RADIOCHEMICAL MONITORING OF WATER AFTER THE CANNIKIN EVENT,
AMCHITKA ISLAND, ALASKA, MAY 1974

By

William Thordarson and Wilbur C. Ballance

ABSTRACT

During May 1974, the U.S. Geological Survey collected water samples from Amchitka Island, Alaska. Tritium determinations were made on 99 water samples, and dissolved gross alpha and gross beta/gamma determinations were made on 34 water samples. No appreciable differences were found between the data obtained in May 1974 and the data obtained before the Cannikin nuclear explosion.

INTRODUCTION

Amchitka Island, Alaska, was the site for three underground nuclear detonations. The Long Shot event was conducted on October 29, 1965, the Milrow event on October 2, 1969, and the Cannikin event on November 6, 1971.

The U.S. Geological Survey, on behalf of the U.S. Energy Research and Development Administration (formerly the U.S. Atomic Energy Commission), started water sampling of wells, streams, and springs on Amchitka Island in 1965 in order to establish pre-nuclear explosion background levels of radioactivity. A long-term water-sampling network was developed in 1967 in order to observe possible effects of nuclear testing on the island. This network was expanded in September 1971 to include the drainage area surrounding the final nuclear explosion, the Cannikin event, and

to include offshore stations. The water-sampling network was sampled by both Teledyne Isotopes and the U.S. Geological Survey from 1967 through September 1971. The Geological Survey has done the water sampling since September 1971.

The network stations were sampled in 1971 in September, November, and December; in 1972 in January, April, and October; in 1973 in August; and in 1974 in May and August. Future sampling will probably be once each year in August.

The techniques and procedures used by the U.S. Geological Survey for collecting, identifying, and analyzing water samples are described in previous reports (Beetem and others, 1971a, 1971b; Schroder, 1971).

Radiochemical and chemical data, obtained by the U.S. Geological Survey from 1965 through 1973, were presented in previous reports (Beetem and others, 1971a, 1971b; Schroder and Ballance, 1972a, 1972b, 1973a, 1973b, 1973c; Ballance, 1974). This report presents the radiochemical data from water samples collected in May 1974.

WATER SAMPLING NETWORK

Water samples were collected from wells, streams, lakes, springs, and seeps. Seawater samples were collected both at the shoreline and offshore. At each offshore sampling station, water samples were collected from near the ocean bottom, two-thirds of the distance from the surface to the bottom, one-third of the distance from the surface to the bottom, and surface.

Figures 1, 2, and 3 show the locations of the sample collection sites. The sampling sites in figures 1, 2, and 3 have reference numbers that are identified in tables 1, 2, and 3. Table 1 presents the radiochemical-sampling stations and types of radiochemical analyses performed on the freshwater samples and

1/ Station numbers were originally assigned by the Laboratory of Radiation Ecology, College of Fisheries, University of Washington during the Amchitka Pacific Apollo Cruise, August 5 to 11, 1971.

the shoreline seawater samples. Table 2 presents the results of radiochemical analyses, and table 3 presents the tritium data obtained from offshore seawater sampling stations.

RESULTS

The data obtained from analyses of freshwater samples collected on the island and seawater samples collected at the shoreline are presented in table 2. In 34 freshwater samples, the dissolved gross alpha activity reported as natural uranium equivalent in micrograms per litre ($\mu\text{g/l}$) ranged from less than 0.8 to 18 $\mu\text{g/l}$. Before the Cannikin explosion, a range of less than 0.4 to 70 $\mu\text{g/l}$ was found in samples from 54 freshwater stations on Amchitka (Beetem and others, 1971a). Nineteen of the freshwater stations sampled in May 1974 were also sampled prior to the Cannikin event. The May 1974 samples from these 19 stations ranged from less than 0.8 to 18 $\mu\text{g/l}$. Before the Cannikin explosion, 19 samples from the same stations ranged from less than 0.6 to 21 $\mu\text{g/l}$ in dissolved gross alpha activity (Beetem and others, 1971a).

The dissolved gross beta/gamma activity that is reported as Cs-137 equivalent in picocuries per litre (pCi/l) ranged from 3.8 to 9.2 pCi/l for the 34 freshwater samples from the May 1974 sampling (table 2). Before the Cannikin explosion, a range of less than 1.0 to 36 pCi/l was found in samples from 54 freshwater stations on Amchitka (Beetem and others, 1971a). The May 1974 samples from 19 freshwater stations ranged from 3.8 to 9.2 pCi/l. Before the Cannikin event, samples from the same 19 stations ranged from 1.2 to 22 pCi/l in dissolved gross beta/gamma activity (Beetem and others, 1971a).

Tritium analyses of freshwater and shoreline seawater samples (table 2) were made using the liquid scintillation counting technique. The minimum tritium-detection level using

this method is 480 pCi/l. Offshore seawater samples (table 3) were analyzed using electrolytic enrichment coupled with liquid scintillation counting techniques. The minimum detection level using this method is about 16 pCi/l.

Freshwater samples having detectable (greater than 480 pCi/l) tritium activity were those collected at the Long Shot site (reference numbers 28, 31, 33, and 34 in table 2). The tritium activity found in water at the Long Shot site is consistent with the activity found after the Long Shot event and prior to the Cannikin event. The greatest tritium values at the Long Shot site prior to the Cannikin event ranged from 7,400 pCi/l, February 1970, in a mudpit at the site to 300,000 pCi/l, August 1970, in a drill hole at the site (Beetem and others, 1971a). Tritium values determined for water samples from these locations in May 1974 were 4,800 and 120,000 pCi/l, respectively.

Sampling and analyses of seawater around Amchitka (fig. 3) are intended to detect contaminated ground water that may have been discharged into the ocean. Tritium activity in seawater samples prior to the Cannikin explosion ranged from 45 ± 3 pCi/l to 350 ± 9 pCi/l (Schroder and Ballance, 1973b). The tritium activity determined from resampling of these seawater stations in May 1974 after the Cannikin explosion ranged from 16 to 190 pCi/l.
