999) analyzed arsenopyrite crystals from placer concentrates from Thompson Pup; they contained as much as 1,964 parts per billion gold, but they may have been contaminated.

Eden (2000) estimated that a total of 3,100 ounces of gold were produced from Thompson Pup between 1904 and 1999. Based on a personal communication in 2001, Kurtak and others (2002) reported that Thompson Pup had a 'measured reserve' of 1,000 ounces of gold in its upper portion.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Active?

Workings/exploration:

From 1929 into the 1960s, Thompson Pup was mined by hand methods, including ground sluicing, and by hydraulic methods. Mechanical mining was reported in 1993 (Bundtzen, 2008 and 2009).

Production notes:

Eden (2000) reports that a total of 3,100 ounces of gold were produced from Thompson Pup between 1904 and 1999.

Reserves:

Based on a personal communication in 2001, Kurtak and others (2002) reported that Thompson Pup had a 'measured reserve' of 1,000 ounces of gold in its upper portion.

Location description and accuracy:

Quartz Creek is a southeast-flowing tributary to Porcupine Creek. It's mouth is about 3 miles west of Coldfoot. A little gold was mined on Quartz Creek at some unknown location and the site is arbitrarily located just upstream from its mouth on Porcupine Creek (WI152) near the center of section 13, T. 28 N., R. 13 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Although Porcupine Creek (WI152) produced substantial gold from 1900 to 2000, Quartz Creek that flows into it has produced only a small amount (Kurtak and others, 2002). Reed (1938) indicated that Quartz Creek produced about 80 ounces of gold by hand mining sometime before 1938. No ground rich enough to mine was subsequently found (Saunders, 1954).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Active?

Workings/exploration:

Quartz creek was hand mined some time before 1938 but only about 80 ounces of gold was recovered

(Reed, 1938).

Production notes:

About 80 ounces of gold was produce by hand mining sometime before 1938 (Reed, 1938).

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Unnamed (near summit of Smith Creek Dome)

Site type: Occurrences

ARDF no.: WI127

Latitude: 67.4765 **Quadrangle:** WI B-1

Longitude: 150.1722

Location description and accuracy:

This site consists of several occurrences near the top of Smith Creek Dome. The coordinates are the top of the Dome which is about 0.6 mile south-southwest of the center of section 26, T. 31 N., R. 12 W. The location is accurate.

Commodities:

Main: Ag, As, Au, Pb, Sb

Other:

Ore minerals: Gold, stibnite

Gangue minerals: Quartz

Geologic description:

The rocks at the top of Smith Creek Dome are Upper Devonian quartzite interbedded with chloritic quartzite and quartz-mica schist . They are thrust faulted over Devonian schist and phyllite (Eden, 2000; Kurtak and others, 2002).

Several parties have described mineralization near the top of Smith Creek Dome. Ebbley and Wright (1948) described a 6-inch-thick quartz-stibnite vein at a caved prospect. Brosge and Reiser (1972) collected several samples in the same area, possibly at the same prospect. Two samples of a quartz-stibnite vein assayed up to 9.2 parts per million (ppm) gold, 5,000 ppm arsenic, and more than 1 percent antimony. Elen (2000) also collected several samples in this vicinity. One was of a quartz vein that cut quartz-mica schist and contained 46 parts per billion (ppb) gold. A sample of schist with pyrite cubes contained 2,234 ppb gold, 7.2 ppm silver and 3,500 ppm lead.

Kurtak and others (2002) located 2 trenches, half a mile north of Smith Creek Dome, perhaps the same prospect described by Ebbley and Wright. The larger is 6 feet long, 3 feet wide and 3.5 feet deep. A select sample of quartz-stibnite vein in this trench contained 436 ppb gold, 297 ppm arsenic, and 28.1 percent antimony. They also collected 8 samples of quartz veins and wallrock just south of the top of Smith Creek Dome. Seven of of the 8 samples contained 9 to 5,095 ppb gold. The quartz veinlets are about 1/8th to 1 inch wide, strike about N55W, and dip 83S. The veins are exposed for no more than 10 feet along strike. They average 3,665 ppb gold, 5.1 ppm silver, 2,931 ppm lead, 103 ppm arsenic, and 126 ppm antimony.

Alteration:

No mention of alteration.

Age of mineralization:

Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Quartz -stibnite vein and low-sulfide gold-quartz vein (Cox and Singer, 1986; models 27d and 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
27d, 36a

Production Status: None

Site Status: Inactive

Workings/exploration:
Four episodes of examination and sampling by government agencies from 1948 to about 2000.

Production notes:
None.

Reserves:
None.

Site name(s): Unnamed (along and at head of Thompson Pup)

Site type: Occurrences

ARDF no.: WI128

Latitude: 67.4956 **Quadrangle:** WI B-1

Longitude: 150.1669

Location description and accuracy:
These occurrences are along and at the head of Thompson Pup, a tributary of Fay Creek (WI112). They are in the southwest quarter of section 23, T. 31 N, R. 12W. The location is accurate. (See WI124 for placer gold in Thompson Pup.)

Commodities:

Main: Au

Other: Ag, As, Cu, Sb

Ore minerals: Arsenopyrite, chalcopyrite, gold, pyrite, stibnite

Gangue minerals: Limonite, quartz, siderite

Geologic description:
Quartz veins with gold have been identified at several locations along and at the head of Thompson Pup. Brosge and Reiser (1972) found a quartz vein at the head of Thompson Pup that averaged 3.4 parts per million (ppm) gold. Kurtak and others (2002) collected a series of 8 samples (presumably along Thompson Pup) from veins 0.5 inch to 2 feet thick that averaged 56 parts per billion (ppb) gold; the highest value was 182 ppb gold. The veins trend N70W and contain sparse pyrite, chalcopyrite, arsenopyrite, and stibnite. Sluice concentrates from placer mining include many arsenopyrite crystals up to 1 centimeter in size. A sample of these crystals contained 1,964 ppb gold. The rocks in the area are mostly Devonian micaceous schist, phyllite, and metasiltstone (Eden, 2000).

Alteration:
None mentioned.

Age of mineralization:
Devonian or younger based on the age of the host rock.

Generic deposit model:

Deposit model:
Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
36a

Production Status: None

Site Status: Undetermined

Workings/exploration:

Limited surface sampling by government agencies (Brosge and Reiser, 1972; Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Unnamed (on lower Wiseman Creek)

Site type: Occurrence

ARDF no.: WI129

Latitude: 67.4144 **Quadrangle:** WI B-1

Longitude: 150.1332

Location description and accuracy:

This occurrence is at the lower end of the Wiseman Creek canyon about 0.5 mile west-northwest of Wiseman. The location is accurate.

Commodities:

Main: Cu

Other:

Ore minerals: Chalcopyrite, chrysocolla

Gangue minerals: Gypsum, quartz

Geologic description:

Brosge and Reiser (1960) reported unspecified copper sulfides and malachite stains in Devonian(?) schist and marble. At the same location, Mulligan (1974) described narrow veins of quartz and dogtooth-spar gypsum in mica schist. Grab samples of quartz and gypsum float contained traces of chalcopyrite and chrysocolla (Mulligan, 1974). Dillon and Reifenstuhl (1990) mapped the rocks in the area as lower Paleozoic(?) or Proterozoic(?) marble and calcareous schist.

Reporter(s): J.M. Britton (Anchorage)

Last report date: 2010-05-14

Site name(s): Unnamed (in Smith Creek)

Site type: Prospect

ARDF no.: WI130

Latitude: 67.4688 **Quadrangle:** WI B-1

Longitude: 150.1991

Location description and accuracy:

This prospect is at an elevation of about 1,950 feet in Smith Creek, about 1 mile east of Nolan Creek. The location is accurate.

Commodities:

Main: Au, Sb

Other:

Ore minerals: Arsenopyrite, gold, stibnite

Gangue minerals: Ankerite, dolomite, quartz

Geologic description:

Eden (2000) describes quartz-stibnite-gold veins at three locations in the vicinity of Smith Creek. Two of the three locations described by Eden (2000, locations 266 & 359) appear to correspond to the Wanemaker & Wortman (WI115) and the Jones & Boyle (WI114) prospects described by Ebbley and Wright (1948). The location described in this record is about a mile further upstream and was not described by Ebbley & Wright (1948). Reports of production of antimony from placer operations on Smith Creek may have covered one or more of these three locations.

The veins here consist of coarse-grained, white quartz with stibnite and arsenopyrite. The gold is mostly in the margins of the quartz veins but rare in the stibnite. Calcite, ankerite and minor dolomite also occur along the margins of the veins. The veins do not exhibit alteration envelopes. Thin quartz-carbonate veins, which represent a later stage of the mineralizing event, cut the quartz-stibnite-gold veins. The mineralized veins are 0.5 to 1.5 centimeters thick, strike N 55 E, and dip steeply (Eden, 2000). Two samples of sulfide-bearing quartz veins contain 1,532 and 1,958 ppb gold, 5,772 ppm and 3,933 ppm arsenic and more than 2,000 ppm antimony (Eden, 2000, samples 11165 and 11166). The veins are near a fault contact between Devonian chloritic schist and a unit of Devonian gray-black phyllite, black slate, and black metasiltstone.

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Sb-Au vein deposit (Nokleberg and others, 1987); or simple stibnite vein (Cox and Singer, 1986; model 27d)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

27d

Production Status: Yes

Site Status: Inactive

Workings/exploration:

The veins were exposed by during placer mining. Apparently there is no other work on the veins beyond sampling.

Production notes:

Five tons of stibnite was recovered from sluice operations in the vicinity of the veins and shipped during World War II (Joesting, 1943).

Reserves:

None.

Site name(s): Unnamed (near southwest end of Midnight Dome)

Site type: Occurrence

ARDF no.: WI132

Latitude: 67.4597 **Quadrangle:** WI B-1

Longitude: 150.1562

Location description and accuracy:

This occurrence is at an elevation of 3,700 feet, 0.2 mile west of hill 3860 on the south end of Midnight Dome. The location is accurate.

Commodities:

Main: Au

Other: Cu

Ore minerals: Gold?, malachite, pyrite

Gangue minerals: Quartz

Geologic description:

This occurrence consists of sulfide-bearing quartz veins in schist or quartzite (Eden, 2000). A sample of vein quartz found in float contains pyrite, malachite, and limonite, 179 ppb gold and 1,469 ppm copper. A sample of quartz vein collected in place contains pyrite and limonite, and 532 ppb gold. Eden (2000) interprets this occurrence as an extension of the system of auriferous quartz veins in the Nolan area. The rocks in the area are Upper Devonian chloritic schist and chloritic quartzite (Eden, 2000).

Alteration:

Iron-oxide alteration.

Age of mineralization:

Generic deposit model:

Deposit model:

Low-sulfide Au-quartz vein (Cox and Singer, 1986; model 36a)

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

36a

Production Status: None

Site Status: Inactive

Workings/exploration:

Only limited surface sampling and geologic mapping.

Production notes:

None.

Reserves:

None.

Last report date: 2010-05-14

Site name(s): Roosevelt Creek; RO; Skroo

Site type: Prospect

ARDF no.: WI134

Latitude: 67.1386 **Quadrangle:** WI A-6

Longitude: 152.9018

Location description and accuracy:

This prospect is near Roosevelt Creek about two miles north of the Malamute Fork, Alatna River. A large claim group which extends about 10 miles east-west and 1 to 1.5 miles north-south, is shown by Dillon and others (1981, Plate 1); the claims are presumed to cover this this prospect. For this record, the site is about 0.5 mile east-northeast of the center of section 30, T. 27 N., R. 25 W. The location is accurate within 1 mile.

Commodities:

Main: Cu, Pb, Zn

Other: Ag?, Au?

Ore minerals: Chalcopyrite, galena, pyrite, sphalerite

Gangue minerals:

Geologic description:

Sparse published information about the Roosevelt Creek prospect principally cites oral communications and reports of unpublished industry data. The most recent of the published reports (Nokleberg and others, 1996) describes the Roosevelt Creek prospect as massive and disseminated(?) sulfides in metavolcanics, pelitic schists and marbles of the Devonian and Mississippian, Ambler sequence. The sulfides are described as probably chalcopyrite, sphalerite, and galena. Dillon and others (1986) map the general area of the prospect as Devonian, metavolcanic rocks and Proterozoic(?) or lower Paleozoic schists of various types, along with local marble. Grybeck (1977) indicates that the geology and geochemistry of the area is similar to that to the west in the Ambler district.

Kurtak and others (2002) examined the area during their study of the Koyukuk mining district. They report that the canyon on Roosevelt Creek exposes Devonian(?) muscovite schist, graphitic schist and metarhyolite in a sequence that trends generally east-west and dips 55o south. Drilling by Anaconda Alaska intersected narrow, discontinuous zones of massive to semi-massive pyrite, sphalerite, galena, and chalcopyrite in schist and metarhyolite.

Several rock samples collected along Roosevelt Creek in the vicinity of the presumed location of the prospect are described in Dillon and others (1981) as felsic schists or felsites, most of which contain 1-2 percent disseminated pyrite. One sample may contain as much as 3 percent disseminated chalcopyrite and another may contain galena. Chemical analysis of these samples showed that only one contained any base metals: it was weakly anomalous in Pb.

Following up a geochemical soil anomaly, industry staked claims over the prospect in 1975 (Kurtak and others, 2002.) The prospect was explored by geophysics in 1976 and 1977. Grybeck (1977, loc. 1) reported that 77 lode claims were staked in 1975, and Dillon and others (1981) show a large claim block over the property that extended at least 10 miles east and 1 to 1.5 miles north. One of two core holes drilled in 1978 by Anaconda Alaska intersected massive-sulfide mineralization. Four more holes drilled in 1979 also intersected mineralization.

Alteration:

Not specifically mentioned.

Age of mineralization:

Correlative with the massive-sulfide deposits in the Devonian and Mississippian Ambler Sequence.

Generic deposit model:

Deposit model:

Kuroko massive sulfide (Cox and Singer, 1986; model 28a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a

Production Status: None

Site Status: Inactive

Workings/exploration:

Based on a geochemical soil anomaly, Anaconda Alaska first staked over the prospect in 1975 (Grybeck, 1977, Kurtak and others, 2002) The prospect was explored by geophysics in 1976 and 1977. Dillon and others (1981) show a large claim block over the property that extended at least 10 miles east-west and 1 to 1.5 miles north-south. One of two core holes drilled in 1978 by Anaconda Alaska intersected massive-sulfide mineralization. Four more holes drilled in 1979 also intersected mineralization.

Production notes:

None.

Reserves:

None.

Additional comments:

Core samples from three drill holes from the Roosevelt Creek and/or RO prospects are stored at the Alaska Geologic Materials Center in Eagle River, Alaska.

Site name(s): Red

Site type: Occurrence

ARDF no.: WI136

Latitude: 67.1964 **Quadrangle:** WI A-6

Longitude: 152.7628

Location description and accuracy:

The Red occurrence is west of lower Mettenpherg Creek, about 5 to 6 miles north of the junction of Mettenpherg Creek and the Malamute Fork, Alatna River. Two small claim groups, approximately 1 to 1.5 miles apart in a north-south direction are shown by Dillon and others (1981, Plate 1 [AOF 133B]); the most northerly of these claim groups is inferred (from very scant data) to correspond to the Red property. The occurrence is near the center of the claim block at an elevation of about 2,150 feet, in the NE1/4 section 2, T. 27 N., R. 24 W.

Commodities:

Main: Cu, Zn

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Almost no information is available on this property. It reportedly is a stratiform Cu-Zn occurrence in an area whose geology and geochemistry is similar to that in the Ambler District to the west (Grybeck, 1977, loc. 2). The area is underlain by Middle(?) Devonian, calcareous schist interbedded with quartz mica schist and marble (Brosge and Reiser, 1971). The Bureau of Land Management made an aerial reconnaissance of the area in the 1990s, but saw nothing to suggest the presence of mineralization (Kurtak and others, 2002). Bureau of Land Management data indicate that 8 claims were located in 1975 and abandoned by 1980 (Kurtak and others, 2002).

Alteration:

Age of mineralization:

If any, Middle Devonian or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Kuroko massive sulfide? (Cox and Singer, 1986; model 28a?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a?

Production Status: None

Site Status: Inactive

Workings/exploration:

Twenty-one lode claims were staked in 1975 (Grybeck, 1977). Bureau of Land Management data indicate that 8 claims were located in 1975 and abandoned in 1978 (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site name(s): Unnamed (near Jones Creek)

Site type: Prospect

ARDF no.: WI137

Latitude: 67.1496 **Quadrangle:** WI A-6

Longitude: 152.5951

Location description and accuracy:

The exact location of this prospect is uncertain. It is probably at an elevation of about 1,100 feet on a north tributary to Jones Creek in the SW1/4 section 22, T. 27 N., R. 23 W., of the Fairbanks Meridian.

Commodities:

Main: Cu, Zn

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Almost no information is available on this property except that reportedly it is a stratiform Cu-Zn occurrence in an area whose geology and geochemistry is similar to that in the Ambler District to the west (Grybeck, 1977). Regional geologic mapping indicates that the rocks in the vicinity of this occurrence are Devonian, Ambler metavolcanic rocks (Dillon and others, 1986). Thirty-six lode claims were staked in 1975 (Grybeck, 1977) and 3 holes were drilled on the prospect in the 1970s by Anaconda Minerals (Kurtak and others, 2002).

Alteration:

Age of mineralization:

Generic deposit model:

Deposit model:

Kuroko massive sulfide? (Cox and Singer, 1986; model 28a?).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

28a?

Production Status: None

Site Status: Inactive

Workings/exploration:

Thirty-six lode claims were staked in 1975 (Grybeck, 1977) and 3 holes were drilled on the prospect in the

1970s by Anaconda Minerals (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Additional comments:

Core samples from three drill holes from the Jones Creek prospect are stored at the Alaska Geologic Materials Center in Eagle River, Alaska.

Site name(s): Suckik Creek; Sickik Creek

Site type: Mine

ARDF no.: WI145

Latitude: 67.2266 **Quadrangle:** WI A-4

Longitude: 151.6962

Location description and accuracy:

Suckik Creek is south-flowing tributary to Timber Creek. The creek is named Sickik Creek on the modern (1970) A-4, 1-63,360-scale topographic map and Suckik Creek on the 1:250,000-scale map. The mouth of Suckik Creek is directly across Timber Creek from Button Mountain. There is little information on the exact location of placer mining on the creek. For this record, the site is placed about 3.5 miles upstream from the mouth of the creek where there was some suction dredging before 2000. The mine is in the northeast quarter of section 27, T. 28 N., R. 19 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Stewart (1949) described a 2-man, placer mining operation in 1948 that included shoveling-in and prospecting. Kurtak and others (2002) examined the creek but found no evidence of mining other than signs of suction dredging about 3.5 miles above the mouth of the creek and the remains of an old cabin and an airstrip near its mouth. Claims were active in 1948 and from 1979 to 1986. Suckik Creek is underlain mainly by Proterozoic or lower Paleozoic(?) schist and local marble, and by smaller areas of Devonian, metavolcanic rocks (Dillon and others, 1986).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Probably inactive

Workings/exploration:

There are reports of mining and prospecting in 1948 (Stewart, 1949) and suction dredging before 2002 (Kurtak and others, 2002).

Production notes:

Probably a small amount of undocumented gold production.

Reserves:

None.

Site name(s): Smalley Creek

Site type: Mine

ARDF no.: WI146

Latitude: 67.0306 **Quadrangle:** WI A-2

Longitude: 150.5125

Location description and accuracy:

The Smalley Creek that has been mined and is described by Reed (1938) is not named on the USGS 1:360,360-scale topographic map. It is about a mile northeast of the Smally Creek named on the map. Both are tributaries to the John River. The midpoint of the creek that has been mined is near the southwest corner of section 31, T. 26 N., R. 13 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Smalley Creek was first prospected in the 1900s (Reed, 1938). The placer gold occurs in the modern stream bed, in alluvium about 17 feet thick. The upper 4 to 7 feet consists of muck, and the remainder is coarse and waterworn gravel with numerous boulders. The gold is principally on bedrock, but also in the lower 6 feet of the gravel. The gold is in very fine, flat flakes; there are infrequent coarse pieces. Reed (1938) noted that the average fineness of the gold was 907. The fineness of five samples of gold collected in about 1985 varies from 853 to 933 (Mosier and Lewis, 1986). The bedrock is black shale and quartz conglomerate; Reed (1938) suspects that the conglomerate was the source of the fine gold in the placer. Reed (1938) reports mining by ground sluicing and shoveling in in 1937. Kurtak and others (2002) visited the site and found several trailers, cabins, and tailings, along about a quarter mile of the creek. They reported suction dredging from 1998 to 2001. Kurtak and others (2002) reported that 75 ounces of gold were produced from 1936 to 1941 and that there were active claims on the creek in several periods from 1956 to 2001.

Alteration:

Age of mineralization:

Quaternary.

Site name(s): Twelvemile Creek; Upper Fork; Lower Fork; Potato Creek

Site type: Mine

ARDF no.: WI147

Latitude: 67.1896 **Quadrangle:** WI A-1

Longitude: 150.4453

Location description and accuracy:

Twelvemile Creek is a large western tributary to the Middle Fork, Koyukuk River. The junction of Twelvemile Creek and the Middle Fork is about 6.5 miles southwest of Coldfoot. Probably the most extensive mining was from about 2.2 to 3.0 miles above the mouth of the creek. The coordinates are at about the middle of the mined area, about 0.6 mile southeast of the center of section 5, T. 27 N., R. 13 W. There has also been prospecting and some mining on the Lower and Upper Forks of Twelvemile Creek and probably on some of its ther tributaries.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Mining began on Twelvemile Creek in 1900 and continued along it and its tributaries during 8 of the years before 1942 (Schrader, 1900; Reed, 1938; Kurtak and others, 2002). From about 1900 to 1910, the modern creek bed was mined by hand methods. Later mining included shafts, open cuts, and drifting (Reed, 1938) There was exploration drilling in 1934 and hydraulic mining in 1937 (Reed, 1938). There was activity from 1953 to 1997 but the chronology and amount of mining during that period is unclear. It probably was done with mechanical earth moving equipment. Kurtak and others (2002) visited and sampled Twelvemile Creek. They found considerable evidence of past mining including remains of sluice boxes and wash plants, trailers, and other equipment along the creek from about 2.2 to 3.0miles above its mouth. The equipment probably postdates WWII, but they found no sign of recent mining.

Reed (1938) reported that the gold on Twelvemile Creek was in three environments: 1) along the modern channel, 2) in a deep channel, and 3) in channels on benches. Mining has mainly been in the modern channel and on the benches. The gold apparently is sporadically distributed. The depth to bedrock in the upstream modern channel is about 5 feet. The gold-bearing gravel on the downstream parts of the modern channel is relatively fine grained with few boulders. The gravel on the upper part of the creek contains more boulders.

There are two high-bench channels: an upper one, called 'primary', and a lower one, called 'secondary'. The secondary bench is about 60 feet wide and 20 feet above the modern stream; it occurs only along the left limit of the Upper Fork (Reed, 1938). The primary bench is about 125 feet above the secondary bench. The primary bench It is 600 feet wide, and lies along the left limit of lower Upper Fork and along Twelvemile Creek downstream as far as the Lower Fork. Below Lower Fork, high channels occur along the right limit of Twelvemile Creek at about the same level as the primary bench. An adit into the primary channel on the lower Upper Fork explored gravels containing gold values of $0.75 per cubic yard (gold at $35 per ounce). There apparently is a deep channel along Twelvemile Creek but it isn't clear whether it contains any gold.

Reed (1938) reported only one active mining operation in 1937, along lower Upper Fork (Reed's 'Middle

Fork'). The depth to bedrock there was 8 to 21 feet, and very fine, flat pieces of gold were distributed throughout the gravel. The values were about $0.35 per square foot of bedrock and the average fineness was 914. According to Reed (1938), several other tributaries of Twelvemile Creek that are not named on the modern USGS 1:63,360-scale topographic maps were explored and/or mined with varying degrees of success.

Kurtak and others (2002) report that 281 ounces of gold were produced from Twelvemile Creek and its tributaries from 1900 to 1942, most of it from 1900 to 1925. Production records after 1942 are not available but Orris and Bliss (1985) indicate that Twelvemile Creek probably produced from 1,002 to 7,500 ounces ounces of gold, but possibly as much as 1,500 ounces.

The bedrock in the Twelvemile Creek area is mainly graphitic and quartz schist (Reed, 1938) . Dillon and others (1986) mapped the rocks as Mississippian to Triassic metagraywacke and phyllite, and Upper Devonian, Hunt Fork schist.

Site name(s): Rosie Creek; Rose Creek; Lake Creek

Site type: Prospects

ARDF no.: WI151

Latitude: 67.1945

Quadrangle: WI A-1

Longitude: 150.1923

Location description and accuracy:

Rosie Creek is 4 miles south of Coldfoot. The site is at the junction of Rosie Creek and a small creek informally named Lake Creek that extends to a small lake about a mile north. The site is about 0.3 mile east of the center of section 3, T. 27 N., R. 12 W. Six shafts were sunk near this junction.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

In about 1900, fine gold was discovered about 2 miles above the mouth of Rosie Creek (Maddren, 1913). Six shafts were sunk in the early 1900s on Rosie Creek and its tributary Lake Creek (Reed, 1938; Kurtak and others, 2002). The depth to bedrock varied from just over 100 feet to as much as 275 feet in one shaft near the head of Lake Creek. A 113-foot shaft near the junction of Rose Creek and Lake Creek worked a thin layer of gravel on bedrock that produced numerous fine flakes of gold. Reed (1938) described several additional shafts at locations from near the head of Lake Creek to about 0.2 mile below the junction of Rosie and Lake Creeks. Only the shafts on Lake Creek found gold as fine flakes throughout the gravel from a depth of 20 feet to the top of the bedrock. Reed (1938) reported that the bedrock on Rosie Creek is greenstone and the bedrock on Lake Creek is schist. According to Dillon and others (1986), Rosie Creek is underlain by metagraywacke and phyllite, and upper Lake Creek is underlain by schist of the Devonian Hunt Fork Formation. Kurtak and others (2002) visited the site but found little indication of prospecting or mining.

Location description and accuracy:

Porcupine Creek is a south-flowing tributary to the Middle Fork, Koyukuk River; its mouth is about 3 miles southwest of Coldfoot. It has been mined for about a mile below the mouth of Quartz creek. This site is at about the midpoint of the mining, near the northeast corner of section 24, T. 28. N., R. 13 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Except for a break in the 1940s and 1950s, Porcupine Creek produced gold consistently from 1900 to 2000 over a length of about a mile below the mouth of Quartz Creek (Kurtak and others, 2002). About 600 feet downstream from the mouth of Quartz Creek, the gravel was about 6 feet deep ; the depth increased gradually to more than 80 feet at the downstream end of mining where the creek flows out on the valley of the Middle Fork, Koyukuk River. No high channels on benches were found A test above the mouth of Quartz Creek with a backhoe was unproductive.

Placer gold mining on Porcupine Creek began in 1901 when four men were producing $8 per man per day (Maddren, 1913). Through the 1930s, mining in the modern stream channel in the upper part of the creek was done by shoveling in and hydraulic methods. In the early years, a section at least 450 feet long in gravel about 30 feet deep was drift mined in the upper part of the creek along a deep channel. Since the 1960s mining has mainly been in the deep channel in the lower potions of Porcupine Creek using dozers, backhoes, and trucks to carry the auriferous gravel to a sluice-box washing plant.

Except for parts of the deep channel, the auriferous gravel is frozen and consists of small worn pieces of schist mixed with coarse sand and many large boulders. The gold is in the lower 3 to 6 feet of the gravel; only a little is on bedrock. The gold is generally fairly fine with an occasional nugget, and is about 854 fine. At the end of the season in 2000, the operator considered that further mining would not be economical in the deep gravel at the mouth of Porcupine Creek (Kurtak and others, 2002).

The most authoritative production figures are those given year by year in Kurtak and others (2002). They indicate that Porcupine Creek produced a total of 7,774 ounces of gold, of which 6,574 ounces was produced from 1909 to 1911. No production records are available from 1964 to 2000, but a substantial amount of gold was probably recovered.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes; small

Site Status: Active

Workings/exploration:

Except for a break in the 1940s and 1950s, Porcupine Creek produced gold consistently from 1900 to 2000 over a length of about a mile below the mouth of Quartz Creek (Kurtak and others, 2002). Placer gold mining on Porcupine Creek began in 1901 when four men were producing $8 per man per day (Maddren, 1913). Through the 1930s, mining in the modern stream channel in the upper part of the creek was done by shoveling in and hydraulic methods. In the early years, a section at least 450 feet long in gravel about 30 feet deep was drift mined in the upper part of the creek along a deep channel. Site name(s): Grubstake Bar

Site type: Mine

ARDF no.: WI153

Latitude: 67.0097 **Quadrangle:** WI A-1

Longitude: 150.4303

Location description and accuracy:

Grubstake Bar as described by Reed (1938) is on the right limit of the South Fork, Koyukuk River about 2 miles above Hanshaw Bar (WI155) Maddren (1913) placed it on the northwest bank of South Fork about 9 miles above Gold Bench. For this record, the site on a sand bar on the South Fork, opposite the mouth of Bear Creek, in the northwest corner of section 9, T. 25 N., R. 13 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Maddren (1913) described Grubstake Bar as a low-bench deposit. Reed (1938) described it as a deposit in the present river channel, similar to Hanshaw Bar (WI155). From incomplete records, Kurtak and others (2002) noted that Grubstake Bar produced 194 ounces of gold from 1900 to 1910. The site was examined by Kurtak and others (2002). They found a camp trailer at the mouth of the creek that enters the South Fork from the northeast (locally called Frisbee Creek, WI158). Tailings from recent mechanized mining covered an area about 300 feet by 1,300 feet in area. The tailings piles were up to 20 feet high. About $4,000 in gold (about 200 ounces) was produced from 1900 to 1909 (Maddren, 1913; Kurtak and others, 2002). Claims were active from the mid-90s to 2000 but production records for that period are not available.

Alteration:

Site name(s): Chapman Creek

Site type: Occurrence

ARDF no.: WI154

Latitude: 67.0953 **Quadrangle:** WI A-1

Longitude: 150.4738

Location description and accuracy:

Chapman Creek is a west-flowing tributary to the Middle Fork, Koyukuk River. The creek enters the Middle Fork at Chapman Island about 1/2 mile upstream from Tramway Bar (WI156). The coordinates are for a location about a mile upstream from the mouth of Chapman Creek, about midway along the workings, and about 0.5 mile west-northwest of the center of section 8, T. 26 N., R. 13 W. The location is accurate.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Gold was found in shafts sunk in 1908-09 along a stretch of Chapman Creek, 1/4 to 1 mile above its mouth (Maddren, 1913). The workings included thirteen or fourteen shafts, 9 to 14 feet deep. A layer of blue gravel composed mainly of schist that is below barren sand and reddish gravel produced gold values of 2-3 cents per pan (gold at $20.67 per ounce). Maddren (1913) reported that gold values of 5 to 10 cents per pan occurred in bench deposits about 2 miles above the mouth of the creek. The gold in the bench deposits was in a 1- to 3-foot-thick layer of blue gravel composed mainly of schist.

There was considerable activity in 1991 when a company built a road to the mine from the Dalton highway, drilled holes 40-55 feet deep, and dug test pits. Kurtak and others (2002) visited the property and noted that it had been heavily mined, evidenced by abundant tailings. Dump trucks, shovels, washing plants, and camp trailers still remained at the site. They did not report production figures but it may have been substantial.

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Gold in fine, flat flakes is distributed throughout 2 to 3 feet of medium to fairly fine gravel and sand on a high-water bar in the channel of the South Fork, Koyukuk River. The paying gravel and sand lie on a false bedrock of clayey sand. Reed (1938) noted that the average value of the ground was $0.23 per square foot of bedrock (gold at $35 per ounce) and that the gold was 907 fine. Mining in 1937 was by shoveling into sluice boxes and washing with water from the South Fork (Reed, 1938). Kurtak and others (2002) visited the site but found no evidence of recent mining. However, Bliss and others (1988) reported that there may have been some recent activity at this site and/or upriver at Grubstake Bar (WI153).

Alteration:

Site name(s): Mailbox Creek

Site type: Mine

ARDF no.: WI157

Latitude: 67.1053 **Quadrangle:** WI A-1

Longitude: 150.4832

Location description and accuracy:

Mailbox Creek is a south-flowing tributary to the Middle Fork, Koyukuk River; its mouth is about 1 mile upstream from Tramway Bar and 4 miles south-southwest of Twelvemile Mountain. Placer mining has been reported 2000 feet upstream from the mouth of Mailbox Creek, about 0.5 mile east-southeast of the center of section 6, T. 26 N., R. 13 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Gold was mined from fairly fine gravel that contains numerous erratic boulders about a half mile upstream from the mouth of Mailbox Creek (Reed, 1938). The fine gravel is derived mainly from conglomerate bedrock in the area. Fine, flaky gold occurs throughout the gravel; coarser gold is in a layer of reddish gravel near bedrock. The value of the ground that was being mined in the mid-1930s was about $0.75 in gold per square foot of bedrock. The gold is 898 fine. Kurtak and others (2002) examined the creek and found a cut opened with a dozer 'in recent years' and a boom dam, about 2,000 from the mouth of the creek.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Inactive

Workings/exploration:

The placer was mined in the 1930s by ground sluicing and shoveling in from an open cut. A cut was opened with a dozer, probably some time in the 1980s or 1990s.

Production notes:

Mining occurred from at least 1934 to 1937; there is no record of the production. Possibly some mining in the 1980s or 1990s.

Reserves:

None.

Site name(s): Unnamed (near head St. Patricks Creek)

Site type: Prospect

ARDF no.: WI161

Latitude: 67.9114 **Quadrangle:** WI D-1

Longitude: 150.4613

Location description and accuracy:

This prospect is on a ridge at an elevation of about 5,200 feet, about 0.6 mile east of the small lake at the head of St. Patricks Creek. It is about 0.3 mile south-southeast of the center of section 27, T. 36 N., R. 13 W. The location is accurate.

Commodities:

Main: Cu, Pb, Zn

Other:

Ore minerals: Chalcopyrite, galena

Gangue minerals: Calcite, quartz

Geologic description:

This prospect on the Lucky Boy claims was staked in 1963, again sometime in the 1970s, and was examined by the Bureau of Land Management in about 2000. The rocks in the area are Cambrian to Ordovician?), andesitic to basaltic volcaniclastic rocks, locally accompanied by tuffaceous phyllite, gabbro, diabase, and black phyllite (Dillon and others, 1986). There is little mineralization. On the ridgetop, numerous quartz-carbonate segregations with galena and chalcopyrite occur in the noses of folds in phyllite. On the east side of the ridge, iron-oxide-stained mudstone is coated with malachite and azurite. The highest values in the several samples collected by Kurtak and others (2002) was 62 parts per million (ppm) lead, 824 ppm copper, and 130 ppm zinc. WGM (1978) reported that samples contained gold and platinum-group elements, but none of the samples collected by Kurtak and other (2002) contained gold and they were not analyzed for the platinum-group elements.

Alteration:

None noted.

Age of mineralization:

Cambrian to Ordovician(?) or younger based on the age of the host rocks.

Generic deposit model:

Deposit model:

Galena-chalcopyrite-quartz segregations.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Inactive

Workings/exploration:

None other than the several claims that were staked by industry and limited sampling by the Bureau of Land Management in about 2000.

Production notes:

None.

Reserves:

None.

Additional comments:

Now in the Gates of the Arctic National Park which is closed to prospecting and mining.

Last report date: 2011-02-01

Site name(s): Seward Creek

Site type: Prospects

ARDF no.: WI162

Latitude: 67.5129 **Quadrangle:** WI C-4

Longitude: 151.6895

Location description and accuracy:

This site is located about a mile up Seward Creek west of Wild Lake where some shafts were sunk prior to 1938. The prospects are near the northwest corner of section 20, T. 31 N., R. 18 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Reed (1938) reported extensive prospecting along Seward Creek including some shafts about 3 miles above its mouth. Kurtak and others (2002) reported that nineteen claims were staked in 1977 but they found no indication of mining.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer gold (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Probably inactive

Workings/exploration:

Some prospecting prior to 1938 and several shafts were sunk about 3 miles above the mouth of the creek. No indications of more recent mining.

Production notes:

Probably none.

Reserves:

None.

Site name(s): McCamant Creek

Site type: Prospect

ARDF no.: WI163

Latitude: 67.3887 **Quadrangle:** WI B-4

Longitude: 151.8853

Location description and accuracy:

This site is somewhat arbitrarily located about 4 miles from the mouth of McCamant Creek in about the center of the area where Kurtak and others (2002) found evidence of mining. Various signs of prospecting or mining are spread along about 5 miles of the upper part of the creek. The site is about 0.5 mile north-northeast of the center of section 32, T. 30 N., R. 19 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

There apparently is no record of prospecting or mining on McCamant Creek prior to the report by Kurtak and others (2002) who noted that claims had been staked in 1957. They found test pits, campsites, the remains of a cabin, suction dredging equipment, and the dump of a shaft along the creek from about one mile above its mouth to about 5 miles above its mouth. They found no evidence of large-scale mechanical mining. The few samples they panned contained no visible gold.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer gold (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Undetermined

Site Status: Probably inactive

Workings/exploration:

Indications of prospecting and possible suction-dredge mining sometime between 1957 and about 2000. No indication of mechanical mining.

Production notes:

Minor at most.

Reserves:

None.

Last report date: 2011-02-01

Site name(s): Unnamed (near Bluecloud Mountain)

Site type: Prospect

ARDF no.: WI165

Latitude: 67.4004 **Quadrangle:** WI B-1

Longitude: 150.4324

Location description and accuracy:

Kurtak and others (2002) reported that WGM Inc. found disseminated galena on the north side of Bluecloud Mountain and subsequently drilled a strong geophysical anomaly on the south side of the mountain. apparently near the coordinates given above. The details of the location are vague. The site is probably in the northwest quarter of section 27 or the southwest quarter of section 22, T. 30 N., R. 13 W.

Commodities:

Main: Pb

Other:

Ore minerals: Galena, pyrite, pyrrhotite

Gangue minerals:

Geologic description:

Bluecloud mountain is cut by the Wiseman fault which thrusts Proterozoic(?) or Paleozoic(?) quartzite and graphitic schist over Devonian schist, phyllite, sandstone, and conglomerate (Dillon and Reifenstuhl, 1990). The Devonian phyllite probably correlates with the Devonian Hunt Fork Shale to the north.

In following up geochemical anomalies identified in 1975, WGM Inc. found disseminated galena along faults on the north side of Bluecloud Mountain. (Kurtak and others, 2002). Subsequent geophysical surveys identified a strong EM anomaly on the south slope of Bluecloud Mountain. One 150-foot hole was drilled in 1978. A small amount of field work and sampling by ASA Inc. followed in 1992; they concluded that the earlier WGM geochemical anomalies only reflected background. There apparently has been no work by industry since. Kurtak and others (2002) found little signs of mineralization other than disseminated pyrite and pyrite in schist. None of their samples contained notable metals.

Alteration:

None noted.

Age of mineralization:

No definitive information; could be as old as Proterozoic.

Generic deposit model:

Deposit model:

No definitive information.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Probably inactive

Workings/exploration:

From 1971 to 1983, WGM inc. conducted geochemical and geophysical surveys, mapped, sampled, and drilled one 150-foot hole (WGM 1976; WGM 1978; WGM, 1979; Nicol, 1983). ASA Inc. reviewed the information in 1992 and collected some samples. The Bureau of Land Management briefly examined the property and collected a few samples in about 2000 (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site type: Mine?

ARDF no.: WI166

Latitude: 67.4749 **Quadrangle:** WI B-1

Longitude: 150.2979

Location description and accuracy:

There is almost no information on a placer on Snowshoe Creek and the site is arbitrarily located at about the middle of the creek, about 1.7 mile west of Nolan. The site is near the northeast corner of section 31, T. 31 N., R. 12 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

The only reference to prospecting or mining along Snoeshoe Creek is Kurtak and others (2002). During a regional mineral assessment, they examined the creek for mineralization and collected several samples. They found test pits along the creek and a small boom dam but no other sign of mining. The gold content of the samples they collected was barely anomalous.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Undetermined

Workings/exploration:

There is no sign of mining on Snowshoe Creek other than some test pits and a small boom dam (Kurtak and others, 2002).

Production notes:

None.

Reserves:

None.

Site name(s): Webster Gulch

Site type: Mine

ARDF no.: WI167

Latitude: 67.4994 **Quadrangle:** WI B-1

Longitude: 150.1917

Location description and accuracy:

Webster Gulch is an informal name for a small creek that flows west into Nolan Creek about 0.7 mile north of Fay Creek. It is in the northeast quarter of section 22, T. 31 N., R. 12 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:

Reed (1938) noted that some gold had been found on Webster Creek. Bureau of Mines records indicate that there was some mining in or prior to 1942, but furnish no details. The area was examined by Kurtak and others (2002) who found the remains of an old shaft near the mouth of the gulch and some placer cuts further up the gulch.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Placer deposits (Garnett and Bassett, 2005)

Deposit model:

Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: Yes

Site Status: Undetermined

Workings/exploration:

There is some evidence of mining, probably before 1942.

Production notes:

The few workings and the absence of reports of mining on Webster Gulch suggest that if any gold was produced, it was probably only a small amount.

Reserves:

None.

Site name(s): Unnamed (benches upper Hammond River)

Site type: Prospect

ARDF no.: WI168

Latitude: 67.5255 **Quadrangle:** WI C-1

Longitude: 150.111

Location description and accuracy:

This site includes extensive,benches underlain by thick gravel, perched on the valley walls on both sides of the Hammond River from the mouth of Canyon Creek to the mouth of Vermont Creek. The coordinates are about at the middle of these benches which cover much of the eastern half of section 12 of T. 31 N., R. 12 W. and the western half of section 7, T. 31 N., R 11 W.

Commodities:

Main: Au

Other:

Ore minerals: Gold

Gangue minerals:

Geologic description:

Kurtak and others (2002) sampled benches on both sides of the Hammond River between the mouth of Vermont and Canyon Creeks. Auriferous gravel up to 150 feet thick rests on phyllite and schist of the Upper Devonian Beaucoup Formation (Eden, 2000). One composite, 0.01 cubic yard sample was assembled by systematically sampling a section of gravel 150 feet thick. It assayed 0.0008 ounce of gold per cubic yard. Another 0.01 cubic yard sample taken on bedrock below the gravel assayed 0.006 ounce of gold per cubic yard. Kurtak and others (2002) estimate an 'inferred resource' of 360,000 cubic yards of material that averages 0.007 ounce of gold per cubic yard.

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Deposit model:

Thick auriferous bench gravels.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

39a

Production Status: None

Site Status: Inactive

Workings/exploration:

The only documented work on these thick, low grade, auriferous gravels is by Kurtak and others (2002). They collected and analyzed two large samples.

Production notes:

None.

Reserves:

Kurtak and others (2002) estimated an 'inferred resource' of 360,000 cubic yards of material that averages 0.007 ounce of gold per cubic yard.

Production Status: Yes

Site Status: Undetermined

Workings/exploration:

Claims were staked on Bear Creek and it was prospected in the 1970s and 1980s. Kurtak and others (2002) visited the creek and found parts of an old bulldozer, mining equipment, stacked rocks and mine tailings about 0.5 mile above the mouth of the creek.

Production notes:

There are no production records from the activity in the 1970s and 1980s but stacked rocks and tailings indicate that some gold was probably recovered.

Reserves:

None.

Site name(s): Tobin Creek

Site type: Mine

ARDF no.: WI172

Latitude: 67.5905 **Quadrangle:** WI C-4

Longitude: 151.5125

Location description and accuracy:
This placer mine is about 4 miles upstream from the mouth of Tobin Creek at the north end of Wild Lake. It is about 0.5 mile north of the center of section 23, T. 32 N., R. 18 W.

Commodities:

Main: Au

Other:

Ore minerals:

Gangue minerals:

Geologic description:
Kurtak and others (2002) found evidence of mining about 4 miles upstream from the mouth of Tobin Creek. The evidence includes a cache with pump, hoses, a sluice box, and a small area of stacked rocks. They thought the equipment and evidence of mining was no more than 3 years old. A placer claim was also staked near the mouth of Tobin Creek in 1954.

Alteration:

Age of mineralization:
Quaternary.

Generic deposit model:
Placer deposits (Garnett and Bassett, 2005)

Deposit model:
Placer Au (Cox and Singer, 1986; model 39a).

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):
39a

Production Status: Yes

Site Status: Undetermined

Workings/exploration:
There is a cache with some mining equipment and a small area of stacked rocks that date to the late 1990s.

Production notes:

Uncertain but possibly a small amount of gold was recovered.

Reserves:

None.

Site name(s): Unnamed (northwest of Dry Bay)

Site type: Prospect

ARDF no.: YA013

Latitude: 59.2566 **Quadrangle:** YA B-3

Longitude: 138.7965

Location description and accuracy:

This prospect consists of a large block of claims covering an area up to about 4 miles wide that stretches northwest along the coast for about 18 miles from the mouth of Dry Bay. The coordinates are at approximately the center of the claims near the center of section 1, T. 31 S., R. 39 E.

Commodities:

Main: Ag, Au, Fe, Ti

Other:

Ore minerals: Gold, ilmenite, magnetite

Gangue minerals:

Geologic description:

Beginning in 2006, Geohedral LLC with financial backing from the Beard Company staked claims over an area up to 4 miles wide and 18 miles long covering about 49,000 acres along the coast northwest of Dry Bay. The claims were believe to have significant quantities of iron, titanium, gold, and silver in black sands on elevated marine beach terraces. Geohedral drilled 11 core holes in 2008. In 2009, their efforts expanded inland to the Tarnis Mesa area (YA014). In 2010, the Beard Company commissioned an independent analysis of the samples and reported that 'Geohedral's mining claims failed to indicate commercial quantities of gold or silver in any of Geohedral's present claims and have shown significantly less magnetite and ilmenite within the Black Sands area than was documented previously.' (Beard Company, 2010).

Alteration:

Age of mineralization:

Quaternary.

Generic deposit model:

Deposit model:

Black sands in raised marine terraces.

Deposit model number (After Cox and Singer, 1986 or Bliss, 1992):

Production Status: None

Site Status: Undetermined

Site name(s): Unnamed (near Tarnis River)

Site type: Prospect

ARDF no.: YA014

Latitude: 59.241 **Quadrangle:** YA A-2

Longitude: 138.5151

Location description and accuracy:

This prospect of uncertain boundaries consists of 521 claims covering about 16,000 acres near Tarnis Mesa, an informal name that probably refers to the hills that occupy most of section 10, T.31 S., R. 41 E. The coordinates are arbitrarily on the top of hill 535, which presumably is the top of the mesa.

Commodities:

Main: Ag, Au, Fe, Ti, Pd, Pt

Other:

Ore minerals:

Gangue minerals:

Geologic description:

In 2009, Geohedral LLC with financial backing from the Beard Company staked 521 claims totaling about 16,000 acres in the Tarnis Mesa area (which probably refers to the unnamed low hills in section 10 that rise above the coastal plain) (Beard Company, 2009 [Annual Report]). These claims were contiguous to the claims they had staked the previous year along the coast (YA013). The Tarnis Mesa claims were believe to have significant quantities of iron, titanium, gold, silver, platinum, and palladium in black sands in elevated marine beach terraces. In 2009, Geohedral drilled 30 holes up to 27.1 feet deep and another 30 holes 3 to 6 feet deep (Beard Company, 2009 [gold discovery]). As reported in a press release: 'Preliminary evaluation of the assays indicates that the unconsolidated materials above the bedrock in the Tanis Mesa area contain appreciable amounts of gold and silver, averaging 0.30 oz/ton of gold and 0.75 oz/ton of silver. The 400 claims of primary interest are projected to produce 34,800,000 troy ounces of gold' In 2010, the Beard Company commissioned an independent analysis of the samples and reported that 'Geohedral's mining claims failed to indicate commercial quantities of gold or silver in any of Geohedral's present claims and have shown significantly less magnetite and ilmenite within the Black Sands area than was documented previously.' (Beard Company, 2010).
