Examination of Dissolved Uranium Concentrations in Regional Shallow Groundwater Relative to Operable Unit 8 of the Denver Radium Superfund Site

By Carleton R. Bern

Abstract

A radium industry existed between about 1914 and 1920 in Denver, Colorado, with operations located along the South Platte River. Sites associated with that industry were contaminated with radium and uranium processing residues and were incorporated into clean-up efforts as Operating Units (OUs) of the Denver Radium Superfund Site. Concentrations of uranium exceeding the U.S. Environmental Protection Agency maximum contaminant level of 0.03 milligrams per liter for drinking water are present in shallow groundwater at OU8. However, previous studies have shown concentrations of dissolved uranium can be naturally high in shallow groundwater of the South Platte River valley compared to other rivers of the world. This report compares dissolved uranium concentrations measured by the U.S. Geological Survey across the South Platte River valley to data collected at the OU8 of the Denver Radium Superfund Site. The U.S. Geological Survey data represent 5 distinct urban or agricultural geographic areas and included 230 sampling events at 114 wells during 1993 to 2013. The OU8 data represent 13 wells and groundwater discharge locations sampled during the years 2017 and 2018. Dissolved uranium concentrations were statistically significantly greater for both years of the OU8 data compared to three datasets from shallow groundwater beneath urban areas in the Denver metropolitan area. However, compared to OU8, concentrations were significantly greater in shallow groundwater from an agricultural area of the South Platte River valley distant from Denver. Additionally, each of the urban area datasets contained some individual dissolved uranium concentrations greater than the greatest concentrations from the two OU8 datasets. Thus, naturally occurring concentrations of dissolved uranium in shallow groundwater that are greater than those observed at OU8 are not uncommon in the South Platte River valley.

Introduction

Previous studies have indicated water in the South Platte River in Colorado is "anomalously rich in uranium in comparison with most other rivers of the world," and the predominant source of uranium is weathering of Cretaceous sedimentary rocks, particularly black shales and uraniferous coal seams (Boberg and Runnells, 1971). Specifically, the Pierre Shale and coal seams in the Laramie Formation are thought to be notable sources of uranium to water in the river (Boberg and Runnells, 1971). The U.S. Environmental Protection Agency (EPA) maximum contaminant level (MCL) for dissolved uranium in drinking water in public water systems is 0.03 milligrams per liter (mg/L), which provides a point of reference (EPA, 2018a). By comparison, one study measured dissolved uranium concentrations in the South Platte River up to 0.039 mg/L in Colorado and up to 0.067 mg/L in Nebraska (Boberg and Runnells, 1971). Shallow groundwater in the South Platte River valley is also enriched in dissolved uranium from natural sources (Snow and Spalding, 1994). Such uranium sources could be present in the alluvium and weathered rock hosting groundwater. The uranium may also have been transported by the river from sources upstream and entered into the adjacent groundwater by natural lateral flow (Snow and Spalding, 1994) or by diversion of river water for irrigation. Downstream, along the Platte River in Nebraska, concentrations of uranium up to 0.258 mg/L and 0.549 mg/L have been measured in shallow groundwater in bottomlands and terraces (Spalding and Druliner, 1981) The situation of anomalously high concentrations of naturally occurring uranium in groundwater in the South Platte River valley is similar to that in the Arkansas River Valley to the south, where parts of the same sequence of Cretaceous rocks are present near the surface under similar climatic and geomorphic conditions (Zielinski and others, 1995; Zielinski and others, 1997; Miller and others, 2010; Bern and others, 2020).

Such naturally occurring concentrations of dissolved uranium in shallow groundwater of the South Platte River valley provide important context for understanding how humancaused uranium contamination of groundwater within the region compares to natural concentrations. Denver, Colorado, straddles the South Platte River. Between approximately 1914 and 1920, the Denver area was a radium production center, and dozens of contaminated sites associated with that legacy were rediscovered and characterized starting in 1979 (Topolski, 1985). The Denver Radium Superfund Site was created by the EPA to address groundwater and soil contamination by radium and uranium processing residues associated with the radium industry. The Denver Radium Superfund Site has 11 Operable Units (OUs), including OU8, a property of the former S.W. Shattuck Chemical Company (EPA, 1992). Groundwater contamination associated with OU8 remains on the EPA National Priorities List (EPA, 2018b).

Purpose and Scope

The purpose of this report is to compile and present U.S. Geological Survey (USGS) data from shallow groundwater in the South Platte River valley to provide context for dissolved uranium concentrations in shallow groundwater associated with OU8 of the Denver Radium Superfund Site. Well construction information, depth-to-water data, and dissolved uranium concentrations from groundwater wells in the South Platte River valley were compiled from three USGS studies. Those data are compared to EPA data collected at OU8 using Wilcoxon rank-sum tests. Description or analysis of the site history, physical or hydrological characteristics of the study area, geochemical processes, remediation actions, or waterquality trends associated with OU8 or the broader Denver Radium Superfund Site are beyond the scope of this report.

Dissolved Uranium Concentration Data Compilation

No new data were collected for this report. The USGS data were obtained from the USGS National Water Information System (NWIS) database (USGS, 2021). The Denver Radium OU8 data were provided by the EPA (EPA, 2018b). All data discussed also are provided in appendix 1.

USGS Shallow Groundwater Data

Three previous USGS studies collected samples of shallow groundwater from wells in the South Platte River valley and measured dissolved uranium concentrations in those samples (Bruce and McMahon, 1998; Paschke and others, 2013; and Paschke and others, 2014). Data from those wells were compiled for this report (app. 1, table 1.1). Some of the included wells had additional samples collected with dissolved uranium concentrations measured by USGS efforts outside the scope of the three studies. Therefore, some wells have multiple measured uranium concentrations spanning multiple years for associated groundwater. Shallow groundwater was the focus of the data compiliation effort and is defined here as groundwater present at less than 50 feet below land

surface. Wells were included in the data compilation if one of three criteria could establish water presence in that depth range: depth to water, sampling depth, screened interval of the well, or depth of the well (USGS, 2021).

The first study and well groupings included in the compilation were part of the USGS National Water-Quality Assessment Project of the National Water Quality Program with the goal of addressing the occurrence and distribution of water-quality conditions in the region (Bruce and McMahon, 1998). Groundwater was sampled from wells in geographically nonoverlapping agricultural and urban areas and completed in the alluvial aquifer of the South Platte River (fig. 1). Of the 30 agricultural area wells in that study area, 29 met 1 of the depth-to-water criteria. Sampling events for the wells spanned the years 1994 to 2013 with 102 individual measurements of dissolved uranium concentrations. Of the 30 urban area wells in the study area, 28 had data available in NWIS, and those data were for a single sampling event per well, all in 1993. Of the 28 samples, 1 sample had a dissolved uranium concentration less than the U.S. Geological Survey National Water Quality Laboratory (Lakewood, Colorado) reporting limit of 0.001 milligram per liter (Faires, 1993; Childress and others, 1999), leaving 27 concentrations greater than or equal to the laboratory reporting limit for 27 individual wells.

The second study and well grouping were related to water-quality conditions in Toll Gate Creek in the Denver metropolitan area, which is a tributary to the South Platte River (Paschke and others, 2013). The goal of this study was to address geologic sources and processes affecting selenium concentrations in Toll Gate Creek, but dissolved uranium concentrations were also measured in groundwater (fig. 2). Groundwater was sampled from 19 wells in generally urbanized areas. Most of the wells were completed in surficial materials, but three wells intersected material of the Denver Formation at depth. All 19 wells met the depth-to-water criteria, and some were sampled multiple times between 2003 and 2011 yielding 36 dissolved uranium concentrations in total.

The third study and associated well groupings was also related to water-quality conditions in Toll Gate Creek (Paschke and others, 2014). The goal of the report was to document selenium bearing rocks and groundwater in a broader region surrounding the Toll Gate Creek watershed. Wells in this study were divided according to land use into agricultural and urban categories (fig. 2), and the wells were completed at the water table in either alluvial materials or shallow bedrock. Of the 32 agricultural area wells, 20 did not meet any of the depth-towater criteria and 1 was dry, resulting in usable measurements from only 11 wells (app. 1, table 1.1). All sampling occurred in 2003, but repeated sampling yielded 14 dissolved uranium concentrations in total. Of the 30 urban area wells, 2 did not meet depth-to-water criteria. Repeated sampling of the remaining 28 wells between 2003 and 2011 yielded 51 dissolved uranium concentrations in total. Altogether, the USGS data represent 230 concentrations of dissolved uranium in shallow groundwater from 114 different wells in 5 distinct geographic areas (app. 1).

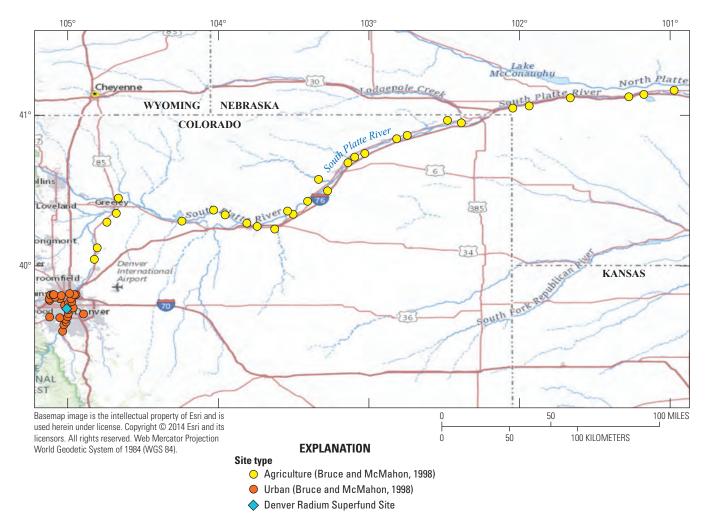

Figure 1. Agricultural and urban areas where shallow groundwater wells were sampled as part of the study by Bruce and McMahon (1998). Only wells that meet depth-to-water criteria are depicted.

Denver Radium Superfund Site, Operable Unit 8 Data

Dissolved uranium concentration data measured at the Denver Radium Superfund Site, OU8, were collected by the EPA (app. 1, table 1.2). Dissolved uranium concentrations were available for water from 10 shallow groundwater wells and 3 stormwater outfall locations. All locations were sampled on both May 11, 2017, and March 7, 2018 (EPA, 2018b; Sandor, 2018). The stormwater outfall locations were presumed to mostly reflect groundwater discharge at the times of sampling because of the absence of rain in the days prior to sampling. One stormwater outfall was dry at the time of the 2018 sampling.

Examination and Comparisons of Dissolved Uranium Datasets

Figure 3 offers a visual means of comparing dissolved uranium concentrations compiled here. Using the EPA MCL for dissolved uranium in drinking water of 0.03 mg/L (EPA, 2018a) provides a point of reference, and each dataset contains some values greater than and some values less than the MCL (fig. 3). The greatest median concentration and greatest individual concentrations of dissolved uranium were measured in agricultural area wells completed in the alluvial aquifer assessed as part of Bruce and McMahon (1998) and extending along the South Platte River valley far beyond the Denver metropolitan area (fig. 1). The median concentrations among the urban datasets were all similar and low compared to the other datasets, although the median for agricultural area wells from Paschke and others (2014) and located closer to the metropolitan area was only slightly greater (fig. 3). Interquartile ranges for those four datasets also show much overlap, and

4 Examination of Dissolved Uranium Concentrations in Groundwater Relative to Operable Unit 8

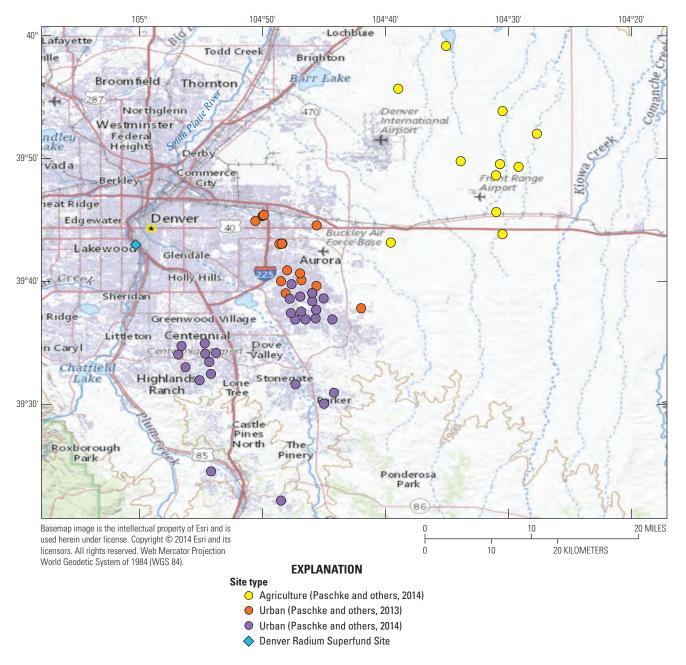

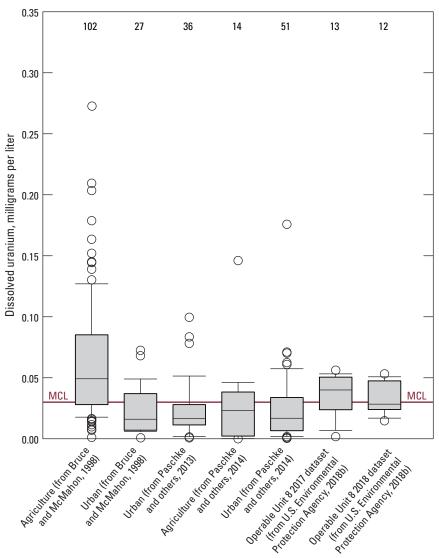

Figure 2. Urban area where shallow groundwater wells were sampled as part of the study by Paschke and others (2013) and the agricultural area and urban area where shallow groundwater wells were sampled as part of the study by Paschke and others (2014). Only wells that meet depth-to-water criteria are depicted.

thus a general similarity exists for dissolved uranium concentrations in shallow groundwater in different parts of the Denver metropolitan area (fig. 3). By comparison, the two datasets from OU8 have medians and interquartile ranges slightly greater than the three urban and one agricultural dataset from in and near the Denver metropolitan area.

The nonparametric, Wilcoxon rank-sum test was used to explore differences between the the USGS urban shallow groundwater datasets and the OU8 datasets. The test was implemented as a one-sided test of whether dissolved uranium

concentrations in the OU8 2017 and OU8 2018 datasets were greater than the USGS urban datasets by using the function "wilcox.test" in the R programming language (R Core Team, 2021). In essentially all cases, the test found the differences to be significant at the 95 percent confidence level ($p \le 0.05$). For the urban shallow groundwater results from Bruce and McMahon (1998), the p-value was 0.052, barely outside the significance threshold, when compared to the OU8 2017 dataset (EPA, 2018b), but the p-value was 0.02 when compared to the OU8 2018 dataset. For the Paschke and others (2014) dataset,

Shallow groundwater dissolved uranium concentrations

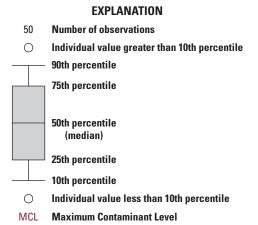

Figure 3. Shallow groundwater dissolved uranium concentration datasets from Bruce and McMahon (1998), Paschke and others (2013), Paschke and others (2014), and U.S. Environmental Protection Agency (2018b).

p-values were 0.04 and 0.01 when compared to the OU8 2017 and OU8 2018 datasets from EPA (2018b), respectively. For the Paschke and others (2013) dataset, p-values were 0.02 and 0.005 when compared to the OU8 2017 and OU8 2018 datasets from EPA (2018b), respectively. Thus, statistical differences between the EPA (2018b) and other urban shallow groundwater datasets can be detected. However, tests also confirmed dissolved uranium concentrations for the agricultural area wells from Bruce and McMahon (1998) were significantly greater than the OU8 2017 and OU8 2018 datasets from EPA (2018b), with p-values in those tests of 0.03 and 0.02, respectively. In contrast, concentrations from the Paschke and others (2014) agricultural area wells dataset were significantly lower than the OU8 2017 dataset from EPA (2018b) with a p-value of 0.047 but not significantly lower than the OU 2018 dataset from EPA (2018b) with a p-value of 0.07.

Overall, substantial natural variability for dissolved uranium concentrations in shallow groundwater of the South Platte River valley was apparent, as demonstrated by the five USGS datasets (fig. 3). Despite variability, distinctions between geographic areas were also apparent. The statistically significant differences between the three urban area datasets and the two OU8 datasets likely reflect a human-caused effect at OU8 when compared to shallow groundwater elsewhere in the Denver metropolitan area. However, there are two factors, which provide more context for human-caused effect at OU8. First, dissolved uranium concentrations in the dataset from shallow groundwater of Bruce and McMahon (1998), which represents the distant agricultural area, were significantly greater than those at OU8. Second, each of the urban area datasets contained individual concentrations greater than the greatest concentration from the two OU8 datasets (0.0563 mg/L; app. 1, table 1.2). The urban area dataset from Bruce and McMahon (1998) contains two such values, Paschke and others (2013) contains three such values, and Paschke and others (2014) contains six such values (fig. 3; app. 1, table 1.1). Thus, some naturally occuring dissolved uranium concentrations occur in shallow groundwater in the Denver metropolitan area that are greater than the highest concentration measured at OU8 in 2017 or 2018 (EPA, 2018b).

Summary

Previous studies show concentrations of dissolved uranium can be greater in river water and shallow groundwater of the South Platte River valley compared to other rivers of the world. Weathering of sedimentary rocks and coal seams are the presumed source of that uranium. Between about 1914 and 1920, a radium industry existed in Denver, Colorado, located along the South Platte River. Dozens of contaminated sites associated with that industry were rediscovered and characterized starting in 1979 and were incorporated into clean-up efforts as Operating Units (OUs) of the Denver Radium Superfund Site. Relatively high concentrations of uranium are present in

shallow groundwater beneath OU8, including some concentrations greater than the Environmental Protection Agency's Maximum Contaminant Level for uranium in drinking water.

This report compares concentrations of dissolved uranium in shallow groundwater from across the South Platte River valley to concentrations in shallow groundwater from OU8 of the Denver Radium Superfund Site. Data representing the broader South Platte River valley come from wells sampled by the USGS over the course of three different studies covering five distinct urban or agricultural geographic areas. The data total 230 sampling events from 115 wells between the years 1993 and 2013. The OU8 data are from 10 wells and 3 stormwater outfall locations assumed to reflect groundwater discharge at the time of sampling, all sampled once each in 2017 and 2018.

Although substantial variability was observed in concentrations of dissolved uranium in shallow groundwater, distinctions between geographic areas were apparent. In all but one case, concentrations were significantly greater for both OU8 datasets compared to the three datasets from shallow groundwater beneath urban areas in the Denver metropolitan area. However, concentrations of dissolved uranium were significantly greater in shallow groundwater from an agricultural area of the South Platte River valley distant from Denver. Additionally, each of the urban area datasets contained some individual concentrations greater than the greatest concentration from the two OU8 datasets. Thus, some naturally occuring concentrations of dissolved uranium in shallow groundwater that are greater than those observed at OU8 are present in the South Platte River valley.
