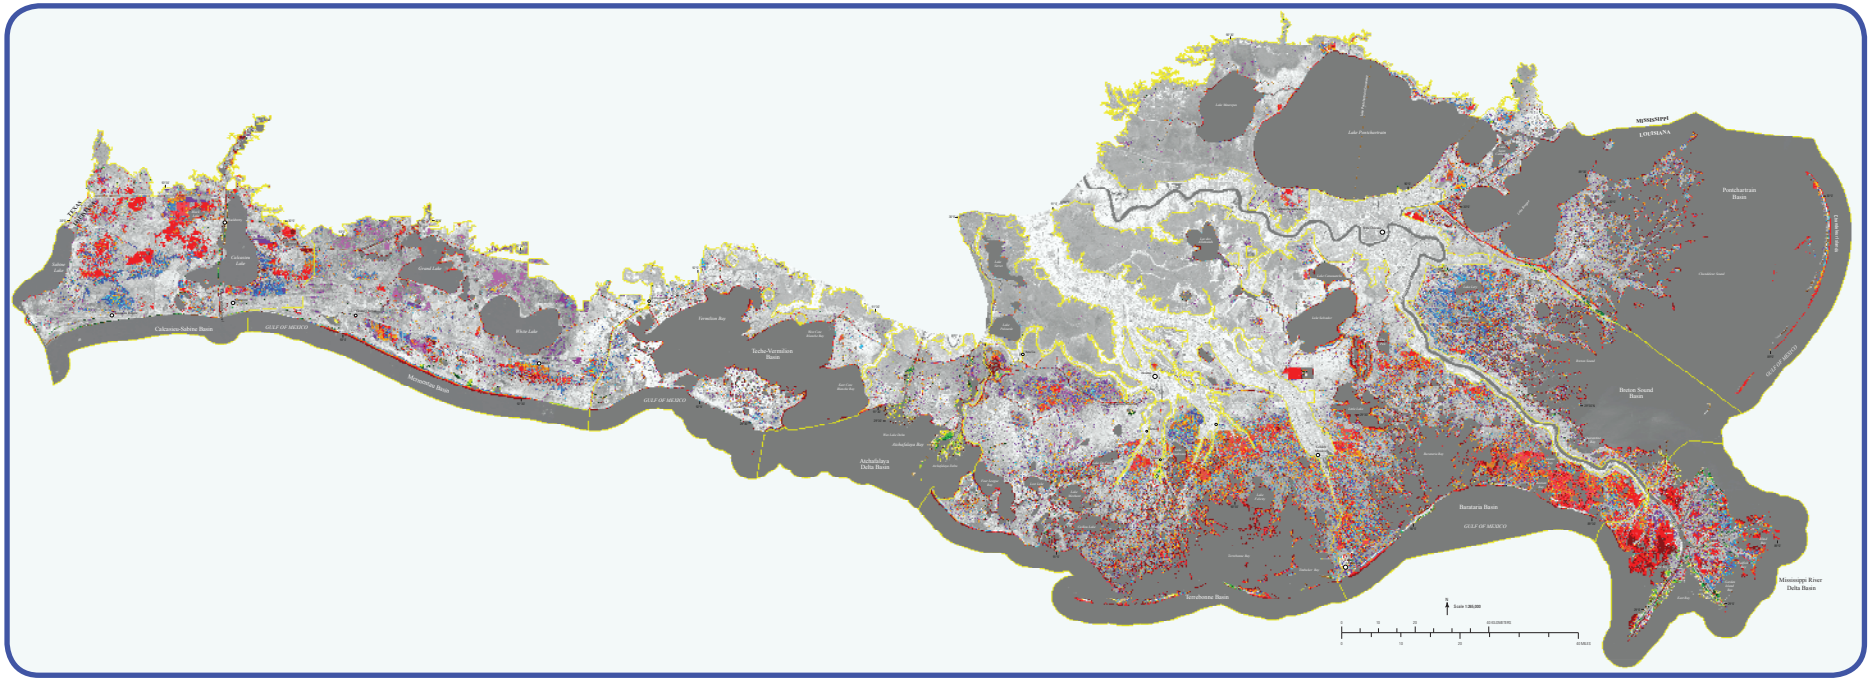
[1]Gain is determined by the last date a particular pixel transitioned from water to land and remained land throughout the period of observation.

[2]Loss is determined by the last date a particular pixel transitioned from land to water and remained water throughout the period of observation.

[3]Because this date range has only one ending dataset, some of these effects may be temporary phenomena.

[4]This date range contains at least one date in which the land/water data were created from Landsat Multispectral Scanner System (MSS).



Land Area Change in Coastal Louisiana (1932 to 2016)

By Brady R. Couvillion, Holly Beck, Donald Schoolmaster, and Michelle Fischer

Abstract

Coastal Louisiana wetlands are one of the most critically threatened environments in the United States. These wetlands are in peril because Louisiana currently experiences greater coastal wetland loss than all other States in the contiguous United States combined. The analyses of landscape change presented here have utilized historical surveys, aerial, and satellite data to quantify landscape changes from 1932 to 2016. Analyses show that coastal Louisiana has experienced a net change in land area of approximately -4,833 square kilometers (modeled estimate: -5,197 +/- 443 square kilometers) from 1932 to 2016. This net change in land area amounts to a decrease of approximately 25 percent of the 1932 land area. Previous studies have presented linear rates of change over multidecadal time periods which unintentionally suggest that wetland change occurs at a constant rate, although in many cases, wetland change rates vary with time. A penalized regression spline technique was used to determine the model that best fit the data, rather than fitting the data with linear trends. Trend analyses from model fits indicate that coastwide rates of wetland change have varied from -83.5 +/- 11.8 square kilometers per year to -28.01 +/- 16.37 square kilometers per year. To put these numbers into perspective, this equates to long-term average loss rates of approximately an American football field's worth of coastal wetlands within 34 minutes when losses are rapid to within 100 minutes at more recent, slower rates. Of note is the slowing of the rate of wetland change since its peak in the mid-1970s. Not only have rates of wetland loss been decreasing since that time, a further rate reduction has been observed since 2010. Possible reasons for this reduction include recovery from lows affected by the hurricanes of 2005 and 2008, the lack of major storms in the past 8 years, a possible slowing of subsidence rates, the reduction in and relocation of oil and gas extraction and infrastructure since the peak of such activities in the late 1960s, and restoration activities. In addition, many wetlands in more exposed positions in the landscape have already been lost. Most notable of the factors listed above is the lack of major storms over the past 8 years. The observed coastwide net "stability" in land area observed over the past 6–8 years does not imply that loss has ceased. Future disturbance events such as a major hurricane impact could change the trajectory of the rates. Sea-level rise is projected to increase at an exponential rate, and that would also expedite the rate of wetland loss.

Introduction

The U.S. Geological Survey (USGS) analyzed landscape changes in coastal Louisiana by determining land and water classifications for 21 datasets. Coastal Louisiana has been losing wetlands because of multiple compounding and interacting stressors including sea-level rise (SLR), subsidence, storms, sediment deprivation, oil and gas extraction and infrastructure, navigation infrastructure, saltwater intrusion, altered hydrology, and others (Penland and others, 2001). The purpose of this study is to provide updated estimates of persistent land change and historical land change trends for coastal Louisiana and for each hydrologic basin from 1932 to 2016. The use of 21 datasets plus the application of consistent change criteria in this study provide opportunities to better understand the timing and causal mechanisms of wetland loss that are critical for forecasting landscape changes in the future.

Study Area

The Louisiana coastal zone encompasses approximately 37,780 square kilometers (km^2) of lowland plains, deltaic lobes, and open water (fig. 1). Coastal Louisiana wetlands are generally considered one of the most important environments in the United States because they support more than 30 percent of the commercial fisheries in the United States, 5 of the Nation's top 20 ports are located in coastal Louisiana, and 20 percent of the Nation's oil and gas comes from or is transported through these wetlands (Costanza and others, 2008; Feagin and others, 2010; Gedan and others, 2011; NOAA, 2010; Twilley, 2007). This coast is also considered to be one of the most "at-risk" environments in the Nation because approximately a quarter of these wetlands have been lost in the past 84 years (Couvillion and others, 2011).

Coastal Louisiana was built by sedimentary material sourced from fluvial and tidally redistributed deposits. The bulk of these deposits were delivered via the Mississippi River as a result of upper catchment glaciation and melting associated with sea-level changes. As glaciers retreated (from about 12,000 until 6,000 years ago), meltwater inundated valleys and transported much of the upper catchment sediments to the lower catchment floodplains that compose

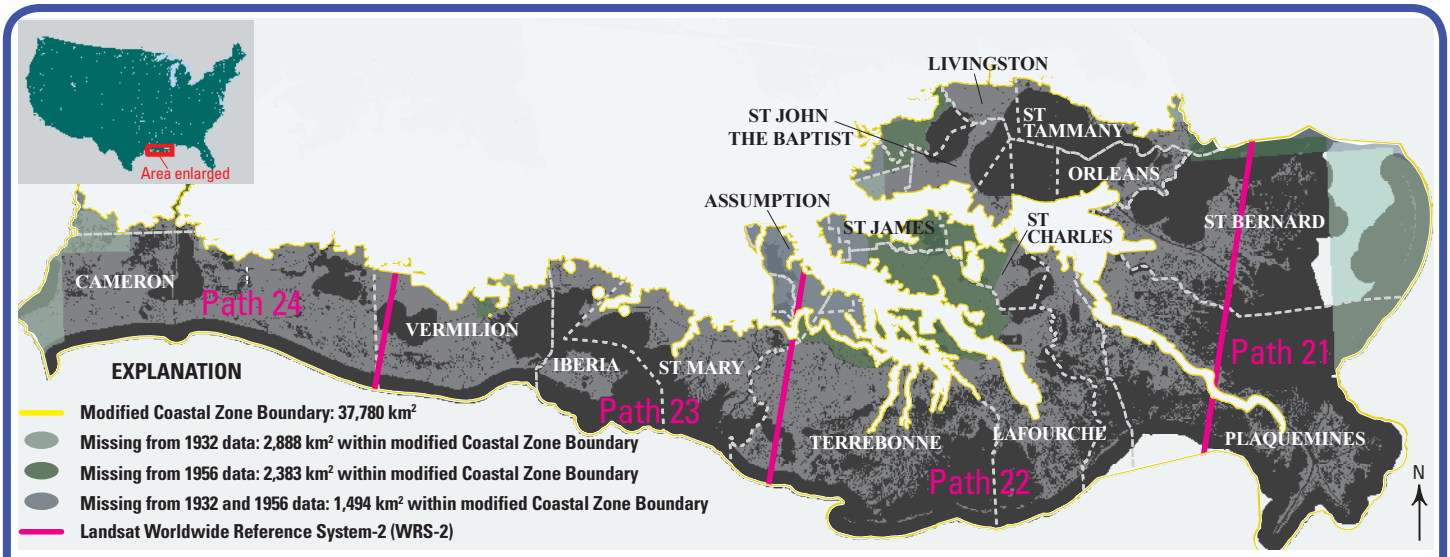


Figure 1. The study area in coastal Louisiana. The coastal zone boundary, the zone for which statistics were calculated, isolates coastal regions while excluding fastlands (defined as developed, agricultural, and other protected areas) from statistical analysis of coastal land change. Of particular note are the areas of non-overlapping data coverage in the 1932 and 1956 datasets (based on survey and aerial data) and in the 1973–2016 datasets (based on satellite imagery data). Because no data exist for these non-overlapping areas, an assumption of no change in those areas has been used for those time periods in the analyses (a reasonable assumption because a majority of these data voids occurs in areas dominated by forested wetlands, a habitat type known to have been particularly stable in past observations). Areas are presented in square kilometers (km^2).

coastal Louisiana today. Periodic floodwaters would carry these sediments, and as the floodwaters retreated, rich sediment left behind formed a vast expanse of fertile deltaic wetlands (Fisk and McFarlan, 1955). Hydrology continues to dictate the geomorphic structure and vegetation distribution of this landscape but in a drastically altered fashion. Flood-control structures including dams and levees were built, not only in Louisiana but throughout the Mississippi River catchment, particularly after the flood of 1927. The construction of these features has led to an overall decrease in the amount of sediment carried by the Mississippi River as a result of dam and levee construction throughout the drainage basin (Meade and others, 1990; Kesel and others, 1992). Anthropogenic controls also vary the distribution of sediment within the river by redirecting or altering the amount of sediment distribution at channel mouths, along channel banks, and across floodplains. These flood-control structures have contributed to a reduced capacity for sediment accretion and thereby reduced the ability of wetlands to maintain elevation in response to SLR and subsidence.

Methodology

This study analyzed changes in the extent of land in coastal Louisiana by using 21 datasets summarizing land and water areas from 1932 to 2016 (table 1; figs. 2 and 3). The datasets were derived from multiple sources including (1) historical U.S. Army Corps of Engineers land loss data (1932) (Dunbar and others, 1990, 1992); (2) National Wetlands Inventory (NWI) data based on aerial photography (1956); (3) Landsat Multispectral Scanner (MSS) data (1973–79); (4) Landsat Thematic Mapper (TM) (1985–2010); and (5) Landsat Operational Land Imager (OLI) (2013–2016) satellite imagery classified into land and water categories. Variable data coverage among the 1932 and 1956 datasets and all subsequent data required an assumption of no change in the area of no data coverage in those datasets. No change is assumed in land area from 1932 to 1956 and from 1956 to 1973 in portions of the dataset that occur outside the boundaries of the 1932 and 1956 data coverage. (Refer to fig. 1 for more information regarding the areas within the coastal basins to which this assumption was applied.) The areas missing from the 1932 and 1956 datasets mostly consist of forested wetlands. These areas are historically stable, so the assumption of "no change" is correct in most instances; however, the area and change summaries should be used with the implicit understanding of this assumption in areas lacking data in 1932 and 1956.

Preprocessing of all datasets included use of ERDAS IMAGINE AutoSync software (Hexagon Geospatial, 2016) that uses an automated process to align common landform features between images. To assess change, the geometric registration between datasets must be highly accurate. Misalignment of features at the same location could produce

invalid land change results. This processing step was critical in ensuring that the 1932 and 1956 data aligned with the later satellite-based data. The Landsat MSS data (1973, 1977, and 1979), which have a native 68- by 83-meter (m) resolution, were first resampled to a 30-m resolution by using a cubic convolution resampling method to facilitate comparability with later Landsat TM- and OLI-based data (native 30-m resolution). All satellite imagery data were then classified into land/water categories by using a methodology which makes use of a modified Normalized Difference Water Index (mNDWI) (Xu, 2005, 2006). The mNDWI enhances water features while cutting down on noise from land, vegetation, and soil (Xu, 2006). The mNDWI is seen in equation 1 below:

$$\text{mNDWI} = (\text{Green}-\text{MIR})/(\text{Green}+\text{MIR}) \quad (1)$$

Mid-infrared (MIR) is used because the wavelengths in this range, 1.55–1.75 micrometers, are particularly informative and discriminatory with regard to categorizing land and water. The green wavelength range is used as it maximizes reflectance of water and vegetation reflects MIR light more than green light (Xu, 2006). Initial mNDWI values were assigned to their appropriate land/water categories by thresholds. Supervised and unsupervised classification was then used to account for areas that may be incorrectly classified by the mNDWI alone. This step focuses on error-prone classes such as floating aquatic vegetation (FAV), shadows, and bridges. These areas were manually recoded to their appropriate land/water categories by expert analyses.

Land area estimates can vary substantially because of environmental variations such as seasonality and, most notably, water-level variations on the date of acquisition (DOA) (table 2) of the data (Morton and others, 2005; Bernier and others, 2006). A composite coastal land-water dataset was developed from the source-classified satellite data for each time period and was then used to derive the land area by date, basin area, and coastal area (table 1). To reduce some of the errors associated with apparent land change caused by misclassification or transient environmental phenomena, two approaches were utilized. Changes must persist for at least two consecutive time periods (of variable length, depending upon availability of cloud-free imagery) following the initial change, and anomalous changes among land and water categories can only occur in less than 20 percent of the remaining datasets. The mapped dataset identifies only these areas of persistent and consistent change. For this reason, recent land changes (2015 to early 2016) cannot yet be defined as persistent because data are not available to confirm that these changes have persisted into the two following analysis periods. These unconfirmed changes are instead referred to as “new land investigation areas” and “new water investigation areas.”

The resulting land area data were summarized by time period and by basin (fig. 3, table 1). Figures 2 and 3 display the long-term trend in land area over the period of observation. The function of change in land area over time was fit with a smoothing method called penalized regression splines by using the Mixed GAM Computation Vehicle (MGCV) package (Wood, 2000) on the R statistical platform (R Core Team, 2014). This method fits land change as a set of polynomials in a piecewise-continuous fashion across the span of years. Trends computed from this spline technique are smoothed and, as such, generalize trends over time. The intent of this study is to provide long-term, coarse-scale rates of change, and therefore these change rates are not appropriate at finer spatial and temporal scales. The complexity smoothing spline, as determined by the dimensionality of its basis function, was set to a maximum of five, but its final value was determined by cross-validation to prevent overfitting.

One of the assumptions of these modeling methods is that each data point provides equally precise information about the response variable. When this assumption is violated, there is non-zero covariance between the model error and the independent variables, which leads to biased estimates. These data clearly violate this assumption because of differences in data-collection methods. To account for differences in methods across years, points were weighted differently on the basis of expert opinion of the uncertainty inherent in each method. The weights affect how strongly each point contributes to estimates of total deviation. Data before 1973 were given half the weight of data after 1984. Data between 1973 and 1984 were given three-quarters weight of data after 1984. The goodness of fit is described by the coefficient of determination (R^2) statistic. Effective degrees of freedom (edf) can be interpreted as being related to the degree of the polynomial fit of the spline (edf = 1 is linear, edf = 2 is quadratic, and so on). We fit the models with and without weighting the data. As suspected, failing to weight the data resulted in overfitting. Specifically, non-weighted models were more complex (larger edf) and had higher R^2 values but generated slightly larger out-of-sample prediction error on average. This suggests that weighting data successfully reduced bias and improved the robustness of the models.

Figures 2 and 3 display the change in land area over time, whereas figures 4 and 5 and table 3 display approximations of the rates of land area change over time. Rates of change were calculated from the fitted models by using finite-difference approximation. The uncertainty of the finite differences was calculated by posterior simulations. Each fitted model was simulated 10,000 times, and the finite-difference estimates of the rates were calculated by using the function derivSimulCI() (Simpson, 2016). The 15.9 and 84.1 percentiles (representing the expected value +/- 1 standard deviation) of each rate estimate were calculated and displayed on the graphs.

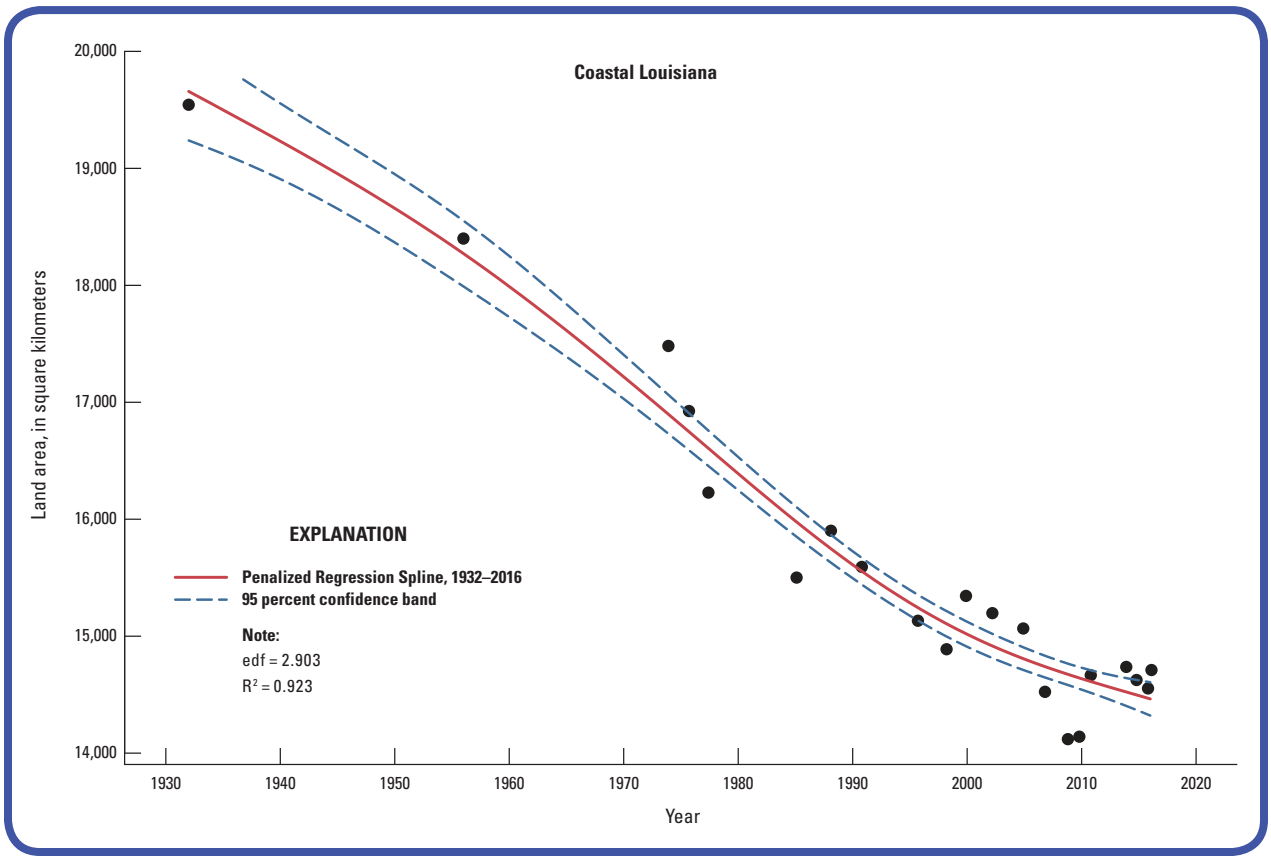

Figure 2. Land area in coastal Louisiana, 1932–2016. (See table 1 for specific area measurements.) The red line represents a penalized regression spline which approximates the data. The blue dotted lines represent a 95-percent confidence interval. Effective degrees of freedom (edf) can be interpreted as being related to the degree of the polynomial fit of the spline (edf = 1 is linear, edf = 2 is quadratic, and so on). The goodness of fit is described by the coefficient of determination (R^2) statistic.

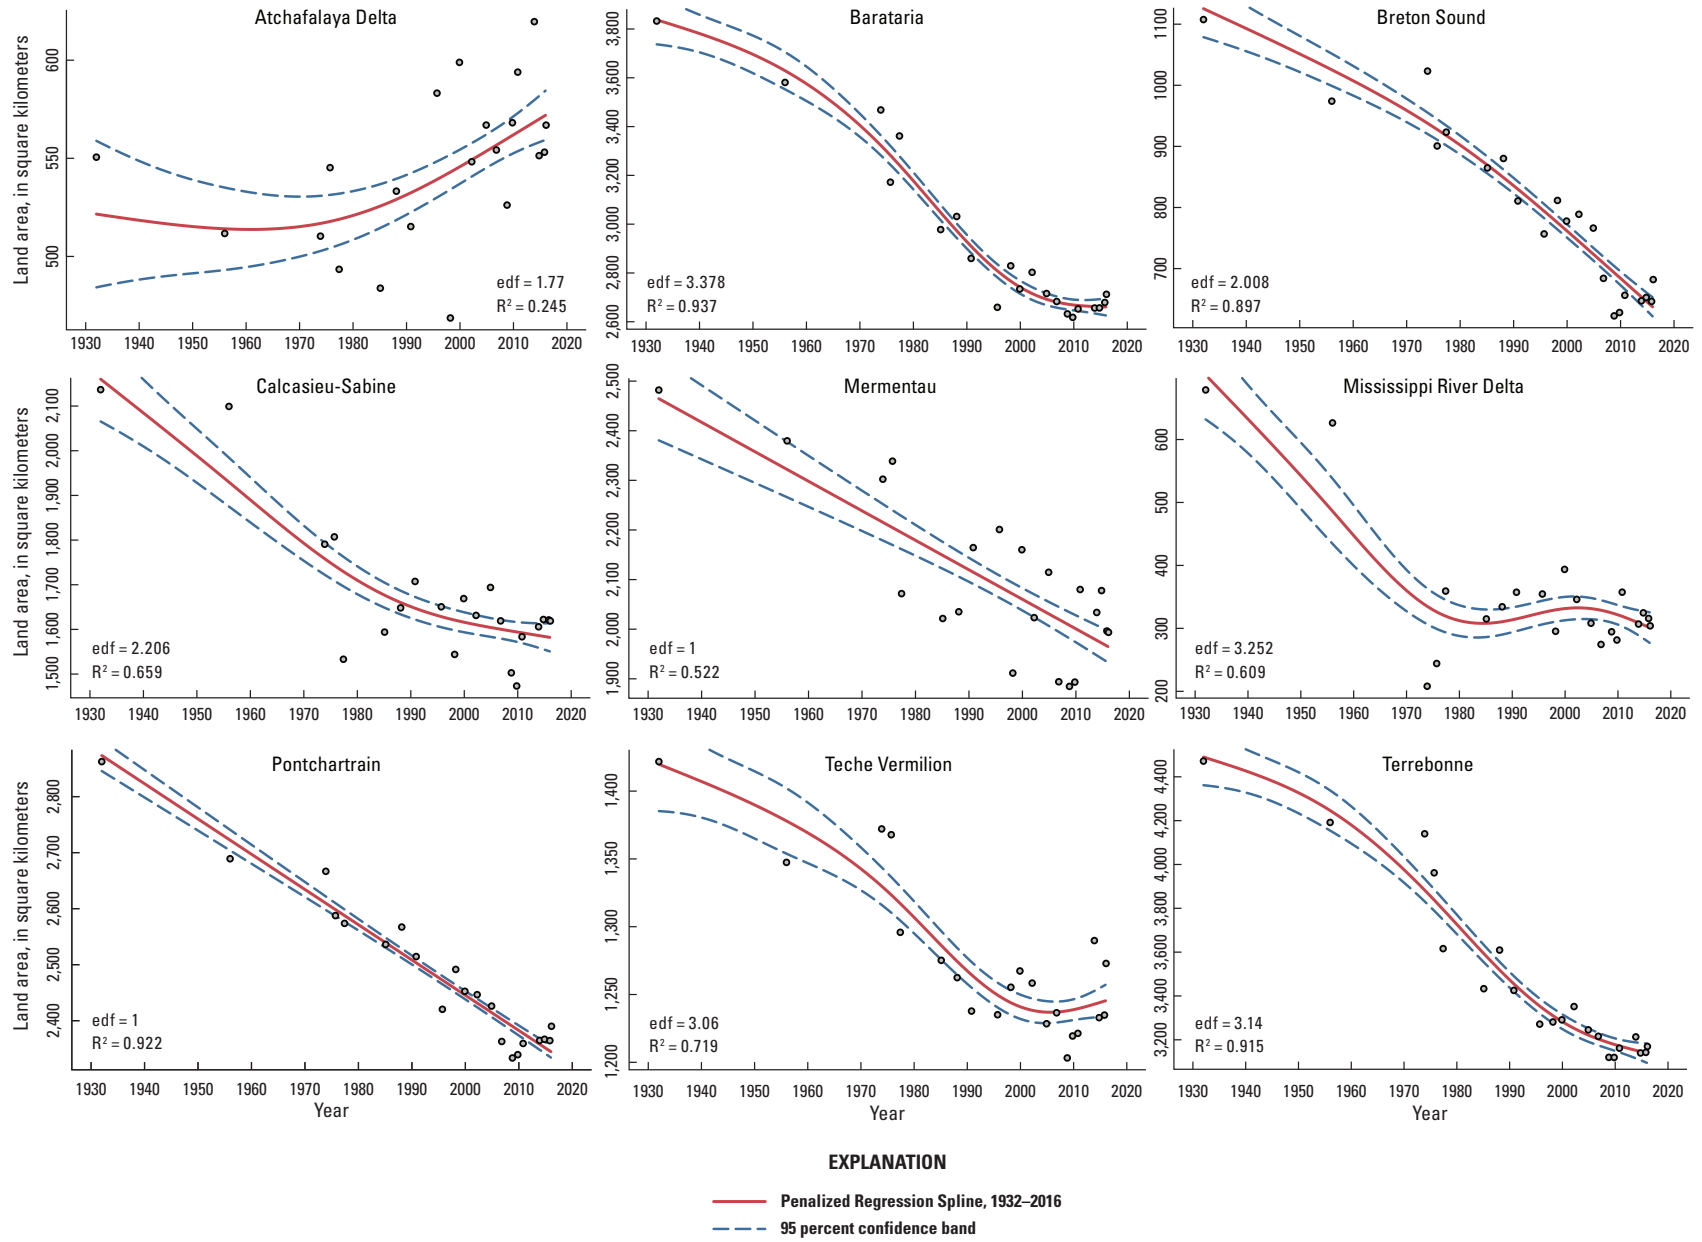

Figure 3. Land area by hydrologic basin in coastal Louisiana, 1932–2016. (See table 1 for specific area measurements.) The red line represents a penalized regression spline which approximates the data. The blue dotted lines represent a 95-percent confidence interval. Effective degrees of freedom (edf) can be interpreted as being related to the degree of the polynomial fit of the spline (edf = 1 is linear, edf = 2 is quadratic, and so on). The goodness of fit is described by the coefficient of determination (R^2) statistic.

Table 2. Water levels at a selected gage (Station ID: 8761724, located near Grand Isle, Louisiana) on the date of acquisition for imagery used in the land area estimates. Elevations provided in meters (m) relative to station datum.

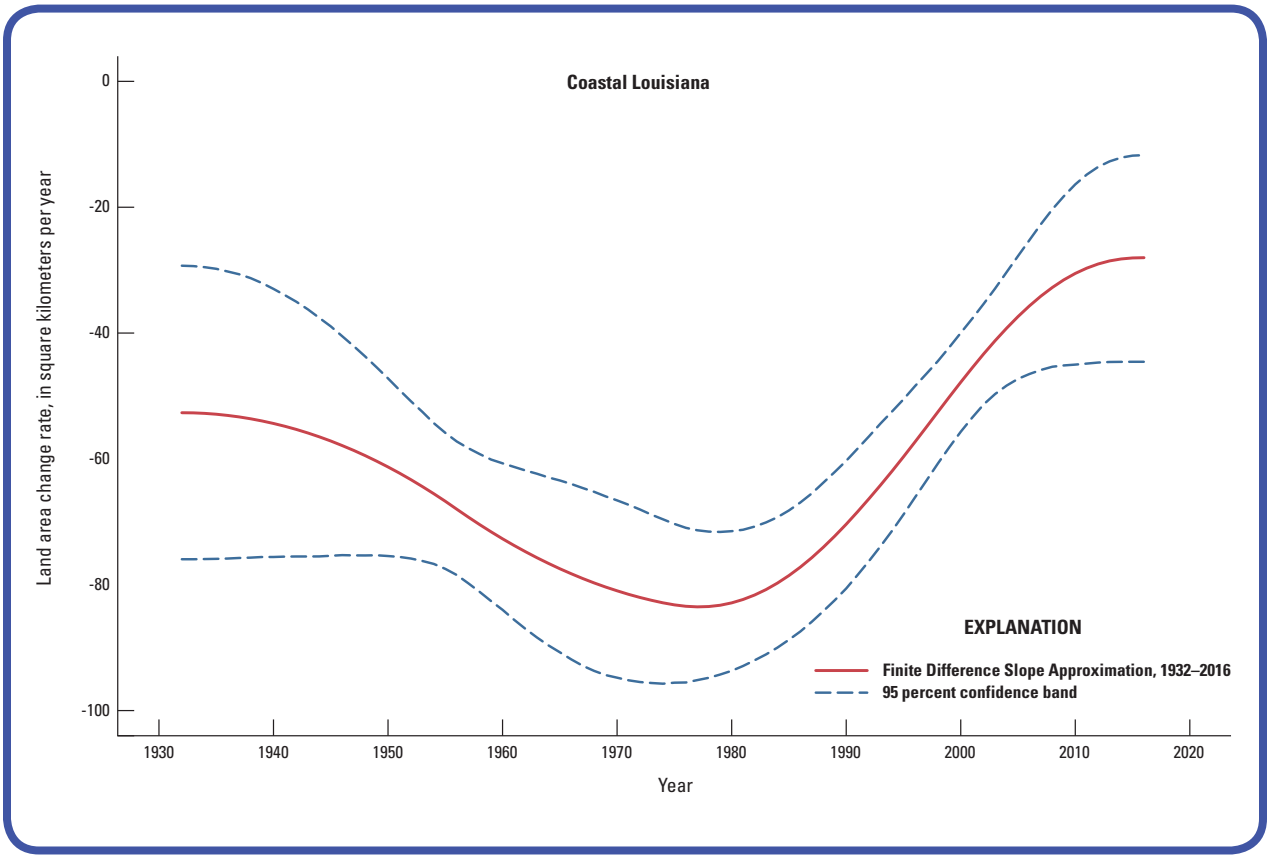

Figure 4. Finite-difference approximation of land area change rates through time in coastal Louisiana, 1932–2016; negative measurements indicate a net land loss rate, whereas positive measurements indicate net land gain rates. See table 3 for specific values.

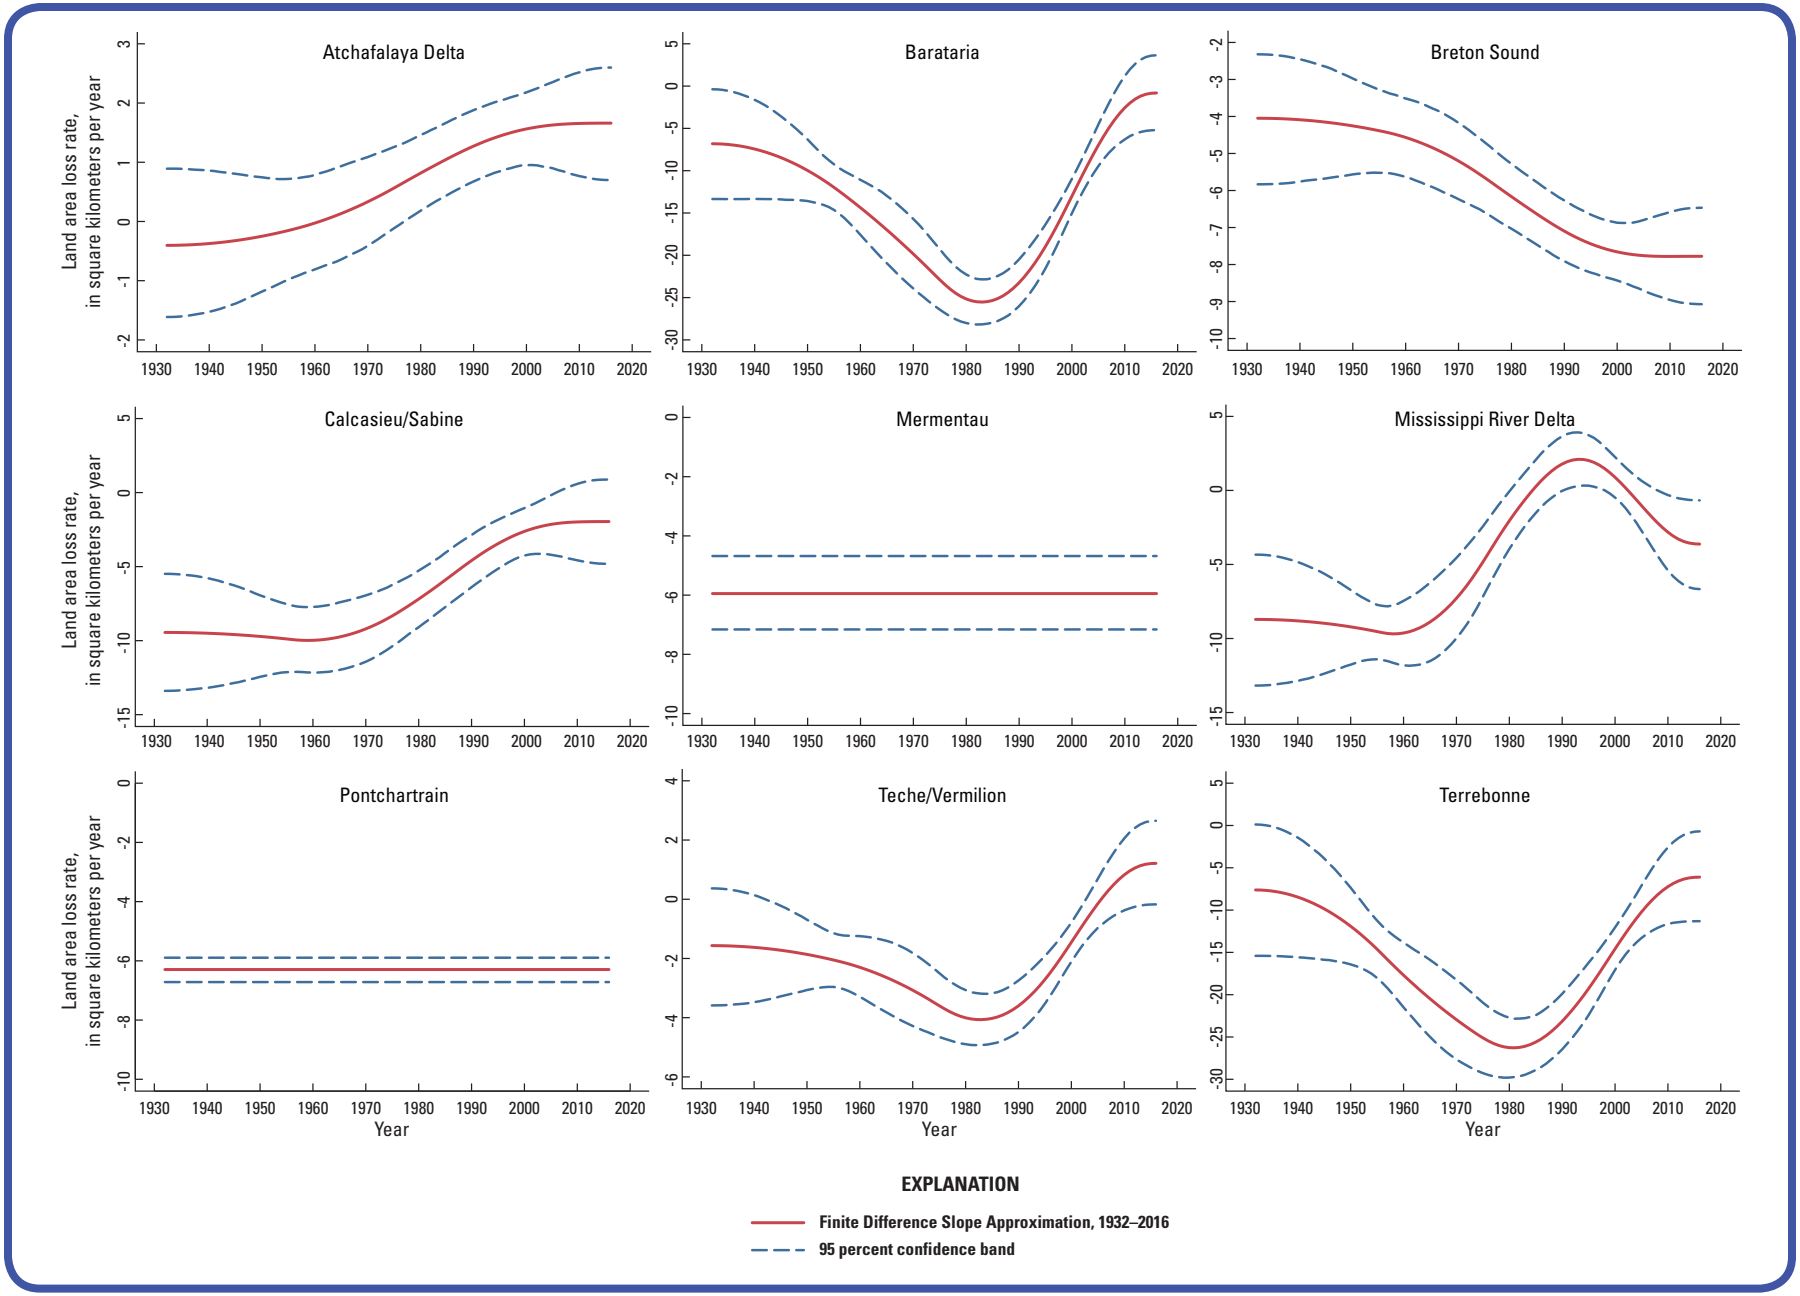

Figure 5. Finite-difference approximation of land area change rates through time in coastal Louisiana by hydrologic basin (as defined by the Louisiana Coastal Wetlands Planning, Protection and Restoration Act Program, n.d.), 1932–2016; negative measurements indicate land loss, whereas positive measurements indicate land gain. See table 3 for specific values.

Table 3. Finite-difference approximation estimates of long-term wetland change rates including standard error (SE) estimates for each hydrologic basin and coastal Louisiana from 1932 to 2016. Units are in square kilometers per year.

Results

Land Area Changes

These analyses show that coastal Louisiana has experienced a net land area change of approximately -4,833 km^2 (modeled estimate: -5,197 +/- 443 km^2) from 1932 to 2016 (fig. 2, table 1), roughly the size of the land area of the State of Delaware. This net change in land area amounts to a decrease of approximately 25 percent of the 1932 land area. Although this decrease in net land area is pervasive throughout much of the coast and the time period analyzed, the land area of recent data points (2013–16) is approximately equivalent and, in some cases, slightly greater than that of the 2010 estimate (Couvillion and others, 2011).

The model which best approximated the coastwide net land area change is similar to that of a third order polynomial (edf = 2.903) (R^2=0.923) (fig. 2). Within these data, 2005 and 2008 land area data from hurricane-induced effects are evident as low outliers. Also evident is a perceived "stability" in coastwide net land area in recent years.

All basins, with the exception of Atchafalaya Delta Basin, have experienced a net decrease in wetland area during the period of observation (1932–2016) (fig. 3). In terms of total area, Terrebonne Basin has experienced the greatest decrease in wetland area (-1,302 km^2 observed; -1,352 +/- 136 km^2 modeled), followed by Barataria Basin (-1,120 km^2 observed; -1,177 +/- 106 km^2 modeled), Calcasieu-Sabine Basin (-517 km^2 observed; -578 +/- 100 km^2 modeled), Mermentau Basin (-488 km^2 observed; -500 +/- 90 km^2 modeled), Pontchartrain Basin (-472 km^2 observed; -529 +/- 30 km^2 modeled), Breton Sound Basin (-426 km^2 observed; -489 +/- 49 km^2 modeled), Mississippi River Delta Basin (-375 km^2 observed; -401 +/- 75 km^2 modeled), and Teche-Vermilion Basin (-149 km^2 observed; -174 +/- 37 km^2 modeled) (table 1). Atchafalaya Delta Basin experienced an increase (+16 km^2 observed; +51 +/- 39 km^2 modeled) in total land area across the entire period of record (table 1). As a percent of starting area, Mississippi River Delta Basin has experienced the greatest percentage decrease in wetland area (-55 percent observed; -57 percent modeled), followed by Breton Sound Basin (-38 percent observed; -43 percent modeled), Barataria Basin (-29 percent observed; -31 percent modeled), Terrebonne Basin (-29 percent observed; -30 percent modeled), Calcasieu-Sabine Basin (-24 percent observed; -27 percent modeled), Mermentau Basin (-20 percent observed and modeled), Pontchartrain Basin (-17 percent observed; -18 percent modeled), and Teche-Vermilion Basin (-10 percent observed; -12 percent modeled). Atchafalaya Delta Basin was the only basin to experience an increase (+3 percent observed; +9 percent modeled) in land area, as a percentage of starting area, across the entire period of record (table 1).

Change in Land Change Rates through Time

Trend analyses from model fits indicate that coastwide rates of wetland change have varied from -83.5 +/- 11.8 square kilometers per year to -28.01 +/- 16.37 square kilometers per year. Excluding the high rates of wetland loss due to the 2005 and 2008 hurricanes (Katrina, Rita, Gustav, and Ike), recent wetland loss rates have decreased from the peak loss rates observed in the 1970s which are known to have exceeded 80 square kilometers per year (km^2/yr) (Britsch and Dunbar, 1993; Barras and others, 1994, 2003). This analysis indicates wetland change rates averaged -83 km^2/yr during the 1973–78 time period, followed by a steady reduction in the rate since that time (fig. 4). Britsch and Dunbar (1993) and Barras and others (2008) observed a similar trend of decreasing loss after 1978.

The rate of wetland change in most basins has changed drastically over the period of record. Only two basins, Mermentau and Pontchartrain, were best fit by a linear model (edf = 1), suggesting that the rate of change has not changed significantly over the period of record in those basins (fig. 5). The remaining basins were best fit by non-linear functions. Barataria, Terrebonne, and Teche-Vermilion Basins follow a similar pattern to that of the coastwide trend of loss rates increasing to a peak in the late 1970s, followed by a reduction in loss rates since that time. In Breton Sound Basin, wetland loss rates have continued to increase and have only recently begun to suggest a decrease in that rate (fig. 5). Calcasieu-Sabine Basin experienced the highest rates of wetland loss prior to the 1970s, with rates slowly decreasing since that time, with the exception of hurricane-induced losses in 2005 and 2008. The Mississippi River Delta Basin experienced a reduction in wetland loss rate since the 1960s, reaching a point of wetland gain, only to be followed by a negative trend due to the effects of Hurricane Katrina in 2005 (Barras, 2006). Finally, the Atchafalaya Delta Basin experienced an increasing land area trend (positive land change slope) since 1961 (fig. 5). Prior to 1961, this basin was initially on a negative trajectory; however, following the opening of the Wax Lake Outlet in 1942, sediment deposition increased, and a subaerial active delta emerged after the flood of 1973.

Discussion

The spatial and temporal patterns of wetland change observed in this assessment reveal a dynamic landscape changing as a result of the complex and often interactive effects of natural and human-induced processes. Coastwide total net land area suggests an increase in land area by 2015 as compared to the previous estimate in 2010 (Couvillion and others, 2011); however, these values are well within the standard error associated with the datasets and, as such, are not necessarily indicative of a true change in the long-term trend. This increase in coastwide net land area may not yet

be interpreted as "gain" because the persistence of said areas has yet to be assessed and much of this may be interpreted as recovery from the ephemeral lows associated with the hurricanes of 2005 and 2008; however, specific areas of gain can be detected in the dataset, many of which are showing persistence throughout the newly added data points.

It is important to note that there is a difference between net land area change (figs. 2 and 3, table 1) and persistent losses and gains (mapped dataset) and long term trends (figs. 4 and 5, table 3). Classification of an area as "loss" or "gain" is dependent on persistence criteria, where the amount of area of persistent loss or gain for a particular period can be less than or greater than the net land area change for that period. This effect occurs because persistent losses in a particular location can be offset by transitory gains in another.

This analysis has fostered an ability to examine variability in rates of wetland change through time by fitting data with non-linear models. Most of the models fit the coastwide and basin-level land area change data well, with a couple of notable exceptions. In the Atchafalaya Delta Basin, a basin in which water levels are known to greatly influence assessments, the R^2 of the model is 0.245 (fig. 3). Mississippi River Delta Basin, another basin in which water levels affect our ability to assess land area, also had one of the lower R^2 values ($R^2 = 0.609$) (fig. 3). The two Chenier Plain basins, Calcasieu-Sabine ($R^2 = 0.659$) and Mermentau ($R^2 = 0.522$), contain several water-control structures and are therefore also subject to variability. Barataria, Breton Sound, Pontchartrain, and Terrebonne Basins all have an R^2 value at or exceeding 0.9.

This analysis has shown decreasing rates of wetland loss after the 1970s. The possible causes of this decline in land change rate are as numerous as the causes of wetland change itself. One of the first possible causes relates to the loss of wetlands. Trends have shown that as wetlands are lost, there are fewer wetlands remaining to be lost, and as such, the rate of wetland loss will decrease. Although there is still a substantial area of wetlands remaining, at some point the influence of this artifact should be considered. Similarly, many of the wetlands in the most precarious locations have already been lost. What remains are wetlands in less "at-risk" positions in the landscape which are consequently less vulnerable and contribute to this reduction in loss rate; however, even stable wetlands may be impacted by a single event or cumulative episodic events over time (Morton and Barras, 2011).

The lack of major storms since 2008 is likely the most influential factor causing the decrease in net loss rates. This period of relative calm has led to fewer disturbances in the form of wave energy, thereby reducing erosion-induced losses. The storm hiatus also allowed vegetation to colonize new areas of shallow water bodies or to reestablish once vegetated areas. Some of these areas may have begun life as FAV but may have since attached to the substrate (Russell, 1942).

Oil and gas extraction in the Louisiana coastal zone began in 1926 and peaked in 1969 (Ko and Day, 2004). Infrastructure, such as canals, pipelines, and other features, contributes to wetland loss not only through direct removal of material but also by altering hydrologic flow. This altered hydrology can lead to indirect effects such as the propagation of wave energy and salinity into interior wetland areas. Following this peak, oil and gas activities started to move from the shallow wetland areas in one of two directions: inland or far offshore. As a result of this shift, Morton and others (2005) concluded that the decrease in the rate of land loss in Barataria Basin was attributable to a decrease in the rate of hydrocarbon production in that area after 1974.

Another contributing factor involves a reduction in tectonic activity and subsidence due to active faulting (Dokka, 2006; Kolker and others, 2011). The extent to which submergence due to natural versus anthropologically influenced subsidence is poorly understood. Regardless of the causes, some evidence is beginning to point toward a reduction in the rate of subsidence. Kolker and others (2011) observed a decrease in subsidence rates which corresponds with the decrease in the rate of wetland loss.

Finally, restoration activities, such as marsh creation and barrier island nourishments, can be observed in the datasets which constitute this analysis. Although these projects may have small effects in the coastwide total land area numbers, in specific areas, they have substantially changed the composition and configuration of the local landscape. These projects are in many cases building new land or sustaining existing land, again contributing to a reduction in loss rates. It is important to note that the effects of restoration projects are not always visible in the persistent change map because areas which were lost and then regained as a result of restoration do not meet the persistent change criteria.

Conclusions

This assessment provides a comprehensive analysis of historical trends and rates of land area change in coastal Louisiana from 1932 to 2016. The primary improvements over past efforts are an improved statistical analysis allowing for the observation of rates other than linear and the inclusion of additional datasets for assessing coastal wetland change since 2010 (Couvillion and others, 2011). This dataset provides the ability to better quantify the amount of wetland loss and the time period in which it was lost. This information will allow gradual loss patterns to be distinguished from losses due to episodic events such as hurricanes. The observed spatial and temporal patterns reveal a dynamic landscape changing as a result of the complex and often interactive effects of natural and human-induced processes.

The temporal frequency of land change provided by this study allows for further investigation of the causal mechanisms of the loss that has occurred. These investigations will provide improved information to develop tools to monitor ecosystems, forecast possible impacts, and plan protection and restoration activities. These data will support the development of strategies to adapt to our changing environment.

While recent trends have shown a reduction in the rate of wetland loss, it is important to note that past trends are not necessarily indicative of future change. Future disturbance events such as a major hurricane impact could change the trajectory of the rates. Sea-level rise is projected to increase at an exponential rate, and that would also expedite the rate of wetland loss. (IPCC, 2013; Doyle and others, 2015).
