Lake Levels and Water Quality in Comparison to Fish Mercury Body Burdens, Voyageurs National Park, Minnesota, 2013–15

By Victoria G. Christensen,¹ James H. Larson,¹ Ryan P. Maki,² Mark B. Sandheinrich,³ Mark E. Brigham,¹ Claire Kissane,² and Jaime F. LeDuc²

Abstract

Within Voyageurs National Park in Minnesota, lake levels are controlled by a series of dams to support a variety of uses. Previous research indicates a link between these artificially maintained water levels, referred to as rule curves, and mercury concentrations in fish owing to the drying and rewetting of wetlands and other nearshore areas, which may release methylmercury into the water when inundated. The U.S. Geological Survey, National Park Service, and University of Wisconsin-La Crosse cooperated in a study to assess the importance of lake-level fluctuation and other factors affecting mercury concentrations in *Perca flavescens* (yellow perch) in the lakes of Voyageurs National Park. For this study, mercury body burdens were determined for young-of-the-year yellow perch collected from the large lakes within Voyageurs National Park during 2013–15. These mercury body burdens were compared to lake levels and water-quality constituents from the same period.

Field properties and profiles of lake water quality indicated that Sand Point, Little Vermilion, and Crane Lakes were anoxic at times near the lake bottom sediments, where sulfate-reducing bacteria may convert mercury to methylmercury. The median dissolved sulfate concentration was highest in Crane Lake, the median total organic carbon concentration was highest in Sand Point Lake, and the median total phosphorus concentration was highest in Kabetogama Lake, all of which is consistent with previous research. All lakes had median chlorophyll *a* concentrations of 3.6 micrograms per liter or less with the exception of Kabetogama Lake, where the median concentrations were 4.3 micrograms per liter for the midlake sites and 7.1 micrograms per liter and 9.0 micrograms per liter for the nearshore sites.

Mercury concentrations in sampled fish varied widely between years and among lakes, from 14.7 nanograms per gram in fish samples from Kabetogama Lake in 2015 to

178 nanograms per gram in fish samples from Crane Lake in 2014. Data from this study can be combined with ongoing hydrologic modeling studies to evaluate trends in the mercury body burden of fish and different water-level management scenarios prescribed by the 2000 Rule Curves and the 1970 Rule Curves.

Introduction

Major sources of mercury to the aquatic environment include erosion of geologic material, urban discharges, industrial discharges, agriculture, mining, and atmospheric deposition (Wang and others, 2004; Pirrone and others, 2009). In many aquatic ecosystems around the world, atmospheric deposition of mercury and subsequent conversion to methylmercury in water bodies has led to elevated fish mercury body burdens (Driscoll and others, 2013). In North America, atmospheric deposition of methylmercury in recreational and commercial fisheries is a concern because of risks to both human and wildlife health (Wiener and others, 2013; Driscoll and others, 2007, 2013). Methylmercury biomagnifies in aquatic food webs (Watras and Bloom, 1992; Morel and others, 1998), potentially reaching concentrations sufficient to induce sublethal, toxic effects in wildlife (Meyer and others, 1998; Sandheinrich and Wiener, 2011; Depew and others, 2012) and humans who routinely consume fish with high mercury concentrations (Shubat and others, 1995); therefore, in 2001 the U.S. Environmental Protection Agency (EPA) issued a criterion of 0.3 milligram methylmercury per kilogram fish tissue wet weight (mg/kg) for the protection of human health (U.S. Environmental Protection Agency, 2001), which is the equivalent of 300 nanograms per gram (ng/g).

In Minnesota, fish in many lakes have high mercury concentrations (Glazer and Bohlander, 1978; Wiener and others, 2006). This is especially true in sensitive ecosystems, such as wetlands or lakes with hydrologically connected wetlands, because biogeochemical conditions in wetlands tend to favor the bacterial conversion of inorganic mercury to methylmercury (Wiener and others, 2006; Driscoll and others, 2007).

2 Lake Levels and Water Quality in Comparison to Fish Mercury Body Burdens, Voyageurs National Park, Minnesota

Sorensen and others (2005) provide evidence that water-level fluctuations in 13 lakes in northern Minnesota, including the large lakes in Voyageurs National Park, were highly correlated with the methylmercury concentrations found in young-of-the-year *Perca flavescens* (yellow perch) collected at the end of the growing season each fall, indicating a possible link between artificial lake-level management and fish mercury body burdens. In a followup study on a subset of the lakes studied by Sorensen and others (2005), Larson and others (2014) determined that relations between mercury concentrations in fish and water level varied substantially among lakes. Drying and rewetting cycles within wetlands or impoundments has been correlated with elevated mercury in fish (Snodgrass and others, 2000) and elevated methylmercury in water (Brigham and others, 2002). Other factors, such as trophic status (Pickardt and others, 2002), wetland morphology (Snodgrass and others, 2000), and sulfate concentrations (Sorensen and others, 2005), also can affect mercury bioavailability to fish.

The water levels in the large lakes in Voyageurs National Park (fig. 1) are controlled by a series of dams that were completed to support a variety of legally recognized uses of these lakes. Because these lakes are international waters, the International Joint Commission (IJC) has regulatory authority and stipulates water-management practices (rule curves) for the private-sector dam operators. In 2000, the IJC changed the rules governing dam operation (International Joint Commission, 2001). Rule curves are bands of allowable high and low water levels throughout the year. The rule curves (fig. 2) were expected to restore water levels to conditions similar to predam conditions for Namakan Reservoir (which includes Kabetogama Lake, Namakan Lake, Sand Point Lake, Crane Lake, and Little Vermillion Lake).

The magnitude of observed water-level fluctuations during 1970–99 was significantly greater than observed water-level fluctuations during 2000–09 in Namakan Reservoir (Christensen and others, 2011). Water-level fluctuation has been linked to water quality and aquatic biological effects in these lakes (Christensen and others, 2013; Cole, 1979, 1982; Kallemeyn and others, 1993); therefore, a better understanding of lake levels and water quality in comparison to fish mercury body burdens was needed. To address this need, the U.S. Geological Survey (USGS), National Park Service (NPS), and University of Wisconsin-La Crosse cooperated in a study to assess the importance of lake-level fluctuation and other factors affecting mercury concentrations in yellow perch in six lakes in Voyageurs National Park during 2013–15. This assessment of factors suspected of having an effect on concentrations of mercury in fish will contribute to the IJC's body of knowledge as a review is performed of information collected regarding the effects of the 2000 Rule Curves on the health of this ecosystem.

The purpose of this report is to characterize the environmental variables, including lake-level fluctuation and other factors, associated with mercury body burdens in young-of-the-year yellow perch in Rainy Lake and Namakan Reservoir,

Voyageurs National Park, during 2013–15. The data collected as part of this study can be used by the IJC and other researchers in decision-making models related to the effect of water-level changes on mercury body burdens in fish and other environmental factors.

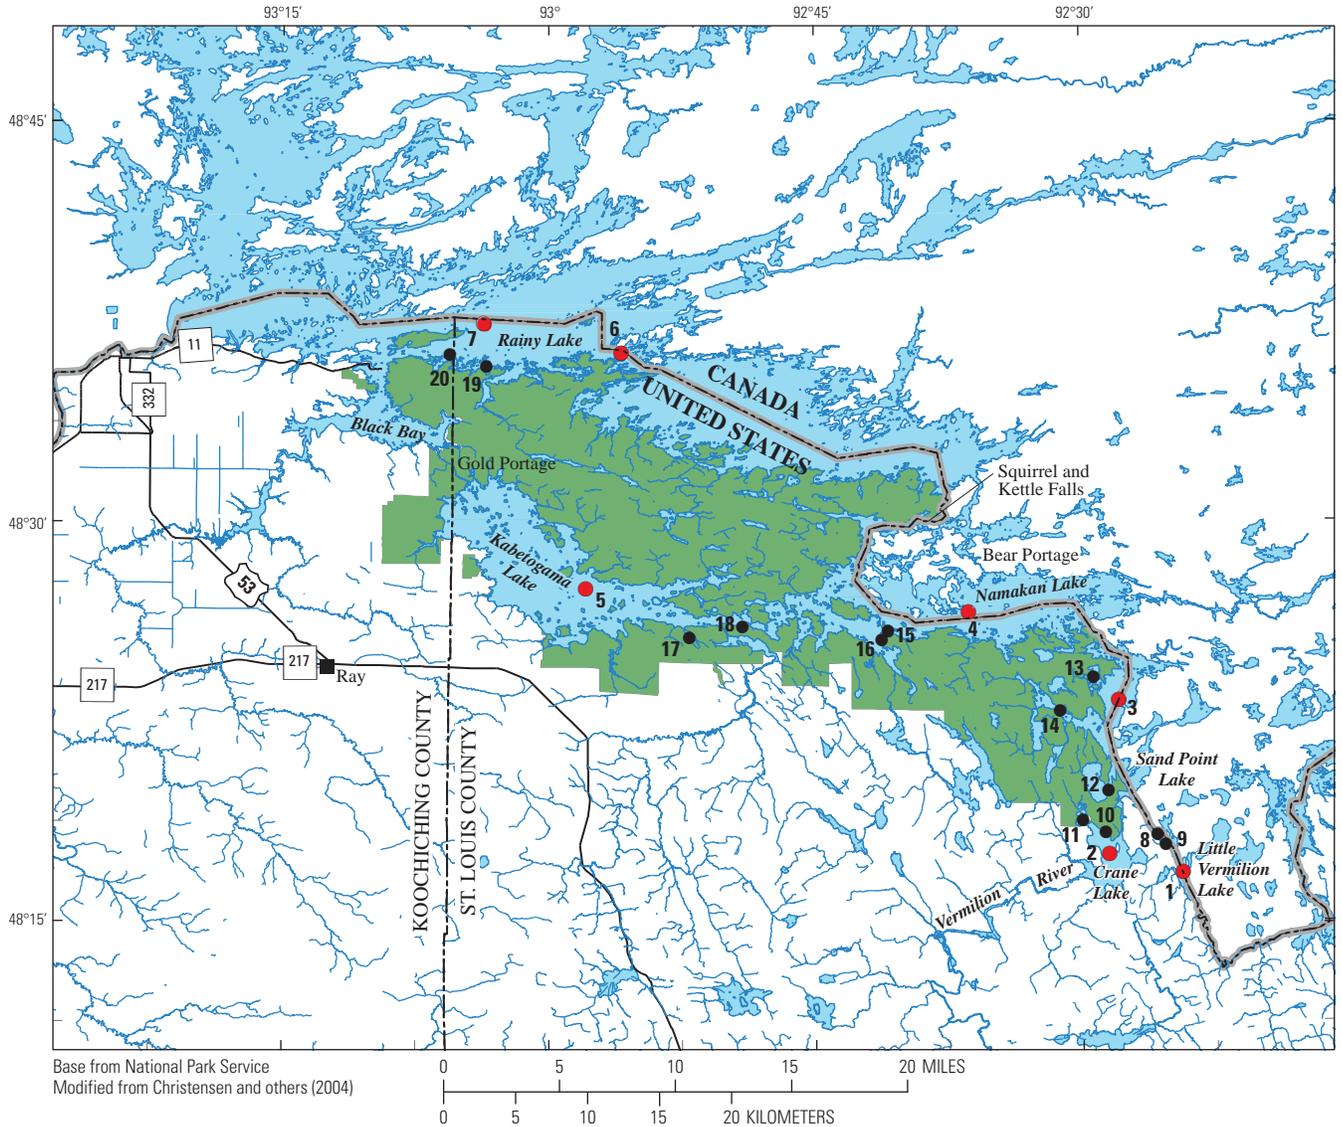

Study Area

Voyageurs National Park, a water-based park in northern Minnesota on the border between the United States and Canada (fig. 1), is in a mercury sensitive landscape (Knights and others, 2005; Wiener and others, 2016). Voyageurs National Park was established to protect “the outstanding scenery, geological conditions, and waterway system which constituted a part of the historic route of the Voyageurs” (Public Law 91–661). The park protects a series of southern boreal lakes on the Canadian (Precambrian) Shield. The ecosystem health of these lakes is of critical importance for many of the recreational uses of the park and the NPS as it attempts to meet its mission of maintaining resources in an unimpaired condition for future generations.

Rainy Lake and Namakan Reservoir are two of the most popular fishing destinations in northern Minnesota; visitors spend an average of more than 700,000 hours per year angling in these waters (Kallemeyn and others, 2003). Fishing is the principal recreational activity in Voyageurs National Park (Kallemeyn and others, 2003), making consumption of fish with high mercury body burdens a potential health risk to visitors.

In the lakes in Voyageurs National Park, a high proportion of deposited mercury is methylated, leading to high concentrations of toxic methylmercury in fish (Wiener and others, 2006, 2013). Mercury concentrations in *Esox lucius* (northern pike) from four Voyageurs National Park lakes sampled during 2000–11 were greater than levels that can have negative reproductive effects on native fish species (Sandheinrich and Wiener, 2011; Wiener and others, 2013, 2016), and the highest mercury concentrations measured for northern pike sampled in Minnesota were in samples collected in two Voyageurs National Park lakes (Wiener and others, 2006). Mercury body burdens of fish in Voyageurs National Park lakes are greater than levels shown to cause sublethal and reproductive effects in fish. Seventy percent of fish sampled in a recent study had mercury concentrations exceeding fish consumption guidelines, whereas 94 percent exceeded the tissue residue criterion set by the EPA (U.S. Environmental Protection Agency, 2001; National Park Service, 2012); therefore, mercury body burdens of fish continue to be a top management concern and necessitate consumption advisories for all sampled Voyageurs National Park lakes (National Park Service, 2012), which are listed for mercury impairment on Minnesota's Impaired Waters Inventory (Minnesota Pollution Control Agency, 2016).

Water-level fluctuations in Voyageurs National Park have a tremendous effect on aquatic ecosystem health (Kallemeyn

and others, 2003), and resource managers have the ability to affect water-level fluctuations in this system. The water levels in these lakes are controlled by a privately owned hydropower dam at the outlet of Rainy Lake and by regulatory dams at Squirrel and Kettle Falls on Namakan Lake. Water levels have been controlled by the dams on Rainy Lake and Namakan Reservoir since the early 1900s (Kallemeyn and others, 2003). Prior to installation of the dams in the early 1900s, all these lakes were natural water bodies. Flows are now regulated to satisfy multiple uses, including power generation and recreation.

Because some of the lakes of the Namakan Reservoir system are international waters, beginning in 1949, private-sector dam operators have had to maintain lake levels using a series of rule curves established by the IJC (Kallemeyn and others, 2003). In order to better regulate water levels, the IJC modified the rule curves in 1957 and 1970. From 1970 through 1999, the 1970 Rule Curves were in effect, by which larger-than-natural fluctuations in water levels of the Namakan Reservoir were used to maintain smaller-than-natural fluctuations in water levels of Rainy Lake (Kallemeyn and others, 2003). During the 1980s, Voyageurs National Park initiated research on the effects of artificial lake-level management on the aquatic ecosystem of the park to develop alternatives to the 1970 Rule Curves (Kallemeyn and Cole, 1990; Kallemeyn and others, 1993). The International Steering Committee of the IJC made recommendations for rule curve changes in 1993. In January 2000, after studying the recommendations by the International Steering Committee, the IJC issued a new

Supplementary Order for the hydrological management of the Rainy Lake-Namakan Reservoir system; this order prescribes the 2000 Rule Curves. The 2000 Rule Curves specify water-level fluctuations that are similar to predam hydrology rather than the water levels specified under the 1970 Rule Curves. The requisite maximum and minimum water levels as defined by the IJC for Namakan Reservoir and Rainy Lake are shown in figure 2.

Methods

Young-of-the-year yellow perch were collected from 13 nearshore sites in Voyageurs National Park (table 1). The 13 sites were included in the study by Sorensen and others (2005) and in the current study. A subset, consisting of six of the sites, has been sampled annually since 2001 and was included in the study by Sorensen and others (2005) and the current study (table 1, footnotes 2 and 3). One of those six sites (Sand Point, west side, near Mukooda Lake; Sorensen and others, 2005) has been sampled annually since 1991 (with the exception of 1995).

Water-quality data, including factors known or believed to affect mercury speciation and methylation (such as pH, total organic carbon, and dissolved sulfate) were collected at the 13 nearshore fish collection sites and 7 midlake sites (table 1). Sampling at one of the midlake sites, Rainy Lake east of Drywood Island, was discontinued in 2013.

The data collected during this study can be compared to historical data to assess whether a change in rules governing dam operation affected mercury body burdens in yellow perch in these lakes. The data collection and interpretation were completed in conjunction with results of other studies assessing the hydrology and bathymetry of these lakes as part of the IJC's efforts to determine the effects of current rules governing dam operation.

Water Sampling and Laboratory Analysis

Water-quality data were collected by NPS personnel at 7 midlake sites and 13 nearshore sites. The midlake sites and the nearshore sites (collocated with the fish-collection sites) were sampled once per year in September or October 2013, 2014, and 2015.

Field properties of water temperature, Secchi-disk transparency, specific conductance, pH, dissolved oxygen, and

acid neutralizing capacity were measured at all midlake and nearshore sites during each sampling event (Wilde and Radtke, 2005). Temperature, specific conductance, pH, and dissolved oxygen were measured at each lake site about 1 meter (m) below the lake surface with a multiparameter sonde calibrated according to USGS methods (Wagner and others, 2006). Secchi-disk transparency was recorded at each site. Because the 13 nearshore sites (fig. 1) were shallow and typically the bottom of the lake is visible, Secchi transparency was measured by moving out into the lake until the Secchi disk was no longer visible at the bottom of the lake. Acid neutralizing capacity was determined on nearshore and midlake water samples by digital titration with a Hach kit in the field laboratory (U.S. Geological Survey, variously dated).

Lake profiles of water temperature, specific conductance, pH, and dissolved oxygen concentration were collected at midlake sites during sampling in 2013–15 with the multiparameter sonde. Profiles were collected generally at 2-m depth

6 Lake Levels and Water Quality in Comparison to Fish Mercury Body Burdens, Voyageurs National Park, Minnesota

intervals, except at Rainy Lake at Brule Narrows (USGS site number 483622092560701), where the intervals were 1 m.

Water samples for laboratory analysis of dissolved sulfate, total organic carbon, total phosphorus, and chlorophyll *a* were collected from nearshore and midlake sites by NPS personnel using a Van Dorn-type sampler, according to methods described by Payne (1991). Water samples were placed on ice and shipped to the USGS National Water Quality Laboratory in Denver, Colorado, for analysis of dissolved sulfate (Fishman and Friedman, 1989) and total organic carbon (Clesceri and others, 1998) and to the Natural Resources Research Institute Laboratory in Duluth, Minnesota, for analysis of total phosphorus by persulfate digestion (American Public Health Association, 1999) and chlorophyll *a* (Arar and Collins, 1997).

All field personnel were familiarized with quality-assurance techniques to ensure sample integrity. The techniques include maintaining field instruments according to manufacturers' guidelines, properly storing calibration standards, recording field measurements in the field, cleaning all field sampling equipment before use according to the USGS National Field Manual guidelines (U.S. Geological Survey, variously dated), and collecting and analyzing quality-control samples to document the variability associated with sample collection. Field blanks and field replicates (table 2) were collected and analyzed each season (10 quality-control samples [5 replicates and 5 blanks] out of 32 environmental samples, or about 31 percent). Field blanks were processed under the same conditions as the environmental samples. Field replicates were split from the environmental samples. Water samples were collected at times of the year when samples were historically collected to ensure comparability of data while minimizing the spatial and seasonal differences in the dataset.

Field blank constituent concentrations were generally less than the laboratory reporting level for 6 of the 10 constituent analyses (table 2). Relative percent differences between the replicate pairs were generally low with the exception of total phosphorus in one sample collected on September 21, 2015, which had a relative percent difference of 50, and chlorophyll *a*, which had a range of 21–60 during 2013–15. Chlorophyll *a* concentrations are spatially variable and previous studies have also had high relative percent differences between replicate pairs of chlorophyll *a* samples (Christensen and others, 2004).

Fish Sampling and Laboratory Analysis

Young-of-the-year yellow perch were sampled once during fall in each of 3 years—2013, 2014, and 2015. NPS personnel collected about 20 yellow perch at each nearshore site—2 sites in Rainy, Kabetogama, Namakan, Little Vermilion, and Crane Lakes and 3 sites in Sand Point Lake (fig. 1). When more than 20 fish were captured at a site, a maximum of 20 fish were analyzed per site. A maximum of 40 fish were analyzed per lake, with the exception of Sand Point Lake where the maximum was 60.

Samples were collected by shoreline seining. Fish were immediately euthanized using tricaine methanesulfonate (MS-222) and then put on ice. Fish were kept on ice in coolers and transferred to a lakeside laboratory. In the laboratory, the water containing MS-222 was poured out of the fish sample bags, and then deionized water was added. The fish samples were put into a freezer until laboratory analysis. Total length was used to identify presumed young-of-the-year yellow perch in the field, and age of fish kept for mercury analysis was verified in the laboratory by inspection of scales prior to analysis

Table 2. Constituent concentrations and relative percent differences in field blank and replicate water samples collected from Voyageurs National Park, Minnesota, 2013–15

[mg/L, milligram per liter; µg/L, microgram per liter; --, not analyzed; <, less than; NA, not applicable]

¹The relative percent difference is the difference between the environmental sample and a replicate collected at the same time. The relative percent difference was calculated as the difference between the concentration of the replicate sample and the concentration of the environmental sample divided by the mean concentration of the replicate and environmental sample multiplied by 100.

for mercury. The fish were collected following methods of Sorensen and others (2005).

In the laboratory, each yellow perch was thawed, measured (total length to the nearest millimeter), and weighed (to 0.001 gram). Each fish was placed into a labeled, zip-seal plastic bag and stored in a domestic chest freezer until lyophilization to a nearly constant mass (change in dry mass less than 1 percent after 24 hours of additional lyophilization). After lyophilization, each whole fish was homogenized in a soap-washed, stainless steel blender, and the homogenate was stored in a food-grade, zip-seal plastic bag in a desiccator until analyzed for total mercury.

The concentration of total mercury in each whole fish was determined by direct mercury analysis, following EPA Method 7473 (U.S. Environmental Protection Agency, 2007). A 40- to 50-milligram sample of dried, homogenized whole fish was weighed into quartz boats and analyzed directly by thermal decomposition and atomic absorption spectroscopy with an automated Milestone (Shelton, Connecticut) DMA-80 Direct Mercury Analyzer. Mercury concentrations in fish were not blank corrected. The detection limit of the instrument (3 times the standard deviation of mass of mercury in 10 blanks divided by the mean sample mass) was 0.53 nanograms mercury per gram of wet fish (ng/g). The limit of quantification (10 times the standard deviation of mass of mercury in 10 blanks divided by the mean sample mass) was 1.77 ng/g.

Moisture content was determined by difference (thawed fish mass minus lyophilized fish mass) and was used to convert mercury concentrations to units of nanograms per gram (fish-mercury concentrations are most commonly expressed in wet-weight units). Precision and accuracy of total mercury concentrations measured for samples were quantified by the analyses of (1) analytical and procedural blanks, (2) replicate samples, (3) certified reference materials from the National Institute of Standards and Technology and the National Research Council of Canada, and (4) spiked samples.

Mean spike recovery for fish samples collected in 2013 ranged from 93.3 to 102 percent, whereas the mean relative standard deviation ranged from 4.89 to 10.4 percent. Results for quality-control of 2014 and 2015 samples were similar with mean spike recoveries ranging from 91.3 to 109 percent and mean relative standard deviation ranging from 2.5 to 9.55 percent. All blank concentrations were less than the limit of quantification of 1.77 ng/g.

Statistical Analysis

Wilcoxon rank sum tests and two-sided seasonal tests (Helsel and Hirsch, 1992) were used to test for differences in water-level fluctuations before and after implementation of the 2000 water-level management plan. The nonnormally distributed data justified the use of nonparametric tests (Helsel and Hirsch, 1992). All statistical tests used a significance level of 0.05; statistical significance was indicated for a probability value (p -value) of less than 0.05.

Lake Levels and Water Quality in Comparison to Fish Mercury Body Burdens

Lake-level fluctuations and water quality were compared with mercury body burdens in young-of-the-year yellow perch from Rainy Lake and Namakan Reservoir, Voyageurs National Park, for the period 2013–15. A synopsis is provided of the assessment of factors suspected of having an effect on concentrations of mercury in fish.

Lake Levels

The 2000 Rule Curves were expected to restore a more natural water regime that would affect water levels, water quality, trophic status, and other environmental conditions in Voyageurs National Park. Lake-level data (1970–2015) from the USGS (Gold Portage Outlet from Kabetogama Lake near Ray, MN, site number 05129290; U.S. Geological Survey, 2016), Water Survey Canada, and U.S. Army Corps of Engineers were compiled by, and obtained from, the Lake of the Woods Control Board (Matt De Wolfe, written commun., April 22, 2016). Lake-level data for Namakan Reservoir at Gold Portage on the west end of Kabetogama Lake and at Squirrel and Kettle Falls on the northern side of Namakan Lake (fig. 1) during the study period are shown in figure 3.

Extreme hydrologic events have affected water levels, which sometimes exceeded the upper rule curves after 2000 (Christensen and others, 2004, 2011; Favari and others, 2015). Previous studies indicated that observed annual water-level fluctuations prior to 2000 were significantly greater than observed annual water-level fluctuations after 2000 for Namakan Reservoir (Christensen and others, 2011). A Wilcoxon rank sum test was conducted with the current dataset (fig. 3), and observed annual water-level fluctuations were significantly lower after 2000 (p -value less than 0.0001). This significant decrease in water-level fluctuations after the implementation of the 2000 water-level management plan occurred despite an increase in frequency of extreme hydrologic events in this system after 2000 (Christensen and others, 2004, 2011; Favari and others, 2015). The difference in the annual water-level fluctuations between the two time periods (prior to 2000 and after 2000) appears to be the result of a substantial increase in the minimum water level (Christensen and others, 2011).

During 2013–15, the rule curve maximums for Namakan Reservoir were exceeded from May 12, 2013, to July 7, 2013, by as much as 0.32 m and again on May 12, 2015, through July 7, 2015, by a maximum of 0.33 m. Minor exceedances also occurred on a few days in fall 2013 and fall 2015. Water levels were less than the lower rule curve on 1 day during the study period, July 11, 2014, by less than 0.01 m. Water-level exceedances are important to note for this study because near-shore areas may become inundated and release methylmercury

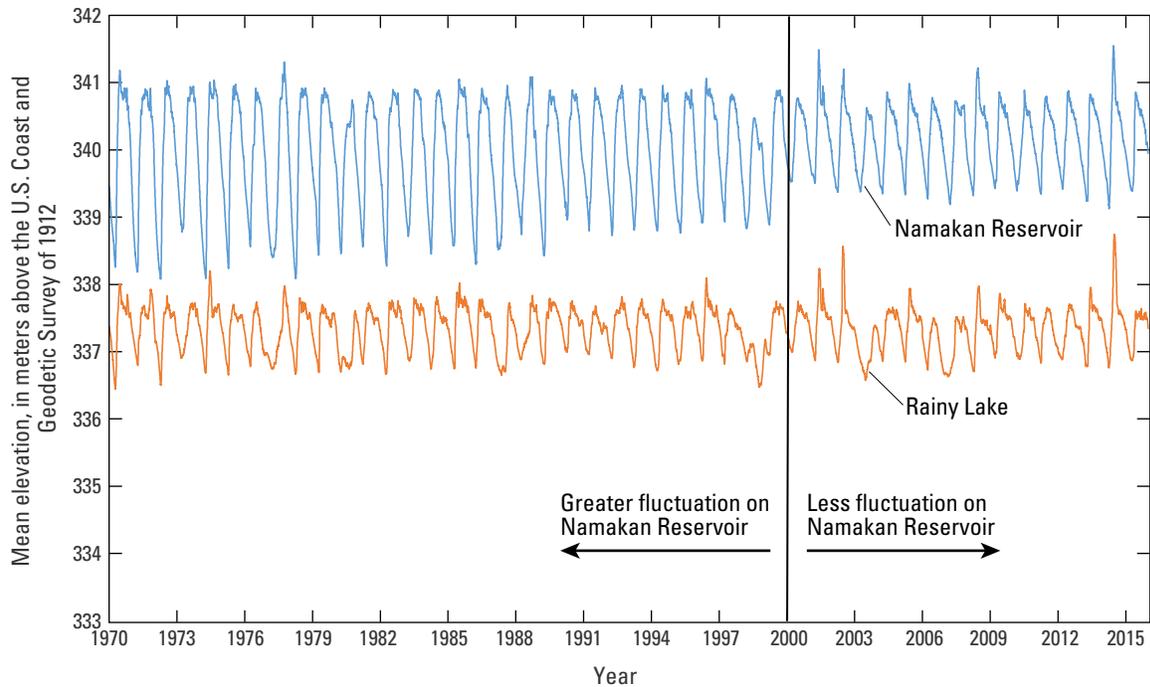

Figure 3. Water levels and water-level fluctuations, Namakan Reservoir and Rainy Lake, Voyageurs National Park, 1970–2015. Data from Lake of the Woods Control Board (Matt De Wolfe, written commun., April 22, 2016).

into the water. The wetlands surrounding these lakes may provide the ideal conditions for mercury methylation, as other researchers have documented in similar forest ecosystems (Driscoll and others, 2007).

Field Properties

Field properties of water temperature, Secchi-disk transparency, specific conductance, pH, dissolved oxygen, and acid neutralizing capacity were measured at all midlake and nearshore sites during 2013–15. The median values of the field properties measured during the three sampling events are shown in table 3. All field properties collected for this study are available from the USGS National Water Information System database (U.S. Geological Survey, 2016) using the USGS site numbers in table 1.

Water temperature varied among sites and was dependent on sampling date and time of day. Median water temperatures for the sites in the study ranged from 7.50 to 15.9 degrees Celsius (°C). Water temperatures in 2013 during the fall sample-collection periods generally were lower than during the other 2 years. The lower temperatures and later fall sampling dates resulted in fewer fish collected at some sites when fish had already migrated to deeper waters.

Secchi-disk transparency also varied among sites during 2013–15. Secchi-disk transparency for nearshore sites in Little Vermilion, Crane, and Sand Point Lakes generally was measured at shallower depths (median values from 1.3 to 1.9 m; table 3) than for nearshore sites in other lakes (median values

from 2.0 to 2.5 m, with the exception of Rainy Lake near Dove Bay, which had a median value of 1.5 m). The median Secchi-disk transparency for midlake sites of Little Vermilion and Crane Lakes (1.7 to 1.8 m) was shallower than for midlake sites at the other lakes (2.7 to 3.8 m). The Secchi-disk transparency, or light penetration, in all six lakes is affected by staining associated with dissolved and organic materials (Payne, 1991; Kallemeyn and others, 2003).

Specific conductance and alkalinity values generally were highest in Kabetogama and Crane Lakes. Higher specific conductance and alkalinity values may be the result of clay deposits rich in soluble minerals found on the southern and western end of Kabetogama Lake (Kallemeyn and others, 2003). Specific conductance in Crane Lake is affected by the Vermilion River and other upstream sources. The median specific conductance values at all sampled sites ranged from 31 to 91 microsiemens per centimeter at 25 degrees Celsius ($\mu\text{S}/\text{cm}$ at 25 °C; table 3).

Median values for pH at all sampled sites ranged from 5.7 to 7.1. Most Voyageurs National Park lakes are slightly acidic, with the exception of Kabetogama Lake, which has a median pH of 7.1. Values of pH are important to this study because the mobility of methylmercury tends to increase in acidified waters (Wetzel, 2001).

Lake profiles of water temperature, specific conductance, pH, and dissolved oxygen concentration were collected at midlake sites during sampling in 2013–15. Lake profile data are available from the USGS National Water Information System database (U.S. Geological Survey, 2016) using the USGS site numbers in table 1 for the midlake sites. In general, water

temperature, specific conductance, pH, and dissolved oxygen concentrations either remained the same or decreased gradually with depth.

Temperature and dissolved oxygen profiles are important because they indicate vertical mixing of the lake. Anoxic conditions, or dissolved oxygen concentrations less than 5 milligrams per liter (mg/L), occurred near the bottom of Sand Point, Little Vermilion, and Crane Lakes. Sulfate-reducing bacteria in anoxic zones can convert mercury to toxic methylmercury (Wetzel, 2001).

Sulfate and Total Organic Carbon in Water Samples

Total organic carbon and dissolved sulfate were analyzed in samples collected during 2013–15 for the midlake sites and the nearshore sites. Median concentrations for the three sampling events are provided in table 4, and individual sample

concentrations are available from the USGS National Water Information System database (U.S. Geological Survey, 2016) using the USGS site numbers in table 1.

Sulfur is widely distributed in igneous and sedimentary rocks (Hem, 1992). When the rocks are weathered and in contact with oxygenated water, sulfur is oxidized to sulfate. Deposition of sulfate sourced from fossil fuel combustion, also is a source of sulfate to lakes in the region (Nichols and McRoberts, 1986), although sulfate deposition to Voyageurs National Park has been declining since the 1980s (Kallemeyn and others, 2003; Brigham and others, 2014). Sulfate concentrations in the water can affect mercury bioavailability to fish (Sorenson and others, 2005). Dissolved sulfate concentrations in Voyageurs National Park lakes ranged from 1.6 to 5.8 mg/L. The lowest concentrations occurred in Little Vermilion Lake, and the highest concentrations occurred in Crane Lake. Generally, median concentrations of dissolved sulfate at the midlake sites were similar to concentrations at the nearshore sites.

Total organic carbon (TOC) is the approximation of the amount of organic material in a water body (Hem, 1992). The concentrations of organic matter affects mercury methylation. Research has indicated that concentrations of total mercury and methylmercury in lakes increase directly with increasing concentrations of dissolved organic carbon (DOC; Wetzel, 2001). The median TOC concentrations in Voyageurs National Park lakes sampled for this study ranged from 9.30 to 12.9 mg/L. The lowest median TOC concentrations occurred in Namakan Lake, and the highest median TOC concentrations occurred in Sand Point Lake. There was very little difference in median values between midlake and nearshore sites.

Total Phosphorus, Chlorophyll *a*, and Trophic Status

Phosphorus can be used in the calculation of a lake's trophic status (Carlson, 1977), and variability in trophic status can correlate with mercury levels in fish (Wiener and Spry, 1996). Algal abundance has been associated with total phosphorus concentrations (Wetzel, 2001) and large inputs of phosphorus into the aquatic environment may cause excessive algal growth. Median concentrations of total phosphorus and chlorophyll *a* for the 7 midlake sites and the 13 nearshore sites for the three sampling events are provided in table 4, and individual sample concentrations are available from the USGS National Water Information System database (U.S. Geological Survey, 2016) using the USGS site numbers in table 1.

Median values of total phosphorus for lakes sampled in this study ranged from 0.007 to 0.035 mg/L. The largest median concentrations occurred in Kabetogama Lake, which has historically had some of the highest total phosphorus concentrations of the five large Voyageurs lakes (Payne, 2000; Christensen and others, 2004). Generally, the nearshore sites had median total phosphorus concentrations similar to concentrations at the corresponding midlake sites.

Water-level fluctuation may contribute to accelerated eutrophication (Hambright and others, 2004), which may affect a lake's trophic status. Trophic status, furthermore, was identified by Pickardt and others (2002) as a factor affecting mercury bioavailability to fish. Trophic status was compiled for several of the lakes in Voyageurs National Park before and after the 2000 Rule Curves were implemented (Christensen and Maki, 2015). Sand Point, Namakan, and Rainy Lakes had trophic state indices between 34 and 39, indicating oligotrophic conditions, whereas Kabetogama Lake and Black Bay in Rainy Lake had trophic state indices of 50 and 51, respectively, which placed them in the eutrophic category.

Median chlorophyll *a* concentrations in samples collected for this study ranged from 0.9 to 9.0 micrograms per liter ($\mu\text{g/L}$). All lakes had median concentrations of 3.6 $\mu\text{g/L}$ or less, with the exception of Kabetogama Lake where the median concentration was 4.3 $\mu\text{g/L}$ at the midlake site and the median concentrations were 7.1 and 9.0 $\mu\text{g/L}$ at the nearshore sites. Unlike sulfate, total organic carbon, and

total phosphorus, median concentrations of chlorophyll *a* varied between midlake sites and nearshore sites. This was not unexpected owing to the high spatial variability of chlorophyll *a* concentrations known to occur in water bodies.

Fish Mercury Body Burdens

The sampling goal was to collect 20 young-of-the-year yellow perch at all near-shore sites during September or October of each year. In 2013 and 2014, fewer fish were collected at some sites, likely because the colder water temperatures caused fish to move to deeper water. In 2015, the sampling effort was moved 1 week earlier, and the minimum of 20 fish were captured at each site. Median concentrations (body burdens) of mercury by sample year for the 13 nearshore sites are provided in table 5, and individual fish sample concentrations are available from the USGS National Water Information System database (U.S. Geological Survey, 2016) using the USGS site numbers in table 1.

The median fish mercury concentrations were variable across the years (table 5). The lowest median concentrations occurred in 2015, and ranged from 14.7 ng/g at Kabetogama Lake below Boblore Island (USGS site number 482603092490501) to 77.0 ng/g at Crane Lake, north shore, near Indian Island (USGS site number 481827092285401). The highest concentrations occurred in 2014 and ranged from 27.1 ng/g at Kabetogama Lake at Blind Ash Bay (USGS site number 482556092521601) to 178 ng/g at Crane Lake, northwest end, near Crane Lake, Minn. (USGS site number 481835092294401). This is consistent with previous research, which indicated that Sand Point and Crane Lakes had the highest fish mercury concentrations of the six lakes (Larson and others, 2014). No individual fish mercury concentration exceeded the EPA criterion of 0.3 mg/kg (or 300 ng/g; U.S. Environmental Protection Agency, 2001). However, smaller young-of-the-year fish have a relatively low trophic position compared to larger, older fish, and people generally consume adult fish. Despite not exceeding the EPA criterion, the mercury concentrations found in fish in this study are high for young-of-the-year fish when compared to other northern Minnesota lakes (Sorenson and others, 2005).

Factors that May Affect Mercury Concentrations in Fish

Accumulation of methylmercury in fish tissue is considered a substantial threat to the health of wildlife and humans (Scudder and others, 2009; Sunderland and others, 2014). Assessing the link between fish mercury concentrations and environmental factors is important because of the human and ecosystem health consequences associated with mercury contamination of fish. If there is a link between annual water-level fluctuations and mercury entering the aquatic food web each year, management action reducing the annual water-level

Table 5. Median concentrations of total mercury in young-of-the-year yellow perch samples from nearshore sites, Voyageurs National Park, 2013–15.

fluctuations may reduce mercury bioaccumulation in Voyageurs National Park fish.

The data from this study indicate that the three lakes with the highest mercury concentrations in fish—Little Vermilion, Crane, and Sand Point—had the lowest pH values, which may indicate that methylmercury is more mobile in acidic waters than neutral or alkaline waters as suggested by Wetzel (2001). These three lakes also had anoxic conditions (low dissolved oxygen) in water near the bottom of the lake, which is another condition that may be conducive to mercury methylation (Eckley and Hintlemann, 2006).

Studies have shown that pH and DOC have strong effects on the fate of mercury in an ecosystem. Increased uptake of methylmercury by diatoms has been shown to be correlated with increased DOC concentrations (Zhong and Wang, 2009). Other studies have shown that for the same species of fish taken from the same region, increasing the acidity of the water (decreasing pH) and (or) the DOC content generally results in higher body burdens of mercury in fish (Krabbenhoft and Rickert, 1995), and the data presented in this report are consistent with those studies. The TOC concentrations for this study generally were highest in Little Vermilion, Crane, and Sand Point Lakes. Sulfate concentrations, however, were less consistent in their relation to fish mercury. Little Vermilion Lake

had low sulfate concentrations, whereas Crane and Sand Point Lakes had higher sulfate concentrations. These are the three lakes with the highest mercury concentrations in fish.

Total phosphorus, chlorophyll *a*, and trophic state results also were less conclusive than pH and TOC results; however, the lake with the highest trophic state, Kabetogama Lake, generally had the lowest fish mercury concentrations, which is consistent with other studies, such as one by Pickhardt and others (2002), which showed that the more eutrophic lakes with algal blooms reduced the uptake of methylmercury in freshwater food webs. Another important consideration is that chlorophyll *a* concentrations in samples collected during September or October may not be representative of chlorophyll *a* concentrations in samples collected during the rest of the year.

This study, in combination with two on-going studies, increases the understanding of factors affecting young-of-the-year yellow perch in Rainy Lake and Namakan Reservoir. Research described by Kallemeyn and others (2009) created a digital elevation model for Rainy Lake and Namakan Reservoir that included both terrestrial topography and lake bathymetry. The digital elevation model allows for calculations of wet and dry land areas under the 1970 and 2000 Rule Curves at any time of year. With the added information provided by the digital elevation model, researchers can better understand

wetland effects and the importance of the drying and rewetting of the perimeter of the lakes resulting from the water-level changes on mercury occurrence in fish. The digital elevation model, in combination with the existing USGS vegetation map of Voyageurs National Park (Hopp and others, 2000), provided the total area of connected wetlands under each set of rule curves.

Kallemeyn and others (2009) describe the output from a hydrologic modeling project for Rainy Lake and Namakan Reservoir, which can be used in conjunction with the results of this study. The output of the hydrologic modeling project includes a summary of lake-level conditions and fluctuations under the 1970 and 2000 Rule Curves. The hydrologic output was based on model runs using the same hydrologic input dataset, consisting of data (inflow) measured in this basin over the last 50–60 years, for each of the two rule curve scenarios; thus, this summary will allow a direct comparison of conditions under each set of rule curves for each water body (Rainy Lake and Namakan Reservoir), independent of the hydrologic differences that have existed before and after the 2000 Rule Curves were implemented. Output from the hydrologic modeling project can be used to test whether a water-level variable (for example, maximum water-level fluctuation within a year) is different in these water bodies under the 2000 Rule Curves than under the 1970 Rule Curves.

Summary

The U.S. Geological Survey, the National Park Service, and University of Wisconsin-La Crosse cooperated in a study to assess lake levels and water quality in comparison to mercury body burdens in young-of-the-year *Perca flavescens* (yellow perch) from six lakes in and near Voyageurs National Park in Minnesota. Additional environmental data were collected to evaluate their importance to the bioaccumulation of mercury in yellow perch.

Lake levels in Voyageurs National Park are controlled by a series of dams for a variety of uses. Rule curves are required to set maximum and minimum water levels between which the private dam owners are required to operate. Despite maximum rule curve exceedances during extreme events at Namakan Reservoir during 2013–15, observed water-level fluctuations

were significantly lower after 2000; however, water-level exceedances are important to this study because nearshore areas may become inundated and release methylmercury into the water.

Field properties and profiles of water quality indicate that Sand Point, Little Vermilion, and Crane Lakes were anoxic at times near the lake bottom. The presence of anoxic conditions is important because sulfate reducing bacteria may convert mercury to methylmercury.

Dissolved sulfur, total organic carbon, and total phosphorus were analyzed because of their possible correlation to methylmercury in fish. The median dissolved sulfate concentration was highest in Crane Lake, the median total organic carbon concentration was highest in Sand Point Lake, and the median total phosphorus concentration was highest in Kabetogama Lake, which is consistent with previous research. Previous research also showed the highest concentrations of mercury in young-of-the-year yellow perch occurred in Crane Lake and Sand Point Lake, and the lowest concentrations occurred in Kabetogama Lake.

Chlorophyll *a* concentrations and the resulting trophic state of a lake can affect mercury bioavailability to fish. All lakes had median chlorophyll *a* concentrations of 3.6 micrograms per liter ($\mu\text{g/L}$) or less with the exception of Kabetogama Lake, where median concentrations were 4.3 $\mu\text{g/L}$ for the midlake sites and 7.1 $\mu\text{g/L}$ and 9.0 $\mu\text{g/L}$ for the nearshore sites. This is consistent with previous studies, which reported chlorophyll *a* concentrations and corresponding trophic state indices that were higher in Kabetogama Lake than other Voyageurs National Park lakes. Fish mercury concentrations varied widely between years and among lakes. Fish mercury concentrations ranged from 14.7 nanograms per liter (ng/g) in fish samples from Kabetogama Lake in 2015 to 178 ng/g in fish samples from Crane Lake in 2014.

The data for this study can be used by the International Joint Commission and other researchers in decision-making models related to the effect of water-level changes on mercury body burdens in fish and other environmental factors. More specifically, the data can be combined with output from ongoing hydrologic modeling projects to test whether a water-level variable (for example, maximum water-level fluctuation within a year) is different in these water bodies under the 2000 Rule Curves than under the 1970 Rule Curves.
