
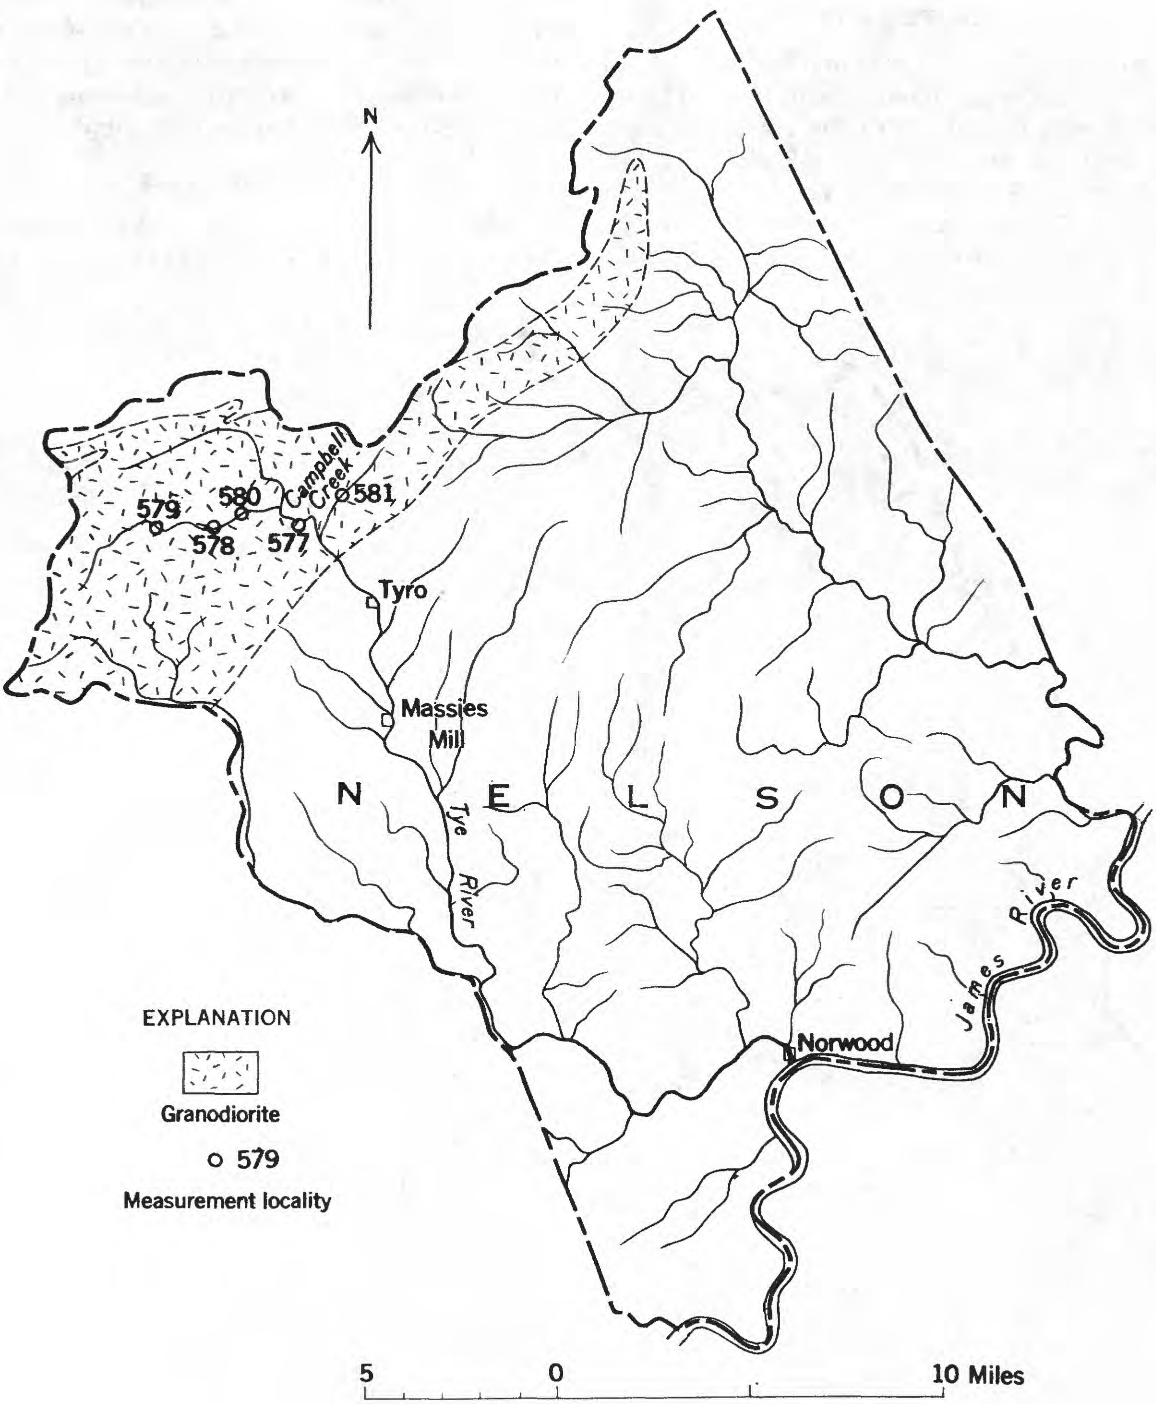

FIGURE 12.—Drainage map of Nelson County, Va., showing the area of granodiorite and the location of measurements in the Tye River basin. Granodiorite area from Geologic Map of Virginia (Va. Geol. Survey, 1928).

The river channels are wide and shallow, dry in summer and fall or with pools of still water. But in winter and spring they run with swift, clear water.

TYE RIVER BASIN

The Tye River, a headwater stream of the James River, drains the east slope of the Blue Ridge in Nelson County, Va. A small segment of the Tye River was studied, as shown in figure 12, from a locality 3.8 miles from the source to a locality 8.6 miles from the source, where its drainage area is 32 square miles. This reach of the river is accessible by automobile, for the stream is followed closely by Virginia State Route 56. The Tye River was selected for study because it flows on slopes that are remarkably steep as compared to those of the other rivers studied. Its bed consists of extremely coarse boulders, which have in places a median grain size of more than 500 millimeters. Many boulders in the stream are over 3 meters in diameter. The entire area studied is underlain by coarse-grained hypersthene granodiorite.

GILLIS FALLS

Gillis Falls, a creek that forms the principal tributary of the South Branch of the Patapsco River, heads in a high

FRANKS MILL REACH OF THE MIDDLE RIVER

A reach of the Middle River about 11 miles long was chosen for detailed study of the bed material and a geologic map of the area was prepared (fig. 35). Within this reach the river crosses several belts of lithologically contrasting rock. Two of them, the Athens limestone and the Mosheim limestone, as used by Butts (1940), are distinctive and can be recognized easily in stream boulders. Fourteen grid analyses were made within the reach. The geology on either side of the stream was mapped, partly to bring to greater detail the existing maps by Butts (1933) and Edmundson (1945), but mainly to acquaint the writer with the rocks along the stream.

The river enters the Franks Mill reach at the western edge of the map in the Beekmantown (Lower Ordovician), a thick succession of cherty limestones and dolomites. Above Franks Mill it crosses rocks of the Lenoir and Mosheim. The Mosheim is a pure, high-calcium dove-gray limestone with conchoidal fracture. The Lenoir is a massive, fossiliferous limestone that contains many small patches and lentils of black chert. At Franks Mill the river enters a broad valley cut in the Athens limestone. The basal beds of this formation are soft calcareous shale; the river follows the shale belt for several miles. The upper part of the Athens is a distinctive very dark chert-free limestone. About one-half mile below locality 597 the river leaves the outcrop belt of the Athens and turns northward in a belt of Lenoir limestone that is exposed in an overturned anticline. The river flows around the nose

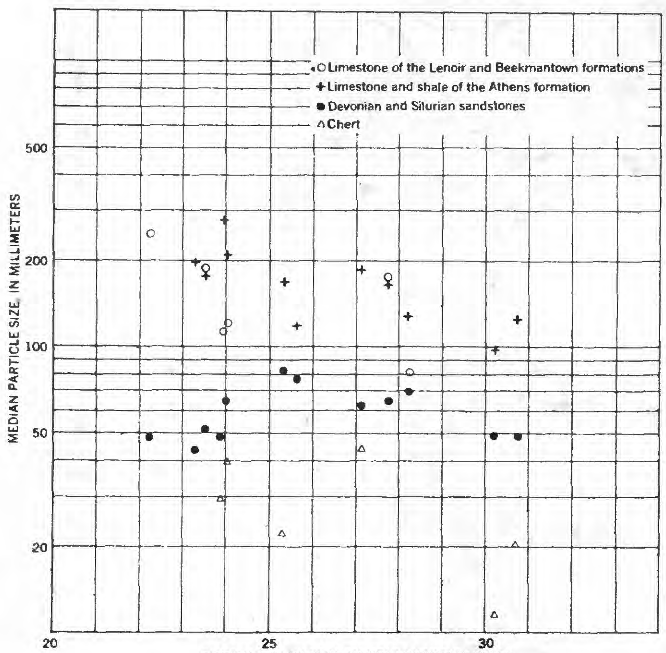

FIGURE 36.—Median particle sizes of limestone, sandstone, and shale in bed material in the Middle River at localities shown in figure 35, determined by grid analyses.

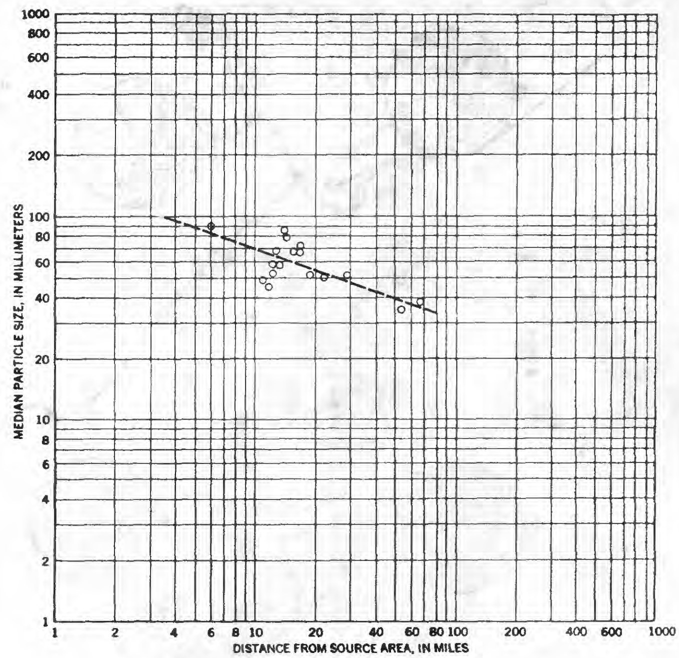

FIGURE 37.—Logarithmic graph showing the rate at which the sandstone component decreases in size away from the source area. Distances are measured along the Middle River from the source area in East Dry Branch.

of this anticline between localities 597 and 619, and at locality 619 it crosses the Staunton overthrust fault and enters the Conococheague limestone (Upper Cambrian). The Conococheague limestone in this area is a thick succession of light-colored thin-bedded siliceous limestone and dolomite, quite different in outcrop from the limestone of Ordovician age.

The lithologic composition of the bed material at the grid-analysis localities is shown in the pie diagrams, figure 35. It is possible to identify with some confidence six components in significant quantities. These are the sandstone carried down from upstream (mainly from East Dry Branch, Buffalo Branch, and Jennings Branch), chert, and four categories of limestone. The Athens limestone and the limestones of the Mosheim and the Lenoir are very distinctive. The Conococheague may be recognized at locality 617, not because it is distinctive, but because by elimination it could be nothing else. The Lenoir and Beekmantown are not particularly distinctive but are believed to constitute most of the limestone in the samples not otherwise classified that were obtained between Franks Mill and locality 619.

Sandstone.—Sandstone constitutes from one-third to two-thirds of the bed material of the river in the Franks Mill area. Its source is entirely in the mountains west of the Shenandoah Valley. The area of sandstone rocks makes up less than 20 percent of the area of the drainage basin of the river at Franks Mill, yet in spite of the greater distance of travel (a minimum of 6 miles at the upper end of the reach) the sandstone is in general the dominant constituent of the bed material.

The median diameter of the sandstone component ranges from 44 to 85 millimeters, averaging around 60 millimeters, as shown in figure 36. Several sandstone boulders over 250 millimeters in diameter were seen.

The percentage of sandstone in the samples within the reach shown in figure 35 is inversely related to the abundance of other constituents. The median size of the sandstone component cannot be shown to change systematically within the area of figure 35, but, considering all the localities within the limestone region along the Middle River, the sandstone apparently (fig. 37) decreases gradually in size from over 100 millimeters in median diameter to less than 40 millimeters after 65 miles of travel in the stream.

The decrease in size or weight of bed material with distance from the source area has generally been expressed as an exponential curve (Schoklitsch, 1933; Pettijohn, 1948, p. 397). The data obtained in this study are insufficient to have any critical bearing on earlier studies relating to the rate of abrasion but are not out of accord with them.

Chert.—Chert is present in nearly all the samples. In fact, it is ubiquitous in nearly all stream channels in the limestone region. In the Franks Mill area the chert must originate above Franks Mill, because none has been found in the Athens limestone. At locality 615, within the outcrop area of the chert-rich Beekmantown dolomite, chert makes up 25 percent of the bed material. In the Athens limestone area it declines to about 3 percent at locality 592.

In all the samples chert is the finest constituent. Its actual median size is probably smaller than the median sizes given in figure 36, because the samples, which were subdivided according to lithologic composition, include only material coarser than 10 millimeters. Sandstone and limestone are major constituents of the coarse fractions; omission of the fine fraction from the pebble count has little effect on the median size of rocks of these kinds, as obtained from the count. Chert, however, is present in only the small fractions but is locally their dominant constituent; omission of the fine fraction undoubtedly results in an exaggerated value for the median size of chert as obtained in the count (fig. 36). Probably the median diameter of the chert averages between 5 and 10 millimeters for the reach. This estimate is based on 3 counts of fine fractions that were divided into size classes by sieving and subdivided into lithologic components by examination under a binocular microscope.

The chert, like the sandstone, is present in the load throughout the Franks Mill area. It travels through reaches where there is no local source and is therefore a resistant as well as persistent component. The chert fragments are small, partly because the chert occurs in the limestone in small irregular masses or nodules, or in thin stringers which, when released from the enclosing rock by solution, abrasion, or breakage, are capable of forming only small fragments. Although very hard, the chert is generally weakened by many fractures and by veinlets of calcium carbonate.

Limestone.—The limestone ranges from about 10 percent to more than 50 percent of the bed material in this region. The many changes that take place within short distances in the kind, amount, and size of limestone fragments are very revealing. At locality 615 limestone, mostly Lenoir and Beekmantown, makes up 18 percent of the sample. Some Conococheague limestone may be present. Below Franks Mill the limestone has increased at locality 575 to 60 percent of the sample and most of this is Lenoir and Beekmantown, transported from above Franks Mill. Probably considerable limestone has been added in the narrow gorge above the mill. The small amount of Athens limestone at locality 575 could have gotten into the stream only by plucking from the bed, for there are no Athens outcrops on either side of the channel, whereas there are two riffles floored by Athens immediately above the locality.

The next significant change is at locality 589, where the Athens has increased to 26 percent. This locality is below a cliff of Athens limestone now being undercut by the stream at a bend (described on p. 79). No Athens outcrops are exposed immediately below this locality, and at locality 588 the proportion of Athens limestone in the bed material has dropped to 8 percent. The river again impinges against a cliff or steep slope of Athens limestone about 0.5 mile below locality 588 and also at locality 592 (described in detail on p. 79). Here the Athens constitutes 50 percent of the bed material, but 0.4 mile farther, after a passage between banks composed entirely of alluvium, the Athens makes up only 17 percent. It is noteworthy that the count of Athens limestone at this place contained pebbles that were reddened and weathered.

In this area, only 2.6 miles from the last Lenoir outcrop along the channel, the Lenoir and Beekmantown have dropped in amount from 47 percent to less than 5 percent. Downstream from this point the Athens limestone continues to fluctuate in percentage of the sample. The fluctuations are obviously related to the proximity of outcrops of Athens along the channel. At locality 593, the river impinges for a short distance against a rocky slope of the Mosheim member of the Lenoir limestone. At this place the Mosheim constitutes 15 percent of the bed material. Three-tenths mile beyond, below a long rocky slope of Athens, the Mosheim has been so reduced in amount that it makes up less than 1 percent of the sample.

Between localities 619 and 617, less than 0.5 mile farther, the river crosses the Staunton fault. The Athens limestone component drops from 42 to 32 percent of the

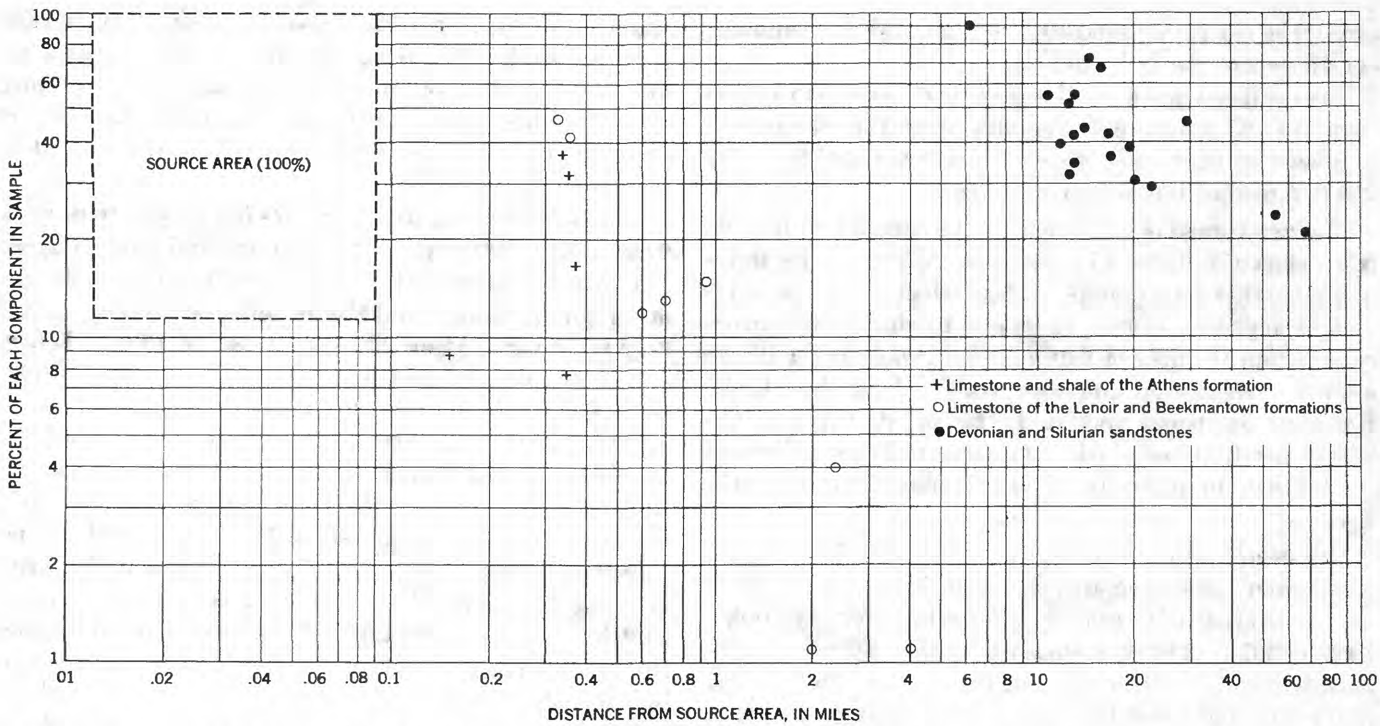

FIGURE 38.—Logarithmic graph showing the relation between distance of travel from the nearest source area and the percentage of three lithologic components of the bed material. The data include only localities along the Middle River.

bed material and the Conococheague limestone, an entirely new component, rises to 24 percent.

The sharp changes in the amount of different kinds of bed material are summarized in figure 38. In this graph the sandstone includes localities outside the Franks Mill area on the Middle River. The sandstone travels long distances from its source, and even after 60 miles of travel in the Middle River through a limestone area it makes up a large part of the sample. At this distance the sandstone source area is only 10 percent of the total drainage area. Limestone from the Lenoir and Beekmantown formations persist in the Franks Mill area for a distance of only about 5 miles below the source area, whereas the Athens ceases to be an appreciable part of the bed material in less than 1 mile of travel.

The median size of the limestone fragments in every sample is considerably coarser than the sandstone, as shown in figure 36. Differences between the Athens and the Lenoir and Beekmantown may not be significant, but the coarsest samples are of Athens limestone, the least resistant component. Variations in size of the limestone fragments within the Franks Mill area do not seem to be systematic. If there are such variations, the data are not sufficient to reveal it. As will be shown by additional evidence in the pages following, the size of the boulders in the bed must be closely related to the distance from the source. The limestone boulders are large because they are near their point of origin, where they were torn from a steep slope or cliff by the lateral cutting of the stream. These blocks do not travel as part of the bed load but are destroyed or worn down within a short distance from the source.

It is probably the susceptibility of the limestone to breakage and abrasion that causes its rapid disappearance, rather than its solubility. Solubility, however, may be a minor factor. During the summer season, calcareous tufa forms on the stream bed at riffles in the Middle River, indicating that for at least a part of the year solution is not even a minor factor. As similar changes in the lithology of the bed material within short distances also occur in rocks that are not soluble in water (like the phyllite of Gillis Falls, p. 85) presumably solution is not a necessary factor. Solution along joint planes and fractures, however, may help to weaken the rock and facilitate breakage, and it may operate to some extent during high-water periods.

Abrasion, like solution, must also be a factor in reducing the bed material to small sizes. No data, however, are at hand by which to evaluate the importance of this factor. Since well-rounded fragments are abundant in the fine fractions of all the samples, and are present in even the coarse fractions, presumably abrasion is an important factor. Considerable study has been given this problem by others and it has been demonstrated that lithologic composition is an important factor determining the rate of wear of stream boulders and gravel (Schoklitsch, 1936).
