### DISCUSSION

This sheet includes maps that show the thickness and the depth to base of uppermost Pleistocene and Holocene (in other words, post-Late Glacial Maximum) deposits for the Offshore of Refugio Beach map area (Map A, B), as well as for a larger area that extends about 115 km along the coast from Hueneme Canyon to Refugio Beach (Maps D, E) to establish a regional context. To make these maps, water bottom and depth to base of the post-Late Glacial Maximum horizons were mapped from seismic-reflection profiles. The difference in the two horizons was exported for every shot point as XY coordinates (UTM zone 11) and two-way travel time (TWT). The thickness of the post-Late Glacial Maximum unit (Maps B, E) was determined by applying a sound velocity of 1,600 m/sec to the TWT. The thickness points were interpolated to a preliminary continuous surface, overlaid with zero-thickness bedrock outcrops (sheet 10 of this report), and contoured (Wong and others, 2012). Data within Hueneme Canyon were excluded from the contouring because the seismic-reflection data are too sparse to adequately image the highly variable changes in sediment thickness that characterize the canyon (Maps D, E).

Several factors required manual editing of the preliminary sediment-thickness maps to make the final products. The Red Mountain Fault Zone (RMFZ), Pitas Point Fault (PPF), and Oak Ridge Fault (ORF) disrupt the sediment sequence in the region (Maps D, E). The data points also are dense along tracklines (about 1 m apart) and sparse between tracklines (1–2 km apart), resulting in contouring artifacts. To incorporate the effect of the faults, to remove irregularities from interpolation, and to reflect other geologic information and complexity, the resulting interpolated contours were modified. Contour modifications and regrading were repeated several times to produce the final regional sediment-thickness map (Wong and others, 2012).

Data to determine the depth to base of the post-Late Glacial Maximum unit was similarly processed and contoured. However, this preliminary dataset was not used in favor of a surface determined by subtracting the modified thickness data from multi-beam bathymetry collected separately (see sheet 1). The depth of this surface in the Hueneme Canyon to Refugio Beach area ranges from 12 to 100 m (Map D; see also Wong and others, 2012).

Five different "domains" of sediment thickness, which are bounded either by faults or by Hueneme Canyon, are recognized on the regional maps (Maps D, E): (1) Refugio Beach to the south strand of the Red Mountain Fault Zone (RMFZ); (2) between the south strand of the Red Mountain Fault Zone and the Pitas Point Fault (PPF); (3) between the Pitas Point Fault and the Oak Ridge Fault (ORF); (4) between the Oak Ridge Fault and Hueneme Canyon; and (5) south of Hueneme Canyon. These data highlight the contrast among three general zones of sediment thickness: (1) the uplifted, sediment-poor Santa Barbara shelf domain 1; mean sediment thickness of 3.5 m; (2) a transitional zone (domain 2; mean sediment thickness of 18 m) and (3) the subsiding, sediment-rich delta and shelf offshores of the Ventura and Santa Clara Rivers and Calleguas Creek (domains 3, 4, and 5; mean sediment thicknesses of 39.2, 38.9, and 28.3 m, respectively).

In the Offshore of Refugio Beach map area, sediment thickness ranges from 0 to 12 m, with a mean thickness of 2.7 m. The thickest sediment accumulations are in a prominent, discontinuous, shore-parallel, nearshore to inner shelf delta-mouth bar directly sourced by steep, local watersheds in the Santa Ynez Mountains to the north. Sediment is notably either absent or very thin in the midshelf to outer shelf area.

The regional pattern of faults and of earthquakes occurring between 1922 and 2010 that have inferred or measured magnitudes greater than 2.0 is shown on Map C.
