
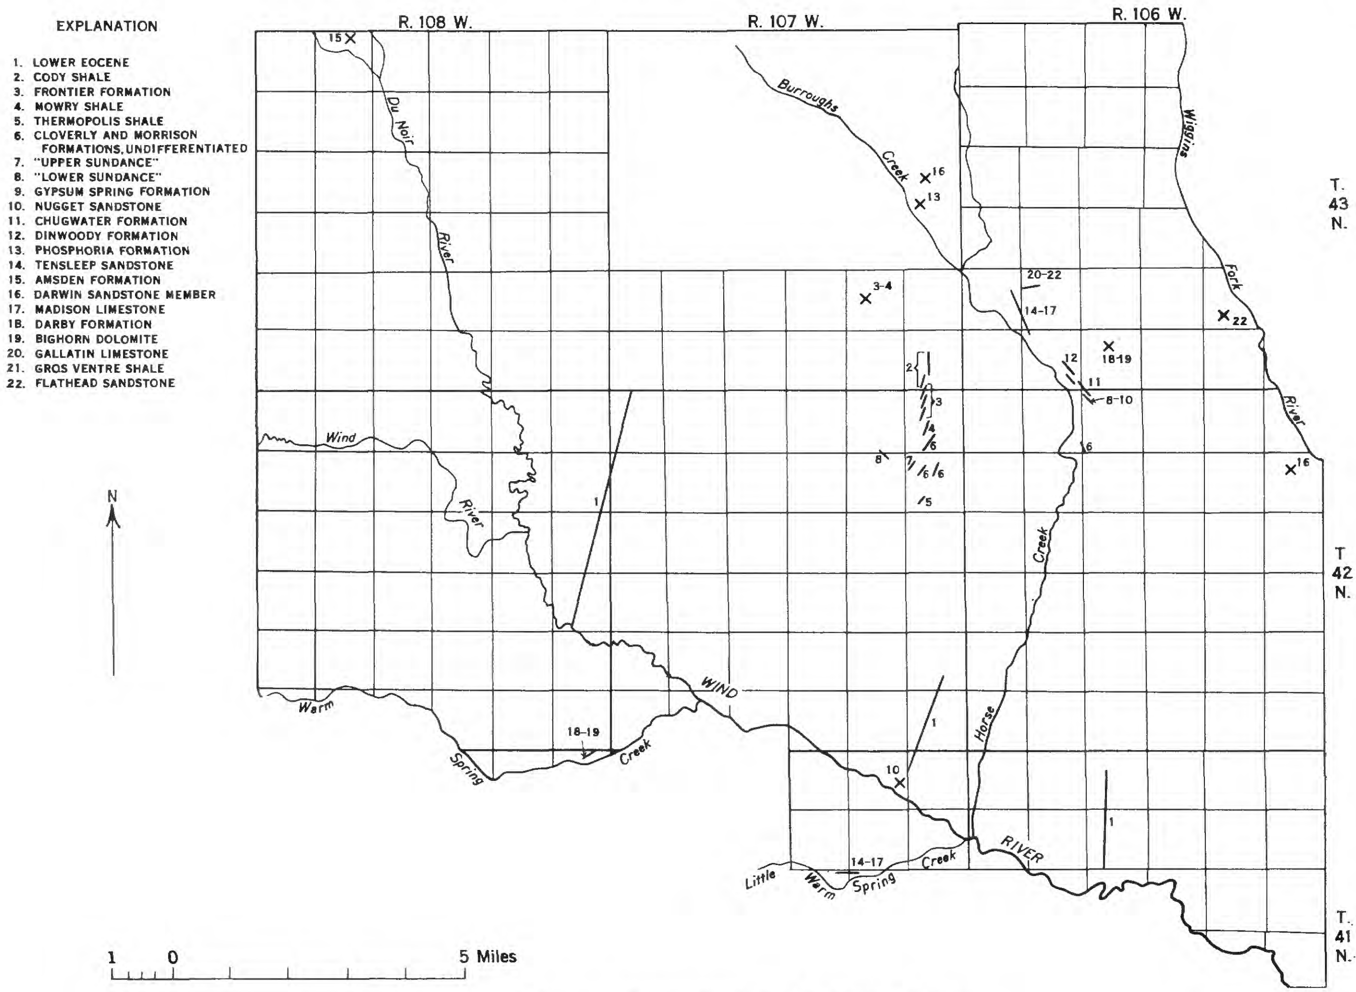

FIGURE 59.—Index map showing location of measured sections.

Complete sections of rocks of Paleozoic age are exposed on the northeast flank of the Wind River Range and at the western end of Spring Mountain. These two sections, which lie only about 10 miles apart, are excellent tie points for correlation and study of the Paleozoic sequence because the outcrop belts diverge basinward along the Owl Creek Mountains on the north and the Wind River Range on the west. Rocks of Mesozoic age are well exposed along Horse Creek and Little Horse Creek; some of the older Mesozoic formations are exposed along the Wind River near Dubois. These occurrences constitute the northwesternmost exposures of Mesozoic rocks in the Wind River Basin and therefore offer the best opportunities for correlation with similar stratigraphic units in regions to the west. Inasmuch as a detailed study of the Mesozoic rocks had been made by the Geological Survey in the Horse Creek area (Love, Tourtelot, Johnson, and others, 1947), the writer has freely drawn from this information for the stratigraphic discussions of those formations. Tertiary strata, which form an uninterrupted sequence about 5,000 feet thick in the central part of the mapped area, cover a large part of the area. A variety of Quaternary deposits, including glacial moraines, landslides, terrace gravels, and alluvium, have been differentiated.

PRECAMBRIAN ROCKS

Precambrian rocks crop out along Warm Spring Mountain and in many places in the northeast part of the mapped area where they form the core of a large anticlinal structure. Detailed studies of the Precambrian rocks were not attempted. Gray and pink coarsely crystalline granite and granite gneiss are the predominant rock types. They consist mainly of quartz, feldspar, and mica. Many of the rocks are schistose; they contain an abundance of biotite and appreciable amounts of pink garnet. Some of the gneissic granites are cut by thin pegmatite dikes and quartz veins.

The unconformity between Precambrian and Cambrian rocks is not readily observed as the contact is commonly obscured by talus from the overlying Flathead sandstone cliffs and by dense forest cover in many parts of the area. It is thought that the contact is relatively even and that local relief along the contact is not pronounced, although the thickness of the Flathead sandstone varies about 50 feet within the area. Regionally, however, the thickness of the Flathead sandstone varies greatly, and this variation is thought by Miller (1936, p. 118) to reflect the relief of the Precambrian peneplain. In some places, where the contact is not sharp, the coarse Flathead arkose beds grade downward through a weathered zone into unweathered granite.

CAMBRIAN SYSTEM

FLATHEAD SANDSTONE

The name Flathead formation was originally proposed by Peale (1893, p. 20–22) from exposures in southwestern Montana to include a basal quartzite or sandstone, termed the Flathead quartzite, and an upper green shale sequence designated the Flathead shales. In the Gros Ventre Range, Blackwelder (1918, p. 417) included the shales in the lower part of the Gros Ventre formation and restricted the term Flathead to the basal sandstone. The Flathead sandstone (Flathead quartzite of many writers) is now generally accepted in this restricted sense and has been recognized over wide areas in western and central Wyoming. In the Wind River Canyon, Miller (1936, p. 124) included both the Flathead sandstone and the Gros Ventre formation in the Depass formation, because there the contact between the two was found to be gradational. Tourtelot and Thompson (1948) however, separated the two formations in that area and present a brief summary of the problems involved in the Cambrian nomenclature. The name Depass has not been generally accepted in central Wyoming.

The Flathead sandstone crops out along Warm Spring Creek and in many places along the margins of Horse Creek Basin and upper Horse Creek valley, where it characteristically forms resistant cliffs above the Precambrian slopes. The thickness of the formation ranges from about 150 to 190 feet. The variation in thickness, which has no uniform trend, is probably due to the relief on the Precambrian peneplain developed before the deposition of Flathead sandstone. The formation consists of pink, reddish-brown, tan, and gray fine- to coarse-grained thin-bedded sandstone. The sandstone is quartzitic for the most part, and many of the beds are thinly laminated with purplish and reddish-brown layers alternating with gray and tan layers. The basal beds are commonly conglomeratic and arkosic with angular fragments of quartz, feldspar, and mica. Some granite pebbles as much as 1 inch in diameter are present. The upper beds are generally softer and shaly. Glauconite and hematite are present in some places. Dip slopes developed on the top of the Flathead sandstone are characteristically partly covered by a rubble of large sandstone blocks which have slid down the slopes; many such slopes are devoid of all vegetation except grass and are conspicuous in an otherwise heavily forested area (fig. 60).

FIGURE 60.—Flathead sandstone (€f) and Gros Ventre formation (€gv) along Warm Spring Creek in SW¼ sec. 30, T. 42 N., R. 108 W. Dip slope of Flathead sandstone in foreground. Death Canyon member of Gros Ventre in distance.

Miller (1936), who made a paleontologic and stratigraphic study of the Cambrian rocks in northwestern Wyoming, concluded on paleontologic evidence that the Flathead sandstone is largely, if not wholly, Middle Cambrian in age. The contact between the Flathead sandstone and the overlying Gros Ventre formation is marked by a change from quartzitic and, in part, shaly sandstone below to soft micaceous shaly sandstone above. The lithologic change is not pronounced, however, and in places it is gradational. The contact is also marked by a topographic change from cliffs below to weathered slopes above.

GROS VENTRE FORMATION

The Gros Ventre formation was named by Blackwelder (1918) from exposures on Doubletop Peak in the Gros Ventre Range, approximately 25 miles southwest of the mapped area. The sequence probably includes the lateral equavalents of the Flathead shales and the lower part of the Gallatin formation of Peale (1893, p. 20–25). At the type section the Gros Ventre formation is 769 feet thick; it can be divided into three distinctive lithologic units: a lower shale unit, a middle limestone unit called the Death Canyon member by Miller (1936), and a thick upper shale and limestone unit. These units are readily distinguishable throughout the mapped area. The formation crops out along Warm Spring Creek and in many places in the northeastern part of the area. Outcrops of the shale units commonly are grass-covered slopes and good exposures are rare; in contrast the Death Canyon member forms vertical cliffs and constitutes one of the most conspicuous units in the Cambrian sequence of this region (fig. 60).

Because of poor exposures no detailed measured section of the Gros Ventre formation was obtained in the mapped area. A generalized section was measured on the northwest end of Spring Mountain, where it is 503 feet thick. The section on Warm Spring Creek in the extreme southwestern corner of the area is 747 feet thick (Miller, 1936, p. 132). In areas to the east Love (1939, p. 15) reported thicknesses ranging from 550 to 700 feet.

The lower unit has a uniform thickness of about 110 feet throughout the mapped area. It consists of greenish-gray, tan, and pink shaly micaceous very fine grained sandstone that is highly glauconitic in most places. The basal part contains some beds similar to those in the upper part of the Flathead sandstone so that the contact in places in gradational. The Death Canyon member, which ranges in thickness from 140 to 219 feet, is characterized by gray thin-bedded crystalline cliff-forming limestone that is commonly mottled tan by the inclusion of granular tan irregular masses.

The upper unit is 421 feet thick on Warm Spring Creek (Miller, 1936, p. 132) and only 254 feet at the Spring Mountain locality. The sequence is composed mostly of soft greenish-gray micaceous shale with varying amounts of thin-bedded gray limestone that increase in abundance toward the top. The limestone commonly contains beds of flat-pebble conglomerate. Best exposures of the shale can be seen in the road cuts along the switchbacks that descend into Warm Spring Canyon southwest of the Harrison ranch.

No fossils were found in the formation by the writer, but a few trilobites and brachiopods have been reported from the Warm Spring Creek section (Miller, 1936, p. 132) and adjoining areas to the east (Love, 1939, p. 16). The fauna indicates a Middle Cambrian age, which agrees with that assigned by Blackwelder (1918) to the type section.

The contact between the Gros Ventre formation and the overlying Gallatin limestone is marked by a sharp topographic break and by a change from predominantly shaly rocks below to predominantly limestone above. Wherever the contact was observed it appeared to be conformable, but the variation in thickness of the upper shale unit may be indicative of a disconformity between the two formations. A disconformity was noted by Miller (1936, p. 122) in the Teton Range and by Blackwelder (1918) at the type section in the Gros Ventre Range. Inasmuch as the Death Canyon member also thins considerably northeastward from Warm Spring Creek the thinning of both of the upper units may be due largely to nondeposition.

GALLATIN LIMESTONE

The Gallatin limestone, the youngest Cambrian formation in the area, was named and described by Peale (1893, p. 22–23) from exposures in southwestern Montana. At the type section it originally included in its lower part limestone and shale of Middle Cambrian age, which probably constitute the upper part of the Gros Ventre formation as that formation was defined by Blackwelder (1918), and limestone of Late Cambrian age in its upper part. Inasmuch as the Gallatin limestone, in its restricted sense, contains only strata of Late Cambrian age and is therefore not completely representative of the type Gallatin as originally defined, Deiss (1938, p. 1104) applied the term Boysen formation for the Upper Cambrian rocks in Wind River Canyon. That name, although extended into the Gros Ventre Range by Foster (1947, p. 1547), has not gained wide acceptance.

The Gallatin limestone is a resistant sequence that forms conspicuous cliffs above the shale slopes of the Gros Ventre formation. In Warm Spring Canyon it constitutes the lowermost series of ledges in the precipitous canyon wall (fig. 61). The formation is also well exposed in the northeastern portion of the area. On Warm Spring Creek it is 365 feet thick. The Du Noir member, which forms the basal unit, was named by Miller (1936, p. 125); the type section is about 2 miles west of the Du Noir tie camp, in the southwest corner of the area.

In Warm Spring Canyon the Du Noir limestone member (Miller, 1936) is an easily recognizable 48-foot cliff-forming unit of gray thin-bedded highly glauconitic and oolitic limestone with some flat-pebble conglomerates. The overlying unit, which is 54 feet thick and generally poorly exposed because of talus

FIGURE 61.—Gallatin limestone (€g) and Bighorn dolomite (Ob) on north side of Warm Spring Canyon, N½ sec. 1, T. 41 N., R. 108 W. Gros Ventre formation (€gv) in foreground.

cover, consists mainly of soft greenish-gray shale and a minor amount of thin-bedded gray limestone. The uppermost sequence which forms the main mass of the formation is a hard resistant series of gray thin-bedded to massive limestones. Some of the exposed surfaces weather with a rough-pitted surface similar to the overlying Bighorn dolomite. The upper part of the unit is commonly mottled with tan small irregular granular limestone masses. The formation in many places contains caverns filled with red earthy deposits which, where exposed on the sides of cliffs, contribute much red staining to the outcrops. Because of this, the outcrops, when viewed from a distance, appear to contain a large amount of red material. The caverns may have been developed and filled during short periods of erosion in Late Cambrian time and as such may represent local disconformities within the formation. On the contrary they may have been formed and filled at a much later date.

Gros Ventre formation.	

Only unidentifiable trilobite and brachiopod fragments were found in the Gal'‑tin limestone. However, in his studies of the Cambri‑n sequence of this region Miller (1936, p. 140–141) collected fossils from many faunal zones in the Gallatin limestone and correlated them with zones in the type St. Croixan (Upper Cambrian) of the upper Mississippi Valley.

The contact between the Gallatin limestone and the overlying Bighorn dolomite is not sharp in the section measured in Warm Spring Canyon, but is marked only by a gradual change from gray limestone below to buff granular limestone and dolomite above. The contact is also difficult to determine in the cliff faces along the canyon. In many places throughout the area, however, a sharp topographic change delineates the contact as the more easily eroded thin-bedded limestone forms slopes beneath the very resistant massive Bighorn dolomite. Love (1939, p. 19) states that the Bighorn dolomite rests with slight disconformity on the Gallatin limestone. In some areas Miller (1936) found an erosional disconformity at the top of the Cambrian; in others the contact appeared to be conformable. Miller (1936, p. 131) noted 100 feet of beds at the top of the Gallatin limestone on Warm Spring Mountain that were absent about 3 miles to the west. Since the Gallatin limestone is Upper Cambrian and the lower part of the Bighorn dolomite is believed to be of Middle or Late Ordovician age (Thomas, 1948, p. 80), this break represents considerable time.

ORDOVICIAN SYSTEM

BIGHORN DOLOMITE

Along the flank of the Wind River Range the Bighorn dolomite, which was named and described by Darton (1904, p. 394–396) from exposures in the Bighorn Mountains, is divisible into three lithologic units: a basal lenticular sandstone called the Lander sandstone member by A. K. Miller (1930, p. 196), an unnamed middle massive dolomite member, and an upper thin-bedded dolomite member called the Leigh dolomite member by Blackwelder (1918). Within the mapped area only the upper two dolomite members are believed to be present, although, owing to its lenticular nature and thinness, the Lander sandstone member may be present in areas where the basal part of the formation is concealed. A 1-foot bed of coarse-grained sandstone at the base of the Bighorn dolomite was observed by the writer along Torrey Creek near the Trail Lake ranch, about 5 miles south of the Fish ranch. Love (1939, p. 18) reported the Lander sandstone member to be present in several places in areas to the east, with thicknesses averaging about 7 feet.

The Bighorn dolomite forms massive cliffs throughout most of its area of outcrop (fig. 61). It is 254 feet thick in Warm Spring Canyon and 296 feet on top of Spring Mountain in the N½ sec. 33, T. 43 N., R. 106 W. The lower massive member ranges from 170 to 250 feet in thickness; it is composed of buff very resistent massive granular dolomite which weathers with a characteristic rough-pitted surface. The lower part of the member is quite limy and commonly more gray in color, but it still retains it granular texture. The Leigh dolomite member at the top, 47 to 84 feet thick, consists of gray to pink platy dense porcelaneous dolomite, the lower part of which weathers chalky white and constitutes a conspicuous unit that generally forms reentrants along the cliff faces. The upper part of the member is similar to the massive dolomite in the lower part of the formation. The variation in thickness of both members is most probably due to the unconformities at the top and bottom of the formation.

the Chugwater formation is Early Triassic in age. Both marine vertebrates and invertebrates are sparsely present in the Alcova limestone member, but there is no general agreement regarding the age of the fauna, which has variously been ascribed to the Early, Middle, and Late Triassic. Love, Johnson, Nace, and others (1945) state that the fauna has little present significance, but that it is more like known Early Triassic assemblages. They further conclude that, since there is no significant physical evidence at the base or at the top of the Alcova to indicate whether it is more closely associated with the beds above or below, it seems better to assign it arbitrarily to the Lower Triassic. Newell and Kummel (1942, p. 949) correlate both the Alcova limestone and the Crow Mountain member with the Thaynes limestone, thus considering those two units to be Early Triassic in age. Marine reptiles and a few pelecypods and plant remains have been collected from the Popo Agie member. The vertebrates have been assigned to the Middle Triassic by some investigators and to the Late Triassic by others. Colbert, who collected vertebrate fossils from the Popo Agie member southeast of Dubois in 1953, believes that the member is of Late Triassic age (written communication to J. F. Murphy, 1953).

The contact between the Chugwater formation and the overlying Nugget sandstone is marked by a sharp lithologic change from red and green shale and ocher-colored claystone below to gray and orange sandstone above. There is a regional unconformity between the two formations, but it is not readily apparent in localized exposures. In some parts of the mapped area the Nugget sandstone is absent and the Chugwater formation is overlain directly by the Gypsum Spring formation.

JURASSIC SYSTEM

NUGGET SANDSTONE

According to present definition in the western part of the Wind River Basin and adjacent regions the Nugget sandstone occupies the stratigraphic position between the Popo Agie member of the Chugwater formation and the Gypsum Spring formation. Its original definition in southwestern Wyoming (Veatch, 1907, p. 56) included all the strata lying between the Thaynes limestone (Lower Triassic) and the Twin Creek limestone (Middle and Upper Jurassic). In the type area near Nugget, Wyo., the formation included a lower red shale member and an upper sandstone member considered to be wholly or in part of Triassic age. The lower red shale unit, possibly the stratigraphic equivalent of the Popo Agie member, was designated the Ankareh shale and the Nugget sandstone was restricted to the upper sandstone unit by Boutwell (1912, p. 58) in the Park City mining district, Utah. The Nugget sandstone was used in this restricted sense by Mansfield (1927, p. 96) in southeastern Idaho.

The Nugget sandstone is present throughout the central and western parts of the Wind River Basin. At some localities in the southern part of the basin where the overlying Gypsum Spring formation is not present it is difficult to determine whether the basal sandstone of the Jurassic system is the Nugget sandstone or a sandstone in the basal part of the "lower Sundance." In adjacent areas to the east of the Du Noir area, where the Nugget sandstone is very poorly developed or entirely absent, its stratigraphic interval was included in the Chugwater formation by Love (1939, p. 43). The name Wyopo formation was applied by Branson and Branson (1941, p. 136) to the Nugget strata near Lander, Wyo., but that term has not been generally accepted.

Within the mapped area the Nugget sandstone ranges in thickness from a wedge edge to at least 120 feet, reaching its greatest development in exposures near Dubois (fig. 64). The formation has a marked north-

FIGURE 64.—Outcrop of Nugget sandstone (Jn) west of Dubois in E½ sec. 2, T. 41 N., R. 107 W. (T̄Rc, Chugwater formation).

ward thinning from Dubois, being 65 feet thick in the Sinclair-Wyoming Oil Co. Dubois well 1, only 31 feet (Love, Tourtelot, Johnson, and others, 1947, p. 9) along Horse Creek about 1 mile north of the EA ranch, and entirely absent about one-half mile northwest of the Horse Creek Ranger Station. The sandstone is gray, white, and orange, fine to medium grained, massively crossbedded to thin bedded and slabby. Large rounded frosted grains are common. A few green shaly beds are present. Where the unit is thick, it forms conspicuous cliffs above the red and ocher-colored slopes of the Chugwater formation.

Sandstone, white, fine-grained, rounded grains, thin-bedded, limy	11
	31

Chugwater formation.

The Nugget sandstone is unfossiliferous, and in the past it has been assigned to both the Triassic and Jurassic systems. It is now considered to be Early Jurassic in age (Imlay, 1950, table 1).

The contact between the Nugget sandstone and the overlying Gypsum Spring formation is marked by a sharp lithologic change from sandstone below to red shale and dolomitic limestone above. Evidence of an unconformity, other than the sharp lithologic change, was not observed in the mapped area. Present data, however, indicate that the northward thinning and disappearance of the Nugget sandstone is caused largely by a regional unconformity between the Nugget sandstone and the overlying Gypsum Spring formation. Love (1948, p. 101) states:

> Studies of electric log data from the northwestern part of the Wind River Basin indicate that successively older beds are cut out from south to north by the unconformity at the top of the Nugget sandstone and that the lowest bed forms the wedge edge along the northern margin of the basin.

Regionally the thinning of the Nugget sandstone is very gradual, but in areas immediately adjacent to the wedge edge the thinning is abnormally abrupt, as is demonstrated in the Du Noir locality and also in the area between the Gros Ventre River and Ditch Creek in Jackson Hole (Love, Keefer, Duncan, and others, 1951). The position of the wedge edge indicates gentle uplift of the region along the northern margin of the Wind River Basin and in the area extending westward from Togwotee Pass to Ditch Creek and erosion before the deposition of the Gypsum Spring formation.

GYPSUM SPRING FORMATION

The Gypsum Spring formation was named and described by Love (1939, p. 45) from exposures on Red Creek, about 15 miles east of the mapped area, and was originally designated the topmost member of the Chugwater formation. Following recognition of its Middle Jurassic age and more detailed stratigraphic studies the unit was later classed as a formation (Love, Tourtelot, Johnson, and others, 1945). In the Du Noir area the Gypsum Spring formation crops out in the vicinity of Dubois, along Horse Creek north of the EA ranch, and at one locality northwest of the Horse Creek Ranger Station.

A detailed section was measured in the NW¼NW¼ sec. 4, T. 42 N., R. 106 W., along the east side of Horse Creek where the formation is 109 feet thick (Love, Tourtelot, Johnson, and others, 1947, p. 9). In the Sinclair-Wyoming Oil Co. Dubois Unit well 1 it is 140 feet thick. The Gypsum Spring formation is a variable sequence of thin-bedded red shale and gray to gray-green dolomitic limestone and dolomite. The limestone and dolomite are commonly dense and very finely crystalline and form ledges in otherwise smooth soft shale slopes. The most prominent bed in surface outcrop is a 20-foot earthy limestone breccia near the base. In the Sinclair well on the Dubois anticline the formation contains anhydrite throughout but most abundantly near the base, and the thickness is correspondingly greater.

Shale, red, soft, with thin green shale at top	14
Interval covered. Apparently mostly red shale	34
Limestone breccia, dolomitic, with cavities filled with gypsum crystals. Apparently this is a residual breccia resulting from leaching out of the main gypsum bed in the Gypsum Spring formation. Thickness maps indicate that probably at least 100 ft of gypsum has been leached out of this section, most of it probably from this unit	19
Shale, red, fine-grained; dolomite nodules near top; a thin purple shale at top	8
	109+

Nugget sandstone.

At the type section on Red Creek the basal part of the Gypsum Spring formation contains a massive cliff-forming gypsum sequence, 127 feet thick, and a minor amount of red shale and limestone, but no limestone breccia. The occurrence of evaporites at the base of the formation is sporadic in surface outcrops, but regional studies in the western part of the Wind River Basin (Love, Tourtelot, Johnson, and others, 1945) indicate that the conspicuous anhydrite sequence is consistently present in the subsurface. Because of the sub-

TERTIARY SYSTEM

PALEOCENE(?) SERIES

FORT UNION(?) FORMATION

The presence of Paleocene rocks in the Du Noir area has not been fully substantiated. The rocks here referred to the Fort Union(?) formation crop out only locally in the Dubois anticlinal complex and have been strongly folded and faulted (fig. 65). They occur as-

FIGURE 65.—Fort Union(?) formation (Tfu) and Mowry shale (Km) strongly folded and faulted at southeastern end of Dubois anticlinal complex, NE¼ sec. 13, T. 42 N., R. 107 W. (T on overriding block of thrust fault; Twdr, Wind River formation).

sociated with Cretaceous rocks and are overlain uncomformably by strata of the Wind River formation (early Eocene). The total thickness of the sequence is not known, but as much as 50 feet is exposed west of Little Horse Creek. The Fort Union (?) formation is largely conglomeratic with the pebbles and rock fragments derived entirely from Mesozoic rocks. Angular light-colored Mowry shale chips form the most conspicuous element in the conglomerate. Fragments of "upper Sundance" limestone and sandstone and Morrison and Cloverly sandstone and siltstone are also present. Red and gray siltstone and claystone are present in some places.

No fossils were found in the Fort Union(?) formation, but the presence of Mesozoic rock fragments, complete absence of Paleozoic rocks, and the structural relationships of the formation suggest that this sequence of conglomerate, siltstone, and claystone is older than those rocks of known early Eocene age. The Fort Union(?) strata were most probably deposited during the initial stages of folding of the anticline.

EOCENE SERIES

INDIAN MEADOWS FORMATION

The name Indian Meadows formation was applied by Love (1939, p. 58) to a series of interbedded red clay, shale, sandstone, and conglomerate nearly 1,000 feet thick which lies along the east side of the North Fork River, approximately 4 miles east of the southeast edge of the Du Noir area. Massive conglomerate beds, containing fragments of granite, Paleozoic limestone, dolomite, and chert, and conspicuous algal-ball limestone beds, were considered to be distinguishing lithologic features of the formation. Vertebrate fossils at the type section indicate an earliest Eocene age, equivalent to that of the Gray Bull faunal zone in the Bighorn Basin. The close resemblance between the fine-grained strata of the Indian Meadows formation and those of the overlying Wind River formation, however, makes it impossible to differentiate the two formations in areas where they occur in juxtaposition except where there are fossils or mappable unconformities. No fossils were found in the strata assigned to the Indian Meadows formation in the Du Noir area; they have been so designated because of their conglomeratic character, similarities to the type section, and structural relationships. In the southeast portion of the mapped area where both the Indian Meadows and Wind River formations are believed to be present, they have been mapped as Wind River and Indian Meadows formations, undifferentiated.

The Indian Meadows formation crops out along the West Fork of the Du Noir River, on the south flank of Spring Mountain, and along the Wiggins Fork River. It is probably also present on the north sides of the Wind River and Wind Ridge fault, but at these localities it cannot be distinguished from the Wind River formation (fig. 66). At the localities where the formation can be observed in contact with the underlying Paleozoic and Mesozoic rocks there is a pronounced angular unconformity measuring as much as 60°. This is best seen along the east side of Horse

FIGURE 66.—View of lower Eocene rocks along north side of Wind River southeast of Dubois. Wind River flows along base of cliffs.

FIGURE 67.—Angular unconformity between Indian Meadows formation (Tim) and Chugwater formation (Ꞧc) on east side of Horse Creek, near junction of secs. 32 and 33, T. 43 N., R. 106 W., and secs. 4 and 5, T. 42 N., R. 106 W. Top of Spring Mountain on skyline at left.

Creek north of the EA ranch (fig. 67). The thickness varies greatly from one place to another, and no detailed section of the formation was measured. The maximum thickness is unknown because on the south edge of Spring Mountain the lower part is delimited by faulting and the upper part is poorly exposed, and because in the southeastern part of the mapped area the total stratigraphic interval represented by the formation could not be determined. The massive conglomerate beds attain an aggregate thickness of as much as 150 to 200 feet near the EA ranch and along the West Fork of the Du Noir River, but the thickness diminishes rapidly northward to a wedge edge as the formation laps up against the highlands along the south flank of the Washakie Range.

The strata assigned definitely to the Indian Meadows formation consist chiefly of red, crudely stratified to massive conglomerate overlain in some places, as on the south flank of Spring Mountain, by variegated fine-grained sandstone, siltstone, claystone, and shale. The conglomerate beds are hard and indurated and form massive cliffs throughout most of their area of outcrop. They consist chiefly of cobbles and subrounded boulders as much as 6 feet in diameter of Paleozoic sandstone, limestone, dolomite, and chert in a matrix of red and gray limy coarse-grained sandstone. No Precambrian rock fragments are in the exposures along the West Fork of the Du Noir River and on the south flank of Spring Mountain, and no volcanic material was observed. The lowermost Eocene rocks along the north sides of the Wind River and Wind Ridge fault, which probably belong to the Indian Meadows formation, consist of 10- to 20-foot beds of conglomerate interbedded with variegated fine-grained strata. These conglomerates are not so coarse as those that lie adjacent to the highlands of folded Paleozoic rocks to the north, and the boulders are not more than 2 feet in diameter. These conglomerates also contain fragments of deeply weathered granite, gneiss, and schist. At some localities along the north side of the Wind River these strata contain algal-ball limestone beds which are characteristic of the formation at the type section. Similar beds were observed at one locality on the south edge of Spring Mountain. These beds are gray and appear to be very conglomeratic, but they consist almost entirely of rounded masses of limestone as much as 2 inches in diameter. The limestone is arranged in concentric layers around a nucleus. A detailed study of these nuclei was not made by the writer, but Love (1939, p. 60) reported that they were commonly *Goniobasis* sp. (gastropod), clay balls, chert, limestone, arkose, shale, sandstone, and granite fragments.

The Indian Meadows strata probably formed during the active erosional period which followed the folding of the Washakie and Wind River Ranges. The red color, which characterizes much of the formation, is very similar to that of the Triassic Chugwater formation. Where the conglomerates are in direct contact with the Chugwater formation, as in the locality north of the EA ranch, the colors are identical. The Indian Meadows formation lies horizontally upon the upturned edges of the folded and eroded rocks of Paleozoic age along the West Fork of the Du Noir River and on both Paleozoic and Mesozoic rocks along the south flank of Spring Mountain. The formation has been involved in later thrust faulting in the southeastern part of the mapped area.

WIND RIVER FORMATION

The term Wind River formation is used throughout the Wind River Basin to include all the strata of early Eocene age except the Indian Meadows formation. A historical summary of its definition and application has been given by Tourtelot (1948, p. 114). In the northeastern part of the basin the Wind River formation is separated into two distinct lithologic and faunal units: the Lysite member at the base and the Lost Cabin member at the top (Tourtelot, 1948, p. 114–119). Faunally, the two members are differentiated by the presence or absence of *Lambdotherium*, which occurs only in the Lost Cabin member. *Lambdotherium*-bearing strata are present in the Du Noir area, but the presence of Lysite strata has not been substantiated.

The Wind River formation is the most widespread lithologic unit in the Du Noir area; it crops out extensively in the southern and central parts of the mapped area. Vertebrate fossils indicate that all the lower Eocene rocks west of Horse Creek belong in the formation. Wind River strata probably comprise the bulk of the lower Eocene rocks east of Horse Creek, but, as previously discussed, could not be differentiated from the finer grained facies of the Indian Meadows formation. The thickness of the Wind River formation varies considerably from one locality to another because of pronounced unconformities both at the base (where not in contact with the Indian Meadows formation) and at the top. The thickest section is in the central part of the area, where the formation crops out in an uninterrupted sequence from the Wind River north to the upper end of Little Horse Creek valley.

Five units were recognized within the formation: a lower variegated sequence, a greenish-gray and drab tuffaceous sequence, a middle variegated sequence, a conglomerate sequence, and an upper variegated sequence. The lower three units are the most widespread and are best exposed along Bench Creek where they are 1,618 feet thick. The units could not be mapped, however, because of the gradational nature of their contacts. A series of generalized sections, presented in figures 68 and 69, shows the writer's interpretation of the relationships between the different facies of the Wind River formation and the approximate positions of fossil collections.

The lower variegated sequence along Bench Creek is at least 554 feet thick, with the base concealed. West-

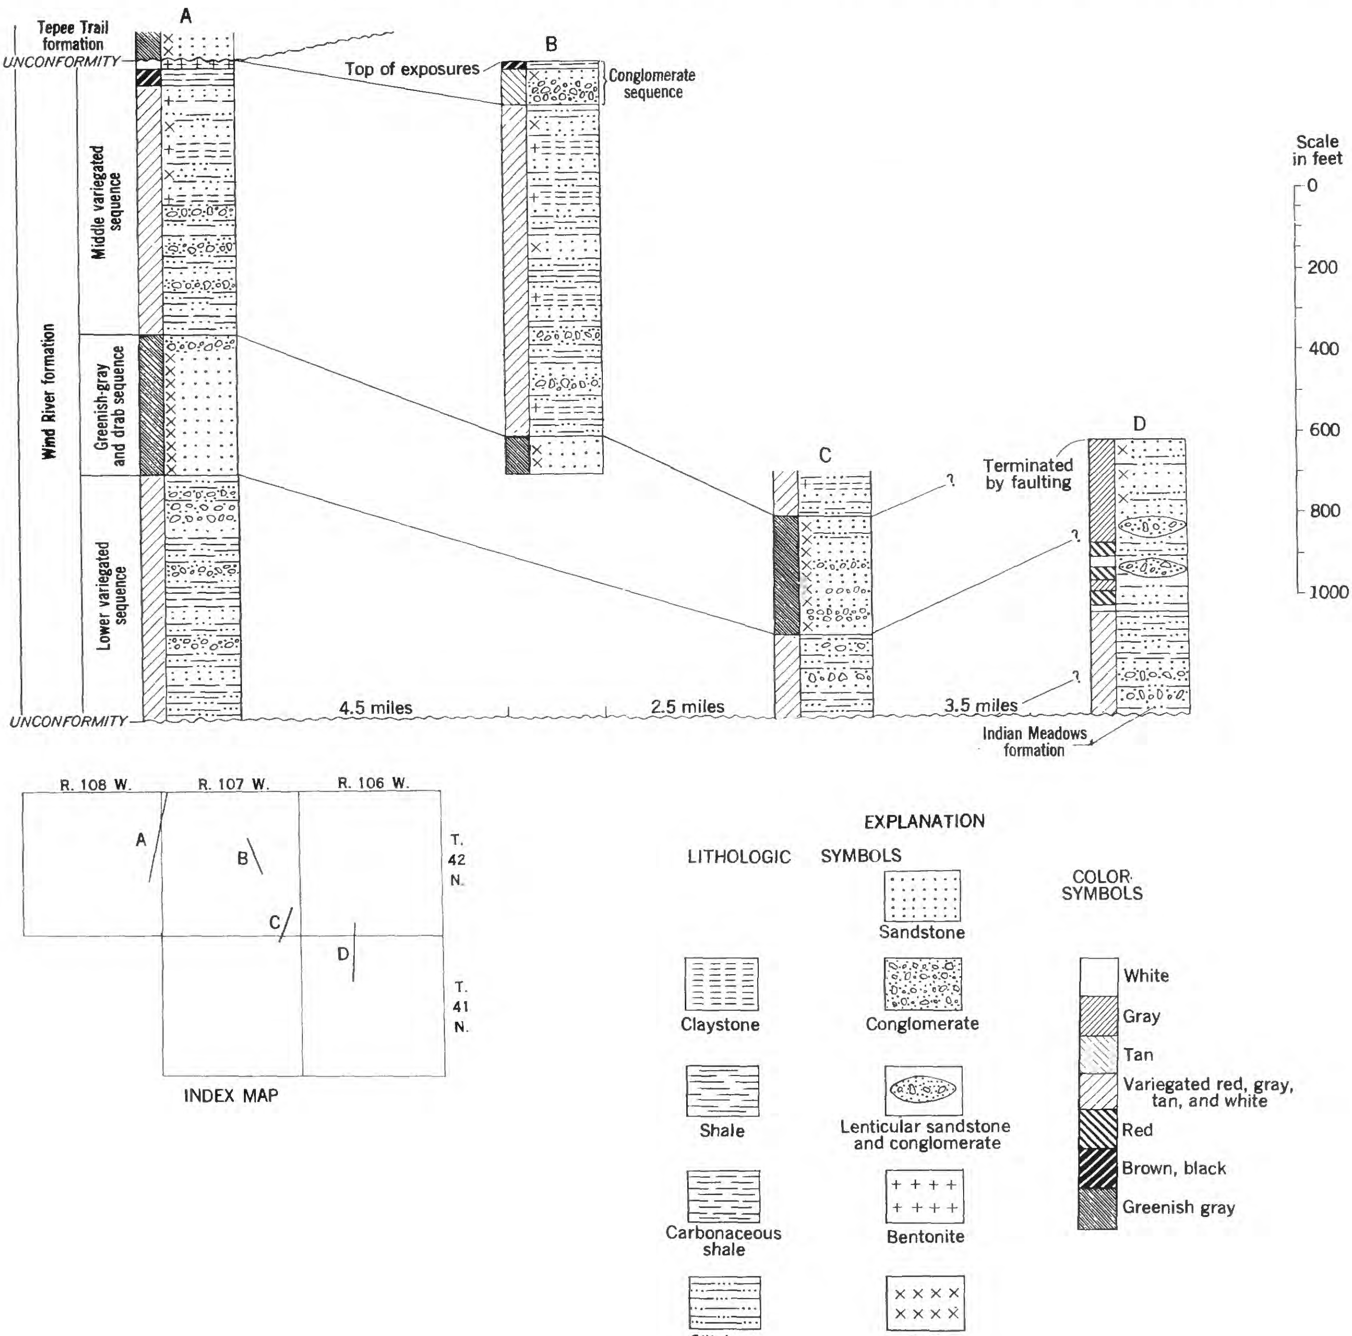

FIGURE 68.—Chart showing lateral variation of the Wind River formation.

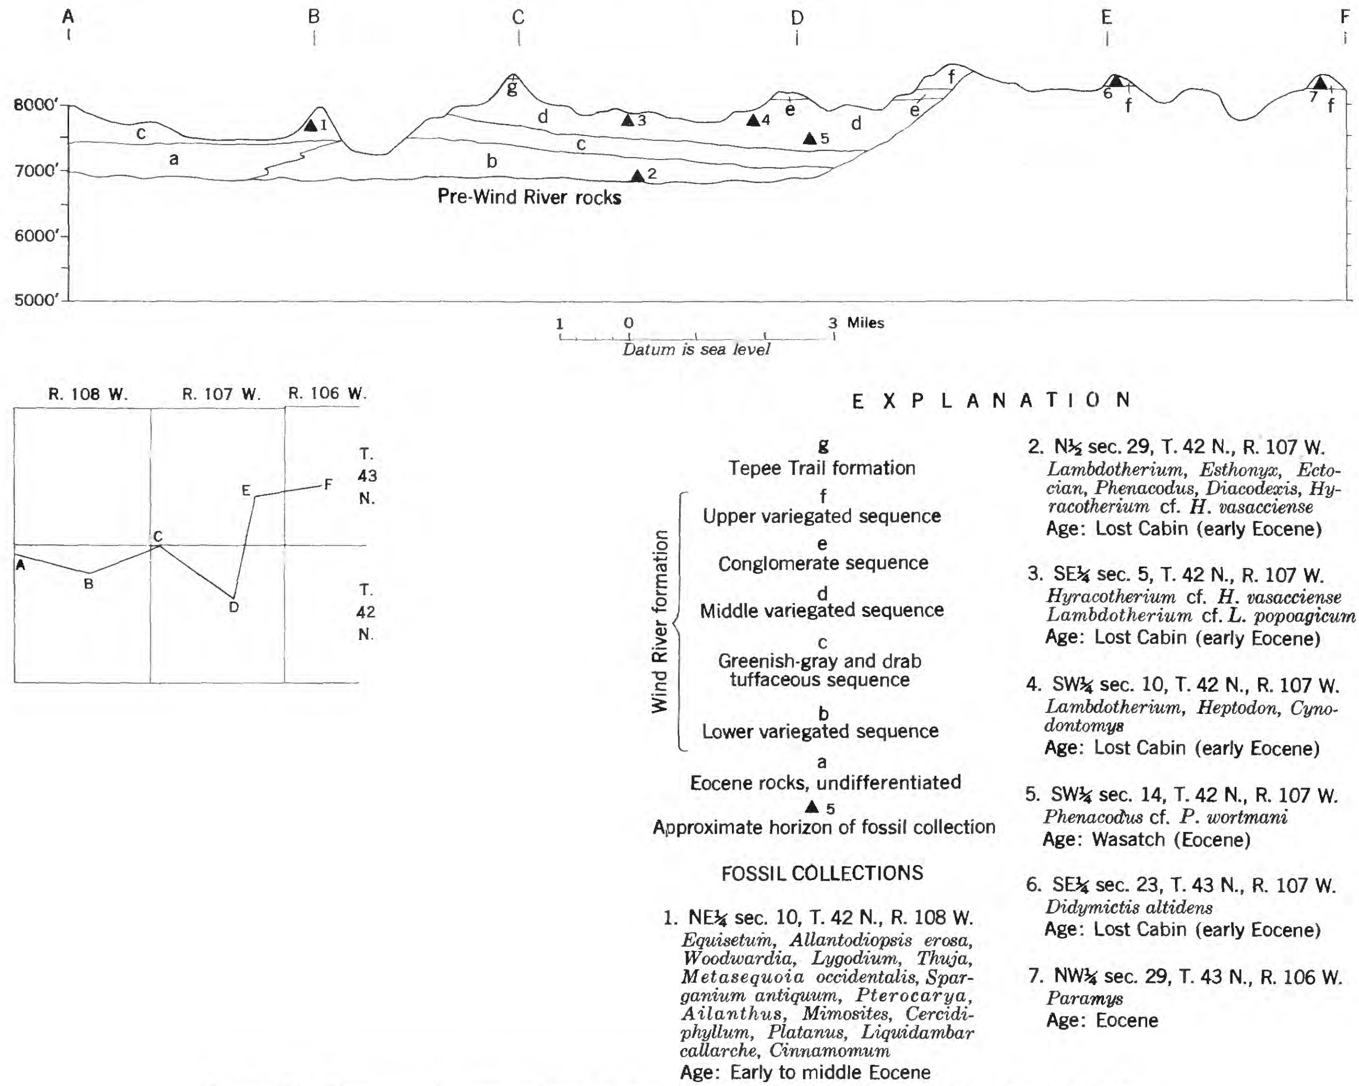

FIGURE 69.—Diagrammatic cross section showing apparent relations of facies of Wind River formation.

ward the thickness decreases to a wedge edge west of the mouth of the Du Noir River, where it apparently intertongues with arkosic facies of Eocene rocks, undifferentiated (fig. 69). Eastward the thickness varies considerably because of the pronounced basal unconformity. The lower variegated sequence, which forms conspicuous badlands, consists chiefly of red siltstone and shale, soft to hard buff fine-grained shaly sandstone, and white to buff cobble and pebble conglomerate. The conglomerate beds contain rounded fragments as much as 6 inches in diameter of rocks of Paleozoic age and a subordinate amount of Precambrian granite. Many of the shale and siltstone beds in the upper part are bentonitic and plastic. Just east of Stony Point, in the SW¼ sec. 19, T. 42 N., R. 107 W., the basal beds are chiefly tan and white arkose interbedded with minor amounts of gray and tan siltstone and brown carbonaceous shale with black coaly partings. The arkose is composed of coarse-grained to granule-sized angular fragments of quartz and feldspar with some dark grains in a fine-grained limy matrix. In a distance of a few hundred yards east of this locality the tan and gray beds grade into redbeds. It is interesting to note that this pronounced color change coincides closely with the base of the redbeds of the Chugwater as the trend of that formation is projected northwestward across the Wind River from the Harrison ranch, suggesting that much of the red sediment in the lower part of the Wind River formation was derived from the Chugwater formation.

The contact between the lower variegated sequence and the overlying greenish-gray and drab sequence is gradational. The interfingering between the two units can best be seen in the high hill on the east side of Bench Creek, NE¼ sec. 13, T. 42 N., R. 107 W. East of Horse Creek are some lenticular conglomeratic sandstone beds, which occur both in the upper part of the lower variegated sequence and the lower part of the greenish-gray and drab sequence making the contact between the two units difficult to determine. These sandstones may be channel deposits.

Vertebrate fossils identified by C. L. Gazin, were found at several localities in the lower variegated sequence. A Lost Cabin age for the basal part of the unit west of Horse Creek is indicated by a collection containing *Lambdotherium* (coll. 2, fig. 69) obtained in the N½ sec. 29, T. 42 N., R. 107 W. North of the 2N Ranch, S½ sec. 32, T. 41 N., R. 106 W., a lower jaw of *Hyracotherium* cf. *H. vasacciense* of possible Lost Cabin age was collected from the base of the lower variegated sequence, suggesting that the Indian Meadows formation is not represented at the base of the lower Eocene this far westward. The following fossils were collected from the top of the sequence in the SW¼ sec. 30, T. 42 N., R. 106 W., opposite the entrance to the Rocking Chair ranch: lower jaw close to *Paramys buccatus* Cope, maxilla with three teeth of *Hyracotherium* cf. *H. index* (Cope), and upper and lower jaws of *Hyopsodus*, close to *H. wortmani* Osborn. The latter suggests a Lost Cabin age as does *Hyracotherium* cf. *H. index* (Cope), which is found associated with *Lambdotherium* in the Green River Basin although it has been recorded from Gray Bull (lowermost Eocene) faunas in the Bighorn Basin as well.

The greenish-gray and drab tuffaceous sequence is well exposed in the high bluff on the north side of U. S. Highway 287 east of the Long Creek Inn and along both Bench and Long Creeks. It is 390 feet thick along Bench Creek, but it thins eastward to 290 feet north of Dubois in the SE¼ sec. 25, T. 42 N., R. 107 W. (fig. 69). Its stratigraphic thickness on the east side of Horse Creek (section *D*, fig. 68) could not be specifically determined because the upper part of the section is cut by faulting and the lower contact is not well defined. The unit consists chiefly of greenish-gray, gray, and olive-drab soft porous friable tuffaceous fine- to coarse-grained sandstone and minor amounts of shale, carbonaceous shale, and conglomerate. A thin-section study indicates that the sandstone contains much clayey material in addition to distinct grains of quartz, plagioclase, and biotite. Both the biotite, which occurs as euhedral hexagonal flakes readily observed in a hand specimen, and the feldspar are probably of volcanic origin but the quartz appears to have been derived largely from nonvolcanic sources. At the locality north of Dubois (section *C*, fig. 68; fig. 70) the unit contains some hard limy highly tuffaceous "cannonball" concretions as much as 4 feet in diameter. The conglomerate beds are 20 to 30 feet thick, commonly lenticular, and contain round stones of Precambrian quartzite, granite, and schist and Paleozoic limestone, sandstone, and chert as much as 6 inches in diameter as well as sporadic pebbles of volcanic rocks. The presence of quartzite fragments, some of which have pressure scars, is especially significant because they have not been observed in any other Tertiary conglomerate

FIGURE 70.—Exposures of a part of the Wind River formation in SE¼ sec. 25, T. 42 N., R. 107 W. (*A*, lower variegated sequence; *B*, greenish-gray and drab sequence; *C*, middle variegated sequence). Top of butte covered by a veneer of coarse gravels, representative of the Black Rock cycle of erosion.

on the north side of the Wind River. They occur in Eocene strata in some places south of the river, however. As far as is known this is also the lowest stratigraphic occurrence of volcanic pebbles in the Eocene rocks of the Du Noir area. Thin sections of these rocks were not obtained. Thin beds of carbonaceous shale and gray shale are present in the sequence at some localities, most notably along the north side of U. S. Highway 287 west of the Long Creek ranch. The contact between the greenish-gray and drab sequence and the middle variegated sequence is not well exposed and their relationships are not readily observed. It appears, however, that the contact is gradational and similar to that at the base of the greenish-gray and drab sequence.

Only one tooth fragment was found in the greenish-gray and drab sequence and it is not identifiable. There is, however, an abundance of well-preserved plant remains at many localities. A large and varied collection of fossil leaves (coll. 1, fig. 69) was obtained in the NE¼ sec. 10, T. 42 N., R. 108 W. Some of the forms were identified by R. W. Brown as follows: *Equisetum* sp., *Allantodiopsis erosa* (Lesquereux) Knowlton and Maxon, *Woodwardia* sp., *Lygodium* sp., *Thuja* sp., *Metasequoia occidentalis* (Newberry) Chaney, *Sparganium antiquum* (Newberry) Berry, *Pterocarya* sp., *Ailanthus* sp., *Mimosites* sp., *Cercidiphyllum* sp., *Platanus* sp., *Liquidambar callarche* Cockerell, and *Cinnamomum* sp. According to Brown (1954, oral communication) this flora is similar in many respects to that found near the middle of the Green River formation of Eocene age in northwestern Colorado and southwestern Wyoming. Another plant collection from approximately the same horizon by Dorf (1953) was interpreted by him to have close affinities with late Eocene to early Oligocene floras of the Pacific Coast region. However, the preponderance of both paleontologic and stratigraphic evidence favors a lower Eocene age (fig. 69).

The middle variegated sequence is best exposed in the high bluff along the north side of Tappan Creek westward from the Warnock ranch, and at White Pass. At the Bench Creek locality, where it is overlain by the Tepee Trail formation, the unit is 674 feet thick, but it thickens eastward to a maximum of about 800 feet (section *B*, fig. 68) in secs. 14, 15, and 23, T. 42 N., R. 107 W. Its total thickness east of Horse Creek could not be determined because of structural complications.

The sequence is characterized by bright red, purple, and gray bentonitic claystone and siltstone and white to gray tuffaceous sandstone and siltstone. The individual color bands are generally thicker and the claystones and siltstones more bentonitic than those in the lower variegated sequence. The lower 300 feet commonly contains 10- to 15-foot beds of sandstone and massive conglomerate with pebbles and cobbles of Paleozoic chert, limestone, and sandstone. The tuffaceous sandstone contains much biotite and is generally silty. In the high hill on the north side of White Pass the top 48 feet of the middle variegated sequence contains a 37-foot bed of brown carbonaceous shale with thin coal partings overlain by 11 feet of white bentonite and bentonitic claystone (section *A*, fig. 68). This highly bentonitic zone can be traced northeastward from White Pass for about 3 miles along the contact between the Wind River and Tepee Trail formations. The middle variegated sequence has been highly folded along the south flank of the Dubois anticlinal complex. Vertebrate fossils collected from about the middle of the unit at various localities along the north side of Tappan Creek indicate a Lost Cabin age (colls. 3 and 4, fig. 69).

In the central part of the mapped area, capping the high bluff on the north side of Tappan Creek and overlying the middle variegated sequence, is a 100-foot conglomerate, sandstone, and carbonaceous shale unit (section *B*, fig. 68). The lower 40 feet is a tan massive conglomerate with rounded to subrounded fragments as much as 6 feet in diameter. Rock types represented include limestone from the Gros Ventre, Gallatin, and Madison formations, sandstone and quartzite from the Flathead and Tensleep sandstones, dolomites from the Bighorn and Darby formations, and Precambrian granite, gneiss, and schist. The matrix is coarse grained and limy, with most of the grains angular. The overlying 40 feet consists mainly of tan fine- to coarse-grained limy sandstone with conspicuous grains of biotite and of minor amounts of gray claystone and brown carbonaceous shale. The upper 20 feet is brown carbonaceous shale with numerous black coal partings.

The conglomeratic sequence is also present on top of the Dubois anticlinal complex where it lies horizontally upon the folded Mesozoic rocks (fig. 71). These conglomerates can be distinguished from those in the Indian Meadows formation, which crop out farther east along Horse Creek, by their color and Precambrian rock content. Although the conglomeratic sequence lies conformably upon the middle variegated sequence along the north side of Tappan Creek, there is an unconformable relationship between the two in the vicinity of the Dubois anticlinal complex where the middle variegated sequence is involved in the folding and the conglomeratic sequence appears to be little disturbed. No fossils were collected from the latter unit.

FIGURE 71.—Angular unconformity between the conglomeratic sequence of the Wind River formation (Twdr) and Mowry (Km) and Frontier (Kf) formations on Dubois anticlinal complex in center of sec. 1, T. 42 N., R. 107 W.

The uppermost beds assigned to the Wind River formation occur in isolated outcrops at the upper end of Little Horse Creek valley and at the northwest end of Horse Creek Basin. These strata, constituting the upper variegated sequence, consist chiefly of gray, greenish-gray, and pale-red highly tuffaceous and bentonitic shale, claystone, siltstone and fine-grained sandstone. Much landsliding has occurred in these beds at the upper end of Little Horse Creek valley. The thickness varies considerably; it is at least 100 feet in the NW¼ sec. 20, T. 43 N., R. 106 W., where the sequence is overlain by the Wiggins formation. A few vertebrate teeth were collected from the upper variegated sequence (colls. 6 and 7, fig. 69). These include *Paramys* and *Didymictis altidens*. C. L. Gazin of the U. S. National Museum concludes that the latter is a Lost Cabin species.

In areas to the east the lower Eocene rocks are overlain by the middle Eocene Aycross formation (Love, 1939, p. 66–75) which is characterized by variegated clays, shales, sandstones, conglomerates, and volcanic rocks. This formation has not been specifically recognized in the Du Noir area because all the uppermost

The sequence consists chiefly of white to tan arkose and sandstone containing angular fragments of quartz and feldspar as much as one-fourth inch long and some dark grains. The beds are commonly limy. At several localities thin beds of carbonaceous shale with coal partings and tan siltstone and shale are interbedded with coarser grained strata. Coal beds, as much as 2 feet thick, are present in the NW¼ sec. 25, T. 42 N., R. 108 W., and have been mined in the past. A notable feature of the Eocene rocks, undifferentiated, is the almost complete absence of red beds that are so prominent in the Tertiary sequence on the north side of the Wind River. Some red strata mapped as Eocene rocks, undifferentiated, occur in an isolated outcrop on the steep dip slope of the Tensleep sandstone in the center of sec. 23, T. 42 N., R. 108 W.

The arkose beds are well exposed on the south side of Hat Butte. There they contain much volcanic material similar to that in both the lower part of the Tepee Trail formation and the middle drab sequence of the Wind River formation. Forming the prominent rim at the top of the butte is a 20-foot bed of brown slabby to crossbedded tuffaceous sandstone and conglomerate that is arkosic in part and contains fragments of chert and quartzite as much as 3 inches in diameter, in addition to smaller fragments of volcanic rocks. The principal constituents of the tuffaceous matrix include quartz, green-brown biotite, hornblende, plagioclase, and magnetite. One volcanic pebble contained an abundance of hornblende. The beds on top of the butte are finer grained and contain fragments of leaves and other organic material.

The relationships of the Eocene rocks, undifferentiated, to the thick sections of Eocene formations on the north side of the Wind River are not fully understood. The beds along the north side of Crooked Creek appear to underlie the middle drab sequence of the Wind River formation. The arkose beds at the base of that formation east of Stony Point are quite similar to those in the Eocene rocks, undifferentiated; both sequences also contain carbonaceous shale. The conglomerate with quartizite and volcanic pebbles near the top of Hat Butte is similar to the conglomerate which occurs at the base of the Tepee Trail formation along Long Creek, although the latter contains no quartzites, and also to the conglomerate near the top of the middle drab sequence of the Wind River formation on the east side of Bench Creek, in the SE¼ sec. 12, T. 42 N., R. 108 W., which contains both quartzite and volcanic fragments. The middle drab sequence of the Wind River formation also contains carbonaceous shale. It seems best, therefore, to correlate the major part of the Eocene rocks, undifferentiated, with the Wind River formation. The rocks with abundant volcanic pebbles may be equivalent to some part of the Tepee Trail formation, and the basal strata may represent some part of the Indian Meadows formation.

OLIGOCENE SERIES

WIGGINS FORMATION

The Wiggins formation includes the youngest Tertiary rocks in the Du Noir area and forms the spectacular scarps which outline the southern margin of the Absaroka Range (fig. 72). Based on a study of the vertebrate fossils the unit, named by Love (1939, p. 79) from the Wiggins Fork River, was assigned an Oligocene age (Love, 1956, p. 88).

In the Du Noir area the Wiggins formation is more than 1,000 feet thick and is composed of flat-lying massive volcanic conglomerates and breccia with volcanic rock fragments as much as 3 feet in diameter, interbedded with fine-grained tuffs. The volcanic rock is commonly dark whereas the matrix is mainly pink, gray, and white and contrasts sharply with the underlying dark-green strata of the Tepee Trail formation. The tuff is generally of lighter color than the conglomerate so that the alternation of tuff and con-

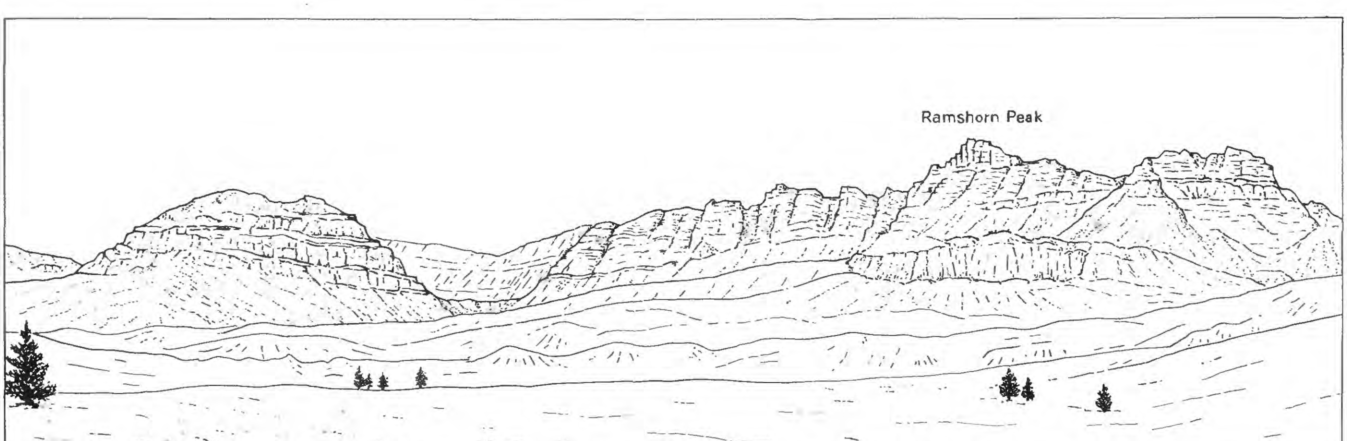

FIGURE 72.—The Ramshorn as viewed from the SW¼ sec. 24, T. 43 N., R. 108 W. Ramshorn Peak is highest point on skyline near right side of sketch. Wiggins formation forms massive cliffs and Tepee Trail sediments form rounded hills beneath.

glomerate produces the pronounced stratified appearance of the sequence. No flows were observed in the Du Noir area, but Love (1939, p. 80) noted some flows near the top of the formation in areas to the east.

A detailed stratigraphic section of the Wiggins formation was not measured, but thin sections of representative volcanic pebbles and tuff from different horizons were examined. The volcanic rocks are predominantly rich in pyroxenes, both augite and hypersthene, and, except for the red pebbles which have an abundance of red-brown hornblende, contain little or no hornblende and biotite. Plagioclase phenocrysts average about Ab_{45}. Olivine is common and magnetite is invariably present. An appreciable amount of what may be a feldspathoid mineral was observed in one pebble. The groundmass of most thin sections is microcrystalline and probably contains some glass. The tuff contains both lithic and crystal fragments and those near the base have a small amount of quartz which was probably derived from nonvolcanic sources.

The volcanic rocks described above differ from those noted by Love (1939, p. 81) to be characteristic of the type section a few miles to the east. There the rocks are commonly rich in biotite and hornblende, and the plagioclase is andesine in about 80 percent of the thin sections studied by Love. Enough data were not obtained in the present study to offer a suitable explanation for this variance in composition of the rocks between the Du Noir area and the type section. In general it would be expected that all the volcanic vents in a given area at a given time would have a common magmatic source but too little is yet known of possible source areas for the volcanic material in the Wiggins to draw any definite conclusions on this point.

Love (1939, p. 110–111) observed that some of the volcanic debris in the Wiggins formation was derived from small localized vents along the southern margin of the Absaroka Range, but suggested that the greater part came from "a great chain of tremendously active volcanos [which] must have extended from this area northwestward to Yellowstone National Park" as indicated by a thickening of the volcanic conglomerates to the north and northwest as well as an increase in the size and angularity of individual boulders. Hague and others (1899) have described large volcanic centers along the eastern margin of Yellowstone Park. The writer agrees that a larger source than small local vents must have existed because of the vast quantities of volcanic detritus involved.

QUATERNARY SYSTEM

Several kinds of Quaternary deposits, including moraines, landslide debris, terrace gravel, residual basalt debris, colluvium, travertine, and alluvium, are present in the Du Noir area. A detailed study of many of these deposits and their related physiographic features was made as an aid in the interpretation of the Quaternary history of other parts of the Wind River Basin. Further, since in this region the Wind River and Absaroka Ranges are in close proximity, an excellent opportunity is afforded for correlation of the glacial and erosional cycles of the two ranges. Although many of the deposits are composed of similar materials, there are sufficient differences in occurrence and terrain to distinguish one source from another in most places.

RESIDUAL BASALT DEBRIS

Extensive areas on Spring Mountain are covered by a deposit of angular boulders and cobbles, which is referred to as residual basalt debris (fig. 73). The debris consists almost entirely of blocks of dark-brown to black very hard basalt as much as 8 to 10 feet on a side and is unlike any of the debris derived from the Wiggins formation. The rock is commonly vesicular and consists mostly of small crystals of labradorite with a moderate amount of olivine and a minor amount of pyroxene. Excellent flow structure is exhibited in thin section. The basalt is not perceptibly weathered and this, in addition to the extreme angularity of the individual fragments, suggests that the rock was derived from a volcanic sequence younger than either the Tepee Trail or Wiggins formations, and that the blocks have been subjected to very little transport. Although the deposit is only a few feet thick, the blocks are sufficiently numerous to conceal effectively the underlying bedrock in most places. The basalt blocks are present at elevations ranging from about 8,600 feet near the top of Spring Mountain to about 7,500 feet along the north side of Little Alkali Creek; the occurrences at lower elevations

FIGURE 73.—Angular blocks of basalt on southwest flank of Spring Mountain, NE¼ sec. 22, T. 42 N., R. 106 W.

One of the most spectacular mudflows in the region occurs north of the junction of secs. 28 and 29, T. 43 N., R. 107 W., near the center of the mapped area. This flow is confined to a narrow valley and is about three-fourths of a mile long. The debris originated in the high cliff at the upper end of the flow and moved down a slope inclined at not more than 15° in some places.

The large earthflow on the southwest side of Horse Creek near the Livingston ranch involves mostly Mesozoic rocks, although the Indian Meadows formation, which crops out near the top of the ridge along the south edge of the flow, contributed some of the debris. The conspicuous red sediments in the debris were derived largely from the Triassic Chugwater formation which underlies the area. High relief was the primary cause of the flow. In some places along its upper, or south, edge small mudflows have developed in the plastic claystone of the Cloverly and Morrison formations. Numerous small lakes and ponds are present in the hummocky terrain. Some of the material in this deposit may have originated as glacial debris, inasmuch as glacial deposits occur at the same level in adjacent localities to the northwest along Horse Creek.

One of the most extensive and clearly outlined earthflows in the mapped area descends northward from the north end of Table Mountain (figs. 74 and 75). The flow originated near the top of the mountain in soft bentonitic strata of the Wind River formation. Some of the movement may have approximated that of a mudflow. The northern edge of the flow rises about 10 feet above the smooth slopes to the north and the material advances down these slopes without any apparent disturbance of the underlying rocks.

Many of the small local slides and flows, except those of special interest, have not been specifically mentioned in the foregoing discussion, since they are so very numerous. Most of them are slumps and debris-slides which occur on steep slopes along the edges of steep hills and cliffs, very similar to those that have already been described. Accumulations of talus debris are common along the escarpments which outline the southern margin of the Absaroka Range, but none of these have been shown on the geologic map.

FIGURE 74.—Mudflow at north end of Table Mountain.

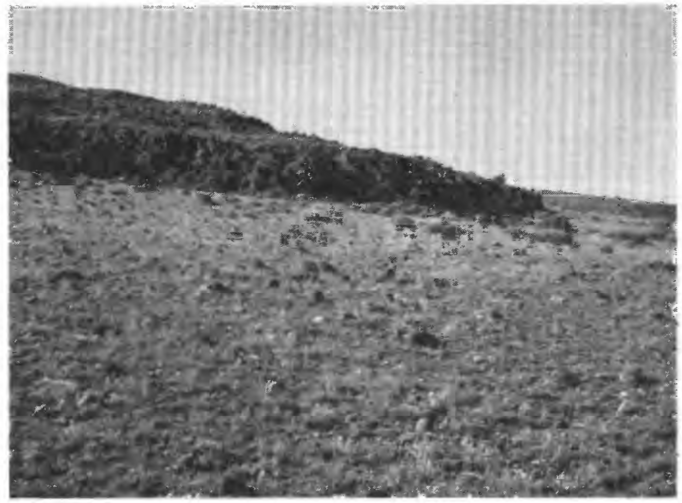

FIGURE 75.—View of front edge of mudflow shown in figure 74. Outermost margin about 10 feet high.

TERRACE DEPOSITS AND COLLUVIUM

Seven levels of terrace deposits, classified according to their respective heights above the present stream drainages, have been distinguished in the Du Noir area. A detailed study of these deposits reveals a complex erosional history for the northwestern part of the Wind River Basin. Inasmuch as the terraces are closely related to glacial features, the detailed descriptions and correlations of the various terraces are given under "Geomorphology."

The term "colluvium" is used in this report to designate gravels which have been let down on the steep slopes which separate major terrace levels. The material is derived from the terrace deposit next above it and has moved downhill by gravity. Deposits of colluvium commonly only a few feet thick were mapped only where the underlying bedrock was completely obscured over wide areas.

TRAVERTINE

Deposits of travertine occur near the mouth of Warm Spring Creek and in the NW¼ sec. 23, T. 42 N., R. 108 W. The travertine is very porous and contains much silty material. In places along Warm Spring Creek much bouldery debris, with some rock fragments as much as 3 feet in diameter, are incorporated in the deposits. Many travertine outcrops also occur near the south (upper) edge of the conspicuous terrace which lies south of the Wind River and east of Warm Spring Creek. Enough data were not obtained within the mapped area to explain adequately the origin of these deposits. In some places it appears that they coincide closely with the contact between the Tensleep and Phosphoria formations. Their nearly linear pattern is suggestive also of fault control, but no faults are present at least west of Warm Spring Creek. That the travertine is closely associated with the development of the prominent terrace level on the south side of the Wind River is clearly evident from the fact that the gravels in the terrace contain much carbonate material which has cemented the terrace deposit into a massive conglomerate. Such an occurrence was observed in the center of W½ sec. 1, T. 41 N., R. 107 W., at the west end of the terrace upon which the Dubois airport was constructed. To the southeast J. F. Murphy (1953, oral communication) found tuffaceous material in travertine deposits. None was observed in the mapped area, but it may be present in small amounts.

ALLUVIUM

Alluvial deposits, which form relatively wide belts along most of the major streams, consist chiefly of gravel, sand, and silt. In the Du Noir valley large alluvial fans, consisting of coarse gravels, have spread valleyward from the mouths of Fivemile and Sixmile Creeks and the East and West Forks of the Du Noir River. In part, the alluvial material has been derived from slope wash of the adjacent steep valley walls; consequently most of the deposits are red because of a partial source in the lower Eocene rocks. In the Du Noir valley, however, the soil has been extensively modified and reworked by the meandering of the Du Noir River and is commonly very dark in color because of the large amount of organic material in it. Unlike the other major streams in the area the Wiggins Fork River, bounded in most places by steep canyon walls, flows through a channel that is entirely covered by coarse boulder and cobble debris. The course of the stream is continuously being changed by the slight shifting of gravels from one place to another within the channel.

IGNEOUS ROCKS

DIKES

The only dike observed in the mapped area occurs near the center of sec. 20, T. 43 N., R. 106 W., cutting vertically through strata in the uppermost part of the Wind River formation. The dike is from 1 to 3 feet thick and crops out for a distance of about 100 feet. The rock is dark green in the center, but it becomes lighter colored and in places red along its outer margin. Thin sections of the rock were not studied, but it appears similar to some of the basalts studied from the Tertiary volcanic conglomerate sequence. It is slightly vesicular, suggesting that the present exposed part of the dike was near the surface at the time of the emplacement of the dike. The significance of this intrusive is not known. Perhaps it represents a small feeder dike for some of the volcanic material in the Wiggins formation and, as such, may be associated with a local vent that now lies buried under the conglomerates of the Wiggins formation of Elkhorn Ridge. On the contrary, the dike may have been emplaced later and is related to the basalt which forms the surficial deposit on Spring Mountain, although none of this residual basalt debris occurs in the vicinity.

STRUCTURE

The Du Noir area is comprised essentially of three major structural divisions: the northeast flank of the Wind River Range on the south, an intervening synclinal basin thought to be a northwestern extension of the Wind River Basin, and the Washakie Range on the north (fig. 76). The relationships between the folds

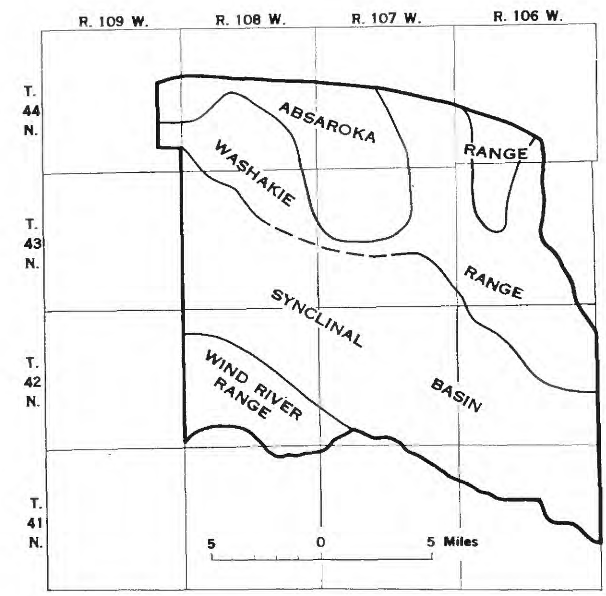

FIGURE 76.—Sketch map showing major structural divisions of the Du Noir area.

and faults in the mapped area to those of adjacent areas are shown in figure 77. No structure is apparent in the Tertiary volcanic rocks along the southern margin of the Absaroka Range, which is an erosional remnant and will not be considered in the following discussion on the structural geology of the region.

The trend of the structural features throughout most of the mapped area is approximately N. 45° W., but in the western part it is more westerly. The most intense folding and faulting has occurred along the south edge of the Washakie Range and in the northern portion of the synclinal basin. Elsewhere, as along the flank of the Wind River Range and in the Du Noir anticline, folding has been more gentle and few faults are present. Asymmetric anticlinal folds have their

River formation along the north side of Sixmile Creek (E½ sec. 15, T. 43 N., R. 108 W.) which may reflect renewed uplift of the Du Noir anticline. However, movement of this fold after early Eocene time is not reflected in the Indian Meadows formation along the West Fork of the Du Noir River so that the inclination of the beds of the Wind River formation may be the result of slumping which is very prevalent in that area. Inasmuch as the lower Eocene rocks rest with marked angular discordance on the Paleozoic and Mesozoic rocks in the southern part of the mapped area as well as in other areas, much pre-Eocene deformation is indicated and the center of the basin may therefore contain broad anticlinal and synclinal folds that are not reflected in the Tertiary strata.

Outcrops of Mesozoic rocks at Dubois and along Horse Creek and Little Horse Creek provide enough data to determine the major structural elements in the central part of the basin. In this part of the basin there are two large synclines separated by the Dubois anticlinal complex (cross section *C—C''''*, pl. 26). Enough data are not available, however, to indicate the structural relief of either syncline, but both are believed to be of major proportions.

The southernmost syncline, which forms approximately the south half of the basin, is hypothetically shown on cross section *C—C'* (pl. 26). At Dubois, northward dips in the Mesozoic strata range from 10° to 15°. The dips in the Mesozoic rocks along the south limb of the Dubois anticlinal complex are 35° southward, but they may steepen considerably at depth, producing much more asymmetry than is shown in the cross section. Geophysical data suggest that the Little Alkali Creek fault extends westward from Horse Creek along the south edge of the anticline. This extension has not been confirmed by drilling and has not been shown on the cross section. Broad flexures in the lower Eocene rocks northeast of Dubois, south of the Wind Ridge fault, lead to the conclusion that there is folding or faulting in the center of the syncline.

The Dubois anticlinal complex is so designated because it consists of several anticlines and synclines superimposed on a large anticlinal uplift. Only the eastern part of the structure is visible on the surface; the western extension is covered by Tertiary strata. The total structural relief between the crest of the fold and the troughs of the adjacent synclines could not be determined accurately; it may be as much as 4,000 to 5,000 feet. Oil is produced from the Phosphoria formation in the Sinclair-Wyoming Oil Co. Dubois Unit well 1 which is on a small independent closure as shown on plate 27. The anticlinal complex is asymmetric to the southwest and, as previously discussed, may be much more asymmetric than is shown on the accompanying cross sections, or even faulted. The small subsidiary folds plunge to the southeast, as does the structure as a whole. Data are not available to indicate whether the anticline plunges to the northwest as well. The oldest strata exposed on the anticline are in the upper part of the "lower Sundance."

The southwest flank of the anticlinal complex was intensely deformed. At least 5 small folds, 3 anticlines and 2 synclines, and 3 thrust faults as well as numerous cross faults and abundant fractures are present. Plate 27 is an enlarged geologic map of this area. The southwest flanks of the anticlines are commonly overturned, but this feature may become less pronounced at depth although the beds are still vertical to overturned in the bottom of the Dubois Unit well 1. The northernmost thrust faults are best exposed on the west side of Little Horse Creek, whereas on the east side of the creek their traces are largely obscured by landslide debris. Both faults have little stratigraphic displacement and involve Morrison and Cloverly strata for the most part. The northern fault places both "lower" and "upper Sundance" upon beds of the Morrison and Cloverly formations in the vicinity of the Dubois Unit well 1, but passes eastward into a small sharp asymmetric anticline. At the west end of the southern fault the Fort Union(?) formation appears to have been faulted over Mowry shale. Eastward along this fault the lower part of the Morrison and Cloverly sequence, rusty beds, and Thermopolis shale are involved. On the west side of Little Horse Creek the plane of the northern fault dips northward about 30°, yet no evidence was found in an electric-log study of the two wells to indicate that faulting had occurred so near the surface in either well. As is suggested in cross sections *A—A'—A''* and *B—B'* (pl. 27) the faults probably become bedding-plane faults; in this case, it would be difficult to detect faulting from the electric logs, and the faults could be much more extensive than shown on the cross sections. There is also the possibility that the two faults may come together at depth, forming one large bedding-plane fault. The presence of an extensive but shallow thrust here could account, at least partly, for the intense folding along the crest of the anticlinal complex.

From available evidence it could not be definitely determined whether any faults are present near the bottom of the Dubois Unit well 1. Only a small part of the Tensleep appears to have been encountered and the structure can be interpreted as being that of an overturned anticline rather than that of a fault (cross section *A—A'—A''*). If a fault is present between the crest of the fold and the bottom of the well, the displacement is slight. However, in following the structural pattern of many of the large anticlines in this region, it is highly probable that the Dubois anticlinal complex is faulted somewhere along its southwest flank, the fault plane being below the bottom of the Dubois well 1. Either the Wind Ridge or Little Alkali Creek faults could extend underneath the complex, but, because of the almost complete lack of subsurface information, such an interpretation has not been presented on cross section *C—C′—C″* or by structure contours.

Another small thrust fault is present at the extreme southeast end of the structure where Mowry shale has been faulted upon beds of the Fort Union (?) formation, which have been sharply infolded along with the Mowry shale directly on the south side of the fault (fig. 65). This fault apparently passes into an overturned syncline to the northwest, but the relationships in the Mowry shale are quite obscure. Tertiary strata are involved in this fault at its extreme eastern end. Only the larger cross faults could be shown on the geologic map; most are normal faults with only slight displacement. Many of the smaller cross faults, which are most conspicuous in the basal white sandstone of the rusty beds, show only lateral movement.

At least two anticlines are present on the north flank of the Dubois anticlinal complex, one along Brent Creek in sec. 26, T. 43 N., R. 107 W. (cross section *B—B′*, pl. 26), and the other southeast of the EA ranch in secs. 8, 9, and 16, T. 42 N., R. 106 W. (cross section *D—D′*, pl. 26). Both are moderately symmetrical and plunge to the southeast. Structure contours on the top of the "upper Sundance" show the writer's interpretation of the relationships of these folds to the main anticlinal structure. Mowry shale is the lowest exposed formation in the fold along Brent Creek, where outcrops are exceedingly poor because of a large amount of landslide material and forest cover. Only the eastern end of the fold is exposed, so that its overall extent and value as a potential oil trap could not be determined. It trends nearly east-west and plunges about 30° eastward. Structural relief between the crest of the anticline and the trough of the adjacent syncline to the north is about 1,500 feet.

The structural relationships of the anticline southeast of the EA ranch are also very obscure. Evidence for the fold is found in the limited exposures of the Cody shale along the east edge of Horse Creek valley. A small outcrop of sandstone and shale, which, because of the presence of sandstone, is at least 1,200 to 1,300 feet stratigraphically above the base of the Cody shale, on the section line between secs. 8 and 9, T. 42 N., R. 106 W., has a northeastward dip of 42°. Southerly dips were obtained in the Cody shale in the vicinity of the junction of secs. 8, 9, 16 and 17. The fold, which plunges eastward, is probably cut at depth by the Little Alkali Creek fault. Its western extent could not be determined; therefore its actual structural relationship to the main anticlinal complex is not known. The syncline adjacent to this fold on the south is well defined in the Indian Meadows formation which overlies the Cody shale in that area.

East of Horse Creek the lower Eocene rocks have, in places, been highly deformed (cross section *E—E′*, pl. 26) in front of low-angle thrust faults. Although no large folds are present in the Tertiary strata, the thrust-fault belt of deformation falls in direct line with the Dubois anticlinal complex. The Wind Ridge fault, mapped and described by Love (1939, p. 95–96), extends northwest from the eastern margin of the mapped area along the south edge of Table Mountain to Horse Creek. No traces of the fault were found west of Horse Creek. The Wind Ridge fault plane is well exposed at many localities (fig. 78). In the SW¼

FIGURE 78.—Wind Ridge fault, SW¼ sec. 34, T. 42 N., R. 106 W. Beds above fault are massive conglomerates of Indian Meadows formation; those below are soft variegated beds of Wind River formation.

sec. 34, T. 42 N., R. 106 W., the dip of the fault plane is 23° north. Southeast of the road that leads from Dubois to Little Alkali Creek massive conglomerate in the Indian Meadows formation is thrust over soft variegated beds of the Wind River formation, whereas northwest of the road fine-grained variegated beds of either the Wind River or Indian Meadows formations occupy the overriding block. This change in stratigraphic horizon is caused by progressively younger beds swinging around the northwest-plunging end of a small anticline on the north side of the fault. This fold is well developed for a mile or more on each side of the road, but at its southeast end it dies out into sharp drag dips along the fault. As the fold has little structural relief and is closely associated with drag folding, it is probably confined to the overriding block.

The thrust fault which passes near the Wind River triangulation station on the eastern edge of the area could not be traced west of Table Mountain. Along this fault Cody shale has, in places, been thrust over Indian Meadows strata.

poraneous, but with different sources of debris, one from the Horse Creek-Tappan Creek drainage basin and the other from the upper Wind River drainage basin.

CIRCLE CYCLE

The Circle cycle of erosion is represented in the Du Noir area by terrace levels that are from 100 to 300 feet above the present drainage. It is evident that two or more subcycles occur within the major cycle, however.

Along the Wiggins Fork River, near the mouth of Little Alkali Creek, are two distinct levels, 100 feet and 200 feet, respectively, above the present river channel. The type area for the Circle terraces is a few miles downstream from Little Alkali Creek along the North Fork of the Wind River where Blackwelder (1915, p. 316) described only one prominent level standing about 150 feet above the river. The terraces near the mouth of Alkali Creek are covered by a thin veneer of unconsolidated gravels underlain for the most part by conglomerate of the Indian Meadows formation from which most of the Paleozoic rock fragments in the deposits were derived. The uppermost deposit is comprised of 75 percent volcanic, 5 percent Precambrian, and 20 percent Paleozoic rock fragments. The lower terrace contains only 10 percent volcanic rocks, with the remainder equally divided between Paleozoic and Precambrian rocks. In contrast, the present riverbed is almost wholly comprised of volcanic debris.

On the south side of the Wind River, extending southeastward from Stony Point, the Circle cycle of erosion is represented by a well-developed series of terraces which lie 150 to 250 feet above the river. Only the western end of this series is within the mapped area. All traces of the terraces have been erased from the north side of the river except for those at Stony Point and the surface upon which the Dubois airport was constructed. Although the detailed relationships between this terrace building and the warm-spring activity along the south side of the Wind River southeast of the Harrison ranch were not worked out, it is clearly evident that the two were closely related.

Southwest of the Harrison ranch, NW¼ sec. 32, T. 42 N., R. 107 W., the gravel consists chiefly of Precambrian quartzites and granites with a minor amount of volcanic and Paleozoic rocks, indicating that most of the material at this point was derived from the Warm Spring Creek drainage area. On the whole, however, where the deposits were not appreciably affected by debris from local tributary streams but were derived chiefly from the drainage basin of the master stream, they contain a large proportion of volcanic rocks. In a cut along the road leading from U. S. Highway 287 to the Dubois airport the gravels are nearly 90 percent volcanic with Paleozoic rocks comprising the remainder. About a quarter of a mile westward, at the west end of this terrace remnant and lying about 60 feet lower than the level of the airport, is a small outcrop of terrace gravel which has been cemented into a conglomerate by carbonate material that was derived from the warm-spring activity farther upstream. This conglomerate, which is comprised chiefly of volcanic rocks and some Paleozoic and Precambrian rock fragments, is at the same level as those directly opposite on the south side of the river which bevel the upturned redbeds in the Chugwater formation. Further evidence of cementation of the terrace gravels by travertine is present around the mouth of Warm Spring Creek where the conspicuous travertine deposits have incorporated many pebbles and cobbles. No distinct terrace levels were observed north of Dubois along Horse Creek, but some of the gently inclined gravel-capped slopes along the east side of the creek, the lower ends of which are about 200 feet above the present valley floor, may be representative of the Circle cycle of erosion.

The broad benchland north of Stony Point is also considered to be a remnant of the Circle terrace, although it occurs about 300 feet above the Wind River, slightly higher than the terraces across the river and farther downstream toward Dubois (fig. 79). Core-drill data obtained from the U. S. Bureau of Reclamation indicate that the gravel underlying this surface is about 200 feet thick near the south end of the terrace. It consists of boulders and cobbles and much sand and silt. Clayey material near the base may have been reworked from the Wind River formation or may have been deposited by ponded glacial melt water. Rounded fragments of volcanic rocks constitute about 80 percent of the debris, and Paleozoic rock fragments make up the remainder. The gradual increase in altitude of the surface northward changes to an abrupt steepening at the north end of the terrace. The slope at the north end contains volcanic cobbles as much as 40 feet above the terrace surface. Paleozoic rock fragments occur farther up the slope and are probably residual gravels derived from underlying conglomerate in the Wind River formation. Because of the thickness of this deposit at Stony Point true terrace deposits probably constitute only the upper few feet of the gravels with the remainder originating as glacial debris. Another terrace level, only 135 feet above the Wind River, is present at Stony Point (fig. 79). This surface contains very little detrital material and is essentially one of erosion.

Two distinct terraces were developed along Warm Spring Creek near the abandoned Du Noir tie camp. The upper level is 130 feet above the present stream channel and may represent a mountainward extension of the Circle terrace, whereas the lower level, 70 feet above the creek, does not apparently represent either the Circle cycle or the younger Lenore cycle. The gravels in the upper deposit consist chiefly of well-rounded cobbles of Precambrian quartzite and a very minor amount of volcanic rock fragments. The deposit is best exposed along the road on the north side of Warm Spring Creek. Along the south edge of this upper terrace the gravel is 10 feet thick and is underlain by arkose and soft gray clay shale of the Eocene rocks, undifferentiated. From here northward steep slopes descend into the drainage basin of Crooked Creek, and the tablelike surface forms the drainage divide between Crooked Creek and Warm Spring Creek in this area. The lower terrace deposits contain a conspicuous amount of granite cobbles in addition to a minor amount of Paleozoic and volcanic rock fragments. Along the north bank of the creek, SW¼ sec. 28, T. 42 N., R. 108 W., is a small outcrop of Tertiary arkose, indicating that the entire series of terraces is underlain by Eocene rocks, undifferentiated. According to J. D. Love (1953, oral communication), Eocene rocks on the Continental Divide, in the vicinity of Fish Lake Mountain near the headwaters of Warm Spring Creek, contain conglomerate with fragments of both quartzite and volcanic rocks. C. L. Baker (1946, p. 581) reports quartzite boulder beds resting on Precambrian rocks 4 miles south of the Du Noir tie camp. These strata would provide a ready source for the material in the terrace deposits. The two terrace levels probably represent successive stages in the downcutting of lower Warm Spring Canyon. Evidence is too fragmentary to attempt a specific correlation of these terraces with those near the mouth of Warm Spring Creek.

LENORE CYCLE

Remnants of the Lenore terrace occur west of the Harrison ranch on the south side of the Wind River, both east and west of Stony Point on the north side of the river (fig. 79) and in the broad alluvial plain near the confluence of the Wind and Du Noir Rivers. These terraces range in elevation from 15 to 35 feet above the present Wind River channel. The deposits are generally finer grained than the older Circle deposits, but, as in the majority of the Circle terraces, volcanic rocks are the dominant constituents. There are two distinct levels downstream from Stony Point; the lower and most conspicuous one is 25 feet above the river and the other is 10 feet higher. The Lenore Plain is probably also represented by the relatively broad alluvial-covered surfaces extending along the north side of the Wind River from Stony Point to the southeast corner of the mapped area, but, because these surfaces are covered largely by locally derived material from the easily eroded Tertiary strata, they have been mapped as alluvium.

POSTGLACIAL EROSION

Downstream from Stony Point the Wind River has become entrenched 20 feet or more below the level of the terraces of the Lenore cycle of erosion. The present flood plains are relatively narrow. Upstream from Stony Point, however, the flood plain becomes very broad and flat and remains so throughout the Du Noir River valley. The Wind River near the western edge of the mapped area is again confined to a relatively narrow steep-walled valley. South of the mouth of the Du Noir River the remnants of the Lenore terrace rise 10 to 15 feet above the present flood plain.

The Du Noir River valley is unique in that it is the only one within the mapped area in which a continuous broad and flat flood plain has been developed during the postglacial period. The alluvium consists chiefly of clay and silt with a large amount of organic material. Miner and Delo (1943, p. 137) concluded that the flat floor of the valley was once the bottom of a large lake, 300 feet deep, that was ponded behind glacial moraines of the Pinedale stage of glaciation which had completely blocked the mouth of the valley, and that the sediments lying in the valley originated as lake silt. The writer did not find evidence to support this conclusion; a more detailed appraisal of this possibility, however, is presented in the discussion on glaciation.

An alternative explanation for the development of the flat-floored valley and the one favored by the writer, is that of lateral planation by the Du Noir River. The local base level of the combined drainage of the Wind and Du Noir Rivers is the narrow gap at Stony Point through which the Wind River now flows (fig. 79).

FIGURE 79.—View looking east toward Stony Point. Wind River flows through gap near right side of picture. Terrace in foreground is representative of Lenore cycle of erosion, whereas those on skyline at the center and left side of photograph are two different levels of the Circle cycle.

The gap is cut in resistant Tensleep sandstone, and limestone and chert of the Phosphoria formation, whereas the valleys of the Wind and Du Noir Rivers upstream from Stony Point are eroded in soft Tertiary strata. The rate of downcutting of the flat-floored valley is directly controlled by the rate of downcutting at Stony Point. As the Tertiary rocks are much more easily eroded, the Du Noir River has reached a temporary grade controlled by the stream level at Stony Point and its erosive power has since been directed toward lateral planation of the valley. North of the Cross ranch the river has been crowded to the west side of the valley by the large alluvial fan developed around the mouth of Sixmile Creek. Conspicuous alluvial fans are also present at the upper end of the valley near the confluence of the East and West Forks.

Perhaps a more difficult problem is to explain why, near the western edge of the mapped area, the Wind River valley, which is also cut in Tertiary strata, is relatively narrow in comparison with the Du Noir River valley. This part of the Wind River valley is choked with much glacial debris, and it is concluded that the erosive power of the river is directed toward downcutting of the morainal boulder debris and has maintained a relatively steep gradient.

GLACIAL STAGES

BUFFALO STAGE

The lateral moraines which occupy the drainage divides on both sides of the Du Noir valley are similar in many respects to the deposits described by Blackwelder (1915, p. 328–333) as belonging to the Buffalo stage of glaciation. Supporting this correlation are the height of the moraines above the present stream drainage and the fact that the associated terminal moraine has been almost completely eroded away. To the writer's knowledge no Buffalo moraines have previously been reported in this region.

The deposits are at elevations of 8,000 to 8,100 feet, about 600 to 700 feet above the present level of the Du Noir River. The best exposure of the moraine on the east side of the valley is found along Fourmile Creek above the Larsen ranch in the SW¼ sec. 24, T. 43 N., R. 108 W. (fig. 80). The moraines are extremely hummocky and contain many small ponds. They are composed of an unconsolidated mass of boulders and cobbles of Tertiary volcanic rocks and Paleozoic rocks in a matrix of finer material. No striae or polish was observed on any of the rock fragments, and most do not appear to be appreciably weathered.

The eastern end of the glacial deposit on the northeast flank of the Wind River Range west of the Harrison ranch forms a high rounded hill and its westward extent is marked only by smooth boulder-strewn slopes. Tertiary volcanic boulders comprise 70 percent of the deposit, whereas Paleozoic rocks make up 25 percent and Precambrian rocks 5 percent. Volcanic boulders of a type not found in place south of the Wind River indicate that much of the debris most probably was derived from the drainage basin of the Du Noir River. The deposit is slightly lower in elevation than the lateral moraines, but it is still about 600 feet above the present level of the Wind River. Isolated outcrops of gravel in secs. 15 and 23, T. 42 N., R. 108 W., also contain conspicuous amounts of volcanic rocks and are thought to be morainal deposits. These deposits lying on the south side of the Wind River are believed to be remnants of a terminal moraine and to be correlative with the lateral moraines discussed above.

FIGURE 80.—Lateral moraine of Buffalo stage of glaciation along Fourmile Creek, SW¼ sec. 24, T. 43 N., R. 108 W. Ramshorn Peak in right background.

Extensive glaciation is also believed to have occurred during the Buffalo stage of glaciation in the Horse Creek-Wiggins Fork region. On the north flank of Spring Mountain the moraines are at elevations of as high as 8,500 feet, nearly 1,400 feet above the adjacent Wiggins Fork valley one-half mile to the east. These are characterized by low ridges which are elongated parallel to the flank of the mountain and probably represent a large lateral moraine. The debris consists chiefly of Paleozoic cobbles and boulders and a minor amount of volcanic rocks.

The highest glacial deposit observed in the Horse Creek-Wiggins Fork area occurs near the top of the high ridge north of the Horse Creek Ranger Station at an elevation of 8,800 feet, about 1,000 feet above the present level of Horse Creek. These gravels contain Precambrian, Paleozoic, and volcanic rocks in about equal amounts. Granite boulders as much as 25 feet in diameter are present. Other prominent hills in the area, such as the one near the junction of secs. 18, 19, 29, and 30, T. 43 N., R. 106 W., also contain remnants of glacial moraines; many of these were too limited in extent to be shown on the geologic map.

Horse Creek Basin, with elevations ranging from 8,100 to 8,200 feet, has gently rolling topography with large alluvial flats separated by ridges composed of coarse boulder debris. There are many small lakes in the basin. Near its eastern end the terrain is more hummocky and irregular; gullies as much as 100 feet deep are cut into the deposits. The terrain of the area lying between the east edge of Elkhorn Ridge and Wiggins Fork Canyon is also slightly hummocky, with a few low ridges elongated parallel to the Wiggins Fork River. Erratics of Bighorn dolomite are common in this area, and many outcrops of Precambrian granite exhibit planed and faintly grooved surfaces. The deposits in Horse Creek Basin appear to have originated as a ground moraine.

The general distribution of these high-level glacial deposits suggest that during the Buffalo stage large glaciers descended both the Wiggins Fork and Horse Creek valleys and probably coalesced in Horse Creek Basin. The ice sheet had a minimum thickness of 400 feet and filled the valleys to heights ranging from 8,500 to 8,800 feet in elevation. No terminal moraines of the Buffalo glaciers were observed in either valley. The precipitous Wiggins Fork Canyon has been cut since the deposition of the moraines.

BULL LAKE AND PINEDALE STAGES

Glacial moraines younger than the Buffalo stage are in the Du Noir area, but no definite criteria were found to enable discrimination between the two younger stages. They are therefore discussed as a single topic.

The glacial deposits which extend northwestward from Stony Point along the east side of the Du Noir valley appear to represent a younger glacial stage than the moraines correlated with the Buffalo period. Although much of the debris consists of small well-rounded water-worn fragments, there are enough large boulders to attest to its glacial origin. This occurrence has been referred to as a lateral moraine of the Bull Lake stage of glaciation by both Blackwelder (1915, p. 327) and Miner and Delo (1943, p. 134). No terminal moraines are in evidence, but the thick sequence of gravels that underlies the Circle terraces north of Stony Point may possibly represent a part of this younger series of moraines. Although Bull Lake moraines commonly rest upon the terraces of the Circle cycle of erosion, Blackwelder (1915) found that in places the two types of deposits were nearly contemporaneous, with the terrace gravels composed largely of outwash material from the glacial moraines.

The Bull Lake glacial deposits have been rather extensively modified by erosion. The downcutting by the Wind River at Stony Point is about 300 feet. The lateral moraine could be traced for only a short distance upstream along the east side of the Du Noir valley, but, because it overlies soft Tertiary strata, it may have been so altered by slumping and erosion as to render it unrecognizable as a moraine. Neither were any certain traces of moraines found along the west side of the valley upstream from the Spencer ranch, but the gravel deposits directly west of the ranch may be remnants of a Bull Lake moraine.

The glacial deposits which lie along the Wind River west of its junction with the Du Noir River, and extending to the west edge of mapped area, are still largely intact and the conspicuous hummocky topography has been preserved. For these reasons they appear to be younger than any of the glacial deposits at the lower end of the Du Noir valley and therefore may be representative of the Pinedale glacial stage. This moraine, which forms a large lobe, is thought to have a direct influence on the course of the Wind River as it bends to the south at the Long Creek ranch. The deposits extend from the present level of the river to about 300 feet above the river. The most conspicuous rock type observed was a dark-brown to black vesicular basalt of a type not common in the volcanic rocks derived from the drainage basin of the Du Noir River, but more like those from the upper Wind River valley in the vicinity of Lava Mountain. The relationships of this moraine to probable glacial deposits upstream on the Wind River were not studied, but it is probably the terminal moraine of a glacier which extended eastward only to the western edge of the Du Noir valley.

Miner and Delo (1943, p. 134–135) reported a lateral moraine, to which they assigned a Pinedale age, about 50 feet above the present valley floor along the east side of the Du Noir valley. They also mentioned glaciers as having existed in the drainage basins of the Fourmile, Fivemile, and Sixmile Creeks during this period. The writer did not recognize any evidence that glaciation younger than the Bull Lake stage occurred either in the Du Noir valley or in its tributary streams. Miner and Delo (1943, p. 137) concluded, furthermore, that the Du Noir valley was completely blocked by the Pinedale moraines behind which was impounded a large lake, 300 feet deep, that drained into Long Creek through the vicinity of Dry Lakes on the west side of the valley and into Bench Creek and Wagon Gulch on the east side of the valley. No evidence of channels were observed in these areas by the writer. The elevation of the Dry Lakes is between 7,700 and 7,800 feet. If a lake had maintained this level, then it would have extended up East and West Fork Canyons one-half mile or more. No evidence of lacustrine deposits was observed in those canyons, although it is conceivable that such deposits could now be completely eroded away. Terrace remnants of the Lenore cycle of erosion, presumably older
