Geologic Framework, Regional Aquifer Properties (1940s–2009), and Spring, Creek, and Seep Properties (2009–10) of the Upper San Mateo Creek Basin near Mount Taylor, New Mexico

By Jeff B. Langman, Jesse E. Sprague, and Roger A. Durall

Abstract

The U.S. Geological Survey, in cooperation with the U.S. Forest Service, examined the geologic framework, regional aquifer properties, and spring, creek, and seep properties of the upper San Mateo Creek Basin near Mount Taylor, which contains areas proposed for exploratory drilling and possible uranium mining on U.S. Forest Service land. The geologic structure of the region was formed from uplift of the Zuni Mountains during the Laramide Orogeny and the Neogene volcanism associated with the Mount Taylor Volcanic Field. Within this structural context, numerous aquifers are present in various Paleozoic and Mesozoic sedimentary formations and the Quaternary alluvium. The distribution of the aquifers is spatially variable because of the dip of the formations and erosion that produced the current landscape configuration where older formations have been exhumed closer to the Zuni Mountains.

Many of the alluvial deposits and formations that contain groundwater likely are hydraulically connected because of the solid-matrix properties, such as substantive porosity, but shale layers such as those found in the Mancos Formation and Chinle Group likely restrict vertical flow. Existing water-level data indicate topologically downgradient flow in the Quaternary alluvium and indiscernible general flow patterns in the lower aquifers. According to previously published material and the geologic structure of the aquifers, the flow direction in the lower aquifers likely is in the opposite direction compared to the alluvium aquifer. Groundwater within the Chinle Group is known to be confined, which may allow upward migration of water into the Morrison Formation; however, confining layers within the Chinle Group likely retard upward leakage. Groundwater was sodium-bicarbonate/sulfate dominant or mixed cation-mixed anion with some calcium/bicarbonate water in the study area. The presence of the reduction/oxidation-sensitive elements iron and manganese in groundwater indicates reducing conditions at some time or in some location(s) in most aquifers. Frequent detections of zinc in the alluvium aquifer may represent anthropogenic influences such as mining.

Along the mesas in the upper San Mateo Creek Basin, springs that form various creeks, including El Rito and San Mateo Creeks, discharge from the basalt-cap layer and the upper Cretaceous sedimentary layers. Streamflow in El Rito and San Mateo Creeks flows down steep gradients near the mesas sustained by groundwater discharges, and this streamflow transitions to shallow groundwater contained within the valley alluvium through infiltration where the subsequent groundwater is restricted from downward migration by the shaly Menefee Formation. This shallow groundwater reemerges at seeps where the land surface has been eroded below the groundwater level. Spring- and creek-water samples contained small amounts of dissolved solutes, and seep water contained substantially larger amounts of dissolved solutes. The pH of water within the creeks was neutral to alkaline, and all locations exhibited well-oxygenated conditions, although typically at substantially less than saturated levels. Changes in the stable-isotope ratios of water between spring and summer samples indicate differences in source-water inputs that likely pertain to seasonal recharge sources. Results of the water-isotope analysis and geochemical modeling indicate little evaporation and chemical weathering at the spring and creek sites but stronger evaporation and chemical weathering by the time the water reaches the seep locations in the center of the upper San Mateo Creek Basin.

Introduction

The water resources of the San Mateo Creek Basin (fig. 1) are important to the citizens of New Mexico, in particular, the town of San Mateo and the city of Grants, for potable-water sources. Citizens and tribal groups in this area are concerned about the possible effects on the water resources from exploratory drilling and possible mining of uranium (U) as currently (2011) proposed by various companies. Uranium mining in this region has historically targeted members of the Morrison Formation, and previous mining operations dewatered aquifers at and above the ore. Water generated during dewatering was discharged to natural waterways without

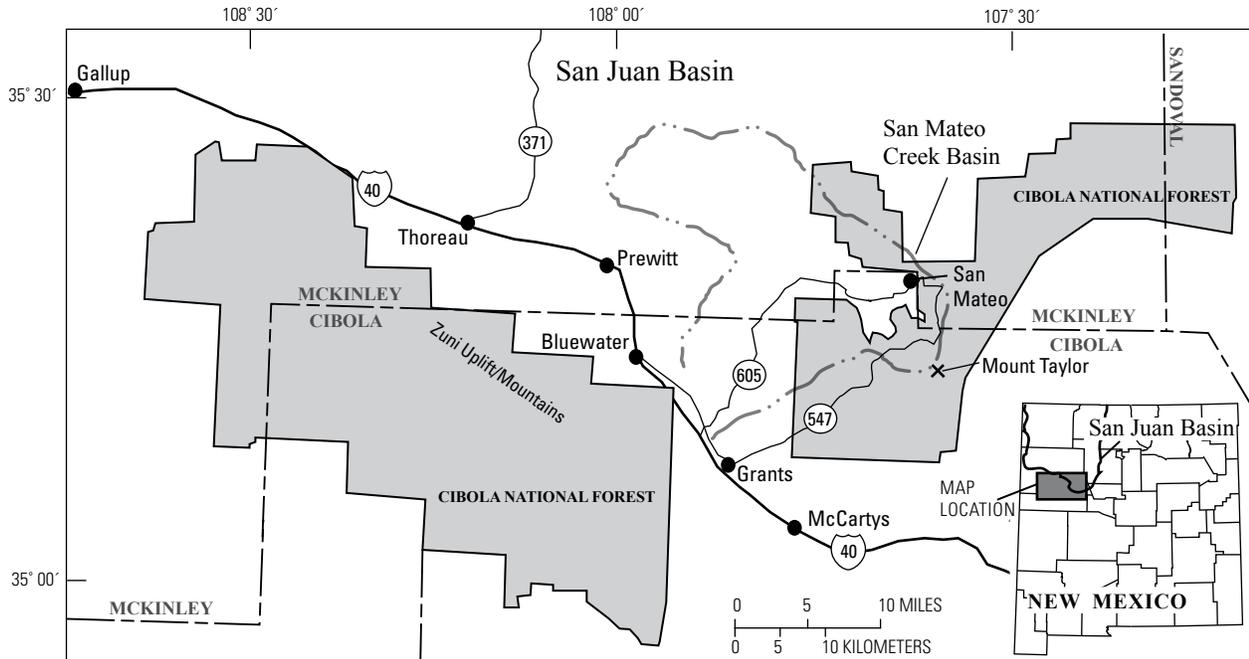

Figure 1. Location of the upper San Mateo Creek Basin.

treatment, because much of the U mining occurred prior to major environmental legislation such as the Clean Water Act. This mine water was a substantial source of contamination of sediment, alluvial aquifers, and deeper aquifers in areas of faulting (Schoeppner, 2008). The New Mexico Environment Department has issued a health advisory for current and future private wells within the San Mateo Creek Basin concerning various contaminants of concern including gross alpha activity, nitrate (NO_3), radium (Ra), and U (New Mexico Environment Department, 2009). The U.S. Geological Survey (USGS), in cooperation with the U.S. Forest Service (USFS), examined the geologic framework; regional aquifer properties; and spring, creek, and seep properties of the upper San Mateo Creek Basin near Mount Taylor, which contains areas proposed for exploratory drilling and possible uranium mining on USFS land.

Purpose and Scope

This report presents the results of a study to characterize the geologic framework; regional aquifer properties; and spring, creek, and seep properties of the upper San Mateo Creek Basin. Existing data (data collected prior to this study; 1940s to 2009) were used to describe groundwater characteristics of major aquifers including general directions of groundwater flow and groundwater composition. New data were collected in 2009 and 2010 to characterize the springs, creeks, and seeps within the upper San Mateo Creek Basin. To

evaluate the geologic framework; regional aquifer properties; and spring, creek, and seep properties of the upper San Mateo Creek Basin, the target area of the study (target area) encompasses the upper San Mateo Creek Basin, but a larger study area composed of parts of the Zuni Uplift and Chaco Slope regions was used to ensure sufficient existing data for evaluation of geologic and aquifer properties relevant to the target area (fig. 2).

Description of the Study Area

The study area is composed of the eastern slope of the Zuni Uplift and much of the Chaco Slope region within the southeastern part of the San Juan Basin (fig. 2). The area was a low-lying plain in the late Paleozoic Era and much of the Mesozoic Era, and the landscape was transformed to the current structure mostly because of the Laramide Orogeny during the late Cretaceous age (Woodward and Callender, 1977; Baldwin and Anderholm, 1992; Cather, 2003). Prior to the Laramide Orogeny, the area was part of the Western Interior Basin, a broad foreland basin that subsided partially in response to tectonic loading in the Cordilleran thrust belt, which allowed repeated transgressive-regressive sequences (Cather, 2003). The Zuni Uplift that constitutes the Zuni Mountains was formed during the Ancestral Rockies and Laramide Orogenies (Strickland and others, 2003). The Chaco Slope represents the northeast flank of the Zuni Uplift where formation dip lessens with distance from the apex of the fold.

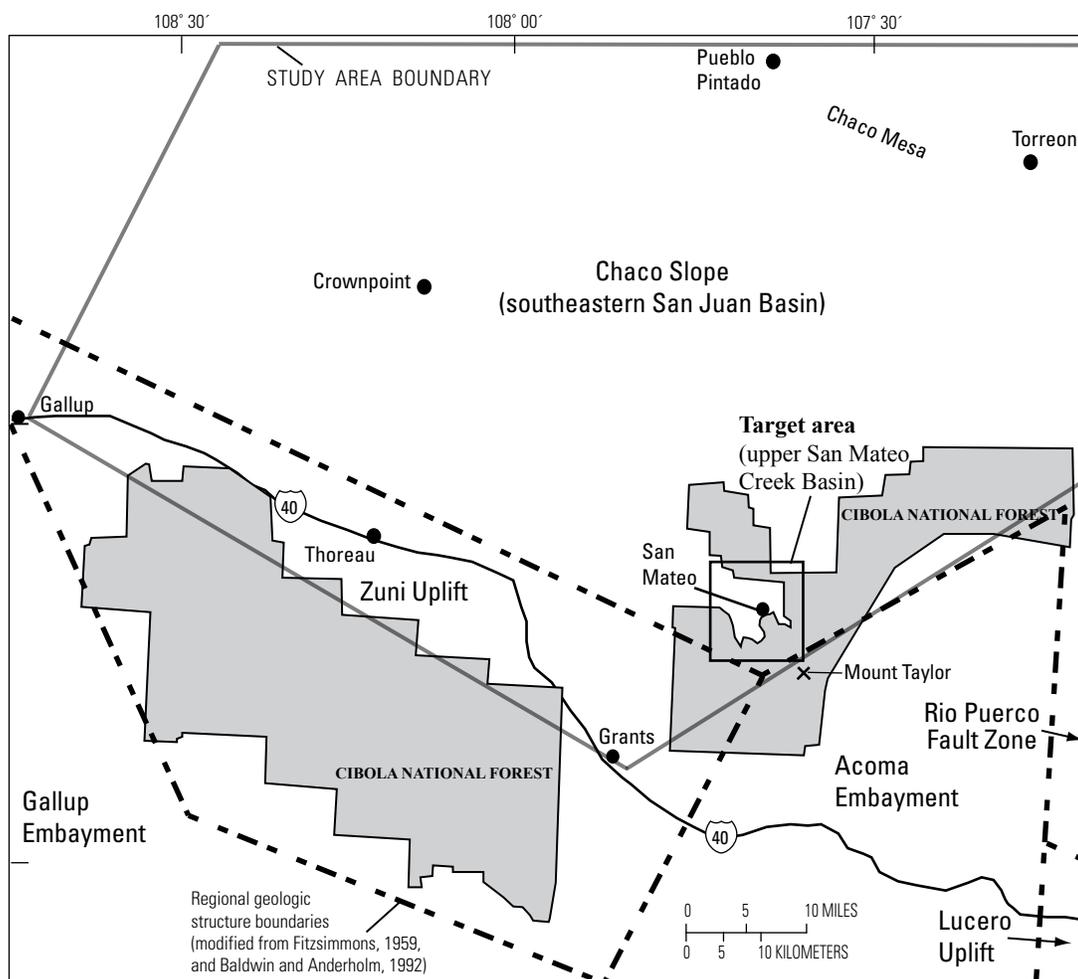

Figure 2. Regional geologic structural areas, study area, and target area.

The Acoma Embayment was a synclinal depositional area east of the Zuni Uplift and now includes Mount Taylor and the Rio Puerco Fault Zone to the east of the mountain (fig. 2). The study area includes valleys and mesas formed from regional folding of the landscape and subsequent erosion of less-resistant strata. The target area of upper San Mateo Creek Basin is the upper, northeast part of the basin above the confluence of San Mateo Creek and Arroyo del Puerto (fig. 3).

Structural and Surface Geology

The Zuni Mountains and Mount Taylor are the major elevated, structural features of the region. The axis of the Zuni Mountains is located about 15 mi west-southwest of Grants and is oriented southeast to northwest. The uplift that formed Zuni Mountains is a monoclinical fold about 75 mi long and 30 mi wide. The study and target areas are located along the east side of the monocline, which has a gentle slope to the north-northeast of about 5 to 10 degrees. The surface geology

of the target area is dominated by Mount Taylor and its associated volcanic flows. Mount Taylor is located about 15 mi northeast of Grants and about 8 mi southeast of San Mateo (figs. 3 and 4). The mountain reaches 11,301 ft and is part of a larger, northeast-trending volcanic field. Mount Taylor is primarily an accumulation of thick, viscous trachydacitic and trachyandesitic lavas with a surrounding apron of lava debris and pyroclastics (Crumpler, 2003). This volcanic activity was caused by extensional tectonics that began in the Neogene and continued into the Quaternary period (Laughlin and others, 1994; Keating and Valentine, 1998; WoldeGabriel and others, 1999). Surrounding mesas tend to consist of an upper layer of Neogene rhyolitic domes and pyroclastic deposits with a resistant cap of basalt lava and scoria (Lipman and Mehnert, 1979; Perry and others, 1990; Laughlin and others, 1994).

An erosional period that followed the Neogene volcanism created the valley forms in the study area. It is estimated that the land surface was eroded up to 150 to 200 feet (ft) below current land surface (Gordon, 1961). Following this erosional

period, the valleys filled with sediment and additional basalt flows to the present land-surface elevation. Sediment from the eroding highlands of the mesas was deposited in the valleys and formed unconsolidated alluvium mixed with boulder-sized basalt rocks that were transported to the valley floors through either colluvial or alluvial action. In the higher elevations of the target area, the alluvium is about 3 to 6 ft thick with increased thicknesses in the downstream direction; alluvium thicknesses can reach 65 ft or more where San Mateo Creek exits the target area (Brod, 1979). Beneath the basalt caps of the mesas, sedimentary formations are exposed in the target area including the Cretaceous Menefee, Point Lookout, Crevasse Canyon, Gallup, Mancos, and Dakota Formations and small exposures of the Morrison Formation of Jurassic age (New Mexico Bureau of Geology and Mineral Resources, 2003).

Subsurface Geology

Igneous and metamorphic bedrock of Precambrian age underlay younger rock throughout the region, and this bedrock is exposed within the Zuni Mountains (Gordon, 1961). No rocks of Cambrian to Middle Pennsylvanian age are present in the region, because this region was likely a stable paleo-highland during that time (Baldwin and Anderholm, 1992). Deposition and preservation of open-marine sediment began in the late Pennsylvanian and transitioned to deposition of continental- and restricted-marine sediment in the early Permian age (Baars, 1962), during which time the Abo, Yeso, Glorieta, and San Andres Formations were deposited (fig. 5). The top of the San Andres Formation was eroded near the end of the Permian or beginning of the Triassic age, then was buried with deposition of the Triassic Chinle Group and Moenkopi Formation (not present in the target area but in the larger study area) when the area was a low plain in a continental and restricted marine environment (Baldwin and Anderholm, 1992). Sedimentary formations overlaying the Chinle Group were deposited during the early Jurassic seas and the Cretaceous Western Interior Seaway by transgressive-regressive sequences (Lipman and others, 1979; Dillinger, 1990) and are exposed at land surface in a stairstep arrangement because of erosion of the Zuni Mountains (fig. 4). The early- to late-Jurassic Entrada, Todilto, Summerville, and Bluff Formations commonly found in northwestern New Mexico are less pervasive in the study area because of erosion and thinning of the deposits, and for this report, these deposits are grouped as the Entrada Complex.

Following deposition of the Mesozoic sediments, the regional area was folded as a result of the Laramide Orogeny starting about 80 million years before present (Ma) (Cather, 2004), forming the Zuni Uplift, Chaco Slope, and Acoma Embayment (includes the McCarty Syncline) (Hunt, 1938; Crumpler, 1982). A cross-section of the San Mateo Creek Basin developed by McCraw and others (2009) indicates a number of confirmed and inferred normal faults bisecting the upper San Mateo Creek Basin (fig. 6). Uranium deposits

within the sandstones of the Morrison Formation have been mined since 1948 in the regional area. The origin of the U is not well constrained, but it was likely deposited at the interface between two fluids of different composition and reduction-oxidation (redox) states that emplaced the tabular and lenticular deposits within the Morrison Formation (McLemore and Chenoweth, 2003). The U deposits consist of U-enriched humic matter coated upon sand grains within the host formation (Fitch, 1980).

Climate and Surface Hydrology

The climate of the region is arid to semiarid—precipitation has averaged 8.7 inches per year at San Mateo (1918 to 1988) and 10.3 inches per year at Grants (1953 to 2005) (Western Regional Climate Center, 2009)—although greater precipitation may accumulate on Mount Taylor (Daly and Weisberg, 1997). San Mateo Creek is a tributary to the Rio San Jose and the confluence has been altered from past human development (note the lack of a confluence shown in fig. 3). From 1977 to 1982, the USGS operated a steamflow-gaging station on San Mateo Creek about 5 miles (mi) west of San Mateo just upstream from the confluence with the Arroyo del Puerto (upper to lower San Mateo Creek Basin) where monthly streamflow averaged 0 to 7 cubic feet per second (ft³/s). Most of the average monthly streamflows were less than 1 ft³/s (U.S. Geological Survey, 2009). Springs are present in the target area and are concentrated near the confluence of San Mateo Creek and El Rito Creek in the upper San Mateo Creek Basin (fig. 3).

Groundwater Hydrology and Primary Aquifers

Substantial groundwater production in the study area typically is associated with three aquifer types—alluvium, sandstone, and limestone (Stone, 2003), such as the valley alluvium, sandstones of the Morrison and Glorieta Formations, and limestone of the San Andres Formation. Intergranular porosity provides the available space for water storage within the alluvium and poorly to moderately cemented sandstones, whereas fractures and dissolution create available storage space within well-cemented sandstones and limestones. Confining units such as the shales of the Mancos Formation or the Chinle Group can produce some water but typically inhibit flow because of their low permeability (Stone, 2003).

Numerous aquifers are present in the study area and typically are found within the various Paleozoic and Mesozoic sedimentary formations and the Quaternary alluvium. Groundwater flow in the valley alluvium generally parallels the surface flow and likely receives substantial recharge from surface drainages (Baldwin and Anderholm, 1992). The groundwater hydraulic gradient in deeper aquifers such as the San Andres/Glorieta aquifer is away from the Zuni Uplift and steepest closest to the uplift (Baldwin and Anderholm, 1992). Wells typically are located in the valley areas of the successive mesa-valley landscape of the study area, and groundwater

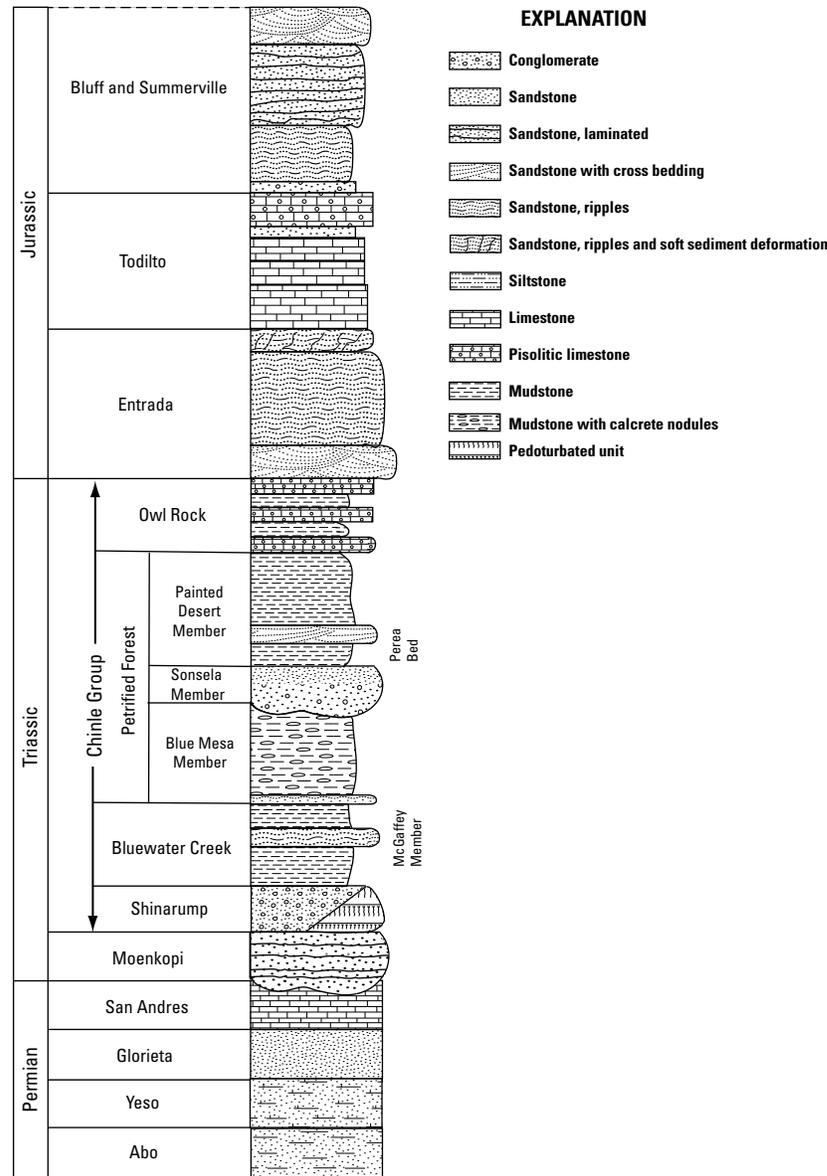

Figure 5. Generalized stratigraphic column of the subsurface geology below the valley forms in the southern San Juan Basin (modified from various figures in Lucas and others, 2003; courtesy of the New Mexico Bureau of Geology and Mineral Resources).

generally is pumped from the valley alluvium or San Andres/Glorieta aquifer (Baldwin and Anderholm, 1992; Agency for Toxic Substances and Disease Registry, 2008). Groundwater in the alluvium is hydraulically connected to groundwater in the San Andres/Glorieta aquifer in areas near the Zuni Uplift, but in other parts of the study area various members of the Chinle Group restrict flow between these two aquifers (Frenzel, 1992). During exploratory drilling in the 1970s north of San Mateo and within the target area, 15 water-bearing units (defined by formations and specific formation members) were encountered between land surface and 3,300 ft below land surface (Gulf Mineral Resources Company, written

commun., 1977) indicating that many of the Mesozoic formations in the area likely contain water and may be hydraulically connected.

Valley Alluvium and Menefee Formation

An unconfined aquifer is present in the valley alluvium and the Menefee Formation in the upper San Mateo Creek Basin. The Menefee Formation is present at the surface in the eastern part of the basin in and near the town of San Mateo, and groundwater discharging from the upper Menefee supplies springs that form El Rito, San Lucas, and San Mateo

8 Geologic Framework, Regional Aquifer Properties (1940s–2009), and Spring, Creek, and Seep Properties (2009–10)

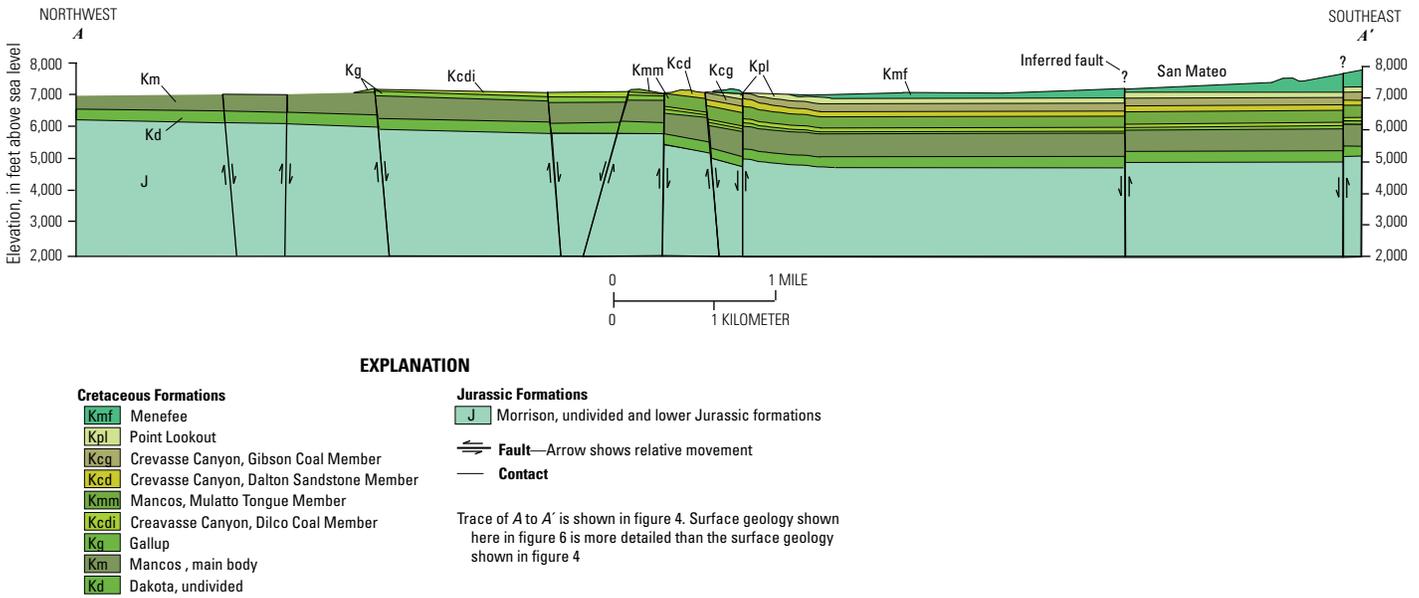

Figure 6. Geologic cross section from west to east through the upper San Mateo Creek Basin (modified from McCraw and others, 2009; courtesy of the New Mexico Bureau of Geology and Mineral Resources).

Creeks in the target area. The upper Menefee has been eroded, and unconsolidated material is present in thin layers in the easternmost part of the valley or along the base of the mesas. The alluvium thickens westward following San Mateo Creek where greater basin area contributes to the deposition of valley alluvium. Near the town of San Mateo, the alluvium aquifer overlies Menefee shales, and numerous intermittent or ephemeral springs and seeps are present in the area of the confluence of El Rito and San Mateo Creeks. West of this location, the Menefee is no longer present as the landscape transitions to older formations exhumed from previous erosion (fig. 4). Within the Rio San Jose Basin, alluvium-aquifer water typically has a specific conductance ranging from 600 to 2,500 microsiemens per centimeter ($\mu\text{S}/\text{cm}$), although values of 6,000 $\mu\text{S}/\text{cm}$ have been reported; dissolved-solids concentrations have ranged from 590 to 14,000 milligrams per liter (mg/L) (Brod and Stone, 1981; Stone and others, 1983). Dissolved-solids concentrations in groundwater from the Menefee have ranged from 200 to 1,400 mg/L (Brod and Stone, 1981).

Point Lookout, Crevasse Canyon, Gallup, Dakota, and Morrison Formations

Besides the Menefee, the Cretaceous Point Lookout, Crevasse Canyon, Gallup, and Dakota Formations (predominantly sandstones) likely have the porosity to contain substantial groundwater. Located between the Gallup and Dakota, the Mancos Formation likely contains small amounts of water, but this clay-rich formation probably is more of a confining

layer than an aquifer. A review of stratigraphic logs at the New Mexico Bureau of Geology and Mineral Resources (NMB-GMR) indicated that the Cretaceous layers can be discontinuous through the area. The Crevasse Canyon Formation can be substantial in thickness and contains two sandstone members (Dalton and Stray) that likely contain water, but these members are spatially variable and not present in many locations across the study area because of erosion (Stone and others, 1983). The underlying Gallup and Dakota sandstones are more likely to be present as aquifers, although deposition of these formations was not prevalent for this area. The southern extent of the Gallup Formation is along the southern boundary of the study area (Stone and others, 1983). Dissolved-solids in the Cretaceous formations have ranged from concentrations of 200 to 700 mg/L for the Point Lookout (Brod and Stone, 1981); 1,200 to 2,200 mg/L for the Gallup (Gulf Mineral Resources Company, written commun., 1979); and 600 to 1,400 mg/L for the Dakota (Brod and Stone, 1981).

Aquifers in the Jurassic formations likely exist in most parts of the study area, and most information is related to U ore extraction from the Morrison Formation. Water was commonly encountered during exploratory drilling and mining of U from the Morrison, and the groundwater was removed for ore extraction (McLemore and Chenoweth, 2003; Yancey and McLemore, 2008). The Morrison Formation is divided into the mudstone, sandstone, conglomerate, and limestone Brushy Basin Member; the conglomerate, sandstone, and mudstone Westwater Canyon Sandstone Member; and interbedded shale and sandstone Recapture Member (Stone and others, 1983). The Brushy Basin Member and Westwater Canyon Member

historically have contained water and were dewatered for U extraction, which caused local water-level declines during mining. Groundwater from the Westwater Canyon Member has contained dissolved-solids concentrations of 360 to 2,200 mg/L (Brod and Stone, 1981). Roca Honda Resources, LLC (2009a) estimated the potentiometric surface of the Morrison aquifer at the Jesus Mesa (fig. 3) to be about 1,000 to 1,300 ft below land surface. Given that groundwater was found in the upper part of the Jurassic formations (Morrison), it can be assumed that the lower Entrada Complex likely contains groundwater.

Chinle Group

The Chinle Group is the only Triassic geologic unit in the study area, but this group can be up to 1,500 ft thick in the region and is composed primarily of mudstone and siltstone with some minor sandstone and limestone components (Stone and others, 1983). A likely discontinuous, confined aquifer(s) is present in the Chinle Group from recharge occurring around the Zuni Uplift, although this aquifer is not considered highly productive (Baldwin and Anderholm, 1992). The Chinle Group tends to act more as a confining unit for the underlying San Andres/Glorieta aquifer (Baldwin and Anderholm, 1992).

San Andres and Glorieta Formations

The confined San Andres/Glorieta aquifer is defined by the Permian San Andres and Glorieta Formations that underlie much of west-central New Mexico and is the primary aquifer of the region. The San Andres consists mostly of limestone and some sandstone and is unconformably overlain by the Chinle Group. The San Andres conformably overlies the Glorieta, which is composed of well-sorted, well-cemented fine- to medium-grained sandstone, and conformably overlies the Yeso Formation. The San Andres and Glorieta are considered to be a single aquifer because of the gradational contact between the formations, and much of the water in this aquifer travels through solution channels within the San Andres (Baldwin and Anderholm, 1992). Joints, fractures, and faults create anisotropic conditions within the San Andres/Glorieta aquifer (Kelley and Clinton, 1960). Groundwater flow is mostly towards the east-northeast away from the Zuni Uplift, and discharge from the aquifer as springs is common (Baldwin and Anderholm, 1992). Dissolved-solids concentrations in the aquifer in the Grants-Bluewater area (fig. 1), typically are less than 1,500 mg/L, and calcium (Ca) and magnesium (Mg) and bicarbonate (HCO_3) and sulfate (SO_4) are the dominant cations and anions (Baldwin and Anderholm, 1992).

Human Influence on Water Resources

Within the study area, municipal, industrial, and agricultural wells were primarily completed in the San Andres/Glorieta aquifer. The city of Grants derives its municipal

water from this aquifer. Prior to the 1940s, domestic and stock wells withdrew small amounts of water from the San Andres/Glorieta aquifer, but in the 1940s, new irrigation wells were completed to supply an increasing agricultural area (Baldwin and Anderholm, 1992). By 1955, 22 wells were supplying 13,600 acre-ft/yr for agriculture (85 percent of total withdrawal), municipal, and industrial use in the Grants area (Gordon, 1961). This increase in groundwater withdrawn from the San Andres/Glorieta aquifer is attributed with decreasing flow in the Ojo del Gallo (minor drainage immediately south of Grants) and substantially lowering the potentiometric surface of the aquifer (Baldwin and Anderholm, 1992). Water levels fluctuated with pumpage, and the largest declines were recorded in the early 1960s during the height of agricultural use. These declines recovered following decreases in agricultural use (Baldwin and Anderholm, 1992).

In addition to agricultural uses, mining influenced groundwater levels within the region because of the need to dewater formations containing U ore and water needed for milling operations. Mining and milling operations relied on water from the San Andres/Glorieta aquifer. Substantial U deposits were discovered in 1955 north of Grants, which initiated a boom in mining, increased the local population, and decreased the amount of irrigated land (Baldwin and Anderholm, 1992). The ratio of San Andres/Glorieta water used for agricultural, industrial, and municipal uses began to change with a greater share going to industrial uses (mostly mining or milling or related uses) and a smaller share going to agriculture with an overall drop in the volume of water withdrawn from the aquifer. By 1982, the volume of water withdrawn from the aquifer had decreased to 3,900 acre-ft/yr, and 38 percent of the water was used for industrial operations (Baldwin and Anderholm, 1992). Mining and milling operations decreased through the 1980s and 1990s, and water needs correspondingly decreased. With the decrease in mining and agriculture, municipal water became the primary use of San Andres/Glorieta water.

Within the target area, there is a small population and no major agricultural land use. Most of the private land in the upper San Mateo Creek Basin outside of the town of San Mateo is part of the Lee Ranch (cattle ranch). Surface-water conveyances have been modified to support ranching operations. San Mateo Creek was dammed immediately above the town of San Mateo where incoming creek flow is allowed to infiltrate and discharges below the dam. Smaller retaining structures are present along El Rito and San Mateo Creeks on the valley floor for stock use. According to the New Mexico Water Rights System database managed by the New Mexico Office of the State Engineer (<http://nmwrrs.ose.state.nm.us/nmwrrs/index.html>; database reviewed in 2010), most of the wells in and around the town of San Mateo draw water from the unconfined aquifer in the valley alluvium and Menefee Formation with the remaining wells drawing water from deeper Cretaceous formations.

Previous Studies

The upper San Mateo Creek Basin has not been studied as an entire hydrologic unit. There are a number of private company reports describing the hydrogeology of various locations in the target area because of the potential for U mining in these locations. These reports are in addition to a substantial amount of geologic work by the New Mexico Bureau of Geology and Mineral Resources such as the recent draft update to the San Mateo quadrangle (McCraw and others, 2009). The New Mexico Environment Department has conducted various monitoring programs in conjunction with regulatory monitoring by the mining companies, but these data have not been compiled by the New Mexico Environment Department to derive an overview of the hydrologic resources within the upper San Mateo Creek Basin.

Study Methods

The characterization of the geologic framework; regional aquifer properties; and springs, creeks, and seeps of the upper San Mateo Creek Basin was performed by compiling and analyzing existing hydrogeologic data supplemented with new data from the analysis of spring-, creek-, and seep-water samples collected as part of this study. Compilation of existing data for the study area consisted of reviewing databases managed by the USGS, U.S. Environmental Protection Agency, and the State of New Mexico along with relevant and readily available journal articles and government and private consultant reports. The data were screened to only include data relevant to deposits and formations found in the target area—upper San Mateo Creek Basin. The larger study area was used to compile sufficient hydraulic and geochemical data to describe the general water-level and geochemical characteristics of the major aquifers that are present in the study and target areas. Most of the existing data compiled for this study ranged from the 1970s to 2009, but some data extend back to the 1940s (date of collection). This large temporal scale was included to allow for comparison of hydraulic and geochemical characteristics of the multiple aquifers relevant to the upper San Mateo Creek Basin.

Existing Data

A review of the study area geology was necessary to establish the geologic framework containing the aquifers. Stratigraphic descriptions were created from existing literature and the review of drilling logs at the New Mexico Bureau of Geology and Mineral Resources. Groundwater hydraulic data (aquifer water levels and hydraulic conductivities) and chemistry data (major and trace elements along with contaminants of concern such as NO_3^- , Ra, and U) were compiled to analyze basin-wide hydrogeologic characteristics. Water-level differences were interpreted to identify general flow patterns

of the major aquifers in the San Mateo Creek Basin where possible. Hydraulic conductivity and transmissivity of aquifers and between aquifers were assessed where available. Aquifers were characterized by comparing concordant data across the various saturated deposits and formations in the study area that were relevant to the target area.

To analyze the data relevant to aquifers in the target area, formation designations were standardized to current (2011) accepted formation nomenclature. This standardization was necessary because of the length of the existing data record (1940s to 2009) during which formation identification has changed with certain formation names dropped from accepted use or added as additional studies continued to update the stratigraphic nomenclature of the region. Although it is a geologic group, the Chinle Group is treated similar to the formation designation because of a lack of discrimination of the Chinle Group's formations in this area regarding hydrogeologic data (it was recently elevated to Group status¹). In addition to this name standardization, data associated with formation members were grouped under the formation name. This grouping increases the variability of the data subsets because of member differences, but this grouping provides a more consistent discussion with all differences described at the formation level. There are a number of alluvial, colluvial, and landslide Quaternary deposits in the study area, and these unconsolidated deposits were grouped under a Quaternary alluvium (Qa) hydrostratigraphic unit designation with the assumption that these unconsolidated layers should hydraulically behave as a single unit. Similarly, the volcanoclastics of the Mount Taylor Volcanic Field also were grouped as a single unit. It is not assumed that these igneous extrusive rocks have similar hydraulic properties, but these units likely contain only young water recently recharged from the surface. For purposes of this report, data associated with the Entrada, Todilto, Summerville, and Bluff Formations were grouped as a single hydrostratigraphic unit described as the Entrada Complex. These early to mid-Jurassic formations have not been well defined for the study area, and the Entrada Formation likely is the dominant formation of these predominantly sandstone and limestone layers. Additionally, a small percent of data were attributed to multiple formations. These multiple-formation samples were assigned to the uppermost formation for analysis. The uppermost formation was assumed to represent the greater thickness of the saturated interval of the well, because it could not be ascertained as to whether the lower formations were fully penetrated by the wells. Designating individual formations for multiple-formation data mostly affected samples collected from the San Andres/Glorieta aquifer. Some data were attributed to the San Andres Formation and some were attributed to the Glorieta Formation, but a substantial part of the data was attributed to both formations. The single-formation designation of multiple-formation data greatly

¹The Chinle Group was elevated from formation status by Lucas (1993), but this status change has not been fully accepted (e.g., Dubiel, 1994, and Woody, 2006). The Chinle Group designation is used for purposes of this report.

increased the San Andres Formation data set compared to the Glorieta Formation data set. In most cases, these two data sets can be considered representative of one aquifer because of the gradational contact between these formations and the two data sets are discussed as one regarding certain data.

Existing water-level data were compiled from publicly available sources to evaluate possible groundwater flow patterns. To visualize likely flow patterns of the aquifers, relative differences in water-level elevations are presented through a categorical analysis of the distribution of water-level values for various groups (deposit or geologic time period). Using the statistical program SPlus (Tibco Software, version 8.1; <http://spotfire.tibco.com/products/s-plus/statistical-analysis-software.aspx>), each water level was assigned to one of seven distribution categories given their relative differences across the entire distribution of the selected group. The presentation is similar to a categorical boxplot but is presented spatially to view relative differences in water-level elevations across the study area. Water levels were not used to construct potentiometric-surface contours because of the substantial length of the temporal record of the data, the variety of collectors of the data, the possible variety of methods for determining depth to water or water-level elevation, and the known anthropogenic and natural influences on water levels in the target and study area during the temporal record of the data. This compilation of data from numerous sources collected over a long temporal record is best viewed from a relativistic perspective than a contoured solution that implies a known hydraulic gradient at some point in time.

The median value and interquartile range (first and third quartiles that encompass 50 percent of the distribution) of water-level elevations were determined for each aquifer to grossly view water-level elevations across the study area. The statistics cannot be used to infer vertical hydraulic relations between aquifers because of a lack of substantial overlap of wells between aquifers within the study area. Erosion of the landscape exposed older formations at the surface in various areas that provides major recharge entry points to the lower aquifer formations. It is assumed that a substantial portion of recharge to the lower, unconfined/semi-confined/confined (depending on restrictive overlying layers) aquifers is occurring at these surface exposures in areas of higher precipitation and concentrated flow that would allow recharge in this semi-arid climate (Zuni Mountains, mesas, Mount Taylor, surface-water bodies), and the groundwater then moves eastward and northeastward in the geologic structure and likely interacts with overlying or underlying aquifers as has been observed for the San Andres/Glorieta aquifer (Baldwin and Anderholm, 1992). The water level of each aquifer reflects the sum of the recharge elevations at any one location. The median of each aquifer's water-level data set represents a center point in the distribution of data that minimizes the influences of local effects such as dewatering from mining or other temporary withdrawals or inputs, and the interquartile range provides an estimation of the similarity or difference in water-level elevation ranges between aquifers across the study area.

Existing major-ion data were screened to eliminate samples missing any of the major cations (Ca, Mg, and Na) or anions (HCO_3 or alkalinity, SO_4 , and Cl). A review of pH values indicated that conversion of alkalinity values to HCO_3 was appropriate (majority of all recorded pH values within the range of 7.0 to 8.5), and a single HCO_3 value was determined for each sample that contained an alkalinity value by multiplying the value by 1.22. The total cation content in the samples (in milliequivalents per liter) had to balance within 10 percent of the total anion content in the samples for inclusion in the water-type analysis. The 10-percent acceptable-balance criteria was used instead of the more accepted 5-percent criteria because of the likely variability of sampling and analysis by different data collectors and laboratories. Samples were aggregated by geologic deposit or formation, and average major-element concentrations, along with dissolved-solids concentrations, were calculated for each aquifer. All groupings by deposit or formation balanced within the 10-percent acceptable criteria for the averaged concentrations. Average concentrations were chosen because median concentrations did not meet the ion-balance criteria.

For dissolved trace-elements and contaminants-of-concern data, estimated concentrations (greater than the method detection level (MDL) but less than the reporting level) were accepted as actual concentrations. Some existing data sources presented MDLs and some sources only indicated nondetect data points. No attempts were made to include nondetect data, because of the lack of consistency in available MDLs and substantial presentation of nondetect data points without any indication of a detection level. Analysis of trace-element and contaminants-of-concern data sets were limited to only the detected presence of the constituents because of the lack of control regarding the left-tail of the distribution with the variable MDLs and non-inclusion of nondetect data.

New Data

To supplement the groundwater characterization, surface-water samples were collected from seven spring, creek, and seep locations in the target area in August 2009 and May 2010 (fig. 7 and table 1). Sites were selected by the availability of water. Three springs were flowing in the target area during the sampling periods. The spring sites are located along the southern (El Rito Creek and San Mateo Creek springs) and eastern (San Lucas Creek spring) rims of the basin (fig. 7) where recharge to the discharging aquifer(s) likely occurs from infiltration of precipitation occurring on Mount Taylor. These springs discharged from sandstone layers underlain by shales immediately below the volcanoclastic caps that form the top layers of the mesas. Samples also were collected downgradient from the springs on San Mateo and El Rito Creeks where the creeks transition from the steep gradients of the mesas to the valley floor. The most downstream sampling locations were seeps where ponding water was found along El Rito and San Mateo Creeks on the valley floor. The seeps

were present where shallow groundwater is near the surface as indicated by numerous salt deposits and visible signs of ephemeral or intermittent springs and shallow water levels in nearby piezometers. All samples were analyzed for field properties (water temperature, pH, specific conductance, and dissolved oxygen), dissolved solids, major elements (Ca, Mg, Na, K, HCO₃, SO₄, and Cl), trace elements (Al, Sb, As, Ba, B, Be, Cd, Cr, Co, Cu, Fe, Li, Pb, Mn, Hg, Mo, Ni, Se, Si, Ag, Na, Tl, V, and Zn), stable isotopes of water ($\delta^2\text{H}$ and $\delta^{18}\text{O}$), and contaminants of concern that have historically exceeded maximum contaminant levels in this area (gross alpha activity, NO₃, Ra, and U; table 2). Stable isotopes of hydrogen ($^2\text{H}/^1\text{H}$) and oxygen ($^{18}\text{O}/^{16}\text{O}$) composing water are reported as $\delta^2\text{H}$ and $\delta^{18}\text{O}$ per mil (‰), which is the ratio of the stable-isotopic abundances of an element in a sample to those of the Vienna Mean Standard Ocean Water (VSMOW; Révész and Coplen, 2008a; Révész and Coplen, 2008b). All samples were collected as grab samples from atmospherically-exposed surfaces and filtered through a 0.45-micron capsule filter using a peristaltic pump and new, individual Teflon-coated tubing at each site.

The creek- and seep-solute concentrations were used to model potential geochemical mass-balance reactions between the creek sample sites and the seep sample sites on El Rito and San Mateo Creeks. These point-to-point locations represent the evolution of creek flow from groundwater discharged at the mesas to infiltration and flow through the valley alluvium and reappearance at downstream seeps. The reemerged shallow groundwater likely undergoes greater evaporation on the valley floor as it reappears at the surface through seep discharge that produces quiescent shallow ponds. Additionally, relative to water that remains on the surface as creek flow, water that infiltrates into the alluvium would be expected to undergo greater rock-water interactions as it migrates more slowly along the valley floor. This rock-water interaction was visible in the addition of clays and likely associated oxide

polymorphs that were apparent in the samples collected from the seep sites. Some of these clays were present in the seep samples following filtration and are considered part of the “dissolved” fraction for concentration analysis because of acid preservation of the samples that draws elements from the clays and oxides into solution. Inclusion of elements associated with the clays that passed through the 0.45-micron filters influences charge balance determination and trace-element concentrations as trace elements sorbed to these very fine particles are not included for determining the charge balance (potential for imbalance with this exclusion) and may increase the concentration of typically low solubility trace elements such as aluminum (Al).

The geochemical model NETPATH (Plummer and others, 1994) was used to model the geochemical reactions between the creek and seep sites using the NETPATH-WIN interface (El-Kadi and Fujiwara, 2009). Each model of the creek to seep flow path for El Rito and San Mateo Creeks was constrained by specific elements that were identified as having substantial mass flux between the creek and seep sites with consideration for the changes in flow type (open channel to shallow groundwater) and the introduction of clays and oxides to the water as shallow groundwater travels through predominantly aluminosilicate alluvium and formations. Mineral phases were chosen based on the local geology, the introduction of aluminosilicate clays and Fe and Mn oxides that passed through the 0.45-micron filter as part of the “dissolved” fraction, and a review of possible mineral phases produced from the calculation of saturation indices (log of the ratio of the ion activity product (IAP) and the solubility product (K_{sp}) from entering all available solute concentrations into PHREEQC (Parkhurst and Appelo, 1999) using the PHREEQCi interface (version 2.17.0); http://wwwbrr.cr.usgs.gov/projects/GWC_coupled/phreeqci/). The selected mineral phases represent the thermodynamically preferred mineral forms given the available element concentrations and general aqueous chemical conditions

(pH, temperature, and dissolved oxygen), but these selected mineral phases are not meant to indicate the only minerals likely to dissolve or precipitate or be available for cation exchange/sorption. These mineral phases are useful for viewing the mass flux of the available solutes between aqueous and solid phases with changes in element compositions and concentrations.

Model results describe the mass transfers of the selected mineral phases that account for the observed changes within the constrained elements. Models were run with creek data representing the initial solution and the seep data representing the final solution. Evaporation was included as an effect along with the dissolution and precipitation of the mineral phases to account for changes in the water chemistry between the initial and final solutions. Cation exchange was attempted in the geochemical models but dismissed as an examinable process because of the leaching of elements from the less than 0.45-micron clays and oxides with acidification of the collected samples that altered the dissolved to exchange-site element ratios. A CO_2 phase did indicate changes between the creek and seep sites, but this phase is not presented because of the lack of organic C data that would hinder this discussion, but this flux is visible in the pH differences between the sites. The mass transfer estimates of the dissolution or precipitation

of mineral phases are represented by a positive (dissolution) or negative (precipitation) value in millimoles per kilogram (mmol/kg) of water, and the evaporation effect is quantified through an estimated value of the remaining water solution in grams as indicated by an outputted evaporation factor (concentrations increased by this multiplier through evaporation).

Quality-Assurance

Surface-water data collection was performed according to USGS quality-control and quality-assurance standards described in the USGS *National Field Manual for the Collection of Water-Quality Data* (U.S. Geological Survey, 2006). One sequential replicate sample was collected during each sampling period at a randomly selected site to evaluate laboratory precision, and matrix-spike samples were collected at the same site to ascertain matrix interference for all constituents. All replicate-sample results were within 10 percent of the environmental-sample results for concentrations greater than the reporting level, and matrix-spike sample results were within allowable laboratory limits. Additionally, laboratory-blank samples were analyzed to examine method contamination and no analytes were detected above the reporting level in the laboratory-blank samples.

Geologic Framework and Regional Aquifer Properties

Regional data were used to describe the geologic, hydraulic, and geochemical characteristics of the aquifers of the study area regarding formations relevant to the target area. Geologic and hydraulic characteristics include stratigraphy, formation properties, groundwater-flow patterns derived from existing water-level differences, and published hydraulic conductivities measured in the field or laboratory. Geochemically, groundwater variation among the aquifers was examined by reviewing existing data for differences in pH, dissolved solids, water type defined by the major elements, trace elements, and contaminants of concern.

San Mateo Creek Basin Geology

The geologic framework of the study area consists of the Zuni Uplift, Chaco Slope, and the Mount Taylor Volcanic Field. Within this structural context, the sedimentary formations provide matrices for local and regional aquifers. Information regarding the study area stratigraphy was compiled along with associated aquifer information to present a table of deposit, formation, and aquifer properties that are relevant to the hydrologic resources of the target area (table 3). For this report, aquifers are described by the individual formations or deposits where groundwater is present. These descriptions are used to refer to the saturated portions of deposits or formations but are not meant to discriminate separate aquifers. Many of the aquifers likely are well-connected, but investigation of those connections is beyond the scope of this report. The distribution of the aquifers is spatially variable because of the dip of the formations and erosion that produced the current landscape configuration where older formations have been exhumed closer to the Zuni Mountains.

The thicknesses and range of deposits and formations present a potentially complex interaction of aquifers in the study and target areas. Many of the deposits and formations likely are hydraulically connected because of the solid-matrix properties, such as porosity and permeability (table 3), but the Mancos Formation (including the Mulatto Tongue) and Chinle Group likely restrict vertical flow given the shaly composition of these formations. The Mancos is a near-surface formation that may not be present in parts of the study and target areas because of thinning and erosion. It is more prevalent on the mesas and strongly visible at the surface of Jesus and San Mateo Mesas (fig. 8). The limited presence of the Mancos in the valley areas lessens its role as a potential inhibitor of vertical flow to the lower aquifers. The Chinle Group is a thick sequence of predominantly shale and silt that likely acts as a strong inhibitor to vertical flow between the overlying Jurassic formations and the underlying Permian formations. The Chinle Group is exposed at the surface west of the target area in the lower San Mateo Creek Basin (fig. 4).

Hydraulic Properties of Major Aquifers

Groundwater in the study area occurs in numerous deposits and formations that form unconfined and confined aquifers, and recharge occurs in highlands such as the Zuni Mountains and Mount Taylor. Horizontal flow is driven by these recharge areas and the regional tilt of the landscape, but local effects such as the McCarty Syncline and differences in recharge locations likely influence local conditions. Vertical flow likely is occurring among many of the formations except where restricted by shaly formations such as the Menefee, Mancos, and Chinle. Existing water-level elevations compiled as part of this study are listed in appendix 1.

Horizontal Flow

Available water-level data were evaluated to try and identify general flow patterns within each of the aquifers. Only water-level data from the alluvium aquifer provided an indication of flow direction in the study and target areas. Water-level elevations in the alluvium aquifer decrease in the downstream direction along San Mateo Creek (fig. 9). This observation is consistent with Baldwin and Anderholm's (1992) determination that groundwater flow in the alluvium aquifer generally is the same direction as that of surface water (or land topology) for this region. The water-level data from the lower aquifers in the sedimentary formations did not indicate similar relative differences in water-level elevations across the study area that could be interpreted as prevalent flow directions across the study or target areas. The relative distribution of water-level elevations in the study area for the lower aquifers is presented (fig. 10) as groupings of water levels for formations from geologic periods to indicate the variability in relative water-level elevations among each of the period groupings and no apparent flow directions from differences in relative water-level elevations. The large temporal and spatial extent of the water-level data (fig. 10 and table 1-1) appears to hinder identification of the general flow patterns for these deeper aquifers. In the target area, it is likely that groundwater in these lower aquifers generally flows eastward given the hydrogeologic framework where formation dip is eastward across the target area and the eastward flow direction identified by Baldwin and Anderholm (1992) for the San Andres/Glorieta aquifer. If the flow direction in the underlying aquifers is to the east in the target area, this flow direction is opposite of the flow direction in the alluvium aquifer in the upper San Mateo Creek Basin. Opposing flow directions would be a result of different recharge areas and the unconsolidated alluvium that conforms to the topological gradient compared to the consolidated formations that have a regional opposing gradient.

The influence of faults on groundwater flow was not investigated as part of this study, but the presence of numerous normal faults in the target area (fig. 6) likely influences groundwater flow. Faults can inhibit flow by disconnecting permeable pathways or by reducing porosity from fault gouge,

Table 3. Stratigraphic, lithologic, and aquifer characteristics of geologic deposits and formations in the study and target areas.

[ft, feet; %, percent; NA, not available; <, less than]

Deposit/formation	Geologic age	¹ Deposit/formation description	Surface location in the target area (figs. 4 and 8)	Thickness (ft)	Porosity/permeability	¹ Direction of flow	Aquifer present
Quaternary							
Alluvium (Qa)	Quaternary—upper Pleistocene to Holocene	Alluvium eroded from surrounding formations	Valley floor	Highly variable	Possibly large permeability	Variable	Yes
Neogene							
Flows and volcanoclastics (Tnv and Tpb)	Neogene	Lava, pyroclastic flows, and associated volcanoclastics from the Mount Taylor Volcanic Field	Forms mesa caps on basin highlands	Highly variable	Possible large porosity in vesicular basalts, but low permeability unless fractured	Away from Mount Taylor	Unlikely as an aquifer. Likely runoff or percolation to underlying formations
Cretaceous							
Menefee (Kmf)	Late Cretaceous	Interbedded mudstones, siltstones, fine- to medium-grained sandstones, mudstones, and thin coals	Northeastern part of basin	² Highly variable (eroded), up to 1,000 ft thick	30% sandstone, 65% shale, decent lense permeability	East to northeast	³ Discontinuous
Point Lookout (Kpl)	Late Cretaceous	Medium to fine-grained, cross-bedded sandstone	Exposed along northern rim areas	⁴ 5120	Likely porous with sandstone dominance	East to northeast	³ Discontinuous
Crevasse Canyon (Kcc)	Late Cretaceous	Interbedded siltstone, sandstone, and coal with thin conglomerates	Exposed along rim	⁵ 800	Highly variable	East to northeast	³ Discontinuous
Mulatto Tongue of Mancos (Kmm)	Late Cretaceous	Thin-bedded, tabular to ripple-laminated sandstone (well to moderately sorted and very fine grained) and black mudstone	Exposed along rim	⁵ 305	Larger porosity than main body of Mancos shale	East to northeast	³ Discontinuous
Gallup (Kg)	Late Cretaceous	Cross-bedded, moderately-sorted, very fine- to fine-grained sandstone	Exposed along rim	⁵ 73–85	Likely porous with sandstone dominance	East to northeast	³ Discontinuous
Mancos (Km)	Middle Cretaceous	Mudstone and silty mudstone with finely laminated to cross-bedded thin sandstone layers (well sorted and fine grained)	Exposed along base of mesas on northern basin boundary	⁵ 125–710	Small permeability given dominance of shale layers	East to northeast	³ Possibly discontinuous
Dakota (Kd)	Middle Cretaceous	⁵ Sandstones derived from marine shore-faces, intertongues with Mancos	Exposed along base of mesa on the southwest basin boundary	⁵ 50–60	Likely porous with sandstone dominance	East to northeast	³ Possibly discontinuous
Jurassic

¹Descriptions from McCraw and others (2009) and New Mexico Bureau of Geology and Mineral Resources (2003) unless otherwise noted. The flow-direction indication depends on the study area of the cited references. According to the references, flow directions were mostly northeastward closer to the Zuni Mountains and more eastward closer to the McCarty Syncline under Mount Taylor (fig. 3).

²Stone and others, 1983.

³Given a review of existing local and regional information, a productive aquifer is unlikely present in these formations within the study area but small amounts of groundwater may be present.

⁴Maximum thickness.

⁵Roca Honda Resources, LLC, 2009a.

⁶Entrada Complex—this term is used solely for this report to describe the early to late Jurassic deposits that have not been well discriminated in the study area. The Entrada is the dominant formation and the presence of the Todilto has been identified by the authors from review of driller's notes. The presence of Bluff and Summerville Formations in this area is debatable and beyond the scope of this report.

EXPLANATION

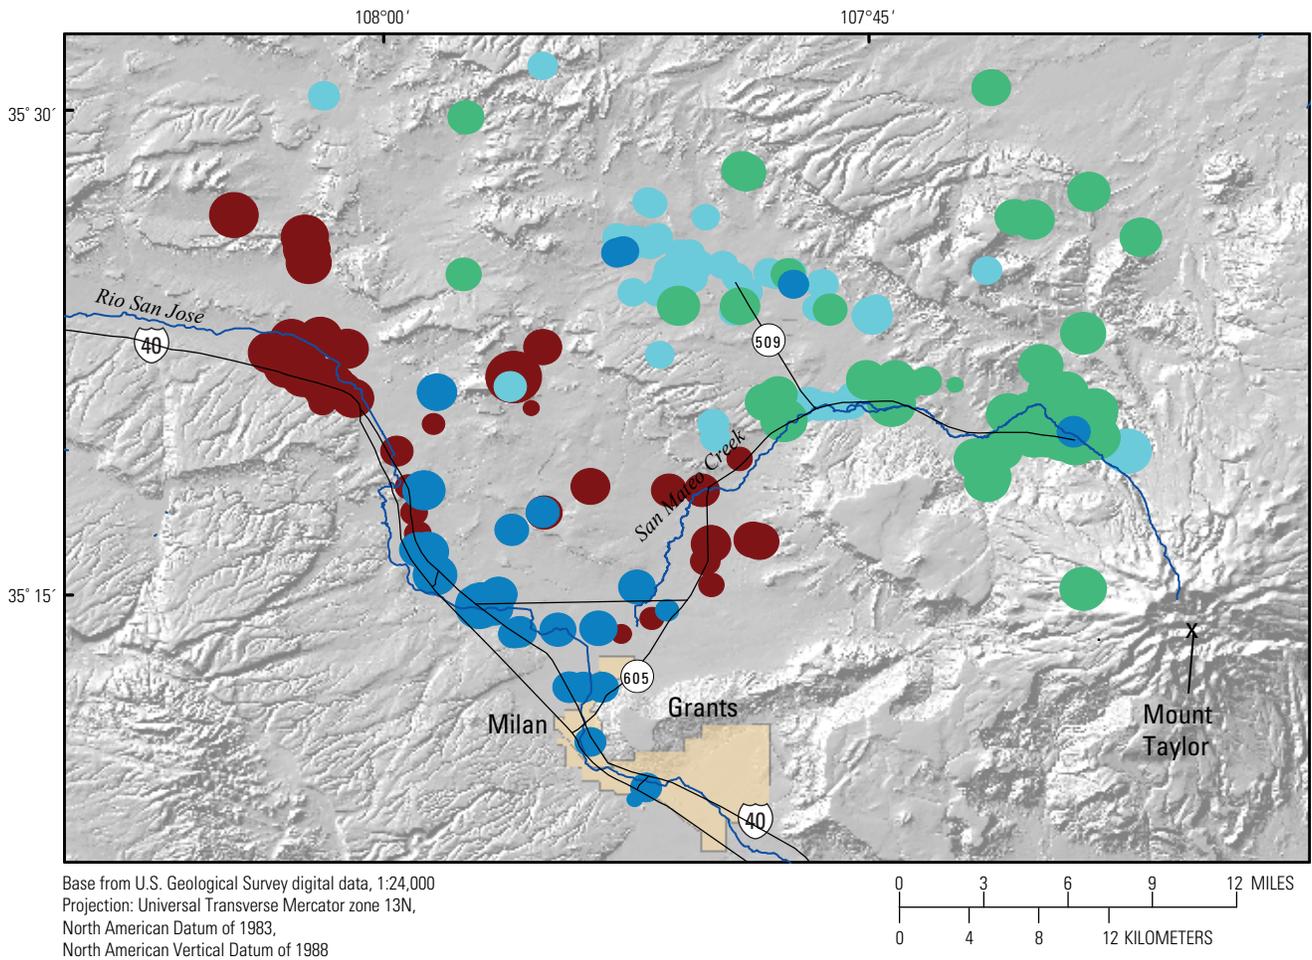

Developed area

The relative difference in water levels is presented through a categorical analysis of the distribution of water-level values. Using the statistical program SPlus (Tibco Software, version 8.1), each water level was assigned to one of seven distribution categories as determined by the overall distribution of water levels found in the Quaternary alluvium for the period of record. The presentation is similar to a categorical boxplot

Water-level elevation comparison

Lower water-level elevation Higher water-level elevation

Figure 9. Relative differences in water-level elevations for the distribution of water-level data compiled for wells with screens located in the Quaternary alluvium. Discrete water-level data are presented in appendix 1.

EXPLANATION

Developed area

The relative difference in water levels is presented through a categorical analysis of the distribution of water-level values for each geologic age grouping (formations grouped by period). Using the statistical program SPlus (Tibco Software, version 8.1), each water level was assigned to one of seven distribution categories as determined by the overall distribution of water levels found in each period grouping. Each period grouping is separate, and similar-sized symbols between period groupings does not indicate similar water-level elevations. The presentation is similar to a categorical boxplot for each of the individual period groupings

Water-level elevation comparison

Lower water-level elevation Higher water-level elevation

Age period grouping of wells

- Cretaceous formations
- Jurassic formations
- Triassic formations
- Permian formations

Figure 10. Relative differences in water-level elevations for the distribution of water-level data compiled for wells with screens located in Cretaceous, Jurassic, Triassic, and Permian formations. Discrete water-level data are presented in appendix 1.

but faults also can create higher permeable pathways along the fault trace (Fetter, 2001). The influence of faults is dependent upon the material in the fault zone. There likely is substantial displacement along some of the faults in the target area (fig. 6), but given the consolidated nature and thickness of the sedimentary formations, it is likely that faults in the study area enhance groundwater flow by increasing hydraulic conductivity across the fault zones, as has been observed on regional scales with porous, sedimentary formations (Garven, 1995). Faults as barriers or conduits for groundwater flow, however, depend on the individual nature of a fault (Garven, 1995).

Water-Level Elevations

Median values and the interquartile range of the water-level elevations were ascertained for each aquifer in the study area. These statistics represent the midpoint of the data set and 50 percent of its distribution that allows water levels in the aquifers to be viewed without influence of outliers that may skew inferences about the data. In the San Juan Basin, it is common for there to be substantial differences in the water levels of the various aquifers in the basin and up to 200 ft or more of difference has been identified (Stone and others, 1983). Within the study area, data for the various aquifers indicate 10s to 100s of ft of difference between median water-level elevations with minimal overlap in the range of uncertainty as indicated by the interquartile ranges except between the Dakota and Morrison Formations (table 4). Higher water elevations are found in the upper formations. Water-level elevations generally decrease with depth, although these

values cannot be compared directly as the data of each aquifer represents only that discrete area within the study area containing each aquifer’s wells (see figs. 9 and 10 for the distribution of wells by age groupings). Insufficient overlap of wells inhibits the interpretation of general vertical flow directions between aquifers in the study area.

The changing basal unit beneath the valley alluvium alters shallow groundwater flow because of differences in permeability of the basal unit that allows or restricts vertical migration of groundwater. In the eastern part of the basin, the presence of the Menefee Formation appears to restrict downward migration of groundwater from the valley alluvium. The Menefee Formation consists of interbedded shales, siltstones, and sandstones and is underlain by the Point Lookout Formation (sandstone) (table 3). It is likely that the portion of the valley alluvium that is underlain by the Point Lookout instead of the Menefee (western part of the target area) allows greater opportunity for downward migration of water from the alluvium aquifer. This geologic transition from the Menefee to Point Lookout has a surface expression of numerous seeps and salt deposits present along the creek from the eastern part of the basin to the confluence of El Rito and San Mateo Creeks. Downgradient or westward of this location, seeps and salt deposits are no longer present, and the Point Lookout Formation underlies the alluvium in this area (figs. 4 and 8).

Groundwater within the Chinle Group is confined (Frenzel, 1992), and upward migration from this aquifer into the Morrison Formation may be possible although the restricted nature of the water-elevation data sets do not allow for such a determination, given the limited overlap of

Table 4. Water-level elevation statistics for aquifers in consolidated formations in the study area.

[All values have been rounded to the nearest 5 feet; values are only shown for aquifers containing nine or more data points; NA, not available]

Deposit/formation	General formation description ¹	Water-level elevation median	Water-level elevation interquartile range ²	Number of water-level values in the study area
Menefee (Kmf)	Mudstone, siltstone, and sandstone	7,190	7,130–7,240	61
Point Lookout (Kpl)	Sandstone	6,975	6,940–7,045	10

²The interquartile range consists of the first and third quartiles, thereby encompassing 50 percent of the distribution.

water-level elevations between these aquifers. Water-level data for the Entrada Complex consisted of only three data points, and median and interquartile range values of the water-level elevation were not calculated. The Entrada Complex, located between the Morrison and the Chinle, should have sufficient permeability (table 3), given its sandstone dominance, to allow vertical movement of water through this formation. Flow through the Entrada Complex will depend upon available flow paths through the sandstones (or lack of restrictive layers such as thin mudstones that may be present in the Entrada Complex) and the local relation between the various potentiometric surfaces.

Hydraulic Conductivity

Hydraulic conductivity (K) is the capacity of a rock to transmit water and represents the volume of water that will move through a unit area of an aquifer's matrix given a specific unit of time and hydraulic gradient (Heath, 1983). With the substantial variation in composition of the deposits and formations in the study area, K values likely are highly variable, horizontally and vertically, within and between formations. The alluvium aquifer's K likely is highly variable, but published values indicate the possibility for relatively quick groundwater flow through the alluvium aquifer (table 5). The K values of other surficial deposits, such as the volcanoclastics atop the mesas, likely are more site specific and dependent upon depositional characteristics and fracturing as indicated by the large estimated K range for these deposits (table 5).

Few K data are available within the study area for the deeper aquifers, but inferences can be made for the various aquifers, given formation characteristics and the limited K data. Generally, matrices that are unconsolidated, composed of larger grain sizes, well-sorted, less cemented, highly fractured, or strongly weathered would have larger K values compared to matrices with opposing characteristics. Brod and Stone (1981) and Stone and others (1983) compiled characteristics of the study area Neogene, Cretaceous, and Jurassic formations within the San Juan Basin related to aquifer K values (table 5). The characteristics listed in table 5 are highly variable but provide an indicator of the gradation of deposition of the nonmarine sediments composing the Cretaceous and Jurassic formations found in the study area. Fracturing of the formations is not inferred by any of these characteristics, and fracturing can provide substantial pathways for flow. None of the characteristics listed in table 5 can be used to estimate the overall K of an aquifer contained within a formation, but taken together these characteristics can potentially indicate which formations may have larger relative K values. The shale-dominated Chinle Group has relatively small horizontal K values (table 5) and correspondingly small vertical K values of 3×10^{-5} to 1×10^{-4} ft/d (area sampled was north of Milan in the lower San Mateo Creek Basin (Hydro-Engineering, written commun., 1983)). Hydraulic conductivities of the San Andres/

Glorieta aquifer can be the largest of all the deeper formation aquifers (table 5).

Groundwater Composition of Major Aquifers

Insufficient data exist to fully describe the geochemical environments of the various aquifers and how they change with time, but sufficient data exist to evaluate overall water types and detections of trace element and contaminants of concern (apps. 2, 3, and 4) in the study area.

Major Elements

Water types in the study area are Na-HCO₃/SO₄ or mixed cation-mixed anion with some Ca-HCO₃ water, and the variation of major elements primarily is between changes in Na and Ca and HCO₃ and SO₄ (fig. 11A, B, and C; app. 2). The major-element variations appear related to typical weathering of silicate minerals and a few common evaporite minerals. Comparison of fresh granitic-type rock to weathered material has shown a possible introduction of the following elements in order of greatest contribution to solution: Na, Ca, Mg, K, Fe (strongly dependent on redox conditions), and Si (Langmuir, 1997). Depending on the level of mineral weathering, clays are primarily aluminosilicates with bound cations that may exchange with groundwater solutes (Bullen and Kendall, 1998). For an aqueous environment in a siliciclastic matrix, major anions primarily are influenced by atmospheric precipitation and soil concentrations because of the lack of these elements in igneous minerals. Bicarbonate is primarily influenced by atmospheric and soil gas inputs (carbon dioxide) and subsequent redox reactions that can decrease HCO₃ in aquifers, although increases in HCO₃ can indicate weathering of CO₃-rich minerals such as limestone (CaCO₃), which are not present in any substantial amount in the study area. The change from a water type of Ca-Mg-HCO₃ to larger dissolved-solids concentrations and Na-SO₄-Cl groundwater is common with dissolution of evaporite minerals such as gypsum (CaSO₄·H₂O) and halite (NaCl) (Vengosh, 2003), which also are not present in the study area in substantial amounts. Very little Cl is present in the aquifers in the study area except for a sample from the Chinle Group, which also indicated SO₄-dominant samples and groundwater with the largest dissolved-solids concentrations. The possible addition of Cl or SO₄ with evaporite mineral dissolution in the Chinle aquifer is difficult to attribute to any specific flow path and interaction with a certain formation in the Chinle Group given the gross nature of this analysis, but evaporite deposits have been observed in the Chinle Group in the region (Heckert and Lucas, 2003). Additionally, the shaly nature of much of the Chinle Group provides ample opportunity for cation exchange that can alter groundwater composition such as the exchange of Ca or Mg for Na (loss of Ca or Mg in solution with gain of Na in solution) (Appelo and Postma, 2005) that may account for some of the Na input instead of just silicate mineral weathering.

Figure 11. Trilinear diagrams of major-element relations for groundwater collected from the deposits and formations found in the study area. The data are a composite of available major-element concentrations collected in the study area from 1958 to 2009.

Trace Elements

A search of existing trace-element data in the study area produced data for Al, Sb, As, Ba, Be, B, Br, Cd, Cr, Co, Cu, Fe, Pb, Li, Mn, Mo, Ni, Se, Ag, Tl, V, and Zn. Very few of these elements were consistently detected in any aquifer, and only Ba, B, Fe, Li, Mn, V, and Zn were detected with any frequency. All existing data sources indicated some data where the elements were not detected at concentrations greater than the MDL(s), although MDLs were not regularly presented in the literature. Nondetect data were not included for analysis in this report because of missing MDLs, which severely limits the statistical analysis of the data because of the bias from this exclusion. The elements of Ba, B, Fe, Li, Mn, V, and Zn are abundant in the Earth’s crust and can be mobile in natural waters, and each element can indicate certain characteristics of mineral weathering and redox-environment changes (Hem, 1989; Nimz, 1998). The presence of the redox-sensitive elements Fe and Mn (and to a lesser degree V) indicates reducing conditions at some time in some location in most formations (table 6). Fe is present in the aquifers in various concentrations (app. 3), and it can enter solution under reducing conditions that substantially increase its solubility (Hem, 1989). As part of the USGS National Water-Quality Assessment Program redox classification system, McMahon and Chappelle (2008), proposed a reducing condition threshold 50 µg/L for Mn and 100 µg/L for Fe. As shown in appendix 3, each aquifer contained groundwater at some time that met one or both of the thresholds for reducing conditions. Given the gross nature of this analysis and data compilation and interconnectedness of the aquifers, persistence of reducing conditions in any aquifer at any specific location is unknown.

Boron is the most common trace element detected and had the largest concentrations except for Fe in specific aquifers (table 6 and app. 3). Boron is an abundant element

in the Earth’s crust and is highly mobile in natural waters (Bullen and Kendall, 1998; Nimz, 1998). Chemical weathering appears strongest in the upper formations because of the frequency of detections of B and Li and the presence of the other common trace elements (table 6), although this could be attributed to sampling frequency. Lithium is common in pegmatites, substitutes for Mg in some minerals, and tends to remain in solution as it is less favored in common-ion exchange compared to other ions (Kelly, 1948; Heier and Billings, 1970). Because of the nature of the data and the likely interconnectedness of the aquifers, the larger presence of these elements cannot be attributed to any characteristic of the upper formations. It is possible that chemical weathering of minerals containing these elements is occurring in overlying formations, such as the Menefee Formation, and being transported into lower formations, such as the Point Lookout Formation. Zinc was most commonly detected in the upper aquifers and the Morrison aquifer, which could represent anthropogenic influences such as mining, where mined water or materials containing Zn were brought to the surface from the Morrison Formation and Zn was transported to the upper aquifers.

Contaminants of Concern

Groundwater in the San Mateo Creek Basin has been contaminated by past mining and milling operations, and a health advisory has been issued for existing and future private wells within the basin concerning contaminant concentrations in excess of Federal drinking-water standards for gross alpha, NO₃, Ra, and U (New Mexico Environment Department, 2009). The sources of contamination are suspected to be naturally occurring ore deposits and former U mines and mills (New Mexico Environment Department, 2009). For purposes

Table 6. Number of detections of frequently detected trace elements in groundwater from the study area.

[Concentrations of the detected occurrence are presented in appendix 3; NA, not available]

Deposit/formation	Barium	Boron	Iron	Lithium	Manganese	Vanadium	Zinc
Alluvium (Qa)	4	39	22	1	7	1	6

San Andres (Psa)	NA	26	27	NA	3	NA	1

of this report, estimated concentrations of contaminants of concern in groundwater (above the MDL but below the reporting level) were accepted as valid detections of the contaminant. All nondetections or less than method detection level indicators were disregarded because of the variety of laboratory analysis methods and MDLs. An estimate of the number of nondetections from analysis of groundwater in the area is difficult to ascertain given the variety of data compiled for this report. For this reason, this discussion only references detected values and only the number of detections is presented with no discussion of concentration levels. A number of negative values were reported for ^{226}Ra , ^{228}Ra , and gross alpha. A negative value implies that the number of alpha emissions detected was smaller than the count of background alpha emissions. These values were disregarded because their negative value implies relatively small concentrations and possible nondetections. The detection counts by formation for the contaminants of concern are shown in table 7. Overall, the contaminants were detected more frequently in the upper aquifers (alluvium, Menefee, and Point Lookout) likely because of sampling frequency targeting mining contamination from surface activities.

Spring, Creek, and Seep Properties of the Upper San Mateo Creek Basin, New Mexico, 2009 and 2010

Snowmelt and precipitation on Mount Taylor and the surrounding mesas provide groundwater to the Neogene volcanoclastics, which recharge the underlying Cretaceous formations. The recharge areas around Mount Taylor and dip of the Cretaceous layers direct groundwater along layers that restrict vertical flow (formation contacts and bedding layers

in the volcanoclastics and sedimentary layers) and produce discharges at springs that form El Rito, San Mateo, and San Lucas Creeks, all of which are oriented northward and exit the mesas within or just below the Neogene volcanoclastics. No active springs were found along Jesus and San Mateo Mesas in the northern part of the target area, because of lack of an upgradient watershed (such as Mount Taylor) to catch sufficient precipitation and provide concentrated flow for recharge in this semiarid environment.

Spring, Creek, and Seep Flow

Discharge was occurring in August 2009 and May 2010 from the springs that form El Rito, San Mateo, and San Lucas Creeks. Late spring and summer discharges were about 1 to 2 ft³/s at all three locations (flows were estimated by determining the cross-sectional area and estimating the streamflow velocity by the float method; Rantz and others, 1983), although quantifying the flow rate was imprecise because of the diffuse nature of the springs. Flow in El Rito and San Mateo Creeks increased between the spring and creek sampling sites. The amount of flow increase varied between the late summer and late spring sampling events, but increased flow was observed in the downgradient direction during both sampling events. This increase in creek streamflow likely is from additional discharges from the underlying Menefee Formation (fig. 12). The spring locations indicate an inhibitor to vertical flow that drives water laterally to a spring, and downslope contributions that increase flow indicate lower saturated layers with similar restrictions to vertical flow and subsequent lateral discharge. Some vertical hydraulic connectivity is likely between the volcanoclastics and formations that compose the mesas, and lateral flow occurs at changes in vertical permeability.

Table 7. Number of detections of contaminants of concern in groundwater from the study area.

[Concentrations of the detected occurrence are presented in appendix 4; NA, not available]

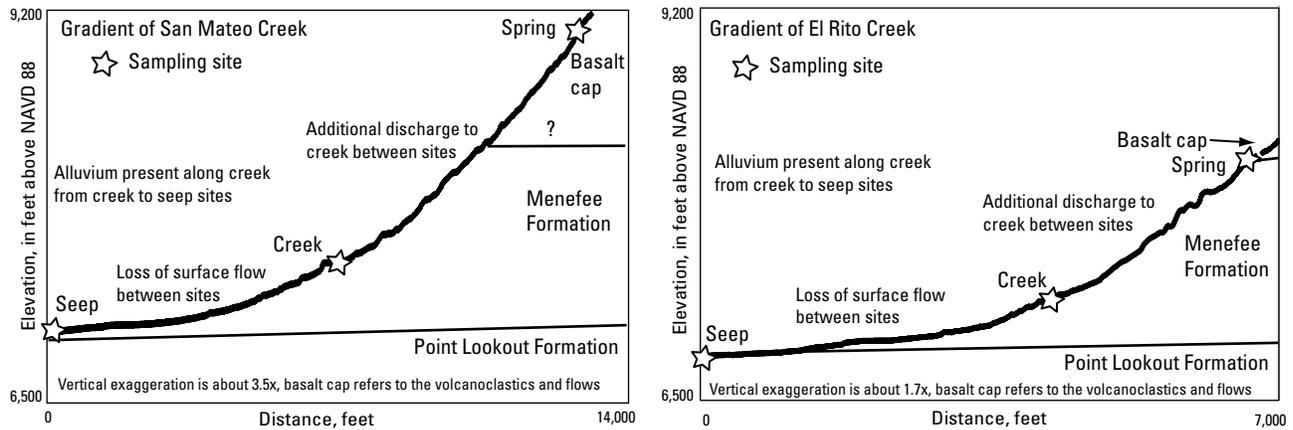

Figure 12. Landform gradients between sampling sites on El Rito and San Mateo Creeks and underlying geologic formations.

Differences in downstream flow of El Rito and San Mateo Creeks were observed between the August 2009 and May 2010 sampling events. Streamflows were larger in El Rito Creek during the May event than the August event, but streamflow was larger in San Mateo Creek during the August event than the May event. El Rito Creek appears to react more quickly to snowmelt from Mount Taylor as compared to San Mateo Creek. This difference may be a result of location and timing of spring snowmelt around Mount Taylor and the watershed orientation of each creek. El Rito Creek drains the western part of Mount Taylor, and San Mateo Creek drains the northern part of the mountain. Remaining snowpack was observed during the May event in the San Mateo Creek watershed but not in the El Rito Creek watershed. The difference in watershed orientation likely is the reason the larger flow was observed in El Rito Creek in May and in San Mateo Creek in August.

Water from El Rito and San Mateo Creeks is captured by man-made diversions for livestock purposes as the creeks exit the higher elevations where the landscape transitions to the valley floor. The creeks were dry below these diversions during both sampling events as the diverted water and remaining creek flow infiltrate into the alluvium aquifer. Springs previously have been mapped in the area and indicators of spring flow (dry discharge points and associated salt crusts) were present along the valley floor near El Rito and San Mateo Creeks. Seeps were present in both creek beds along the valley floor as stagnant water that supported wetlands and small wetted depressions. During both sampling events, there was no flowing water in San Mateo or El Rito Creeks along the valley floor in the upper San Mateo Creek Basin.

Spring, Creek, and Seep Water Composition

Spring- and creek-water samples from the target area contained small amounts of dissolved solutes, and seep water

contained substantially larger amounts of dissolved solutes (tables 8 and 9). The specific conductance of water exiting the springs and within the creeks was less than 200 $\mu\text{S}/\text{cm}$, and dissolved-solids concentrations were less than or equal to 150 mg/L during August 2009 and May 2010. Dissolved solids did not substantially increase between the spring and creek locations, although a larger increase was present between the spring and creek locations on San Mateo Creek as compared to El Rito Creek (tables 8 and 9), which may be because of the greater distance between these locations on San Mateo Creek (figs. 8 and 12). The small difference in dissolved solids and similar composition between the spring and creek locations in each system (tables 8 and 9) indicates similar composition for water discharging from the Menefee Formation (indicated by increased downstream flow) as compared to the upper volcanoclastics supplying the springs. Dissolved-solids concentrations substantially increased at the downstream seep sites for El Rito and San Mateo Creeks (tables 8 and 9) indicating mineral dissolution and likely evaporation that concentrated solutes in the water. Samples collected from the seep locations contained particulates less than 0.45-micron in diameter (after filtering), which likely were clay particles and various oxide complexes as indicated by their tannish color. The presence of the small-sized particulates contributes to the “dissolved” concentrations listed in tables 8 and 9. Such particulates were not present in the water from the creek and spring sites following filtering.

The pH of water within the creeks was neutral to alkaline, and all locations indicated oxygenated conditions (dissolved oxygen concentrations were greater than 3 mg/L for all samples; although nearly all samples were undersaturated) that reflects atmospheric exposure (fig. 13, tables 8 and 9). The pH of El Rito Creek did not substantially change from site to site or between August 2009 and May 2010, but the pH of San Mateo Creek changed substantially from site to site and between August 2009 and May 2010. Water in El Rito Creek

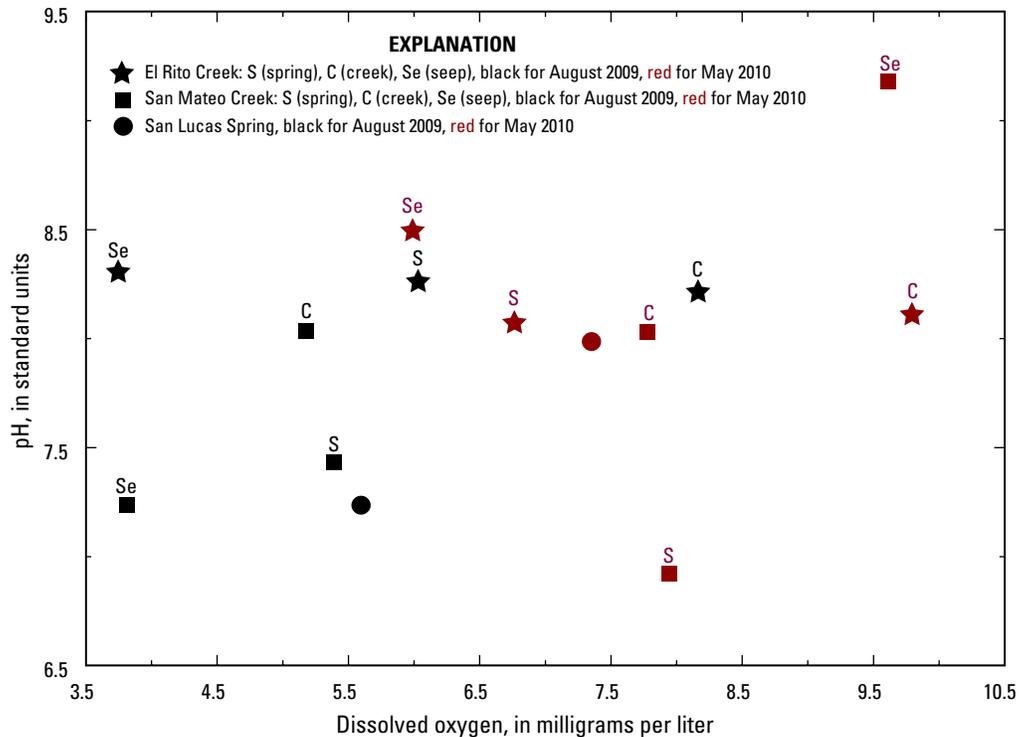

Figure 13. Dissolved oxygen and pH relation for water from El Rito, San Lucas, and San Mateo Creeks.

indicated a greater increase in dissolved-oxygen percent saturation with flow from the spring to creek locations as compared to San Mateo Creek, likely because of the larger topological gradient on El Rito Creek between the spring and creek locations (more turbulent flow). Dissolved-oxygen concentrations and percent saturation were equal or greater during the May 2010 sampling as compared to the August 2009 sampling for all locations.

Water Isotopes and Evaporation

The variation in isotopic composition of precipitation may allow discrimination of recharge because of changes in the isotopic composition from temperature changes during formation of precipitation and additional evaporation (Genereux and Hooper, 1998; Ingraham, 1998). The $\delta^2\text{H}$ and $\delta^{18}\text{O}$ values in the two creek systems generally plot near the global meteoric water line (GMWL) (fig. 14), which is atypical of the southwestern United States, where the semiarid climate generally produces values for any surface water or groundwater that plot below the GMWL with a reduced trend slope (evaporation line) because of a greater fractionation influence on H than O (Friedman and others, 1992; Kendall and Coplen, 2001). Only the seep samples indicate values below the GMWL. The larger values of the seeps indicate heavier isotope ratios or greater loss of the lighter isotopes likely from fractionation during evaporation, assuming no other water sources of

different isotopic composition (no identifiable upward leakage sources given the geologic framework and likely vertical flow directions).

The water isotopes also indicate differences in source waters and (or) evaporative effect between El Rito and San Mateo Creeks. The seep in El Rito Creek contained water with a heavier isotopic value for the August sample compared to the May sample, which is expected given the higher rate of evaporation during August. This seasonal influence was different for the seep in San Mateo Creek, which contained a heavier isotopic value for the May sample. This contrast in seasonal influences between the two creeks, indicates differences in source-water inputs between the two sampling events that likely pertain to differences in source-water mixing (winter precipitation and snowmelt compared to summer thunderstorms) and evaporation during snowmelt. This difference may be the quicker melt in the El Rito Creek watershed, given the observed lack of snow in this watershed and the presence of snow in the San Mateo Creek watershed during the May sampling event, as discussed in the Spring, Creek, and Seep Flow section. Such seasonal differences in the stable isotopes of water is common for shallow groundwater where the isotope signal is not attenuated (seasonal sources are not mixed) prior to discharge from the springs or seeps (Leibundgut and others, 2009). A lack of attenuation of the seasonal isotopic signal indicates that seasonal changes in flow or solutes will be visible in the spring, creek, and seep discharges.

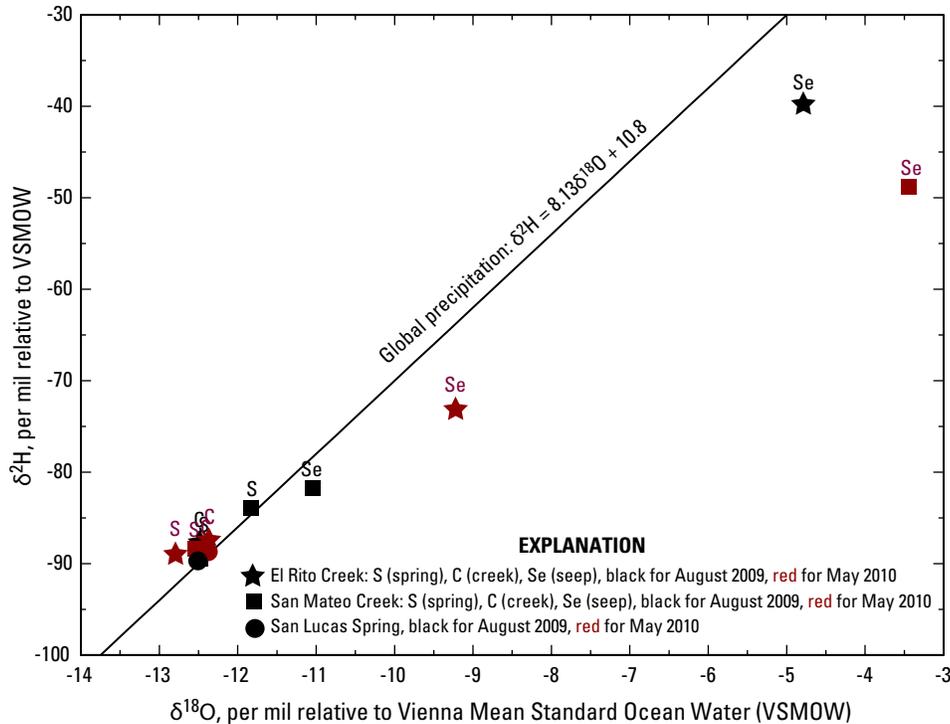

Figure 14. Stable isotope ratios for water from El Rito, San Lucas, and San Mateo Creeks.

Major Elements

The ion-exchange pool at any location in a flow path exemplifies water-rock interactions and atmospheric inputs, and ions will exchange at the mineral surfaces at relatively constant rates that reflect clay mineralogy, water pH, and water chemistry (Bullen and Kendall, 1998); although, water-rock interactions that produce mineral dissolution or adsorption can result in nonconservative solute behavior that limits the utility of major-element and trace-element concentrations for identifying source waters and flow paths (Langmuir, 1997). Results from the creek sampling indicated similarities in composition between the El Rito and San Mateo Creeks at comparable sampling sites (spring to spring or creek to creek) and large changes in downstream composition in each creek, mostly as a result of changes in Na and smaller changes in SO_4 between the creek and seep sites (fig. 15 and tables 8 and 9). These changes alter the composition in El Rito and San Mateo Creeks from a mixed cation- HCO_3 water type at the spring and creek locations to Na- HCO_3 at the seeps, which can occur with silicate weathering or cation exchange (Stumm and Morgan, 1996).

The major-element data indicated a strong electrical (cation-anion) imbalance for the sample from the seep along El Rito Creek in August 2009 (14 percent greater anion charge). Water at the seep along El Rito Creek in 2009 appears to contain additional buffering compounds such as hydroxides

(largest pH value of all samples), borates (largest boron value of all samples), aluminosilicates (largest aluminum value of all samples), and organic ligands (largest concentrations for many of the trace elements) (table 8), which resulted from the inclusion of very fine suspended particles passing through the 0.45-micron filter and were visible to the naked eye. The major cations and anions also did not balance for the sample collected from the spring at San Mateo Creek during the August 2009 sampling event, but this unbalanced charge was positive. This location appears to be influenced by a change in oxidation conditions. Water from the spring was oxygenated (5.43 mg/L dissolved oxygen at a saturation level of 53 percent), but the water contained relatively large concentrations of Fe (610 $\mu\text{g/L}$) and Mn (100 $\mu\text{g/L}$). It appears that reducing conditions may be present in the aquifer contained within the young, cap-forming basalts. The water chemistry of the aquifer may not be fully represented by the spring sample site as the water becomes oxygenated and kinetic reactions of various soluble or insoluble solutes occur at different rates with the transition from reduced to oxygenated conditions.

Saturation Indices

The presence of the major elements and trace elements in surface water in the upper San Mateo Creek Basin may allow various mineral compounds and phases to either dissolve in or precipitate from solution given the elements' concentrations.

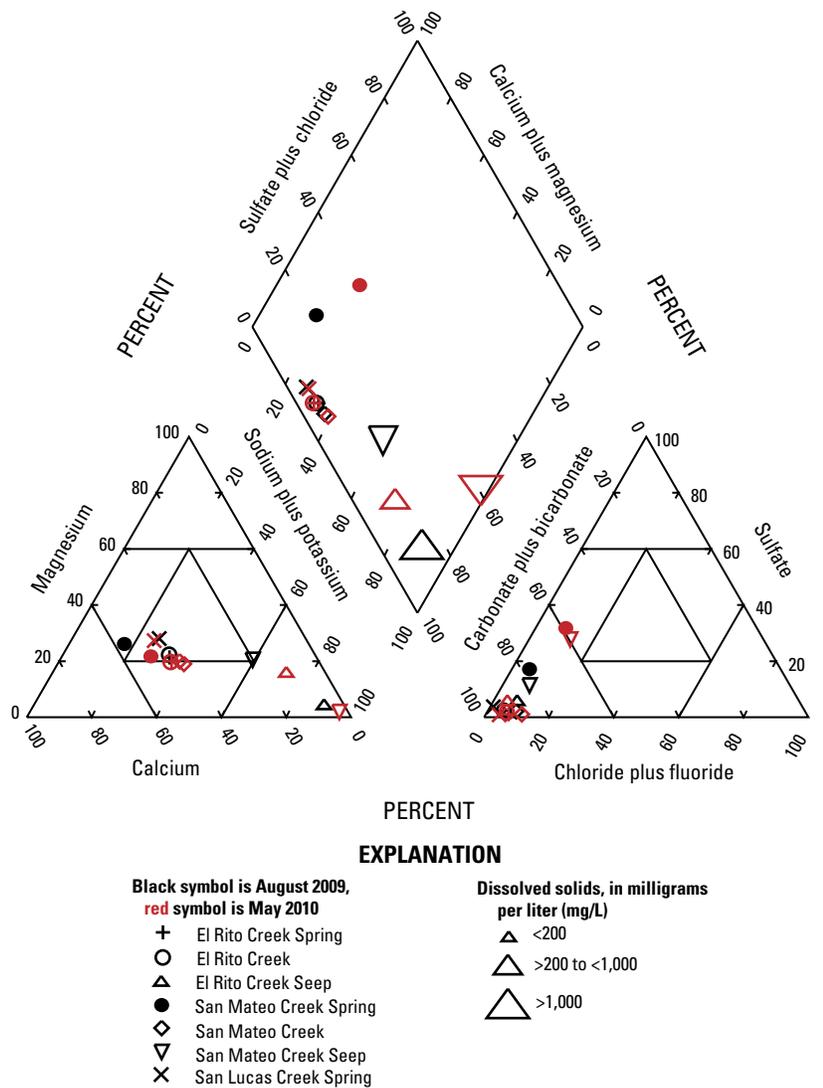

Figure 15. Trilinear diagram of major-element relations for water from El Rito, San Lucas, and San Mateo Creeks.

The saturation indices of possible common mineral forms were determined for the water samples from the August 2009 and May 2010 sampling events (tables 10 and 11). Negative values indicate undersaturation where a mineral might dissolve in the water and positive values indicate supersaturation where a mineral may precipitate from the water. The saturation indices indicate similar water composition and solute concentrations for spring to creek flow paths indicating no inputs of different water chemistries (tables 10 and 11). The increased flow between the spring and creek sites that was observed for El Rito and San Mateo Creeks is a result of the addition of water that is similar in composition to that discharging from the springs. The change from an open channel flow to infiltration into the alluvium from the creek to seep sites allows increased mineral weathering and provides available surfaces

for sorption and cation exchange as seen with the substantial differences in mineral phases (tables 10 and 11). Such a change in the flow system can induce large changes in the aqueous chemical environment as the elemental composition is altered with new inputs/outputs from weathering, cation exchange, and possible precipitation of various minerals along with sorbed elements (Bullen and Kendall, 1998).

Creek Flow Paths and Geochemical Model of Transition from Creek to Seep

El Rito and San Mateo Creeks are fed by precipitation (seasonal snow and rain) around Mount Taylor that feed the springs forming these creeks near the base of the mountain.

Table 10. Saturation indices of possible common minerals for water collected from the spring, creek, and seep locations along El Rito Creek in the target area.

[Saturation indices were calculated in PHREEQC (2.17.0) and represent the log of the ratio of the ion activity product (IAP) and the solubility product (K_{sp})]

El Rito and San Mateo Creeks transition from steep gradients along the mesas where flow is sustained by groundwater discharges from mesa volcanoclastics and the Menefee Formation to low gradients in the valleys where surface flow has infiltrated into the valley alluvium. The subsequent shallow groundwater is restricted (or retarded) from downward migration by a shaly layer in the Menefee Formation. This change from open-channel flow to shallow groundwater substantially alters the influences on the chemistry of the water. The upper creek flow that originates at the springs is influenced by infiltration of precipitation from Mount Taylor that remains dilute indicating relatively quick entry into the surface-water system without substantial addition of dissolved solutes that could occur with longer residence times in these upper layers of the mesas (additionally shown with the lack of isotopic signal attenuation for seasonal inputs described in the Water Isotopes and Evaporation section). With transition to the lower gradient valley floor of upper San Mateo Creek Basin, creek flow infiltrates into the valley alluvium but does not progress to substantial depths because of an apparent shale layer within the underlying Menefee found near the surface in the eastern part of the basin. The transitions from the mesa to the valley floor were geochemically modeled to compare the potential evaporation and water-rock influences on the water chemistry of the creeks.

All geochemical data were entered into NETPATH for the El Rito and San Mateo creek and seep locations. Each model was constrained by changes in Al, C, Ca, Fe, K, Mg, Mn, Na, and S, which were the elements that indicated large changes in concentration between the creek and seep sites in each system. Each model also was constrained by mineral phases

that were chosen according to the local geology and changes in typical minerals according to the saturation indices derived for each location (tables 10 and 11). Results of the geochemical modeling (table 12) are indicative of changes in water chemistry from the dissolution and precipitation of various minerals (including the presence of very fine clay particles from weathering) and cation exchange/sorption as solutes enter the system from water-rock interaction and the increase in concentration of solutes from evaporation. As visible in the concentrations (tables 8 and 9) and saturation indices (tables 10 and 11), elements of the selected minerals typically increase in groundwater concentration from creek to seep locations, which conforms to the conceptual model of chemical weathering and inputs of additional elements between these locations; although, certain minerals decrease in prevalence (become more undersaturated), such as gypsum in the August 2009 El Rito Creek samples, reflecting the changing element composition and preferred mineral forms. The mineral phases presented in table 12 are not meant to represent the entire chemical environment, but are common minerals that are thermodynamically preferred given the elemental composition of the waters. The mineral phases do reflect the presence of clays (thermodynamically preferred phases of montmorillonite and kaolinite possible in these solutions) that were observed in the filtered solution from the seeps. These clay phases do not represent the only clays present, but reflect the presence of very fine weathered aluminosilicate particles in solution. In addition to the likely substantial chemical weathering from creek to seep locations, the model results indicate a strong evaporative effect between the creek and seep locations (table 12). The evaporative effect was stronger in the May 2010 results

Table 12. Geochemical model results for creek to seep locations along El Rito and San Mateo Creeks.

[Aug 2009, August 2009 sampling event; May 2010, May 2010 sampling event; positive value represents an addition of the elements composing the mineral phase to the solution through dissolution in millimoles per kilogram of water (mmol/kg); negative value represents a subtraction of the elements composing the mineral phase to the solution through precipitation (mmol/kg); evaporation values are based on 1 kilogram of solution; <, less than]

Phase	Mineral composition	El Rito Creek		San Mateo Creek	
		Aug 2009	May 2010	Aug 2009	May 2010
Albite	NaAlSi ₃ O ₈	2.37*	2.78	4.03	13.54
Calcite	CaCO ₃	2.54	2.53	6.76	6.64
Ca-Montmorillonite	Ca _{0.165} Al _{2.33} Si _{3.67} O ₁₀ (OH) ₂	-17.37	-16.35	-39.94	-53.03
Goethite	FeOOH	.01	<-.01	<-.01	<.01
Gypsum	CaSO ₄ ·2H ₂ O	.12	.09	.50	2.13
Halite	NaCl	.26	<.01	.63	<.01
Kaolinite	Al ₂ Si ₂ O ₅ (OH) ₄	19.05	17.65	44.51	55.02
Rhodochrosite	MnCO ₃	<.01	.00	.01	<.01
Talc	Mg ₃ Si ₄ O ₁₀ (OH) ₂	-.03	.06	.25	.02
Grams of water (H ₂ O) remaining after evaporation		539	400	829	543
Evaporation factor (divisor)		1.85	2.50	1.21	1.84

*A secondary model was run with cation exchange (Ca substitution of Na on clay surfaces) as an additional influence. Results of this model were similar to the model results shown in the table except for the lack of albite dissolution and proportional decreases in Ca-montmorillonite and kaolinite (silicate layered clays).

(2.50 and 1.84 evaporation factors) as compared to the August 2009 results (1.85 and 1.21 evaporation factors). These results support the conceptual model of substantial mineral dissolution with increased water-rock interaction because of the entrance of the creek flow into the subsurface with the transition to the valley floor followed by substantial evaporation of the water as it reappears at the surface from seeps near the confluence of El Rito and San Mateo Creeks.

Summary

The water resources of the San Mateo Creek Basin are important to the citizens of New Mexico, in particular, the town of San Mateo and the city of Grants, for potable water sources. Citizens and tribal groups in this area are concerned about the possible effects on the water resources from exploratory drilling and possible mining of uranium as currently (2011) proposed by various companies for U.S. Forest Service land in the upper San Mateo Creek Basin. Existing data were used to describe the geologic framework and regional aquifer properties, and new data were collected to characterize the springs, creeks, and seeps in the upper San Mateo Creek Basin. The geologic framework of the study area consists of the Zuni Uplift, Chaco Slope, and the Mount Taylor Volcanic Field. The major landscape features of the San Mateo Creek Basin are a result of folding and tilting during the Laramide Orogeny and the Neogene volcanism associated with the Mount Taylor Volcanic Field. Within this structural context, the sedimentary formations provide matrices for local and regional aquifers.

Groundwater in the study area occurs in numerous deposits and formations that form unconfined and confined aquifers, and recharge occurs in highlands such as the Zuni Mountains and Mount Taylor. Existing water-level data indicate topologically downgradient flow in the Quaternary alluvium aquifer and indiscernible general flow patterns in lower aquifers. According to previously published material and the geologic structure of the aquifers, the flow direction in the lower aquifers likely is in the opposite direction compared to the alluvium aquifer. These opposing horizontal-flow directions are a result of different recharge areas, the unconsolidated alluvium that follows the topological gradient, and a regional opposing gradient of the lower sedimentary formations.

Insufficient data exist to fully describe the geochemical environments of the various aquifers and how they change with time, but sufficient data exist to evaluate general water types in the study area. Water types in the study area are sodium-bicarbonate/sulfate or mixed cation-mixed anion with some calcium-bicarbonate water, and the variation of major elements is primarily between changes in sodium and calcium and bicarbonate and sulfate. The major-element variations appear related to typical weathering of silicate minerals and a few common evaporite minerals and cation-exchange processes. The presence of the reduction/oxidation-sensitive

elements iron and manganese indicates reducing conditions at some time or in some location in most formation aquifers. The large concentrations of zinc in the alluvium aquifer could represent anthropogenic influences such as mining.

Snowmelt and precipitation on Mount Taylor and the surrounding mesas provide groundwater to the Neogene volcanoclastics, which recharge the underlying Cretaceous formations. The upgradient recharge areas and regional dip of the Cretaceous layers towards the north-northeast direct groundwater along likely bedding planes that restrict vertical flow and cause discharges at springs that form El Rito, San Mateo, and San Lucas Creeks. Streamflows were larger in El Rito Creek during May 2010 compared to August 2009, but streamflow was larger in San Mateo Creek during August 2009 compared to May 2010. El Rito Creek appears to react more quickly to snowmelt from Mount Taylor than does San Mateo Creek. This difference may be a result of location and timing of spring snowmelt around Mount Taylor because of differences in watershed orientation. Water from El Rito and San Mateo Creeks is captured by man-made diversions for livestock purposes as the creeks exit the higher elevations where the landscape transitions to the valley floor. The creeks were dry below these diversions during the sampling events in 2009 and 2010. The diverted water and remaining creek flow infiltrate into the alluvium aquifer, but some of this water did reemerge in seeps in the center of the upper San Mateo Creek Basin near the confluence of El Rito and San Mateo Creeks.

Spring- and creek-water samples from the target area contained small amounts of dissolved solutes, and seep water contained substantially larger amounts of dissolved solutes. The specific conductance of water exiting the springs and within the creeks was less than 200 microsiemens per centimeter and dissolved-solids concentrations were less than or equal to 150 milligrams per liter during August 2009 and May 2010. The pH of water within the creeks was neutral to alkaline, and all locations indicated oxygenated conditions with nearly all samples being undersaturated for dissolved oxygen. Results of water-isotope analyses indicate limited evaporation at the spring and creek sites but greater evaporation by the time the water reaches the seep locations in the center of upper San Mateo Creek Basin. Variations in water isotopes between El Rito and San Mateo Creeks indicate differences in source-water inputs between the two sampling events that likely pertain to spring snowmelt compared to summer-thunderstorm precipitation.

Results from the creek sampling indicated similarities in composition between the El Rito and San Mateo Creeks at the comparable sampling sites (spring to spring or creek to creek) and large changes in downstream composition in each creek, mostly as a result of changes in sodium and smaller changes in sulfate between the creek and seep sites. These changes alter the composition in El Rito and San Mateo Creeks from mixed cation-bicarbonate water type at the spring and creek locations to sodium-bicarbonate water type at the seeps. Geochemical modeling of the transition from creek to seep locations along El Rito and San Mateo Creeks indicates chemical weathering

and additional element inputs through water-rock interactions and possible element composition changes from cation exchange. Additionally, the model results indicate an evaporative effect between the creek and seep locations and differences in the chemical weathering and evaporation effects by season.

Appendix 1.—Historical Groundwater-Elevation Data

Existing groundwater-elevation data in the study area are presented in table 1-1. The spatial distribution of the associated wells across the study area is shown in fig. 1-1 (individual well locations can be located through latitude and longitude coordinates presented in table 1-1). The water-level data set is a compilation of multiple sources and is presented in order of increasing geologic age of the associated formation. Initial formation designations were determined by the authors/data collectors of the source references (references listed following the table). Groundwater-elevation data without formation designations were not included for analysis in this study. For this study, formation designations were homogenized to currently (2011) accepted formation nomenclature. This homogenization was necessary because of the long data record (1940s onward) during which formation identification has changed with certain formation names dropped from the lexicon or added as additional studies continued to update the stratigraphic nomenclature of the region (see Methods section).

Table 1-1. Historical groundwater-elevation data in the study area, 1946–2009.

EXPLANATION

-  Developed area
-  Well location from which data were collected

Figure 1-1. Spatial distribution of historical groundwater-elevation data in the study area.

Appendix 2.—Historical Groundwater Major-Element Data

Existing major-element data in the study area are presented in table 2-1. The spatial distribution of the associated wells across the study area is shown in fig. 2-1 (individual well locations can be located through latitude and longitude coordinates presented in table 2-1). The major-element data set is a compilation of multiple sources and is presented in order of increasing geologic age of the associated formation. Initial formation designations were determined by the authors/data collectors of the source references (references listed following the table). Existing major-element data without formation designations were not included for analysis in this study. For this study, formation designations were homogenized to currently (2011) accepted formation nomenclature. This homogenization was necessary because of the long data record (1950s onward) during which formation identification has changed with certain formation names dropped from the lexicon or added as additional studies continued to update the stratigraphic nomenclature of the region (see Methods section).

Table 2-1. Historical groundwater major-element data in the study area, 1958–2009.

EXPLANATION

- Developed area
- Well location from which data were collected

Figure 2-1. Spatial distribution of historical groundwater major-element data in the study area.

Appendix 3.—Historical Groundwater Trace-Element Data

Existing trace-element data in the study area are presented in table 3-1. The spatial distribution of the associated wells across the study area is shown in fig. 3-1 (individual well locations can be located through latitude and longitude coordinates presented in table 3-1). The trace-element data set is a compilation of multiple sources and is presented in order of increasing geologic age of the associated formation. Initial formation designations were determined by the authors/data collectors of the source references (references listed following the table). Existing trace-element data without formation designations were not included for analysis in this study. For this study, formation designations were homogenized to currently (2011) accepted formation nomenclature. This homogenization was necessary because of the long data record (1940s onward) during which formation identification has changed with certain formation names dropped from the lexicon or added as additional studies continued to update the stratigraphic nomenclature of the region (see Methods section).

Table 3-1. Historical groundwater trace-element data in the study area, 1942–2009.

[NAD 83, North American Datum of 1983; Ba, barium; µg/L, micrograms per liter; B, boron; Fe, iron; Li, lithium; Mn, manganese; V, vanadium; Zn, zinc; Qa, Quaternary alluvium; NA, not available; Kmf, Cretaceous Menefee Formation; Kpl, Cretaceous Point Lookout Formation; Kcc, Cretaceous Crevasse Canyon Formation; Kg, Cretaceous Gallup Formation; Km, Cretaceous Mancos Formation; Kd, Cretaceous Dakota Formation; Jm, Jurassic Morrison Formation; Je, Jurassic Entrada Complex (includes Entrada, Todilto, Summerville, and Bluff Formations); TRc, Triassic Chinle Group; Psa, Permian San Andres Formation (including Glorieta Formation)]

EXPLANATION

- Developed area
- Well location from which data were collected

Figure 3-1. Spatial distribution of historical groundwater trace-element data in the study area.

Appendix 4.—Historical Groundwater Contaminants-of-Concern Data

Data for the contaminants of concern in the study area (NO_3 , U, Ra, and gross alpha) are presented in table 4-1. The spatial distribution of the associated wells across the study area is shown in fig. 4-1 (individual well locations can be located through latitude and longitude coordinates presented in table 4-1). The contaminants-of-concern data set is a compilation of multiple sources and is presented in order of increasing geologic age of the associated formation. Initial formation designations were determined by the authors/data collectors of the source references (references listed following the table). Contaminant data without formation designations were not included for analysis in this study. For this study, formation designations were homogenized to currently (2011) accepted formation nomenclature. This homogenization was necessary because of the long data record (1940s onward) during which formation identification has changed, with certain formation names dropped from the lexicon or added as additional studies continued to update the stratigraphic nomenclature of the region (see Methods section).

Table 4-1. Historical groundwater contaminants-of-concern data in the study area, 1942–2009.

[NAD 83, North American Datum of 1983; NO₃, nitrate or nitrate plus nitrite; N, nitrogen; mg/L, milligrams per liter; U, uranium; µg/L, micrograms per liter; Ra, radium; pCi/L, picocuries per liter; Qa, Quaternary alluvium; NA, not available; Kmf, Cretaceous Menefee Formation; Kpl, Cretaceous Point Lookout Formation; Kcc, Cretaceous Crevasse Canyon Formation; Kg, Cretaceous Gallup Formation; Km, Cretaceous Mancos Formation; Kd, Cretaceous Dakota Formation; Jm, Jurassic Morrison Formation; Je, Jurassic Entrada Complex (includes Entrada, Todilto, Summerville, and Bluff Formations); TRc, Triassic Chinle Group; Psa, Permian San Andres Formation (including Glorieta Formation)]
