THE INFLUENCE OF VOLCANIC RESEARCH IN HAWAII

The by-products of the popularity of our volcanoes have been the National Park and its improved roads; the Mauna Loa road and camps; the military recreation camp; the Chain of Craters road; the Haleakala road and Park; the Hilo-Volcano road; the Uwekahuna Museum; the projected Hilo-Kona road; increased tourist visitation effects of this on Island business; the coming expansion of the National Park and its road system; the pleasure visitation of Mauna Loa and Kilauea by airplanes; the gradual opening of Mauna Loa to visitation and science; the completion of topographic maps of the whole island; science guiding the police, the ranchers to safety, and the public to sight-seeing, through ten lava crises. All of these things we have seen grow up during the last twenty-five years.

What Did the Science Do?

It measured continuously the materials and the movements coming forth out of the three active volcanoes Kilauea, Mauna Loa and Hualalai. Having this experience led in part to the **social** benefits enumerated. The latest of these is the **social** contract with a British presidency, another volcanic island, seven thousand miles away.

Larger Meaning of Measuring the Earth

The following are results of measuring the earth's powers: Boulder Dam, the Panama Canal, the Tennessee Valley Authority, the Mississippi Flood Control, the Great Lakes Drainage Project, the Golden Gate Bridge, Earthquake Insurance, Earthquake-proof construction. Geophysical prospecting for oil. Finding radium, caesium, selenium, tungsten, vanadium, uranium, rhodium, fluorine, helium and nitrogen. Prospecting the soil for its real meanings, a far cry from the days of guano and Chilean nitrate. Developing the air drill, the Diesel tractor, the new explosives for moving mountains. Tying up the earth in roads, pipe lines, telefer wires and aqueducts such as the world never

dreamed of. Penetrating fogs. Steering by sea-bottoms. Mapping by airplanes And traversing Antartica by the tools of modern science.

All of this is the work of that man of science called the engineer. He has become utterly **Social.** He has a fine ethics like the physician. This is because his responsibility is for public safety, and for justifying a **measurement** of the earth that he has made for service. It makes him sober, to know that he has the responsibility of serving **socially** a million people in the future.

There is a still larger social aspect to the sciences of the Earth. We hear much of extravagance, of colossal expenditure, and the question "Who is going to pay for it all?" But pay for it in what? If the labor of the nation is doing it, and the result is doing the nation good, why not look back and say "Who has ever paid for the free franchises, free farms, free rights of way, and free public utilities of the American people? Who has ever paid science for improving the earth for man's occupancy? What modern men of science ever work for profit?

Is anyone now asking who will ever pay the great inventors for the extravagance, the colossal expenditure in blood and brain and spirit, of Jesus, Lincoln, Goethals, Walter Reed, Gorgas, Darwin, Faraday, Pasteur or Curie?

Do we realize that one man or woman somewhere and somewhen, produced a future billion dollars, in prospecting the Earth with his brain, for each great engineering and social achievement, among such constructive discoveries as those I have enumerated, like the Boulder Dam or the rare metals? For the Boulder Dam is just as much a discovery as the North Pole, and requires a hundred times more courage and brains.

The bonded debts of the world can never be repaid in coins. Money is the blood of youth and the labor of men. The earth furnishes some raw material and power for blood and labor to use. There is no other wealth than the good-will of men, and the self-sacrificing measurements of progressive learning, in economizing happily the energies of men. The energies of men are banded together to discover moral power and earth power. By moral we mean "MORES," improved human habits. This is the whole of education.

The Earth is yielding much to the chemist. It is not being made to yield enough of its resources to the engineer. Our sea-bottoms are not mapped, our deserts and mountains are almost untouched, our oceans are not working for us, our sunlight is not yet running our cars and planes. We live too much in city laboratories. There is here a gigantic field for the employer of labor.

Science is not yet extricating Society from its foolish city congestions: and sending MEN out in vast employments, to discover THE EARTH, with the new **social** tools of modern physics and engineering. Here is a chance for the benefactors of mankind to rethink social science. T. A. J.

THE VOLCANIC AREA OF BUFUMBIRA, UGANDA

The following excerpts and paraphrasings from "The Volcanic Area of Bufumbira" by A. D. Combe and W. C. Simmons,

The west tilt cellar on Kilauea crater floor, housing clinoscope pendulum for daily readings.

published in 1933 by the Geological Survey of Uganda, shows many striking similarities to descriptions of Kilauea at various times.

The volcano Nyamlagira is in about 1° 25' south latitude and about 29° 12' longitude east of Greenwich in Belgian territory. The summit is 10,026 feet above sea level. It rises gently to a height of about 5,000 feet above its base. The mountain has been built by the piling up of successive lava flows apparently of large volume and in a very fluid state.

The caldera or crater depression is over a mile in diameter and it is surrounded by a vertical wall from 200 to 300 feet high, which is breached on the northwest side by a gap between 500 and 600 yards wide. The main part of the floor of the depression is formed by a flat terrace with a general crescentic outline and possibly 800 yards in width over its widest part. The breach in the caldera wall is on a level with this terrace, and thus one can walk onto it from the slopes of the mountain without climbing down. This terrace is in part bordered by a narrower one from 100 to 150 yards in width and about 100 feet lower. From the lower terrace there is a descent of perhaps 100 feet to an irregular elliptical depression which occupies the greater part of the southern portion of the caldera, the floor of which is covered with ropy and pahoehoe lava. It is on this that the pools of liquid lava are situated. On the south-east side of this depression there is a direct drop from the upper terrace and on the southern side a direct descent into it from the high wall surrounding the caldera as a whole. In the southwest corner of the depression there is a pit from 150 to 200 feet lower with an irregular elliptical outline, vertical sides, and perhaps from 250 to 300 yards across. The floor of this pit is the lowest part of the caldera. The southwest side of the pit is formed by the main wall of the caldera which is there from 400 to 450 feet high, while the west side descends directly from the upper terrace.

At the time of Combe's visit nine centers of activity could be seen. The largest was a pool of boiling lava, perhaps 70 yards in width, from the surface of which jets of lava, probably caused by the escape of juvenile gases, issue at frequent intervals. The rim of the pool has been built up above the level of the adjacent floor. The others have built up small cones from which large volumes of steam and sulphurous gases are given off. Liquid lava was seen in several of these cones. In many places jets of gas and steam issue through the surface of the ropy lava. At the time of his visit small intermittent streams of liquid lava issued from under the solid ropy rock and dropped over the steep wall into the lowest part of the caldera. These did not reach the bottom in a liquid state, but became partly solidified and dropped as lumps of scoria which have formed a large pile along the base of the wall resembling the ash heap of a power plant.

A striking feature of the structure of the volcano is that the wall surrounding the caldera, the terraces and the sides of the lowest depression are formed by a homogeneous lava in horizontal layers. The edges of the layers present a generally jagged surface cut off vertically, which suggests that they have been broken off by subsidence within the caldera. In many places large strips and blocks have broken away from the edges of the terraces. Over the floor of the terraces lines of fumaroles issue from fissures, the gases of which appear to be mainly of steam and sulphurous types, but in one place there was a strong smell of sulphuretted hydrogen. Native sulphur has been deposited adjacent to some of the fumaroles.

It is quite clear that the present-day caldera has been formed by the direct subsidence of the upper part of the volcano. The mode of origin of the flat layers of homogeneous rock, none of which exhibits columnar structure, is not so clear.

No recent flows have been derived from Nyamlagira itself that reach any considerable distance down the mountain side, for the lower slopes are clothed with dense forests.

On the whole the activity of Nyamlagira appears to have been rather quiet, but that violent explosions have taken place is indicated by the large number of bombs and ejected blocks, some of which are as much as two feet in diameter, scattered over the slopes of the mountain and over the upper terrace.

The lavas of Nyamlagira are mainly medium-grained leucite-basanites in which porphyritic crystals of plagioclase, augite, and a brownish olivine are set in a holocrystalline groundmass.

One of the fundamental tenets of science is that like causes produce like results. Nyamlagira is a volcano which, like Kilauea and Mauna Loa, yields chiefly basic, fluid lavas. Consequently the resulting volcano and volcanic structures and topography are much alike.

The matter abstracted above regarding Nyamlagira reads very much like various descriptions of Kilauea written during the nineteenth century.—H. S. Palmer.

EARTHQUAKES IN UNITED STATES

It is not generally realized how wide has been the range of seismic disturbances in what now comprises the United States of America. Practically every state in the Union has recorded earthquakes within the last hundred and sixty years and Indian tradition constantly refers to such occurrences in earlier times. Students of the geology of the North American continent can point to abundant evidence of many great upheavals that have occurred within comparatively recent geologic time.

Probably the greatest earthquake of modern times in North Amrica was the catastrophic series of shocks that commenced early on the morning of December 16, 1811, and affected an area extending from Cairo, Missouri, along both banks of the Mississippi River through Arkansas to the vicinity of Vicksburg in the south. While the greatest destruction occurred within these limits, the effects were felt over an area of 50,000 square miles while the vibrations were clearly perceived by persons in upper Canada as well as in Detroit, Washington, and Boston. This actually means that the shocks of this great earthquake were felt over a million square miles, half of the area which became the United States of today.

We take the liberty of reviewing a most interesting account of this great disaster by Thomas Ewing Dabney, appearing in a recent issue of the magazine section of the New Orleans Times-Picayune. The gifted pen of the author has conjured up a vivid picture of the occurrence.

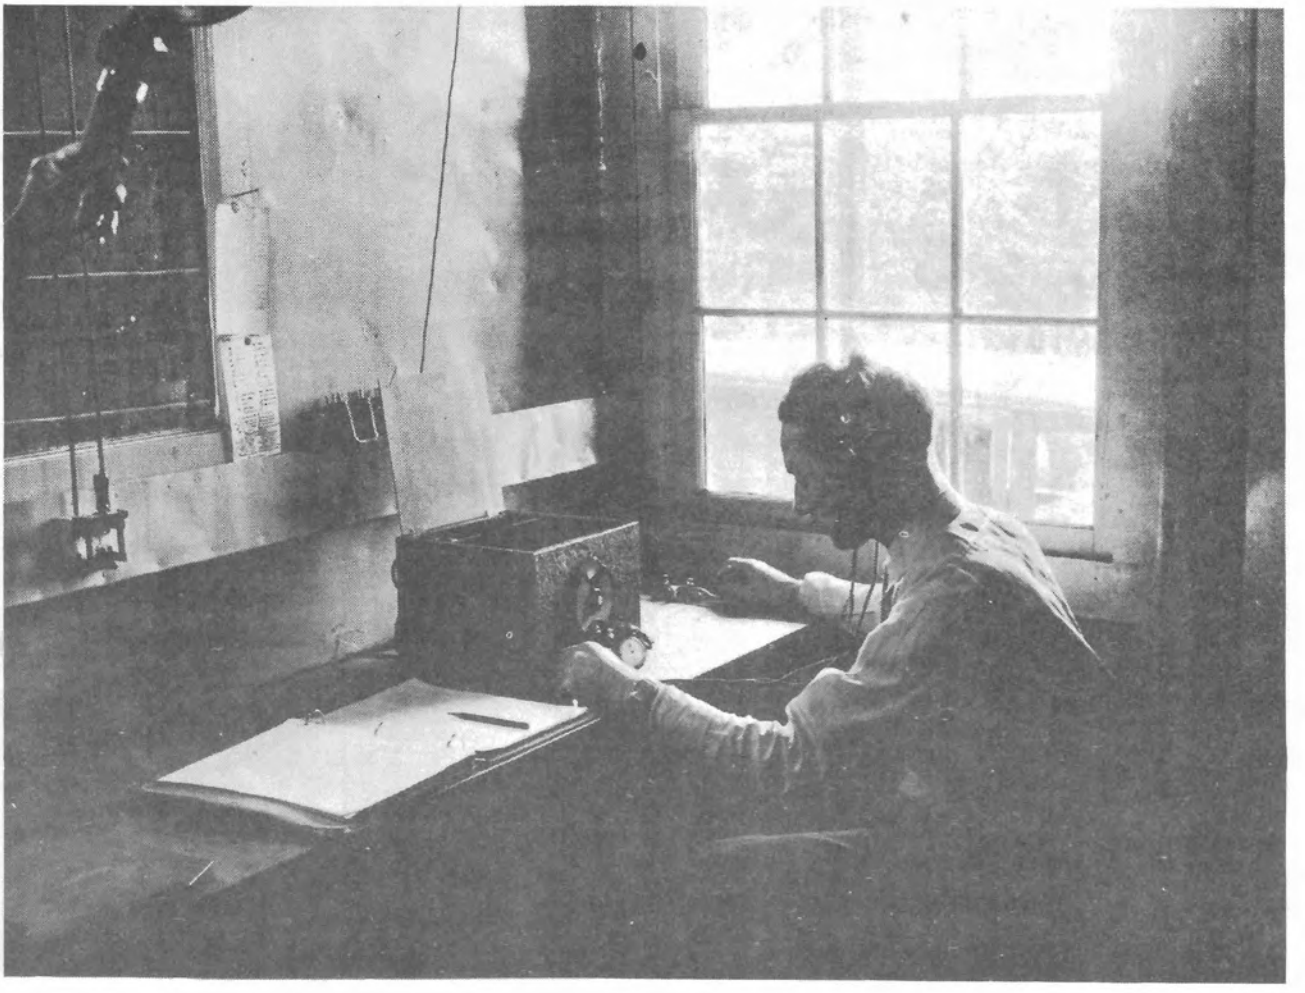
"Trees," he says, "began to move on a windless day, then clashed together like flailing clubs. High bluffs leaned forward, poised in fearful dignity, bowed into the river with enormous splashes. Waves of earth rolled over the land; rose higher and higher and burst. Back flowed the Mississippi; waterfalls raced above its surface, cast their roarings into the chaos.

"The shocks began soon after 2:00 a.m. on December 16. The crash of falling chimneys, the groaning and creaking of house timbers and the noise of overthrown furniture drove the inhabitants of New Madrid outdoors. A horrible darkness pressed down from the sky; strange odors released by the breaking earth filled the air. Daybreak came with dreadful rumblings; the ground rose and fell so that one could not stand erect. Forests fought and fell; a welter of sound rose from the tortured rivers."

Throughout that day and the next, the shocks were incessant but steadily decreasing in intensity. There was a savage renewal on January 23, 1812, followed by two weeks that were almost normal. But there was a renewal of the upheaval on February 7 and for many days after that the earth was shaking constantly. The shocks gradually ceased, but for more than twelve months afterwards recurrences kept the people in a state of alarm.

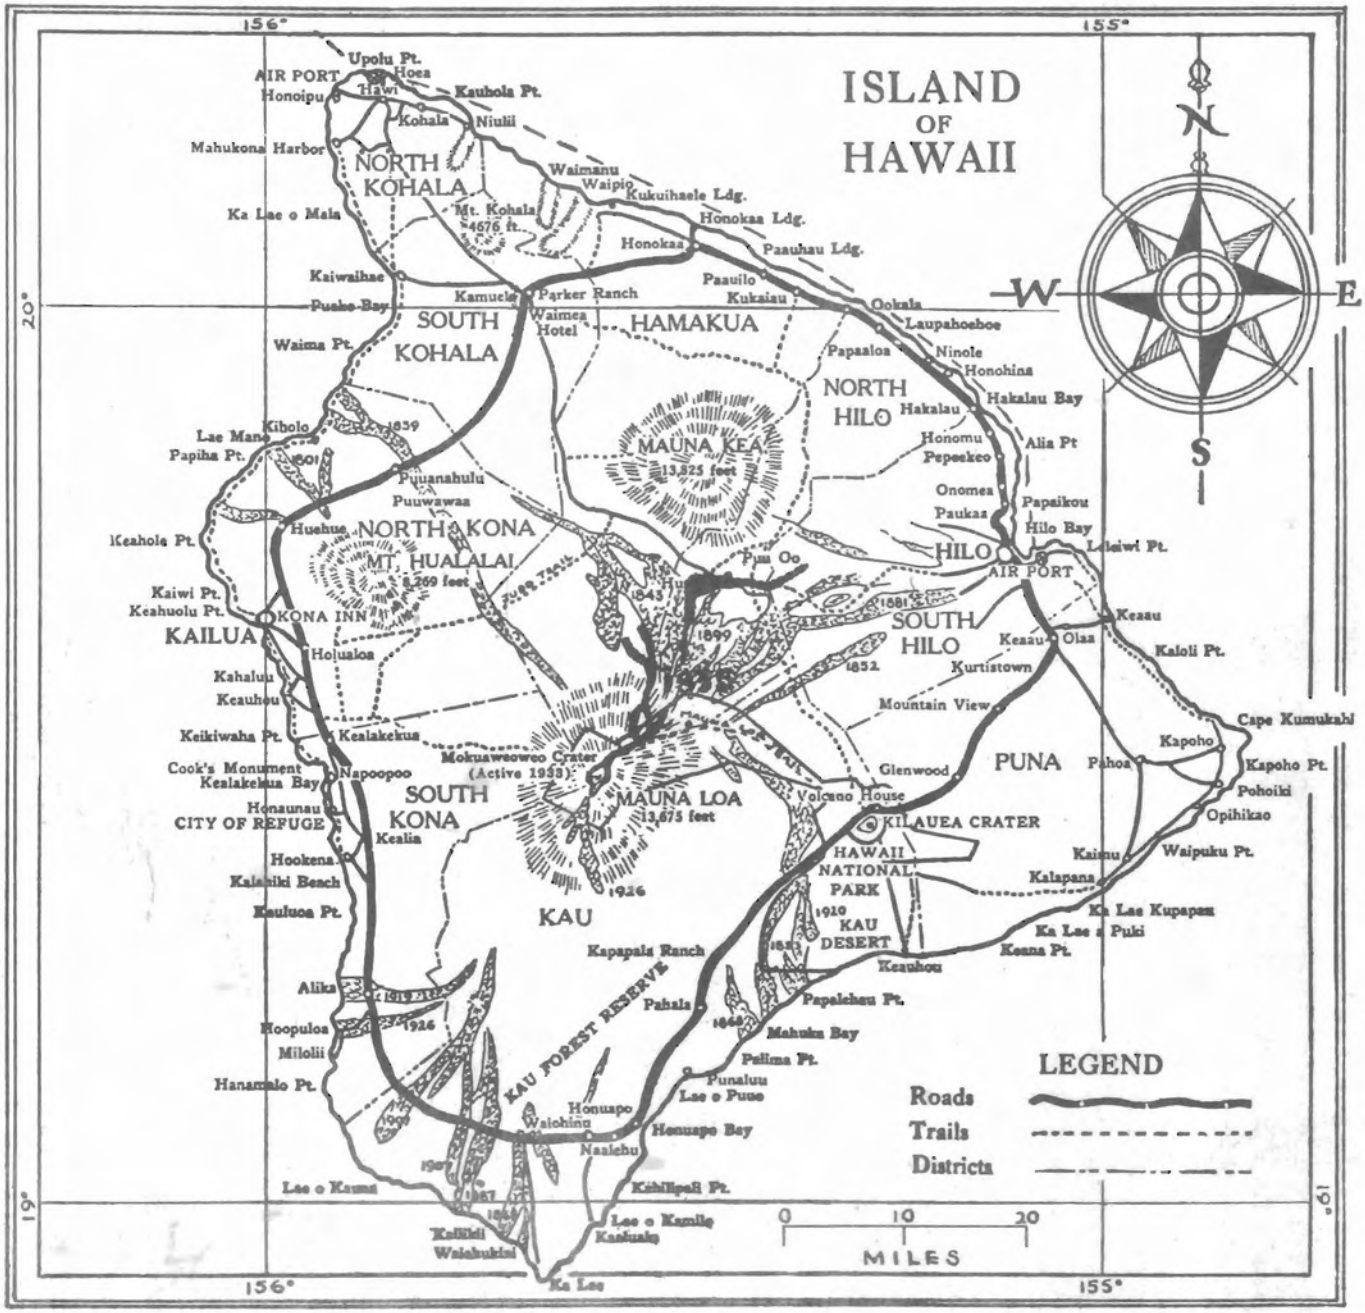
"One observer who attempted a systematic record counted 1,874 shocks between December 16, 1811, and March 15, 1812. This count was made in Louisville, far away from the main disturbance. Unfortunately no record was kept in New Madrid where, as one man said, 'the world seemed to be blowing up with loud explosions.'

"Passengers on the river steamer New Orleans which visited the devastated areas, described the enormous changes which had taken place.



"New Madrid itself, they found, was practically destroyed. Much of the town had been swallowed by the river and the houses on higher ground had collapsed. Further down the river, the prosperous agricultural community of Little Prairie (the Caruthersville of today) had become a desolate waste of sand and water spewed up from the splitting earth. The whole channel of the Mississippi River appeared to be up-tilted so that the water ran backward towards its sources for more than an hour and until the current broke its way through the upthrust material, the river was a crazy thing. One account speaks of a great waterfall six feet high and half a mile wide, apparently formed by the water being violently sucked into some chasm in the river's bottom. The same narrator speaks of another fall of the same character eight miles below New Madrid.

What are now called the "sunken lands' 'of western Tennessee, southwestern Missouri, and northwestern Arkansas covering hundreds of square miles were made in this subsidence to which Reelfoot Lake also owes its origin.



In other sections, land was raised and navigable streams went dry. A fifteen-mile stretch or territory in southeast Missouri, once a part of the flood plain, was raised nearly twenty feet. There was widespread fissuring, due to the opening of the earth after the main wave-motion had swept through the surface strata. Mr. Dabney tells us that some of these openings were several hundred feet long and were so numerous that in some sections men felled trees against the direction of the movement and clung to them to prevent being engulfed. It is worthy of note that while many of these fissures were twenty feet in width, their depth was shallow and reached only to the quicksands underlying the surface alluvium. Through many of these fissures tremendous ejections of sand, water and carbonaceous material took place, burying the fertile land. At one place the skull of the long extinct musk ox was thrown out on the surface and was later placed in the Museum of Natural History in New York.

The loss of life, owing of course, to the scanty population, was astonishingly small. Should such a shock occur in these present days of closely crowded people and tall buildings, most of which are anything but earthquake proof, the loss of life would be almost too appalling to contemplate. Congress passed an act allowing the sufferers from the disaster to locate on an equivalent amount of land in any other part of the public domain open to entry. But after a year of frequent earthquake shocks, the survivors had become so accustomed to them that of the five hundred certificates issued only twenty were located by the original claimants in person.

Mr. Dabney, in his able article, has made a valuable contribution to American literature on this important subject.—deV-N.

Short wave radio set in Volcano Observatory for receiving time signals from Washington and imprinting them on seismograms through a telegraph key.

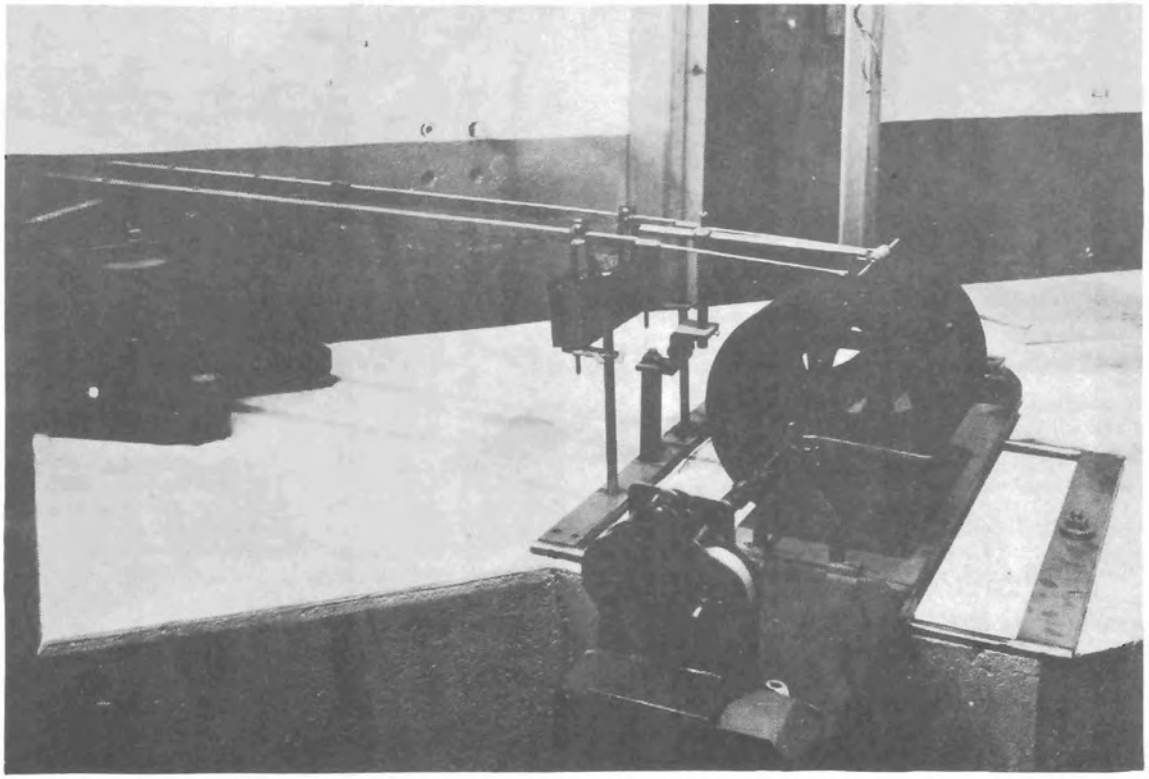
THE VOLCANO LETTER

No. 435 — Monthly, Department of the Interior, National Park Service, May, 1936

Hawaii National Park
Edward G. Wingate, Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar, Volcanologist



HAWAIIAN VOLCANO OBSERVATORY REPORT FOR MAY 1936

HAWAIIAN VOLCANO OBSERVATORY

Routine work at the Volcano Observatory was ably carried on during the month by H. Yasunaka, who at times was assisted by Asao Okuda, carpenter and mechanic, both Volcano Research Association employees. This work consisted of caring for seismographs, changing of records, recording meteorological data, recording tilt at clinescope stations and caring for the Observatory grounds, buildings and equipment.

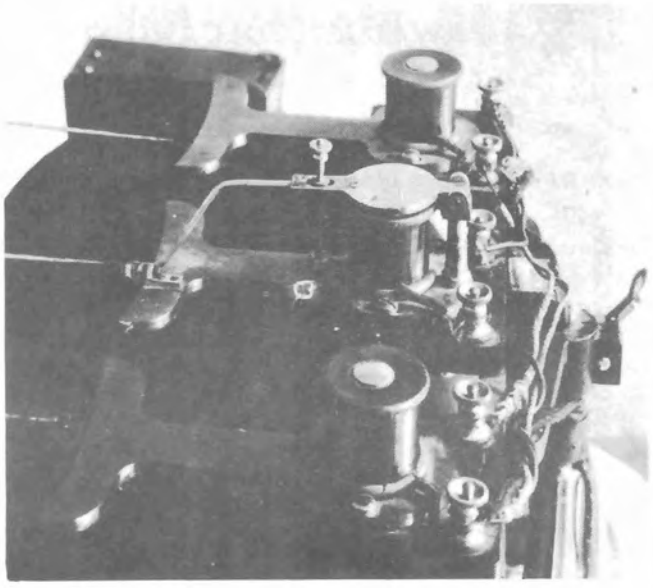
In the absence of both Volcanologist T. A. Jaggar and Assistant Geologist Waesche, weekly reports were written by Superintendent Wingate. Dr. Jaggar is on an expedition to the island of Montserrat in the West Indies by invitation of the Royal Society of London. He is studying a volcano on that island which has given indications of a possible eruption at an early date. H. H. Waesche was absent on annual leave from the park on a trip to the Orient, but returned to resume his regular duties at the Observatory May 23.

M. S. Seger, Associate Landscape Architect of the National Park Service, accompanied Mr. Waesche on the trip to the Orient. An inspection of Japanese national parks was made, including visits to the volcanic parks of Aso, Unsen and Fuji.

Strong-motion seismograph with low magnification to record those earthquakes that are too big for the other instruments.

Other parks visited were Inland Sea and Nikko. A visit was made to the national park headquarters in the Home Office Building in Tokyo, where members of the administrative staff were met. Dr. Tamura of the Japanese National Parks presented Mr. Waesche with a bomb from the summit of Mt. Fuji. This is a "sister rock" to the one presented to Ambassador Grew, in ceremonies in Tokyo, as a present from the Japanese national parks to those of the United States. The Mt. Rainier rock was part of the exchange of courtesies of this nature between Mt. Rainier National Park and the Japanese National Parks. Sakarajima Volcano was visited. Inspection was made of the seismological institute of Tokyo Imperial University as well as the seismological research department of the same institution. In addition to Japan, China, Manchukuo and Korea were visited.

SEISMOGRAPH ROUTINE 1
Checking the clock time against a stop-watch, Uwekahuna Seismograph.



KILAUEA AND MAUNA LOA OBSERVATIONS

Kilauea and Mauna Loa have both been quiet throughout the month. As late as May 16 fume was reported seen at the rift cones of the 1935 eruption of Mauna Loa. Sulphur deposits around the cones were said to be increasing. No fume has been noticed the latter part of the month. Fuming at the sulphur spots in Halemaumau continues about the same. Slides have been few and small.

Seismic activity has been comparatively moderate. There were feeble earthquakes May 2, 7 and 26, none of which was reported felt. All other disturbances were classed as very feeble or as tremors. Spells of continuous tremor of 5 minutes duration were reported for May 8 and 9. Most of the disturbances for the month originated in the Kilauea area.

Crack measurements showed abnormal opening of No. 46 on the NE rim of Halemaumau near the point where a large section of the rim disappeared into the pit in March.

Addition was made to the Observatory equipment of a Leitz precise level.

SEISMOGRAPH ROUTINE 1a:
The pens for east-west, north-south, and up-down, pendulums. The spools are electro-magnets lifting the pen-tips every minute.

TABLE

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Distant Earthquakes	Local* Seismicity
May 10	19	4	1	0	7.75
" 17	22	3	0	0	7.00
" 24	41	3	0	1	11.75
" 31	39	9	1	1	15.25

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at the Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant quakes were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began at the times indicated and whenever such determinations were possible, the depth of focus is given.

* For local seismicity, see Volcano Letter 371.

May 6, 8:55 pm, very feeble, located 0.6 mile deep in Kilauea Crater, 1.0 mile SW of the Observatory. 19° 25' 2N; 155° 16' 2W.

May 7, 6:51 am, very feeble, located 1.9 miles deep in Kilauea Crater near SE rim. 19° 24' 7N; 155° 15' 9W.

May 7, 8:07 am, feeble, located 0.4 mile deep in approximate center of Kilauea Crater 1.5 miles SW of the Observatory. 19° 24' 9N; 155° 16' 5W.

May 10, 6:57 pm, very feeble, located 1.2 miles deep under W portion of Kilauea Iki. 19° 25' 0N; 155° 15' 1W.

May 14, 4:42 pm, very feeble, located 1.6 miles deep under SE rim of Kilauea Crater and 0.4 mile W of Keanakakoi Crater. 19° 24' 2N; 155° 16' 3W.

May 14, 9:04 pm, very feeble, located 1.2 miles deep and 0.6 mile S of the Twin Craters and 1.2 miles E of Kilauea Crater rim. 19° 25' 4N; 155° 14' 6W.

May 16, 6:35 am, very feeble, probably located under S rim of Kilauea Crater.

May 21, 2:31 pm, very feeble, probably located in Kilauea Crater.

May 21, 2:46 pm, very feeble, located 1.7 miles deep and 0.4 mile N of Keauhou Ranch House. 19° 26' 6N; 155° 16' 9W.

May 25, 10:46 am, very feeble, located 1.1 miles under Waldron Ledge, NE rim of Kilauea Crater. 19° 25' 5N; 155° 15' 5W.

May 26, 11:48 am, feeble, located 1.4 miles deep under Waldron Ledge. Same as preceding quake.

May 28, 3:09 am, very feeble, located 9.0 miles deep in the Hilina-Kapukapu Fault system, 3 miles N of Keauhou Point. 19° 19' 3N; 155° 14' 8W.

May 30, at 6:19 am, very feeble, probably located in NE rift of Mauna Loa.

The preliminary waves of a teleseism began recording at 4:45 pm, May 19, and the indicated distance from the Observatory was 3630 miles. The reported location was in the vicinity of the Solomon Islands 7° 7S; 159° 6E. On May 28, at 8:35 am, the secondary waves of a distant earthquake began to register. The reported location was about 900 miles off the SW coast of Honduras. 9°N; 103° 5W.

Microseismic motion was moderate, May 10, 11, 15, 19; the remainder of the month it was light.

SEISMOGRAPH ROUTINE 2
Removing the drum covered with smoked paper.

TABLE OF TILT

Week Ending	Observatory	Halemaumau Clinoscope Stations West	Southeast	Pit Resultant
May 10	0" 83 N 27°E	4" 77 N75°W	4" 47 N 36° E	2" 87 from
" 17	0" 57 N 54°W	5" 19 S 78° W	2" 27 N 30°E	4" 25 from
" 24	0" 85 N 4°W	1" 01 S 23°W	2" 27 N 5°W	1" 33 toward
" 31	1" 24 S 82°W	2" 21 N 58°W	5" 57 S60°W	1" 14 from H.H.W.

SEISMOGRAPH ROUTINE 3
Installing a fresh drum and pulling over the pen points with a horseshoe magnet.

Tilting of the Ground

The following table shows tilt by weeks from seismograms at the Volcano Observatory NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts for two clinoscope towards or away from the Pit.

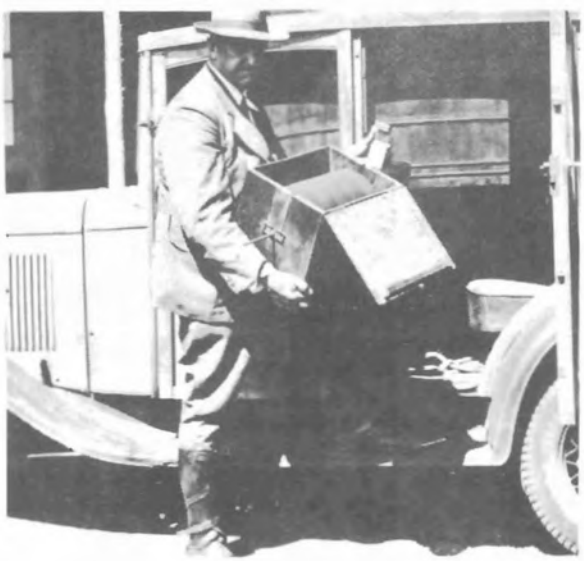
At the Observatory the total accumulated tilt for the year ending May 31, was 4" 20N and 1" 9E.

THE METHODS OF THE HAWAIIAN VOLCANO OBSERVATORY

From trying everything experimentally, in 1912, to a routine of measurement in 1936, there was growth of method at Kilauea in the effort to discern what a volcano is doing underground. One of the impressive results of the Observatory approach to volcanoes, is the failure of underground lava to announce its intentions. Newcomers to volcano science always think a hot crack at the edge of a live crater will get hotter when an eruption is impending. They solemnly measure with a thermometer. The eruption comes and goes, and nothing whatever happens to their hot crack.

Or it may be earthquakes. The lava gushes up in the bottom of the pit, and immediately the tremors may become fewer than before. Or the shakes temporarily flare up, if measured very close to the crater, and then die away before the eruption ends.

The idea that a beautiful fever chart would show everything, before the disease breaks out, is a dream doomed to disappointment. Lava is there all the time. It is a substance which suddenly releases thermal and kinetic energy, apparently from great depths. But **how,** chemically and physically, this release proceeds, is still a mystery.



The mere finding out that the lava is there all the time is a real discovery. It is proved by the sudden geysering of gas and red hot froth at the edge of a plug in the pit bottom, when a new eruption begins. By experimental drilling into Kilauea crater we found places growing hotter downward. By watching the walls of the pit when a big cave-in occurred, we found red hot avalanches 600 feet down. And when a thick new flow cools off, we find the under parts stay hot for years.

Comparing the dull times when the lava in the pit was sluggish but liquid, and the dull time now when it is crusted and hard, there is no essential difference in behavior: sulphurous hot gas always rises, the rim cracks move, the earth tremors increase and decrease, and the top of the mountain is a flexible shell that tips inward, or tips outward. Always the ground is **alive,** and very different from the terra firma of Honolulu.

Four things, weather, earthquakes, slow movement, and gas emission are the things we set ourselves to measure after twenty-five years of Observatory work. First, the measured changes of the weather. We must know what weight of rainwater loads the mountain, what pressure and temperature of the air may make changes in the rock, and how wind and storm and sunshine may deceive us in viewing steam or vapor from cracks.

Second comes the locating of earthquakes. This looked like a delightful prospect in 1912. We would find out who felt the quakes most. We would make a nice little instrument for everybody. Then Kona would tell us the December quake there was of Grade 2, Kohala would have Grade 1, Hilo would show Grade 6, and Kilauea would be Grade 8. Ergo, Kilauea was strongest, and Kilauea lava made the shake.

But nothing like that happened. When it came to **feeling,** people in one end of Hilo town felt quakes that nobody noticed in the other end. With a magnifying seismograph in Hilo and at Kilauea, Kilauea got many tremors that did not show at all in Hilo. When a nice little earthquake was felt in Kohala, Kona, Hilo and at Kilauea, all at the same hour, and surely the same shock, nobody felt it more strongly than anybody

SEISMOGRAPH ROUTINE 4
Carrying case for drum, transported by car to be changed, and the record varnished.

else: it seemed to have been felt equally all over the island. This was most disconcerting. It raised such baffling questions as "What is an earthquake, anyway?" And so we were led to phases, and compression, and angle of emergence, and vertical component, and depth of origin. And to the question, what is an origin? Is it a snapping open, or a scraping slip, or a closing bump?

The entire science of seismology was painfully reviewed and investigated and experimented with; complicated seismographs were set up and discarded and tried anew; at Kilauea, Hilea, Kona, Puu Waawaa, Waikii, Honokaa, and Hilo. Trials of simplified shock recorders were made. The telephone was used to send the same time-keeping to different stations. Wireless was installed to get the same time-signal to each station. Some instruments were made to write with a beam of light on photographic film. And all of this had a **geographical** motive, to

SEISMOGRAPH ROUTINE 5
Fixing the smoked seismogram with varnish bath.

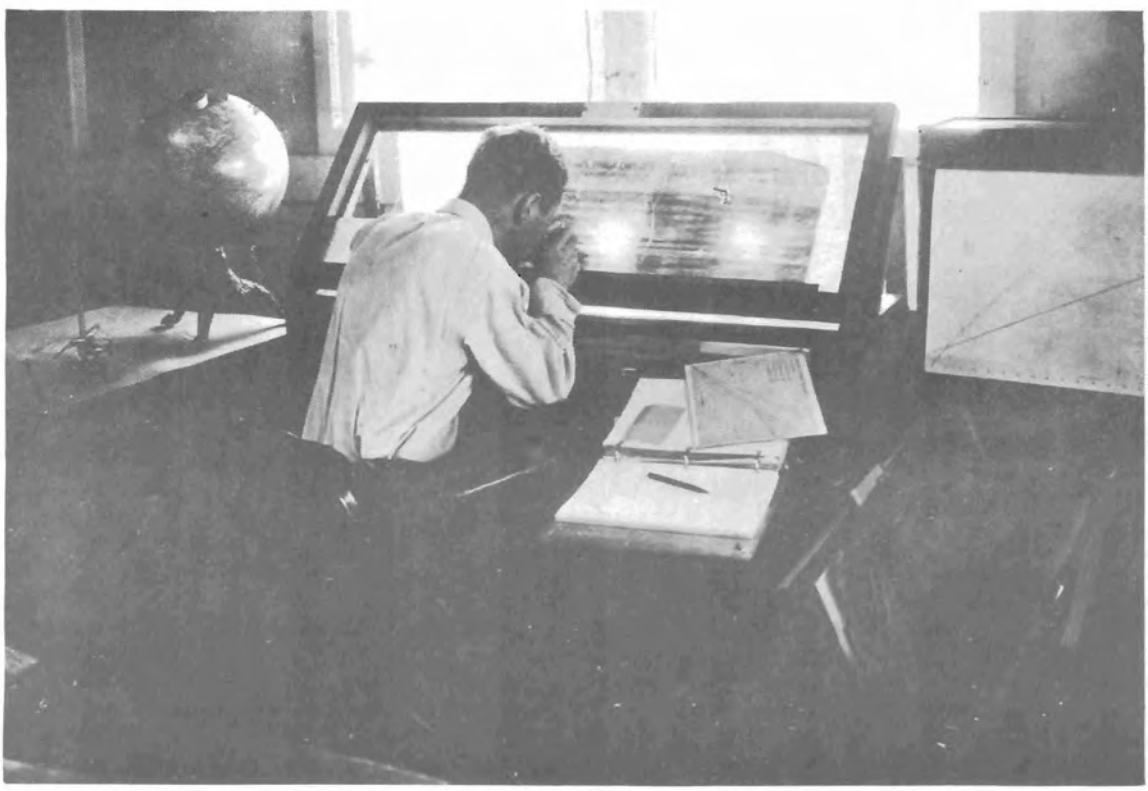
cover the whole island. The result was a deadlock, for the whole island had to be covered with skilled physicists, an obvious impossibility. The workers were faithful amateurs, but a seismograph properly requires a highly trained scientist.

So the Observatory muddled through, getting a result here and a result there, and an improving list of earth movements. The dream of 1912 faded away. The harnessing of an island with amateurs is still awaiting a suitable instrument. Three stations have been maintained at corners of a triangle. Theoretical seismology has improved, and the routine is shown in the accompanying photographs. The horizontal pendulum three-component seismograph, with smoked-paper records, is still used, and the earth has written thousands of autographs. The locating of a place underground, where an outbreak appeared above ground, was done on Mauna Loa in 1935. This was the result of careful studies for two decades by faithful seismologists. But we are still far from knowing exactly what an earthquake is.

The third quest of the Observatory concerns finding out what is the secular strain under which a volcano is laboring. Not only does the ground shake, but it rises and tilts. This involves a long engineering program, again harnessing an island. Kilauea Crater has been proved to move more, through a period of twenty years, than Hilo. The movements up and down were big, before and after the pit exploded in 1924. They were up before, down afterward. The mountain swelled for ten years, then its top was let down suddenly. At the same time the lava was withdrawn, water must have rushed in below, and steam gushed out. Probably the lava flowed out under the ocean.

All of this story from 1912 to 1926 was told by R. M. Wilson in engineering language, "Ground Surface Movements at Kilauea Volcano," (University of Hawaii Research Publications No. 10, 1935, 56 pp. with maps and charts). The work has been done repeatedly by levelling, tide gauge reading, triangulation, setting up nets of flags, bench marks and towers across the volcano, and by comparing the results of 1897, 1912, 1922, 1927 and other times.

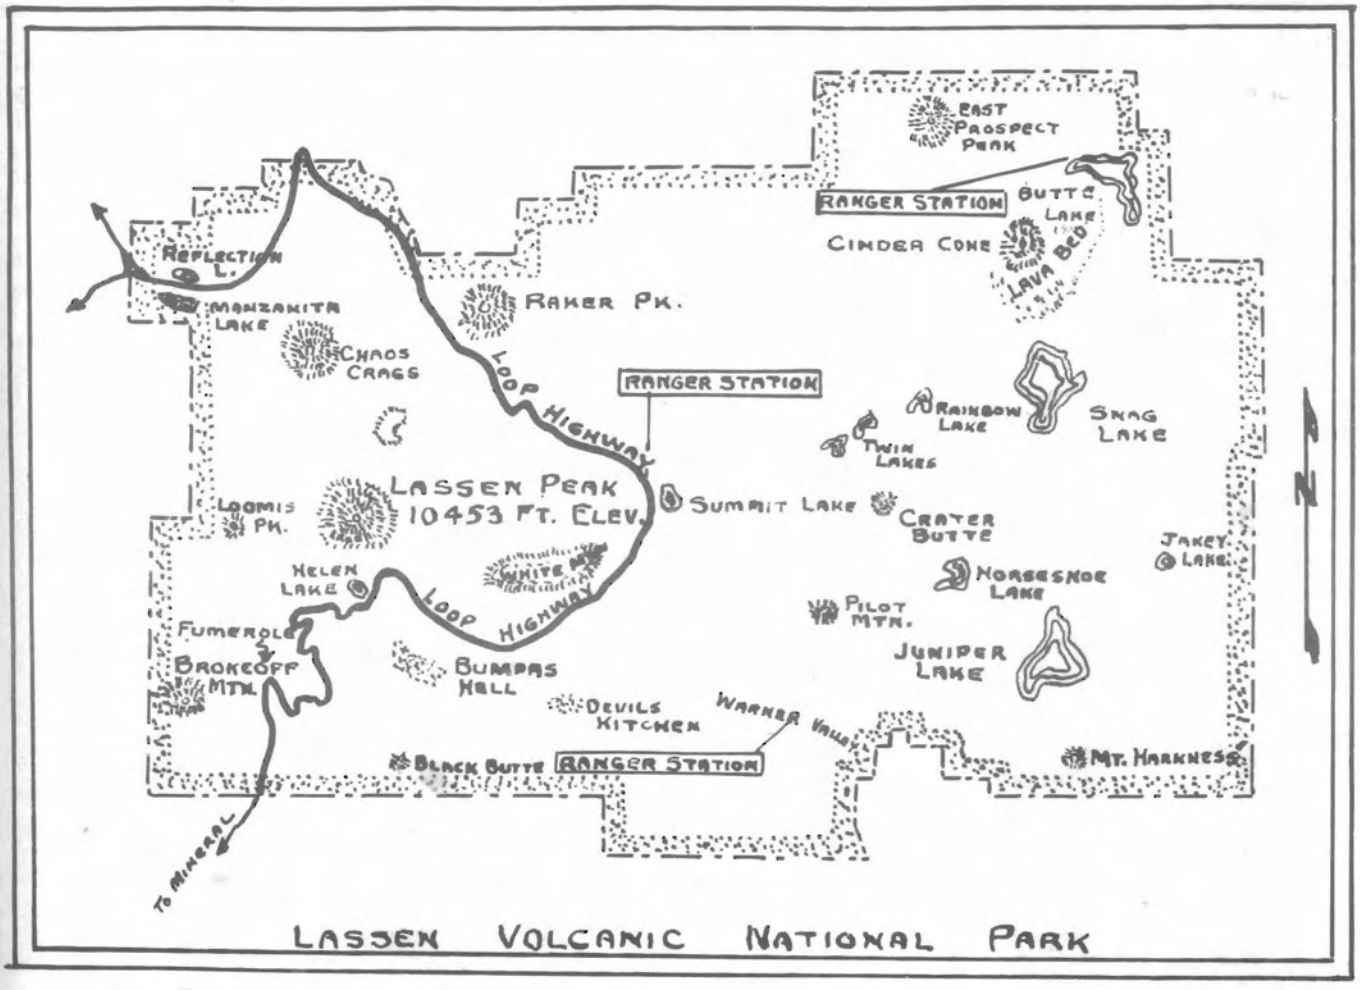
This has been supplemented by the pendulums of the Observatory, writing on smoked paper, from day to day, many years. This writing showed tilting of the ground away from Kilauea very strongly after 1918. And there was strong tilting back again towards the crater in 1924. The Volcano House rose bodily about two feet during the years before 1924. It



sank as much after the lava collapsed in 1924. And the edge of the inner pit Halemaumau sank **thirteen feet,** and the walls on opposite sides of the crater **approached each other.** This was proved by measuring horizontal angles with a transit, in the triangulation.

All of these laborious discoveries might have applied equally to the great crater on the summit of Mauna Loa, if men and means had been available, before and after the eruptions of Mauna Loa in 1914, 1916, 1919, 1926, 1933 and 1935. What Wilson began at Kilauea has gradually been added to by the weekly and monthly measurements at the Observatory, with level and transit. This was set in motion by E. G. Wingate, who succeeded Wilson as topographic engineer. Some of our illustrations show the surveying instruments used to line up the changing geometry of the crater.

The fourth and most elusive high ambition of the Hawaiian Volcano Observatory, in its methods of studying the chemistry and physics of the inner earth, deals with the emission of gases, especially hydrogen. To collect new or "juvenile" gas from live lava, to trap and analyze it, to develop a technique that can be applied at any sulphurous volcanic vent or actual flame, is the volcano student's dream. Whenever the mighty fountains play above a gushing rift on Mauna Loa, there are flames. When the gushing stops, there are steam jets and sulphur and selenium and alum. The so-called "solfataric" mild activity (Sulphur Bank) of quiescent volcanoes, is still **in communication by gas ducts** with potentially live lava below. We see such gases on the sun, and both volcano and sun yield free hydrogen. Free hydrogen at high temperature is not to be trapped. No laboratory container will restrain it. At lower temperature it has been trapped at Kilauea, in small percentages. Its oxide, water vapor, appears in large percentages. The lower the water vapor, the higher the hydrogen. This ratio leads to the suspicion that if spectroscopic or other method could find out, what is the Hawaiian gas before it vanishes in flame, we might discover hydrogen to be the prime mover of all volcanism. It is certainly a primary element in all chemistry, and in astro-physics: and water vapor is nothing more than burned hydrogen.



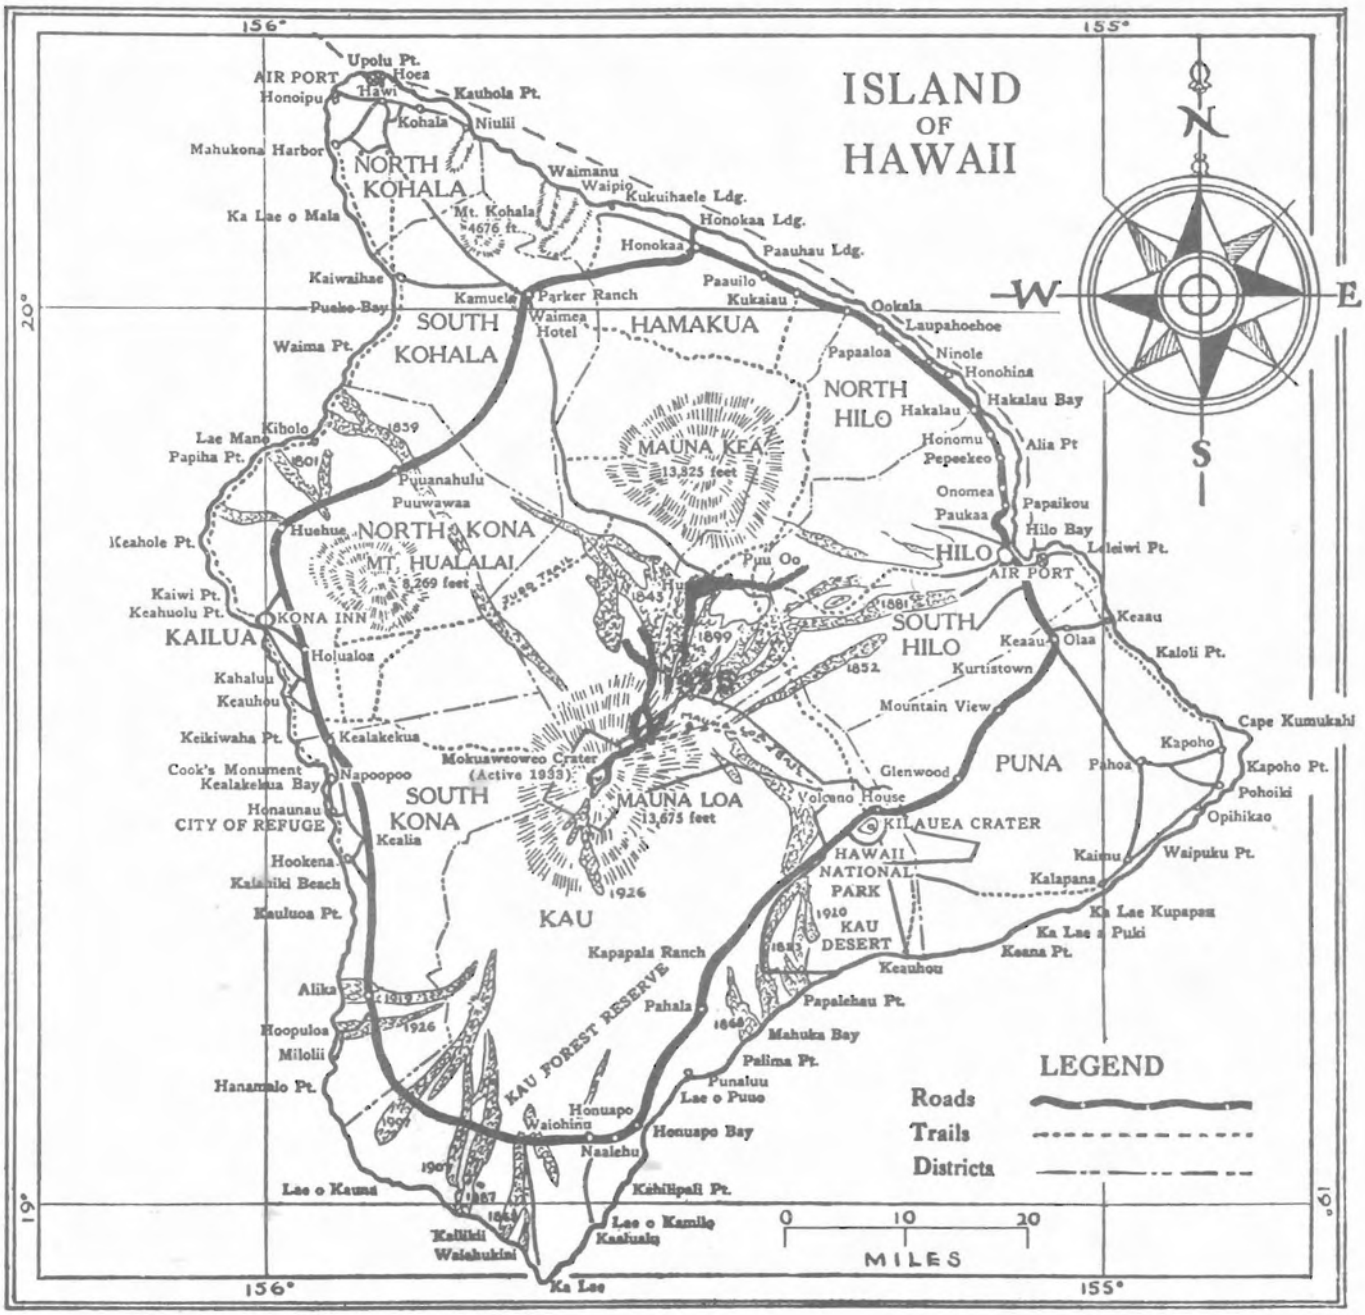
The methods of attacking the gas problem are illustrated in some of the photographs. Vacuum tubes are thrust behind a flame, or into a sulphurous crack, and the tip is melted or broken deliberately. The glass is sealed and the contained gas carried to a laboratory for analysis. This work is now being improved by special researches by the Physics Department of the University of Hawaii; in which the spectroscope will play a part.

The illustrations appearing in this issue of the Volcano Letter show the seismograph routine; other apparatus in regular daily use will be shown in succeeding issues. T. A. J.

SEISMOGRAPH ROUTINE 6

Studying and measuring the seismogram, calculating the epicentral location, and entering in record book.

EARTHQUAKES IN LASSEN VOLCANIC NATIONAL PARK DURING MAY, 1936



Carl R. Swartzlow
Park Naturalist

More earthquakes occurred in May, 1936, than in any previous month. The shocks were all of low intensity. Only four were of No. 5 intensity, according to the McAdie Scale, and the rest were less severe.

The earthquakes were accompanied by considerable tilt during the periods of greatest activity.

With a few exceptions the epicenters were located within the park boundaries. Most of the shocks did not center under Lassen Peak as many people believed but were located along fault zones in the eastern part of the park. The Warner Valley fault zone was the center of greatest activity, with some minor shocks felt in the Butte Lake District.

The hot spring activity has remained practically normal throughout the month. On April 30, four columns of steam rose from the crater of Lassen Peak to a height of between 200 and 300 feet, but activity on the peak has been normal since that day, although a little abnormal activity was noted in Bumpas' Hell early in the season. Conditions in the Devil's Kitchen in Warner Valley have been normal during the period of observation.

THE VOLCANO LETTER

No. 436—Monthly, Department of the Interior, National Park Service, June, 1936

Hawaii National Park
Edward G. Wingate, Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar, Volcanologist

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JUNE, 1936

Naka-dake Crater, Pit No. 2, of Mount Aso Volcano, Japan

REPORT OF VOLCANO OBSERVATORY FOR JUNE, 1936

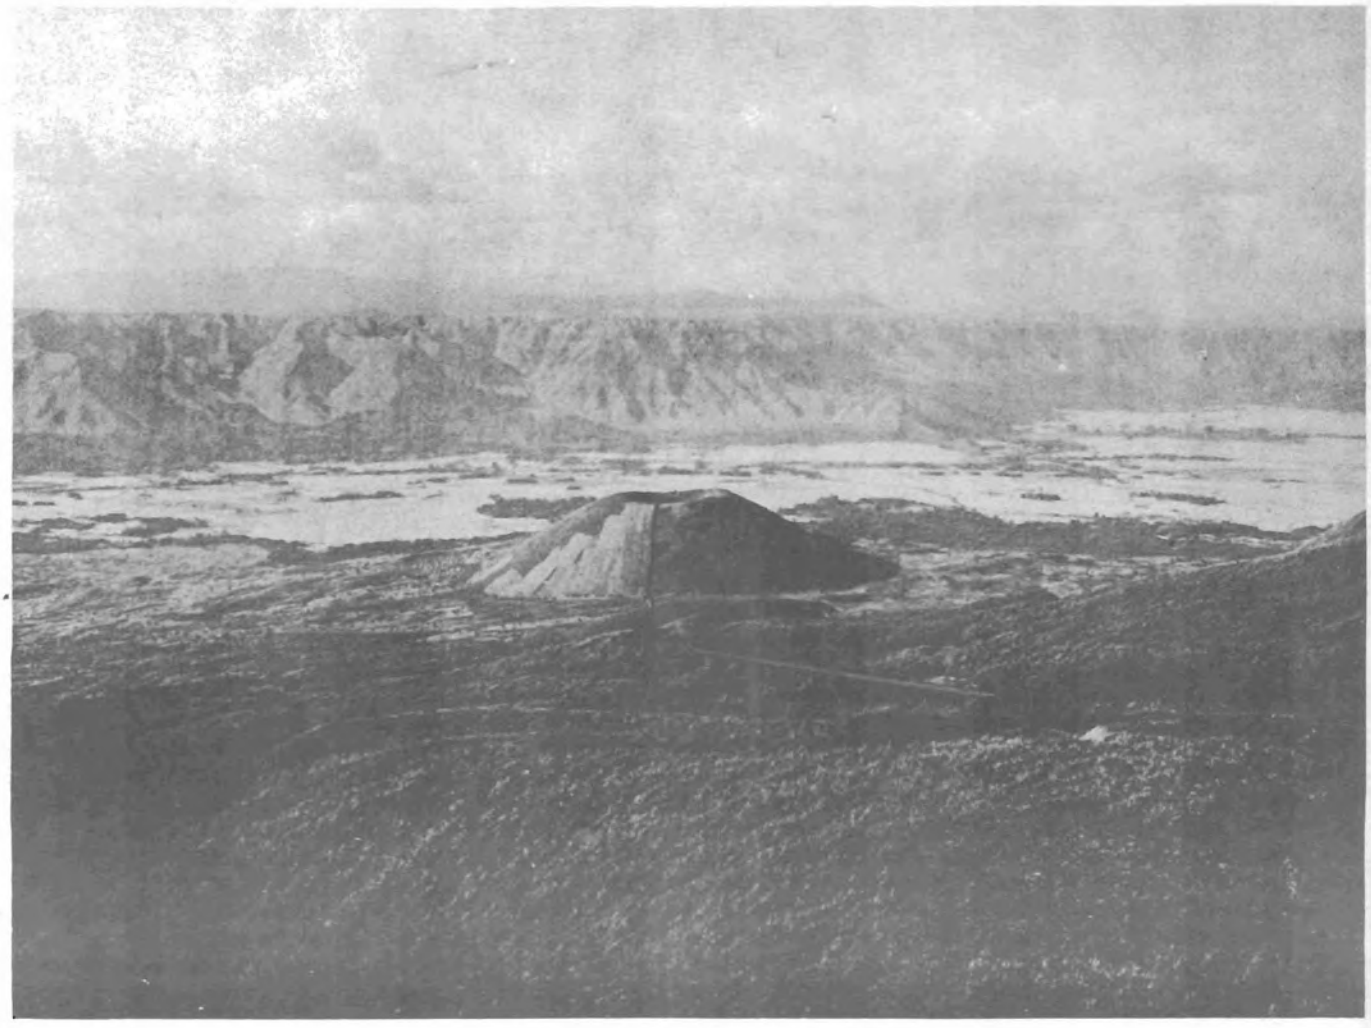
The normal schedule of routine activities has been carried on at the Volcano Observatory during the month. Regular records have been kept of daily activities and of observations of Mauna Loa and Kilauea. The usual daily trips to the seismograph stations and tilt stations for observations have been made. Daily meteorological records have been kept.

The Volcanologist, Dr. Jaggar, is still absent on a scientific expedition studying conditions at Montserrat for the Royal Society of London.

Mauna Loa and Kilauea have been quiet throughout the month. June 14 ended a week of exceptional quiet at Kilauea, during which no rock slides from the walls of Halemaumau were reported. This is the first time that such has been the case for over a year. Active sliding was again resumed the

week of June 28. A party accompanied by Ranger Murray made a trip to the summit of Mauna Loa June 13 to 16. They report that there had been considerable activity in the NE section of Mokuaweoweo, the summit crater, during the November, 1935, eruption. The trail, one-half mile below the crater, was covered by a new lava flow. Fuming, though greatly diminished, was continuing at the source cones at the 1200-foot elevation and deposits of sulphur were reported large around their base. All trails and markers in the NE portion of Mokuaweoweo have been obliterated. The summit rest house was unharmed.

Seismic activity has been moderate and fairly consistent as shown by the numbers of disturbances for the successive weeks of 32, 32, 21 and 32. Of these one was a feeble quake on June 4, 26 were very feeble shocks and the remainder was made up of tremors. Three minutes of continuous tremor began at 11:26 P.M. June 2. On the morning of June 30 at 3:59 twenty-eight minutes of continuous tremors began recording. Most of the disturbances are of Kilauea origin.



Crack measurements around Halemaumau for the month showed very little change except number 46, located on the NE rim, which has consistently opened at an abnormal rate of 4.5 millimeters per week.

Mr. F. Chase of the Department of Geology, Harvard University, visited the Park on June 10-17. He spent considerable time studying at the Observatory and made a trip to the summit of Mauna Loa. He had been two years in Australian gold mining work and was returning to Cambridge to resume his duties there.

View of Mount Aso Crater, Japan

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant quakes were located with the aid of the seismograms from stations at Hilo and Kealake-

Boiling Mud at Hot Springs, near Beppu, Japan

kua. The disturbances began at the times indicated and whenever possible determinations of depth of focus have been made.

June 1, 6:33 pm, very feeble, probable location in Kilauea Crater.

June 1, 7:53 pm, very feeble, located 2.5 miles SSW of Pit seismograph station in Kau Desert. 19° 22' 3N; 155° 18' 0W.

June 3, 8:13 pm, very feeble, located 1.5 miles deep in Kilauea Crater 1:0 mile SW of the Volcano Observatory. 19° 25' 2N; 155° 16' 1W.

June 4, 1:21 pm, very feeble, located 2.5 miles under SE rim of Kilauea Crater 19° 24' 7N; 155° 15' 8W.

June 4, 3:18 pm, very feeble, located 1.8 miles deep in Kilauea Crater, 1.0 mile SW of the Volcano Observatory. 19° 25' 2N; 155° 16' 1W.

June 4, 3:21 pm, feeble, located 3.0 miles deep in Kilauea SW Rift zone 0.4 mile west of Halemaumau in vicinity of the Rift Cones. 19° 24' 6N; 155° 22' 8W.

June 5, 4:09 pm, very feeble, located 1.2 miles under Pit Seismograph in Kilauea Crater. 19° 24' 3N; 155° 17' 0W.

June 7, 9:53 pm, very feeble, located 0.8 mile deep under SE rim of Kilauea Crater. 19° 24' 5N; 155° 15' 9W.

June 7, 11:28 pm, very feeble, located 1.2 miles under N rim of Kilauea in vicinity of Kilauea Military Camp. 19° 26' 3N; 155° 16' 8W.

June 11, 5:05 pm, very feeble, located 1.4 miles deep in Kilauea Crater 5.0 miles SW of the Volcano Observatory. 19° 25' 6N; 155° 16' 0W.

June 14, 8:31 am, very feeble, probably located in Kilauea SW Rift zone 8 to 9 miles SW of Halemaumau.

June 17, 12:55 am, very feeble, located 1.4 miles S of Pit seismograph and 1.9 miles deep. 19° 23' 2N; 155° 18' 0W.

June 18, 12:03 am, very feeble, located 2.5 miles under W rim of Kilauea Crater 0.7 mile SW of Uwekahuna. 19° 25' 1N; 155° 18' 0W.

June 22, 2:37 am, very feeble, probable location in vicinity of Hilina Pali.

June 23, 7:19 am, very febele, probable location in Kilauea Crater.

June 25, 8:34 pm, very feeble, located 3.7 miles deep and 1.1 miles SW of Puu Ohale. 19° 20' 9N; 155° 17' 7W.

June 25, 8:37 pm, very feeble, located 3.1 miles under NW rim of Kilauea. 19° 25' 9N; 155° 17' 4W.

June 26, 6:57 am, very feeble, located 1.6 miles deep and 0.3 mile S of S rim of Kilauea Iki. 19° 24' 6N; 155° 15' 1W.

June 26, 9:25 am, very feeble, probable location in NE portion of Kilauea Crater.

June 26, 2:54 pm, located 1.6 miles deep and 0.8 mile S of Twin Craters. 19° 24' 4N; 155° 14' 2W.

The surface (L) waves of a distant earthquake began recording at the Observatory at 11:02 pm, June 2. The reported location was off the Coast of British Columbia. 40° 7N; 125° 5W.

Three minutes of continuous tremor registered, starting at 11:26 pm, June 2.

Microseismic motion was moderate, June 2, the remainder of the month it was light.

Tilting of the Ground

The following table shows tilt by weeks from seismograms at the Volcano Observatory NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts for two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending June 28 was 5".08 N and 0".74 W.

H.H.W.

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory June 9, compared with similar measurements March 16 and April 15, showed little change across Halemaumau but indicated opening across the crater from rim to rim in a NW-SE direction. March 16, to April 15, Halemaumau showed opening of 0".11 and April 15, to June 9, it closed 0".52. Across the Crater there was an opening of 0".75, and April 15 to June 9, an opening of 2".18.

View of Sakurajima, Kagoshima in Foreground, 1914 Eruption

NOTES ON JAPANESE VOLCANOLOGY, AND ON SEISMOLOGICAL RESEARCH

H. H. Waesche

Cherry blossoms, temples, and volcanoes are three things that every visitor to Japan becomes conscious of as soon as his ship docks at one of the Empire's many ports. He may not see the cherry blossoms as they are a seasonal exhibit only, and a visit could be made without seeing any of the shrines or temples, but evidence of volcanic activity, either past or present, cannot be overlooked. Volcanoes are a part of the everyday life of all the Japanese. Volcanism is a major motif in their art, it enters into religion, and even in their play at various hot-spring resorts or "spas," as they are called. Fujiyama is known the world over for its grace and symmetry of form. This dormant volcano is exhibited in practically all Japanese arts and being sacred it influences the thought of the entire country. It is probably the typical volcano. Volcanic eruptions, destructive and otherwise, have been a part of the history of Japan from its very beginning. There are many volcanoes which are periodically active, such as Asama, Mihara (Oshima), Aso, and Sakurajima among the more famous, and others at scattered localities from Hokkaido in the North to Kyushu in the South. Anyone interested in volcanology and its related subject, seismology, will find both well represented in their many phases in the "Land of the Rising Sun."

H. Waesche, Assistant Geologist at the Hawaiian Volcano Observatory, and Merel S. Sager, Associate Landscape Architect of the U. S. National Park Service, visited Japan during April and May, 1936. Trips to the volcanic areas of Mt. Fuji, Beppu, Sakurajima, Mt. Aso and Unzen were made during their stay. They also visited the Department of Geology, and the Research Institute of the Tokyo Imperial University. Acknowledgment is made of the many courtesies extended and helpful information given by Dr. S. Tsuboi of the Department of Geology, Dr. M. Ishimoto of the Research Institute, and Drs. Imamura and Matuzawa of the Seismological Institute. The trips to the National Park Areas were made most enjoyable and profitable through the very kind assistance of Dr. T. Tamura, of the Japanese National Park Association, his assist-

ant Mr. Kato, and the local directors of the several parks, as well as local prefectural officers. All contributed toward making the trip one of outstanding value.

The morning of April 17 was spent inspecting Hot Springs in the vicinity of Beppu. This city is one of the most famous of Japan's 1200 spas. It is located on the east coast of the Island of Kyushu bordering the famous Inland Sea. Here in a volcanic area of about twenty square miles are found over a hundred thermal springs and fumaroles exhibiting a variety of characteristics. They are known as "Big Hells" or to the Japanese as jigoku. Associated with many of the hot springs are smaller areas several feet in diameter of boiling mud similar to the "paint pots" seen in Yellowstone. These latter are noisily and continuously agitated by escaping steam. The largest of the hot springs is known as Umijigoku and is thought to be over 400 feet in depth and has a temperature of 195° F. at the surface. The water of one spring visited possessed a bright red color which appeared to be caused by the presence of iron, evidently in the form of ferric oxide. Articles of clothing and other materials dipped in the red water and stained were valued souvenirs by many visitors. The name of this spring was Chinoikejigoku or "blood pond." Most of the fumaroles produced sulphurous odors. No native sulphur deposits were observed, however. A popular novelty along the seacoast at Beppu is the so-called "sand bathing." Hot springs bubble up through the sand beaches where the bathers bury themselves in the sand and take a modified turkish bath.

The next stop after leaving Beppu was made at the city of Kagoshima in the southern part of the Island of Kyushu. This city is located on the shores of Kagoshima Bay. In the Bay and two miles east of the city, towering 3,500 feet above the water, is Sakurajima, one of Japan's mightiest volcanoes. This cone marks the scene of the greatest eruption in the annals of the Island Empire which took place beginning in January, 1914. It is of interest that this eruption was expected, and the local residents being thus warned were prepared, with a consequent loss of life of only 35 people and some millions of dollars in property damage. Warnings concerning the possibility of an explosive eruption were made as early as 1909 following rather violent earthquakes in the vicinity. In 1913 violent eruptions began at Kirishima Volcano some thirty miles to the north of Sakurajima. The last two eruptions there occurred on November 8 and December 9, consequently expectations at Kirishima were high when January 9 arrived, but nothing happened. However, at Sakurajima an outburst of earthquake swarms transferred suspicions to that vent. Four hundred and seventeen earthquakes were recorded at Kagoshima between 4 am January 11 and 10 am January 12, after which the main eruption began. The morning was cloudy so that the activity was not visible until after 10 am when the

Meteorological Observatory on Sokojio Unzen, Japan.

clouds dissipated. At that time a swelling balloon of black smoke in the middle of the mountain was seen rising from the ground where an hour before there had been orange orchards and cultivated, terraced fields. The column of smoke went up some 30,000 feet in the air and then bent eastward, strewing dust all over Central Japan. A smaller column arose on the east flank of the mountain having started ten minutes after the western one with which it later merged. There were booming concussions, flashes of lightning and in the lower part of the cloud, being thrown to great heights were ashes, sand and bombs. At night these latter were seen to be red hot. At 6:29 pm a violent earthquake shook Kagoshima and it was in the destruction caused by this shock to buildings and in landslides that most of the casualties resulted. This shock was recorded on seismographs in Europe. It was followed by lava emissions. Their flow continued several months, filling in new craters, pouring into the sea and on the east side of the Island filling in a strait, changing the Island into a peninsula. This happened the afternoon of February 1. Much pumice was formed and so great was the quantity floating in the bay that boats traveled with difficulty. Fortunately for the City of Kagoshima the eruption was not concentrated at the one western vent pointed in its direction as its fate might have been similar to that of St. Pierre on the Island of Martinique when Mt. Pelee erupted in 1902. The water of the Bay around Sakurajima was warmed considerably and near the lava flows measured as high as 138° F. More than 4,000 acres of lava were poured out above sea level in two months. Ash measured 70 inches in depth near the volcano, a thin film 30 miles away and some even fell in Tokyo 600 miles away on the third day of the activity. Precise geodetic measurements of Sakurajima showed that an elevation on the mountain had risen 10 feet whereas a point submerged in the bay had lowered 10 feet. This would seem to indicate that the volcano had swollen with lava inside while the surrounding land had subsided with the release of pressure and emission of lava.

On April 18 of this year Sakurajima was quiet when visited. In the early morning a moderate cloud of fume or vapor was seen rising from the summit crater. This was obscured by clouds shortly before noon. A boat trip was made to the tip of the most westerly lava flows from Kagoshima. The party landed on a beach composed of pumice. The lava was of a rough fragmental nature, black in color, very similar to the aa of Hawaii. It is said to be a hypersthene-hornblende andesite. The flow at this locality was piled up probably two hundred feet in thickness. Reports said that the eastern flow was 300 feet above sea level in localities formerly covered by 200 feet of water. The upper slopes of the volcano were bare of vegetation, were light reddish in color and seemed composed of soft materials of the nature of ashes and cinders. Sakurajima is of the usual conical shape much like the volcanoes of the Cascade Range of the Northwestern United States. Although not now active in a spectacular way it is an inspiring sight.

Leaving Kagoshima by train, the City of Kumamoto was reached the evening of April 18. The night was spent at the Tsukasa Inn. Early the next morning the party, consisting of Mr. Matsumuro, Director of Aso National Park, Mr. Goto, the Assistant Director, and a Japanese policeman by the name of Jiro Kurageno, left Kumamoto for Mt. Aso Volcano. Mr. Matsumuro left the party after going a few miles out of Kumamoto. The policeman went along as translator, being the only Japanese of the group who could speak English. At Bochu a bus was taken for the point of greatest activity. The bus was a very sumptuous one including swivel chairs as in a railway parlor car. Besides the driver there were two Japanese girls, one who described the places of interest in sing-song Japanese and another who translated it into English. The latter girl's name was Sumi Araki formerly of Honolulu, Hawaii, and spoke excellent English. She is now employed by the Great Aso Motor Bus Company in charge of the other girl employees and as a translator for foreign visitors. The bus used was one which had been especially built the preceding year for the exclusive use of Prince Takamatsu when he was a visitor to Mt. Aso. At the summit Mr. Henry K. Haraguchi, owner of the park concessions, was the party guide. The road from Bochu to the summit was finished five years ago, having been built by the Imperial government, and is now operated by the National Parks Association of Japan. It is about nine miles long and at no point is the grade more than 1:12. At the end of the road, which was about one-half mile from the active crater, there was located a seismograph station. Here there was an instrument of moderate magnification registering on a smoked drum. In the valley below Aso, toward Kumamoto, the Kyoto Imperial University has an observatory where studies of all changes and activities at Aso are being continuously made.

The Aso Volcano is the largest of a chain of vents extending along a zone of crustal weakness from Mt. Kuju to the east to Mt. Unzen to the west. This zone of weakness is supposed to be a continuation westward of the depression zone of the Inland Sea. The mountain proper covers the major part of the two provinces of Higo and Bungo and its base extends 30 miles E-W and 28 miles N-S, including some 700 square miles. It consists of a "somma" which attains a height of 3,200 feet above sea level, topped by an oval crater, 10 miles wide and 15 miles long, the floor of which is sunk an average of about 1,600 feet below the rim of the outer slope. The wall of this caldera is nearly perpendicular with talus accumulated at its base. This huge crater is thought to have originated by depression, as have those of Hawaiian volcanoes, due to the outflow of immense volumes of lava. The caldera is attained from Kumamoto on the west through the Futaye Pass cut into the rim to a depth of over 2,000 feet. Another pass known as the Tateno Break occurs to the south of Futaye Pass. Breaks in the rim walls along fracture zones aided by water erosion are supposed to be responsible for these two gaps. Rising near the center of this huge crater, said to be the largest in the world, are the central cones called the "Five Peaks of Aso." The most important of these is one known as Naka-dake, the scene of current activity. Standing west of Naka-dake is the highest cone, Taka-dake, rising a mile above sea level and around 3,600 feet above the floor of the caldera. Surrounding these central cones are the plains extending to the crater wall which are known as the "atrios." The part to the north of the cones is the Aso valley and to the south is the Nango valley. These atrios, consisting of volcanic ash, sand, lapilli and gravel, form a fertile soil on which lives a population of some fifty thousand people including 11 villages. The stratification of the materials composing the crater floor suggests the existence of a former crater lake, which was later drained through the passes previously mentioned.

Naka-dake possesses a series of five pits composing the summit crater. These are numbered consecutively from north to south and share honors as centers of activity with the number 1 pit having the majority to its credit. Number 3 pit is next in frequency of eruptions. Number 4 pit was active 10 years ago and continued intermittently for several years. In 1926 number 2 pit was described as a small kettle-shaped depression, at times filled with water and never very active. At present this is a large depression and the center of activity. It broke out with an explosive eruption in 1934 which was the largest in 150 years. Bombs and boulders were thrown over three hundred feet in the air and literally peppered the ground for several square miles around the vent. Much ash and cinders were ejected but no lava flows. A huge column of

smoke now billows above the vent, rising high in the air and easily visible almost the entire trip from Kumamoto to Bochu. Viewed from the rim of the pit, it is seen to be rushing out with considerable force and is accompanied by loud roaring sounds below. Evidently this cloud of fume is composed principally of steam with considerable sulphur fumes, as shown by the amber color in reflected light and bluish in transmitted light. This pit is now over 3,000 feet long by 1,500 in width and is about 450 feet from the rim to the throat of the funnel-shaped aperture from which issues the huge cloud of vapor. The throat is supposed to be about 35 feet across. Occasionally incandescent material is visible below. Number 1 pit is about 400 feet, number 3 about 250 feet and number 4 about 475 feet in depth. Their floors are dotted with fumaroles and solfataras. Historical records indicate that Naka-dake has erupted between 60 and 70 times. These have always consisted of emissions of mud flows, ashes and fragmental materials but never any trace of a lava flow.

The rocks of Mt. Aso are petrographically classed as andesites and are comparatively basic, many of them containing olivine or angite or both. The olivine-bearing rocks are found in the central cones and are younger than hornblende-bearing rocks found on the outer slope of the crater.

Aso Volcano is without doubt one of the most interesting sights to be seen in Japan today. It is apparently putting on an excellent and impressive performance at all times whether of a violent nature or otherwise. Five hundred thousand visitors annually are reported to look into the awesome depths of the rumbling pit. As is true of Mihara and Asama, Aso seems to be an attractive spot for those Japanese suffering from suicide manias. An average of 200 of these unfortunates is reported to make the leap from the rim of number 2 crater per year.

The next volcanic district as a part of the Japanese itinerary was that of Unzen, also a National Park and a very popular hot springs resort, catering mostly to foreigners. It is located on the Shimabara Peninsula, western coast of the Island of Kyushu and is the western terminus of the volcanic chain of which Mt. Aso is a part. The group of mountains at Unzen consists of a central cone called Fugen-dake and associated peaks of Kunimi, Myoken, Takaiwa and Kinugasa. The whole mound consists of a more acidic type of rock than was found on Mt. Aso.

Within historic times there have been several recorded eruptions at Unzen. One is reported to have started in 1657 A.D. and marks a period of activity lasting for more than 20 years. Others occurred in 1663 and 1664. The most eventful activities started with a series of earthquakes in the winter of 1792. On the morning of February 9 that year, Fugen-dake erupted with loud explosions, throwing heavy smoke clouds, mud and rocks. Lava broke out in the valley of Anasako February 25, overwhelming the village of Semboki. This lasted several months. A heavy earthquake shock on March 11 was followed by over 300 slighter shocks that night and over 100 during each of the next two days. Around April 1 a huge landslide following earthquake shocks occurred on the southeastern part of Mea-yama, a mountain on the seacoast south of Shimabara. About one-sixth of the entire mountain mass slid into the sea, producing severe tidal waves. Two villages were completely buried under the debris. The portion of this huge mass which slid into the sea gave rise to between two and three hundred islets of which many still exist. Today these are called "Ninety-nine Islands" and are partly covered by vegetation. The boat which runs from Misumi to Shimabara affords excellent opportunity to see the scar left by the slide and the islands which resulted. Whether this was really a volcanic explosion or not is a moot question. Casual observation from the boat suggested structural failure rather than volcanic activity. Various phases of diminished activity continued until February, 1793. Eruptions of this nature are of interest in exhibiting, specifically, relationship to a marked degree of volcanic activity and seismic activity. Other than a heavy earthquake in December, 1922, and minor shocks from time to time no further evidence of activity except hot-spring and fumarolic emissions has occurred.

In the recently erupted flat dome of Obiyama, past volcanic activity is indicated by numerous hot springs and fumaroles. This is the famous spa district of Unzen where are located the many hotels for the thousands of visitors who come from all over the world annually. The springs are usually acidic and contain sulphur compounds. Near the vents, siliceous sinter and deposits of sulphur are being built up. The spa is 2,200 feet above sea level. A nine-hole golf course is located at the foot of Mt. Myoken.

An excellent view of the surrounding country may be had from the summit of Kinugasa-yama. This mountain, over 3,000 feet above sea level, is the location for a meteorological station under the control of the Nagasaki Prefecture. Here are housed various instruments such as barometers, anemometers and thermometers. In a separate building is an Omori seismograph and quarters for an attendant. Unzen posseses a charm deserving of its great popularity.

The supreme expression of volcanism in Japan, at least to the popular mind, is the world-famous Mt. Fuji. Rising to a height of over 12,000 feet above sea level, it is usually surrounded by clouds and during most of the year there is a mantle of gleaming snow on the upper portion. Wherever Japanese art has gone, there also has gone Fuji. It is the very symbol of Japan itself and as previously mentioned is held in sacred veneration by the Japanese people. It well deserves this consideration. Its perfect cone is considered the classic type shape for a volcano of the explosive type. When the weather is favorable, Mt. Fuji may be seen from Yokohama, where visitors from North America first land, from Kamakura, parts of Tokyo and from the main line railroad between Yokohama and Kobe.

Mt. Fuji is characterized by a long, gentle slope of similar inclinations on all sides except the southern, where there is an explosion crater. Halfway up the inclination is 17° and at the summit it is 34°. A typical summit crater is found at the top of the mountain which is a funnel-shaped depression, 720 feet deep and 1,970 feet in diameter at the uppermost level.

Mt. Fuji has been active several times within history. In 800 A.D. a lava stream flowed down the Katsura-gawa and eached the Enkyo bridge following a violent eruption. In 864 A.D. two great streams of lava poured down the northern slope. The last major activity occurred in 1707 when a large explosion took place on the southeastern flank, producing the Hoeisan Crater. No lava was emitted but great quantities of bombs were thrown out. This was followed by small explosions in 1708 and 1792. The volcano seems dormant at present although reports mention fumaroles on the east side and on the top, none of which are very active. Numerous spas and hot springs dot the countryside around Fuji, however, of which some of the best known were visited at Myanoshita and in the Hakone District. One of these, visited May 9, 1936, known as the "Big Hell," was emitting quantities of sulphurous vapors, was surrounded by sulphur deposits, and was of comparatively high temperature. At Myanoshita, waters from the hot springs are run into very imposingly appointed baths at the Fujiya Hotel for the use of guests. Dr. Tamura of the National Parks Association presented a bomb from the summit crater of Mt. Fuji to H. H. Waesche. This was a sister rock of the one

presented to Mt. Rainier National Park in the United States as an exchange of goodwill between the respective countries. They were both brought down by Mr. Kato, Landscape Architect of the Japanese National Parks. The bomb was oval-shaped and about seven or eight inches in maximum diameter. Like other Fuji rocks it is of an andesitic composition. One of the best views of Fuji is obtained from Nadao Pass to the south, reached by bus from the Fujiya Hotel at Myanoshita.

On May 11 a visit was made to the Tokyo Imperial University. Dr. Tsuboi, the head of the Department of Geology, was host to the party. Activities of the Geology Department were discussed and results exhibited. Geological work was in progress on the Mount Fuji region and much areal mapping had been done. Instruments used for petrographical and mineralogical work were inspected. The department was up to date in all respects and seemed to be carrying on an extensive as well as progressive program of research with emphasis on the geological phases of volcanism, earth movements and structures, petrography and mineralogy. There was a large collection of thin sections of rocks from all parts of Japan. Everything was being carried on with the customary Japanese thoroughness.

Dr. Ishimoto, Director of the Earthquake Research Department, next took charge of the visitors. He has a large, well-equipped department with many seismographs of various types. Most of them were modified Galitzins of the accelerometer type, having a vibration period in some cases as long as 0.7 second. One vertical instrument had a pendulum extending three stories up to the roof of the building with a period of 7.0 seconds. Photoelectric recording was the preferred method, although many instruments utilized very thinly smoked drums. In all cases the drums were rotated by means of synchronous motors. They made in most cases four revolutions per hour. A few seismographs used no timing. Instrument magnification ran from 100 to 500 and on low magnification instruments from 2 to 10. The time marks were recorded on the drums by means of electrical solenoids which jarred the frames, thus widening the pen's trace at that instant and were controlled by master clocks. Tilting of the ground in Tokyo is given considerable attention because of its possible value in earthquake predictions following observed tilts of blocks between fault lines. One very interesting tilt instrument consisted of a long horizontal pipe partially filled with water and buried several feet in the ground. The open end of the pipe was faced with glass where the water level could be seen. Regular daily micrometer measurements of the changes in level of the water were taken and from them tilt calculations made. This seemed to be quite practical for tilt measurements in one plane and had the advantage of being earthquake proof. One laboratory room was used for testing seismographs and accelerometers with a standard rocking machine. Various types of harmonic motion could be produced in this manner with known values, making possible the determination of instrument peculiarities and characteristics. A similar instrument is in the shop at the Hawaiian Volcano Observatory and has been used for tests on instruments now in use. A great deal of attention is given to initial movement determinations. Both vertical and horizontal instruments are used. Models of glass representing the disturbed area are made, with small silk threads showing deformation of the earth near the focus as indicated by interpretation of initial earth movements at a number of localities.* All the instruments at the Earthquake Research Laboratory are located one to two stories below the ground level for better control of variable conditions, such as temperature changes and in order to reach a good rigid sub-stratum. Gravity determinations of localities on the earth's surface is a source of much active research along with the seismological studies.

As guests of Dr. Ishimoto, luncheon was enjoyed at the faculty restaurant in the company of Drs. Tsuboi and Imamura, as well as the host. After luncheon Mr. Sager called at the Architectural Department while H. Waesche accompanied Dr. Imamura to the laboratories of the Seismological Institute, of which he is Director Emeritus. The Institute is an older organization than the Earthquake Research Institute. It was previously under the direction of the late Professor Omori, world-renowned seismologist, and is now directed by Dr. T. Matuzawa. Possibly the work of the two organizations overlaps. The primary interest of the Seismological Institute, though, seems to be the study of the cause and effect of earthquakes with their possible prediction of occurrence in mind. Here they are interested in what happened in Tokyo and Yokohama in 1923 and what can be done to prevent recurrence of such catastrophes. More attention is given to local shocks. The Earthquake Research Institute, on the other hand, is more interested in the theory of wave propagation, physics, and mathematics of seismology. The day was concluded with Drs. Matuzawa and Imamura conducting the remainder of the party through their laboratories. It was noticed that an instrument identical to the one in use at Uwekahuna was in operation. Many old obsolete seismographs were on display as well as various other instruments of a seismological nature. Pictures of earthquake destruction were plentiful. Seismology is taken seriously in Japan—and it should be, with the occurrence of such catastrophes as some of the past earthquakes have caused. These two seismological research institutions are working day and night to learn more about one of Japan's principal problems. Knowledge is not a guarantee of protection but it will go a long way toward making Tokyo a safer place in which to live, and prediction of earthquake activities more reliable.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY, 1936

VOLCANOLOGY

A fresh scar was found on July 1 on the west end of the north wall of Pauahi Crater in the Chain of Craters. Other scars representing recent slides were noticed in Makaopuhi, along with an increase of fuming and sulphur stains.

The week ending July 12 was peculiar in that no rock slides were reported from Halemaumau. Fumes continued to issue from the west floor solfatara, and a more intense puff of fume than usual rose over the NW rim of pit July 11, 10:15 am.

Measurement of 32 marked concentric cracks around Halemaumau, showed changes each week from the week before, as follows, with certain notable openings of Crack No. 46, which is about 150 feet back from the ENE rim:

Six days ending July 3, 6 opened, 4 closed, aggregate opening 5.5 mm. Crack 46 opened 4.5 mm.

Eight days July 11, 13 opened, 2 closed, aggregate opening 11.0 mm. Crack 46 opened 5.5 mm.

Week ending July 18, 7 opened, 5 closed, aggregate opening 5.5 mm. Crack 46 opened 4.5 mm. Fresh cracks opened on the ENE rim.

Six days ending July 24, 7 opened, 1 closed, aggregate opening 9.0 mm. Crack 46 opened 6.0 mm.

Eight days ending August 1, 7 opened, 3 closed, aggregate opening 10.5 mm. Crack 46 opened 8.5 mm.

Thus through five weeks the aggregate openings have been 5.5, 11.0, 5.5, 9.0 and 10.5 mm, and crack 46 has opened 4.5, 5.5, 4.5, 6.0 and 10.5 mm, these facts showing progressive increase of yawning open of cracks northeast.

Rock Slides in Halemaumau

June 29, new dust on floor and scar on wall 400 feet below Crack No. 29, NE. At 12:45 pm a NE slide made dust cloud visible for 5 minutes.

June 30, 3:50 pm, small slide. Others occurred at 5:35 pm, 6:18 pm, 6:25 pm and 6:30 pm, all NE.

July 2, 8:55 pm, SW wall, 9:10 pm, NE wall.

July 13, two large slides sent up dust 3:20 and 3:24 pm.

July 18, 9:58 am, noise of rocks falling at SE wall.

July 20, avalanche scar NE.

July 21, noon and 3 pm, dust from slides NE, followed by dribbling slides.

July 22, more scars, small slide 9:37 am, a larger one 1:19 pm, and others 3:43 and 4:30 pm.

July 23, slides from NE wall 9:13 am, 9:52, 10:01, 10:07 am. Northeast chasms on the edge were widening.

July 24, dust clouds from slides 8:15 am and 1:24 pm.

There appear to have been increases in sliding northeast, along with the opening of cracks.

All of this means that a portion of the northeast wall of Halemaumau is "working," whether because of movement on the deep rift blocks, or because of lava motion, cannot yet be told. T.A.J.

TABLE

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Distant Earthquakes	Local* Seismicity
July 5	29	9	2	0	2	20.75
" 12	18	7	0	0	0	8.00
" 19	38	12	0	2	1	22.25
" 26	45	4	0	0	0	13.25
Aug. 2	44	3	0	0	0	18.50

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant quakes were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began at the times indicated and, whenever possible, determinations of depth of focus have been made.

June 30, 7:28 am, very feeble, located 4.0 miles deep and 0.5 mile SW of Pit Seismograph. 19° 24' 0N; 155° 17 3W.

July 1, 2:31 pm, feeble, located 15.0 miles deep and 3.0 miles SW of Halemaumau in Kilauea SW Rift zone. 19° 22' 3N; 155° 18' 6W.

July 1, 2:32 pm, feeble, same locality as preceding quake and both reported felt in Hilo.

July 2, 12:47 pm, very feeble, probable location in rifts 2.3 miles west of Pauahi Crater.

July 3, 6:27 am, very feeble, located 4.0 miles deep and 1.6 miles S of Pit Seismograph, 1.0 mile west of Ahua Kamokukolau. 19° 22' 9N; 155° 17' 1W.

July 3, 1:25 pm, very feeble, located 1.8 miles deep in Kilauea Crater. 19° 24' 7N; 155° 16' 3W.

July 5, 7:04 pm, very feeble, 1.3 miles deep and 0.7 mile E of Pit Seismograph in Kilauea Crater. 19° 24' 4N; 155° 16' 4W.

July 6, 7:41 pm, very feeble, located 0.9 mile deep in Kilauea Crater, 0.5 mile W of Byron Ledge. 19° 24' 9N; 155° 16' 1W.

July 9, 8:48 am, very feeble, probable location under E portion of Kilauea Crater.

July 12, 6:22 am, very feeble, located 2.0 miles deep in Kilauea Crater. 19° 24' 7N; 155° 16' 3W.

* For local seismicity definition, see Volcano Letter 371.

July 12, 3:46 pm, very feeble, located 15.0 miles deep under N slope of Mauna Kea, 4.0 miles below summit. 19° 52' 6N; 155° 26' 5W.

July 15, 5:16 pm, very feeble, probable location in Kilauea Crater.

July 15, 9:40 pm, very feeble, located 1.7 miles deep and 0.5 mile S of Kilauea Iki. 19° 24' 4N; 155° 14' 9W.

July 15, 11:12 pm, very feeble, located 1.5 miles under SE rim of Kilauea Crater near Keanakakoi Crater. 19° 24' 4N; 155° 16' 2W.

July 15, 11:39 pm, slight, located 1.6 miles deep under S rim of Kilauea Iki. 19° 24' 7N; 155° 14' 9W. Reported felt in the Kilauea Area and in Hilo by several persons.

July 16, 4:14 am, very feeble, located 0.9 mile under Byron Ledge E rim of Kilauea Crater. 19° 25' 1N; 155° 15' 7W.

July 18, 6:21 am, very feeble, located 1.7 miles deep under NE rim of Kilauea Crater. 19° 25' 8N; 155° 16' 0W.

July 18, 8:24 am, slight, located 2.8 miles deep under SE portion of Kilauea Iki. 19° 24' 9N; 155° 14' 8W. Reported felt by several persons at Military Camp and at the Volcano House.

July 18, 12:45 pm, very feeble, probable location SE portion of Kilauea Crater.

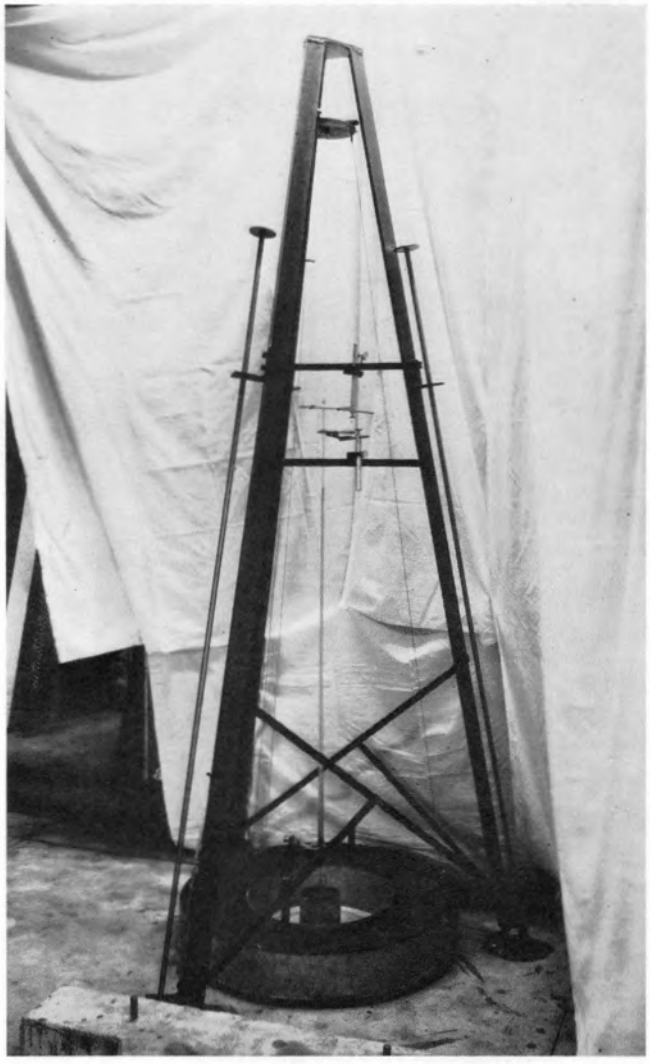
July 20, 8:50 am, very feeble, located 1.8 miles deep, 3.3 miles SW of Pit Seismograph and 2.0 miles W of Aloi Crater. 19° 22' 0N; 155° 15' 3W.

July 23, 6:41 pm, very feeble, probable location Mauna Loa NE Rift, about 5.0 miles from Summit Crater.

July 25, 4:41 pm, very feeble, probable location under E slope of Hualalai about 5.0 miles from summit.

July 27, 4:58 pm, very feeble, probable location under Mokuaweoweo, Summit Crater of Mauna Loa.

The preliminary waves of a distant earthquake began recording at 4h 45m 14s HST, June 30. Newspapers reported quake as being 4100 miles NW of Pasadena, California. The distance from the Volcano Observatory was 3190 miles. Reports from the Central Station of the Jesuit Seismological Association gave the location near N portion of Japan Trough off the S end of the Kamchatka Peninsula. 51° 0N; 161' 1E. The preliminary waves of a distant earthquake began recording at 8h 37m 4s, HST, July 5. The estimated distance from Kilauea was 5650 miles. Reported location was the southern extremity of the Philippine Trough, N of Moluccas. 4° 0N; 124° 9E. The preliminary waves of a distant quake began recording at 12h 55m 45s, HST, July 13. Its estimated distance from Kilauea was 6480 miles. Reported location, in Chile Trough off the N coast of Chile.



At 3:59 am, June 30, 28 minutes of continuous tremor began registering. At 7:38 pm, July 19, three minutes of continuous tremor began. 24 minutes of tremor began at 11:31 am July 30.

Microseismic motion of the ground at Kilauea was moderate July 15, 17 and 18; the remainder of the month it was light.

Tilting of the Ground

The following table shows tilt by weeks from seismograms at the Volcano Observatory NE rim of Kilauea Crater and at Halemaumau, the algebraic sum of radial tilts tor two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending August 2, was 4" 35N and 1" 81W.

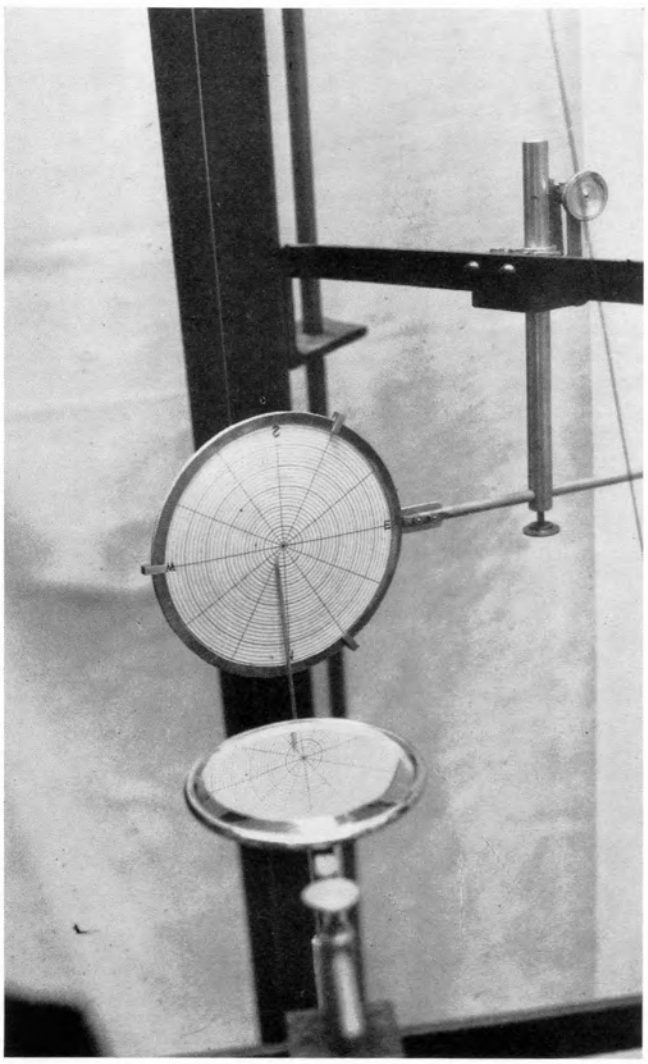
The tiltmeter or clinoscope designed by Wingate and Jaggar, and installed in the three cellars around Halemaumau. A heavy ring weight in oil moves when the ground tilts the tripod. The top of the boom is pointing to a disc marked in directions and distances from a center. The reading of the bottom surface of the disc is made daily with a mirror. The adjusting rods on the tripod bring the boom back to center.

TABLE OF TILT

Week Ending	Observatory	Halemaumau Clinoscope Stations		
		West	Southeast	Pit Resultant
July 5	0".76 N 16°W	5".22 N 83°W	3".73 N 4°E	2".15 from
" 12	0".39 N 15°W	3".23 S 60°W	3".92 N 29°W	0".90 toward
" 19	0".12 N 3°E	0".36 N 49°W	2".43 N 36°E	0".51 toward
" 26	0".30 N 28°W	9".24 N 64°W	1".20 S	8".87 from
Aug. 2	0".86 N 51°E	3".04 S 86°W	5".83 N 18°W	2".54 toward H. H. W.

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory, July 24, compared with similar measurements June 9, showed slight closing across Halemaumau and slight opening across the Crater from the SE rim to Uwekahuna on the NW rim. The amount July 6 was a closing across Halemaumau of 0".83 and an opening across the Crater of 0".4. Between July 6 and July 24, the Halemaumau angle opened 0".41 and the Crater angle opened 0".84.



H. H. W.

MORE ABOUT VOLCANO OBSERVATORY METHODS

Tilt Measuring Instruments

We have seen in the May number and in the pictures of the April number, how the Hawaiian Volcano Observatory makes seismograms, measures cracks, receives time signals, collects gases, watches the weather, and surveys the land to prove its rising and falling, swelling and shrinking, and the spreading apart of the cliffs of the Crater.

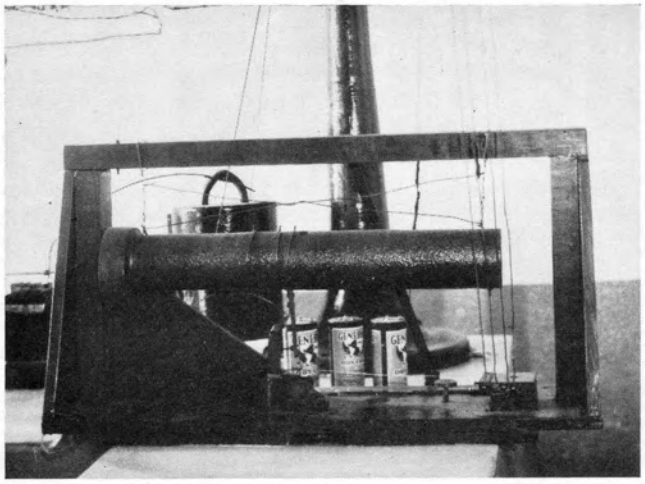
Here and in Japan, the study of earthquakes has led the workers increasingly to watch the tipping or tilting of a piece of ground. Just what does this mean? It obviously does not mean that the ground was level before. It means that a plumb-bob, hung on a thread and allowed to come to rest, has its thread making a certain definite angle with the surface of the ground at any place. If the ground tilts between January and July, the thread will make another angle, in another direction, when the weight is hung over that same place.

Mirror and dial of Hawaiian Volcano Observatory clinoscopes.

What we need, then, is a weight hanging in one place from a support over a level floor, and a device for measuring the angle that the thread makes with the floor. If the floor were really level, the thread would be at right angles to it with reference to all points of the compass.

But no floor is level. We are not measuring in degrees but in seconds, and a second is one-thirty-six-hundredth part of a degree. A tilt of two seconds would be a disturbing event for the foundation of an astronomical telescope used for measuring the position of the stars. Imagine, then, how an astronomical telescope would fare, when the edge of Kilauea Crater tips eight seconds in two days!

Sometimes these tippings are sudden and are accompanied by earthquakes. This means that the mountain block where our level floor is built has suddenly shifted and our floor is no longer level. At other times the motion is more gradual as though the shell of the mountain were bending like a bow. There are many possibilities. The man of science must think of all these possibilities and select the one that fits best. We had a little seismograph station in February, 1929, at the southeast edge of Halemaumau, the inner pit of Kilauea Crater. The instrument was a pendulum hinged against an upright post like a door with the plane of the hanging at right angles to a radius of the pit. The outer end of the boom attached to the hanging weight wrote a line on smoked paper driven by clockwork. If the ring formed by the upper edge of the pit were lifted, the ground would tilt away and the boom would move away from the pit, and the line on the paper would move with it. On the other hand, if the mountain under the pit should shrink, the pit edge would lower and the door-like weight would swing toward the pit.



The main purpose of such an instrument is to write a zigzag when an earthquake occurs. But its second purpose is to measure tilting of the ground by the position of the line on the moving paper, with reference to a fixed mark on the instrument. It measures tilt in one line of direction only, and that is the line at right angles to the hanging plane.

On February 19, just before midnight, this instrument showed sudden tilting, accompanied by small earthquakes, straight away from the center of the pit, and the moving of the boom away from the pit increased, and kept it up for two hours. Then molten lava gushed up in the bottom of the pit, and the eruption lasted a day and a half. When the eruption ceased, the tilt pendulum moved back towards the center of the pit, and a trembling which it had registered while the lava fountains were operating, rather suddenly ceased.

This splendid demonstration of a relationship between tilt and eruption, the whole pit swelling before the eruption began, and the whole pit sinking when the eruption ended, at once suggested the importance of having two more instruments on other sides of the pit. Thus the idea of a special "Clinoscope" was born.

We proceeded to build the "Clinoscopes" in the Observatory shops. This tilt meter is shown with its parts in the accompanying pictures. It seemed desirable to make it show both direction and angular amount of the change in position of a weight hanging vertically from a single piano wire, so a heavy ring-shaped weight was hung from a seven-foot tripod in a bath of automobile oil, and a magnifying boom or lever was led vertically upward from the space in the middle of the

ring. A sharp point at the top of this lever nearly touches a horizontal circular card, which is ruled in points of the compass and in concentric circles. A mirror makes it convenient to read the bottom surface of the card and see where the sharp point lies. By centering it every day, after seeing how far and in what direction it has migrated, we can tell the direction and the amount of tilt of the floor of the cellar where the tripod is placed. The three cellars are at the points of an equilateral triangle around the pit and are built to avoid change

Earthquake Annunciator: Heavy cylinder hangs on wires. Connecting needle magnifies the motion. Tip makes mercury contact and rings bell.

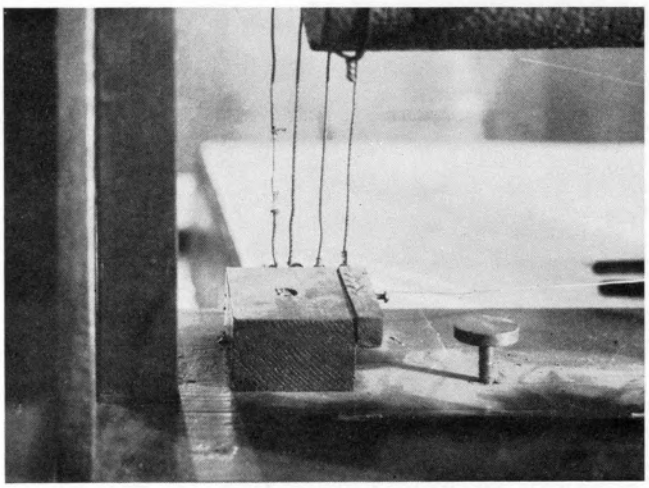
of temperature. Each instrument is read every morning, and the findings are entered in the Observatory records.

The results of running these instruments for some years have not shown that all eruptions in the pit behave on the three sides the way the 1929 eruption behaved on the one side. The principal discovery made with the Clinoscope is that the Kilauea Rift Belt goes across the pit in a straight line and the tipping is right and left with reference to that belt. It is not "all around" with reference to the center of the pit on radial lines. This is very interesting. It means that the circular pit is only a detail of a linear crack. For tilt measurements the crack is the important thing, the blocks on each side of it lifting or tilting away from or towards the crack. We know where the crack crosses, and both the western and northern cellars are on the Mauna Loa side of the crack, while the cellar near the Tourists' Stand is on the ocean side of the crack.

The Clinoscopes are unfortunately not earthquake-proof. This gives us a great deal of trouble because fifty or sixty earthquakes and tremors occur every week. The large earthquakes certainly derange the delicate pivots. Any slightest derangement of a pivot makes the record erroneous where there is such high magnification. We are now redesigning the instruments and hope to make them entirely earthquake-proof, the reading to be done with a microscope without using any pivots. We ought to have a larger number of these instruments around the outer rim and inner floor of Mauna Loa Crater, and also around the rim of the larger Kilauea Crater, and at some distance away on the radiating highways.

An Earthquake Annunciator

Three of our pictures show respectively a rough hanging cylinder in a wooden frame, a very sensitive long needle under the cylinder balanced horizontally about a vertical axis, and a common electric bell annunciator showing four numbers just as used in the office of a hotel to show signals from four bedrooms.



The hanging cylinder is in the seismograph cellar of the Observatory, the annunciator bell is in the seismologist's room above. The object of the device is to notify the seismologist when four different sizes of weak earthquakes occur, all in the class too feeble for him to feel. The bell rings, notifies him that an earthquake is going on, and he may take action accordingly.

The cylinder is a very heavy piece of shafting hung to swing from a beam in an east-west direction. It is appropriately connected with the short arm of an aluminum lever, the long needle. The magnification is about one hundred. This is like the magnification of our sensitive seismographs. The tip of the long arm of the lever, when an earthquake moves the beam back and forth, makes contact electrically with four drops of mercury spaced out in a line, progressively farther from the tip. If the earthquake is big enough to reach number four mercury drop, the number four arrow of the annunciator dial springs sideways and points to the figure four. The same with the other numbers.

This annunciator proved unexpectedly useful during the eruption of Halemaumau Pit, two miles from the Observatory, in September, 1934. The little cone on the floor of the pit became violent with gas explosions every few hours. These explosions were rhythmical. Every time they began, a tremor impulse or shock was sent through the earth to the distant Observatory, and the annunciator bell started ringing with a rhythm exactly accordant with the explosions. Thus a record could be kept by an observer sitting quietly in the Laboratory of the recurrent spasms of explosions at the Pit, two miles away.

Meteorological Instruments

There is little to be said about the thermograph, rain gauge, or the maximum and minimum thermometers, except that their showings have been recorded here for twenty-five years. The Observatory has been a volunteer station of the United States Weather Bureau. The wet- and dry-bulb thermometers, which Mr. Waesche is shown swinging in the breeze, attached to an instrument called the Hygrodeik, is for registering the moisture of the air; the relative humidity at the edge of Kilauea Crater is very high owing both to the climate and to the innumerable steam cracks.

Earthquake Annunciator: Tip of needle opposite four mercury cups. These are for four different intensities of earthquake motion.

Crack Movements at Halemaumau

This subject has already been illustrated on page three of the April issue, but it is just now an appropriate time to show another picture of a special caliper built for measuring the extremely large cracks on the edge of the pit.

Earthquake Annunciator: Bell and numbers record by arrows earthquake intensities 1, 2, 3 and 4. This notifies the seismologist what the seismographs are doing when he does not feel the quake. Shows also timepiece and mercurial barometer.

For several months, as indicated in the reports, we have had excessive movement at crack number forty-six, which lies some distance back from the northeast edge of the pit and this is merely an extension of a crack emerging at the edge of the pit as in the photograph. A section of the rim bounded by one of the regularly measured cracks, fell in between March 15 and March 22, 1936, and in our March issue we illustrated some of these cracks. The aggregate opening of all cracks on March 14 was more than 54 mm. This is excessive, and these movements of cracks at times have yielded very useful data for the National Park Service. The change will come gradually or suddenly and some portion of the rim of the pit may become dangerous and have to be roped off.

Just before the eruption of February, 1929, described above, there was such a disturbance at the eastern margin of Halemaumau so that the entire Tourists' Stand had to be changed in position and a new station built.

There appears to be a complicated relation between local earthquake, tilting of the ground, rise and fall of the pit rim, and the avalanches which fall from the walls of the pit. The complication concerns the question of whether the avalanching and the cracking make the local earthquakes or whether the local earthquakes make the avalanching and the cracking. Both kinds of relations have been discovered on different occasions. T. A. J.

DES MOINES SEISMOLOGICAL STATION

Editor's Note: We are privileged this month to publish a brief account of the only earthquake-recording station in America, designed, constructed and operated by a woman. To Mrs. M. M. Seeburger, a talented scientist from whose facile pen comes the article which follows, and to whose patient study and steadfast work seismology is indebted, we tender respectful esteem and cordial appreciation.—Ed.

The establishment of the Des Moines Seismological Station was the outgrowth of a number of years of study of volcanic activity by the writer. Inspired by annual visits to the Lassen Observatory in California, where the Hawaiian-type instruments were in use and the laboratories at Pasadena and Berkeley, where various types of optical instruments were developed and operated, the writer's interest in seismology grew, and plans were made to establish a station in Des Moines with teleseismic instruments sufficiently sensitive and accurate to supply needed records in the midwest area, where stations are far apart.

The instruments were designed and built by the writer, the first component being started in operation December 20, 1934, and the second March 15, 1935. They are modified Bosch-Omori in type, and record on smoked paper, one drum being used for both components. The period is 9 seconds and a magnification of 15 was used until this month, when it was increased to 25. A 24-kilogram heavy mass is used, this being adjustable along the pendulum. A pivot is used for the lower suspension and a fine piano-wire suspension at the top of the upright is adjustable back and forth for change of period and from right to left to correct tilt.

Weather Recording: Swinging wet-bulb and dry-bulb thermometers for relative moisture content of the air.

The magnifying system is a new device, designed to reduce friction, which is the great problem in lever magnification. A steel rod, attached to the end of the boom by a three-way adjusting device, ends in a U-shaped fork, having a needle eye at the end of each tine. The fork moves in the same plane as a clock wheel, mounted on a pinion, working in polished bearings in a frame, the wheel being mounted between the two ends of the fork. A groove is cut in the rim of the wheel. A fine silk thread, knotted at one needle eye, passes around the groove in the wheel, thence through the other needle eye and back to the steel rod, where it is kept at unvarying tension by a tiny weight. A 17 cm. recording arm of .006 aluminum is

Weather Recording: Thermograph, rain gauge, maximum thermometer, minimum thermometer.

riveted to the wheel, ending in a fork with an arbor set in polished bearings. The arbor carries the balanced stylus which has just enough weight to remain on the smoked paper. When a movement occurs the fork with the silk thread turns the wheel, oscillating the recording arm and resulting in the variation from the straight line which records the earthquake's message.

Oil damping is used. Time control is provided by a regulator clock closing a circuit every minute and lifting the stylus by means of an electromagnet. Time is checked twice a day by radio signal.

Records are sent to the United States Coast and Geodetic Survey and the Jesuit Seismological Society. During 1935, the first year of operation, 29 earthquakes were recorded at the Des Moines station, varying in distance from the Nebraska earthquake, March 1, 1935, 250 miles distant, to the December 26 shock near Sumatra, 9,700 miles distant. From January 1 to September 1, 1936, 20 shocks have been recorded.

The Seeburger family home offered a good location for the station, being located on a street undisturbed by heavy traffic. A special room was provided, with no windows, and well insulated to keep temperature as nearly uniform as possible. The cement work and casting of lead cylinders was done by the writer, assisted by her husband, who is city solicitor of Des Moines, and a high school son. The assistance of a machinist and a jeweler was required for some parts of the mechanism. Designing, experimenting, and final construction of the instruments required about a year's work.

ADVENTURES AND METHODS IN STUDYING WEST INDIAN VOLCANOES

The bombing of Mauna Loa December 27, 1935, was followed by the stoppage of the lava flow before it damaged Hilo. The preparation for this engineering job was twenty-four years of recording and experimenting on Kilauea and on Mauna Loa. The action taken was not suddenly inspired, but was methodically thought out sixteen years earlier. The coming of this particular 1935 eruption of Mauna Loa was published early in 1934 for time, place, possible direction, earthquake accompaniments, preparedness, and method of airplane attack.

The volcano excelled itself in coming to time. Predicting is the test of right interpretation of physical processes. At Hawaiian Volcano Observatory mere descriptions and photographs of eruptions gradually gave place after the first six years of work to systematic measurements of earthquakes, tilts, tremblings, gases, and temperature. The effort was always to see what lava is doing underground. Photographing and describing it above ground during eruptions, and comparing the earth motions during eruptions, gave information of what lava is and how it may be acting underground all the time. Gradually the non-erupting times became very interesting as pointing to the places and depths where lava was working its way upward.

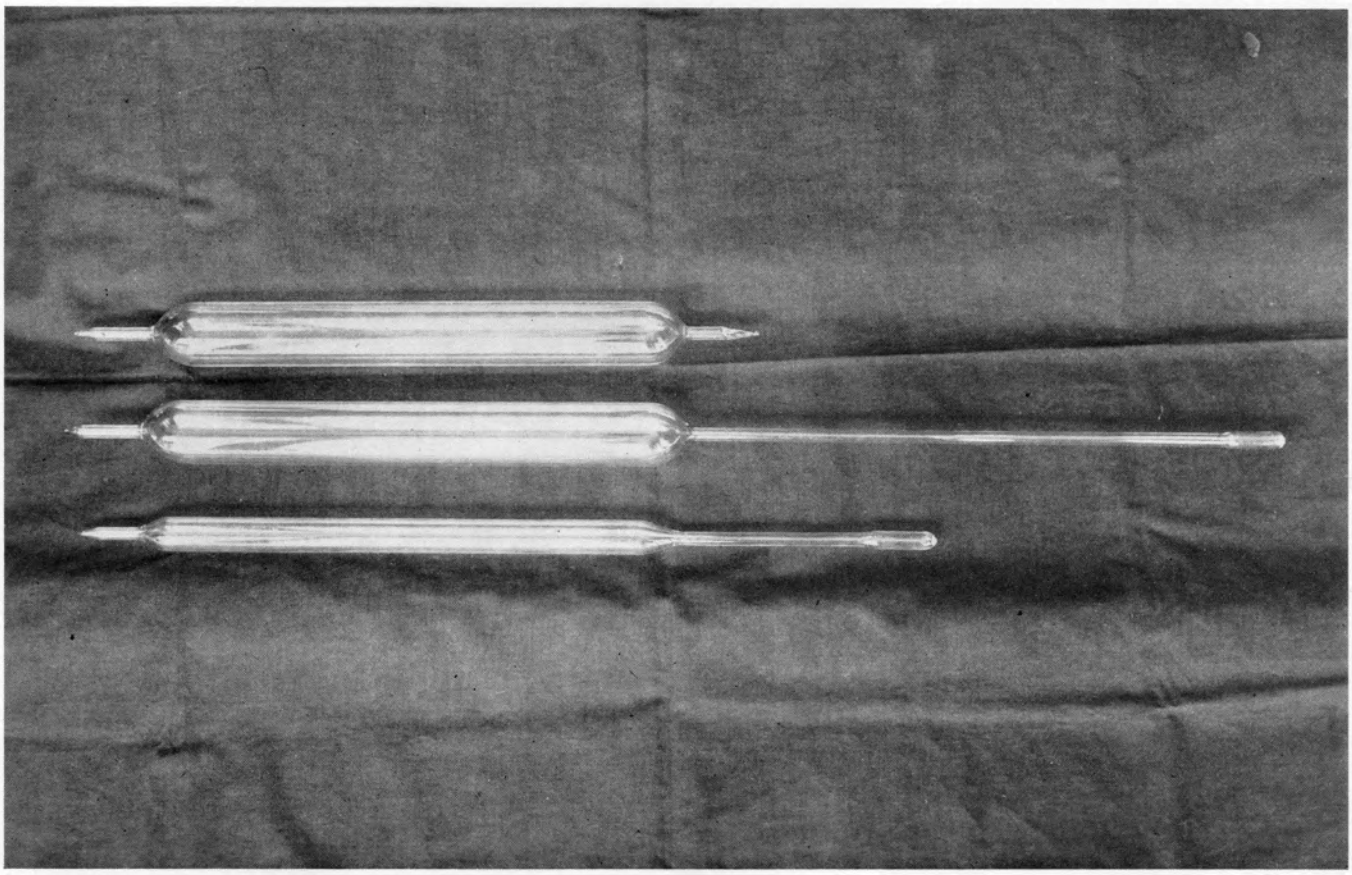
This has all led to the investigation of three main projects which in scientific terms may be described as locating earthquake centers underground, measuring the year to year elevation or sideways motion of the ground, and measuring the ejection of matter, either lava or gas, or both. There is always gas being emitted, but not always lava. Sometimes the lava takes it out in lifting the mountain by swelling inside.

When I had opportunity in the spring of 1936 to visit Montserrat in the West Indies, which had been violently shaken by many earthquakes, I had these principles in mind. There was no observatory on Montserrat, but some good earthquake observers had made lists of shocks, and some agricultural chemists had studied the sulphur banks in the craters.

The West Indian volcanic adventures of the last few years have come on several different islands along a curved line of several hundred miles of active volcanoes. They are like the Hawaiian Islands in being thirty or forty miles apart, and long ages past they poured out black lava. But now they are shoving up stiff lavas which are more crystalline and contain more silica. These masses underground react violently with water, the way Kilauea did in 1924. The result was the terrible eruption of Mont Pelé in 1902, which sent out a downward blast of scalding steam and destroyed 26,000 people in St. Pierre. The day before this the volcano Soufrière in St. Vincent made a similar eruption with similar destruction. Mont Pelé during the next year sent up a stiff plug of siliceous lava from its crater. Soufrière did not do so, but filled its crater with a lake of hot water which gradually cooled off during the decades since. Mont Pelé renewed its eruptions in 1929 after twenty-four years of quiet and again increased its height by thrusting up a central plug.

It was just after this last event, which came to an end in 1932, that Montserrat started making a nauseating smell of sulphurous gases in its crater, which is 146 miles northwest of Mont Pelé. It is the same kind of a crater, with several valleys containing sulphur banks, and boiling springs and steaming chemicals. These are all the products of lava somewhere below and the reaction of its acid gases with the rocks of the island and with water. Immediately thereafter, Montserrat started to shake. About every six months in 1934 and 1935 the swarms of earthquakes increased in number and vio-

lence, and most of the churches were shaken down. The morale of the people was upset, for everyone remembered the scalding hot blasts of Mont Pelé.



The shift of activity in 1902, 111 miles from St. Vincent to Mont Pelé in 17 hours, and the shift of activity of a different kind, 146 miles from Pelé to Montserrat in a year in 1933, shows that we have to deal with something like the shifts of activity from Kilauea to Mauna Loa, and also such changes from outside eruption to inside heaving, as we had in 1929 when Kilauea stopped erupting and North Kona started shaking. Here are shifts in Hawaii from one place to another, for much shorter distances, than the distances in the West Indies. But the kinds of action are much the same, with due allowance for a different kind of lava.

After making such allowances it is evident we can apply our three methods in the West Indies, if we locate earthquake origins, measure slow motions of the ground, and measure the kinds and temperatures of gases. All of these things are measurable there all the time. The chemistry of the hot solfataras, and there are scores of them in the West Indies, is very interesting and very significant. But before any predicting can be done it is essential to combine the changes in gases and the changes in sequences of earthquakes. This means we must know what the little earthquakes were in numbers and intensity during the quiet time before the crisis developed. For this same time we must know what the gases were and how hot they were before the nauseating and excessive gaseous emission became conspicuous. These are just the facts that we do not possess, in the absence of an observatory. The same thing was true in 1901, the year before Mont Pelé and Soufrière erupted.

What methods, then, should be recommended for understanding any such active volcano? Clearly the measurement must be repeated and continuous. The little earthquakes, the changing elevation of the ground, and the gases, must be measured every week or month or year, and the measurements entered in a record book. Montserrat appears now to have quieted down. What place in those ten or twelve active volcanoes, in those eight or nine islands, along those 350 miles of curved volcanic crack, is now going to do something unusual in 1937 or 1938 or 1939, following upon the shift from Martinique to Montserrat?

There have been many difficulties and disappointments in studying Kilauea and Mauna Loa. There are enormous difficulties and disappointments for the Dutch engineers in studying with airplane and otherwise the many volcanoes that destroy human beings in densely populated Java. But these Hollanders remained manfully at their posts in the jungle amid poisonous reptiles and poisonous gases, and they are getting results. This kind of work of the Geographical Engineer is growing more important, all the world over, because men must know the power and the materials of the earth that is their home.

T. A. J.

Vacuum tube styles for breaking or melting the tip in a gas-hole or volcanic flame: and one tube which has been sealed with gasoline torch.

Use of caliper for measuring large cracks at Halemaumau. The crack is equipped with copper studs and, after setting, the caliper opening is measured with steel tape. An improved caliper is made with arc and clamp.

THE VOLCANO LETTER

No. 438 monthly **Department of the Interior National Park Service** **August 1936**

Hawaii National Park

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR AUGUST, 1936

Campfire Lecture. Grand Canyon, Arizona.

SCIENCE IN THE NATIONAL PARKS

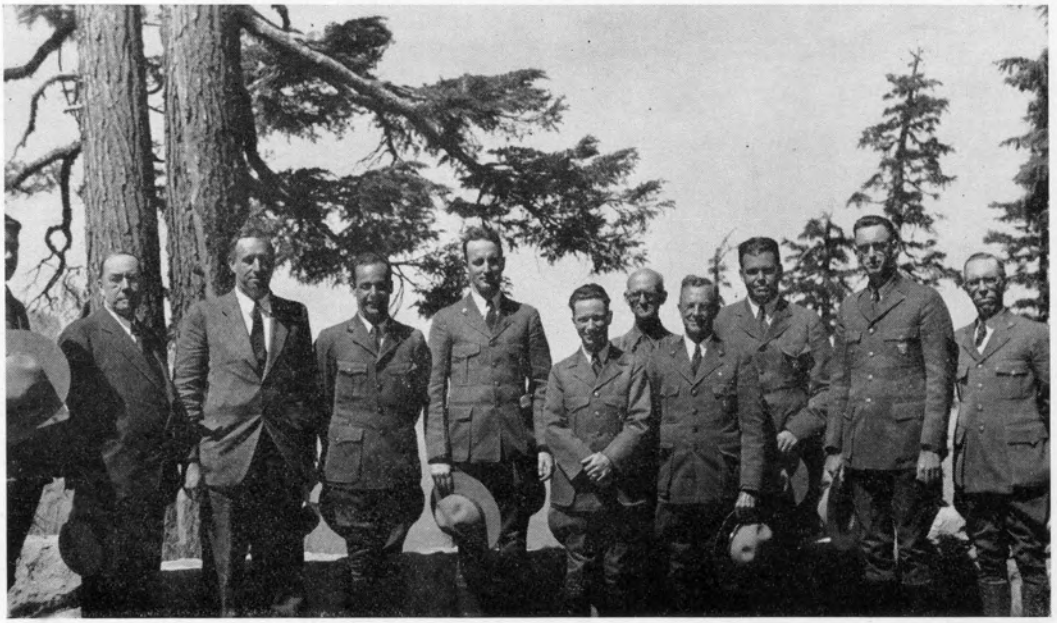
The opening of the Uwekahuna Museum at Kilauea April 18, 1927, was the occasion for an address by the writer to the delegates of the "First Pan-Pacific Conference on Education, Rehabilitation, Reclamation, and Recreation," which met in Hawaii at the call of Secretary of the Interior Dr. Work. Mr. Stephen T. Mather, Director of the Park Service, attended this meeting and the subject of the talk was the geographical

opportunity that the Parks offer for experimental studies by measurement of geologic processes (Bulletin Hawaiian Volcano Observatory, April, 1927).

The present address was delivered to the University of Hawaii Summer School at Kilauea, June 20, 1935, in order to outline the growth of educational work in natural science in the National Parks (which has been greatly added to in the last few years), and to show how the several volcanic Parks may add important data to the science of volcanology that is being studied experimentally at Kilauea and Mauna Loa.

It was in 1872 that Yellowstone region was created the first National Park on earth "set apart as a public park or pleasuring ground for the benefit and enjoyment of the people; the preservation from injury of all natural features; and their retention in their natural condition."

The National Park Service as a great organization under the Department of Interior was established August 25, 1916, and owes its original solidity and growth very largely to Stephen T. Mather who was its guiding spirit until January 28, 1929. The idea of creating free nature guides for travellers began at Yosemite in 1919 and this became the Division of Research and Education under Dr. Harold C. Bryant in 1930. A large growth in numbers of Naturalists and Ranger Naturalists attached to the Parks took place during the formative period, and the importance of visual education and photographs* was accented after 1923.



A committee on the educational problems in the Parks made an extended study of the question of developing museums in close proximity to the places where the exhibits came from. There were many places where the actual landscape spread out before the traveller gave life and reality to these exhibits. And there were many other places, like our footprints of the old Hawaiian natives in the Kau desert, where the whole significance of a specimen depends on seeing it in its natural environment. Hence arose the "trailside museum" where a group of fossils or crystals or objects of organic life may be both preserved from harm and seen in their natural relations under advantageous lighting.

The committee on the study of educational problems consisting of Messrs. Merriam, Bryant, Atwood, Bumpus, Kellogg, and Oastler made critical studies of such Parks as the Yellowstone, the Yosemite, Crater Lake, and Lassen; with the assistance of the American Association of Museums, the American Library Association and the Rockefeller Foundation.

From 1924 on, a field school of natural history had been established in the Yosemite. The expenses of the visiting committee of educators were provided after 1928 by the Laura Spelman Rockefeller Memorial which also supplied $118,000 for Yellowstone Museums, near Old Faithful and at Mammoth Hot Springs.

The report of the committee in 1929 pointed out the necessity and the advantage of further research in science as a service to the visiting public, and as service to educators and investigators, "to increase the general and special knowledge of the phenomena represented in the Parks."

In 1928 a trailside museum was built at Yavapai Point in the Grand Canyon. In 1929 the Museum at Yosemite was built. The Loomis Museum was accepted as a gift from private donors at Lassen.

A Group of Educators and Park Officials at Crater Lake in 1934.

Archeological museums were now springing up in Parks having remains of Cliff Dwellers and Indians, the cooperation of the Smithsonian Institution had been secured, fish culture was in progress, the preservation, feeding and study of animals in their native habitat had become a large branch of the work, and to this the Biological Survey contributed, as did the Bureau of Forestry to the protection of National Park Forests.

In 1930 at Craker Lake a memorial was built to Congressman Sinnott of Oregon. This is a rough stone observation station, inside the rim of the crater, with mounted field glasses, specimens and relief map, all in a commanding position with parapet overlooking the lake. An archeological museum was built at Mesa Verde, and an Indian museum at Acadia (Mount Desert).

At this time several Parks had adopted the practice of conducting automobile caravans from place to place in the care of trained naturalists, and the cooperation in research by government bureaus had become a regular practice. In the cliff dwellings of the southwest, Dr. A. E. Douglas, who had developed the science of interpretation of tree-rings in relation

to sun-spot intervals and the climatal changes that affected trees, applied his knowledge to the beam cores of the cliff dwellings, so as to determine their age.

In 1931 lectures and field trips had become the first aim of the Naturalist Branch, a Chief Historian was appointed to cover history and archeology, and Dr. Bumpus succeeded Dr. Merriam as Chairman of the Educational Advisory Board. The Fishing Bridge Museum and Trailside Shrine at Obsidian Cliff were built in Yellowstone Park. At Dinosaur National Monument in Utah an actual fossilized skeleton of a large extinct reptile was excavated in relief by the American Museum of Natural History in its natural site.

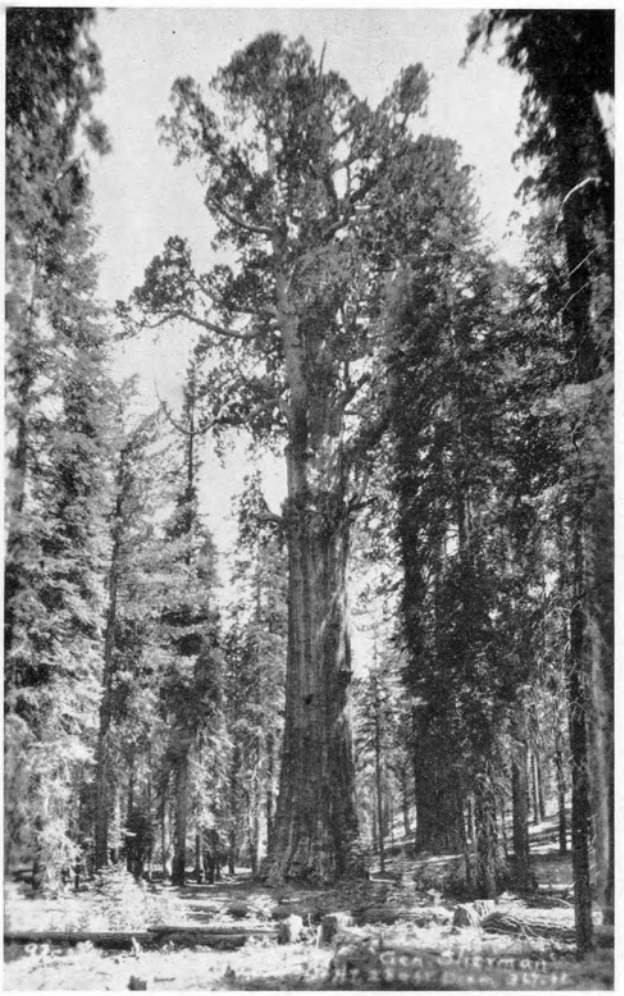
Three-year studies of wild life conditions were begun, particularly in the Yellowstone; and for the elk, a cooperative survey was made for the migration routes, the life history and the forage requirements. The Biological Survey, the Forest Service, and the Montana Fish and Game Commission collaborated in this.

In 1932, the native Indians were employed to show their arts and crafts. A ranger-naturalist at the Grand Canyon accompanied privately operated airplane flights. In Acadia a sunrise breakfast caravan was led to the top of Cadillac Mountain, and in the Yellowstone an evening caravan was led to suitable places for stalking game with the camera. Informal campfire talks to five hundred people at a time were held in the Yosemite and the Yellowstone.

The use of the National Parks by university classes was increasing; the principal subjects of investigation being the group relations to each other of plants and animals, and the geology. Graduates of the Yosemite Field School are now serving as ranger-naturalists in other Parks. Thus the Park Service becomes a University for training its own men.

In pure science, cosmic ray investigations have been made in Hawaii and at Mount McKinley. In the Yellowstone, and the Absaroka Mountains to the east of it, university groups of highly trained specialists have investigated the origin of granite, and the geology of the Rocky Mountains.

In 1933 the Emergency Conservation Program was at work in numerous C. C. C. Camps of the National Parks, and the preservation of historic sites was one of the activities of the Educational Board. Sea caravans of motorboats were added as a new feature at Acadia, to study sea-life. Indian pageants were organized, a wayside museum of archeology was built at the Grand Canyon, and a wayside exhibit of the life history of the beaver was established at Yellowstone. In two lookouts there, long-range telescopes were set up. Botanic gardens have been created at Yellowstone and Crater Lake, and a new garden was presented to Yosemite Park.



As examples of the utilization of cooperative research in the National Parks, we have had out here in Hawaii Dr. Meinecke of the Bureau of Plant Industry, and Drs. Day, Shepherd and Allen of the Carnegie Institution. Dr. Wetmore, ornithologist of the Smithsonian has taken a great interest in the Parks and has also been to Hawaii, and the Biological Survey has contributed the work of Drs. Palmer and Murie. Dr. Hommon of the Public Health Service has studied Park problems, and Dr. Hazard of the Bureau of Fisheries. In history Dr. Leland has called in the Council of Learned Societies and a group of leading historians for the numerous battlefields and other places related to the history of the country. So it is with the prehistoric sites where ancient man lived and worked and tilled the soil. The universities of Michigan and California have collaborated in studies of the Teton Range, a National Park in the Rocky Mountains immediately south of the Yellowstone.

National Park Science in Hawaii

The foregoing outline sketches the growth of public interest in the many branches of natural and human science that are related to the preservation forever of large tracts of natural wilderness, or smaller ones of historic land.

The tendency of industry is to tear the land to pieces for raw materials, agriculture, transportation or construction and congestion of cities.

The National Park idea has in some measure preserved the natural frontier which our forefathers met in their restless march seeking freedom and wealth. There is still a frontier and a restless march. The tools of the primitive American frontier were the axe, the plow and the rifle. The tools of the new frontier are the airplane, the radio, and the chemical bal-

Sequoia National Park. General Sherman Tree.
Height, 280 ft.; Diameter, 36½ ft.

ance. By the ever-widening range of these new tools, which look outward to the universe, and inward to the core of the earth, the frontier of the human spirit today knows no boundary.

The outlook of the Hawaiian Volcano Observatory on its frontier, hewing its way with metaphorical axe and plow and rifle to a visionary palace of science on the top of Mauna Loa Volcano, differs somewhat in its aim of education and research from most of the enumerated activities above outlined.

The word "research" means searching over again, and the historical viewpoint is conspicuous in the attitude of scholar-

ships. How did the elk and buffalo originally live? How did the beaver behave when undisturbed by man? How did the cliff dwellers live? How was that battle fought? How did those mountains grow? How did the dinosaur behave? How does the undisturbed trout breed and meet his enemies? How did the tree rings vary in the seventeenth century? What were the customs of the original Indians? How did the primitive forests grow?

It is a curious and inevitable trait of education and scholarship that the past is more detailed and elaborated than the present and the future, in current methods of research.

In contrast to this, the activities of the present are studied in the chemical laboratory, the growth of living cells in the microscope, the interaction of plants and animals on land and sea; and the effect of planting of gardens and forests and the culture of fish and insects.

The seismologists look inward at the shells of the globe for echoes from distant big earthquakes; and the magneticians and gravity physicists do the same with the compass needle and the pendulum.

The day to day changes, and the statistics of the present are used by laboratory and field science, and the widely distributed National Parks are very valuable for these sciences, whenever a variety of latitudes, elevations or climates affects the process that is being studied. Science goes to the beach when it has to study sea-life, and it goes to the mountain top when it has to study effects of elevation. The Middle Ground, between University and Universe, is apt to be neglected.

On the other hand, the astrophysicists study the universe, and the ultimate atomism of physics, but frankly acknowledge little interest in the earth, the moon and the planets. The earth is chiefly a nuisance, because of the disagreeable optical properties of its atmosphere.

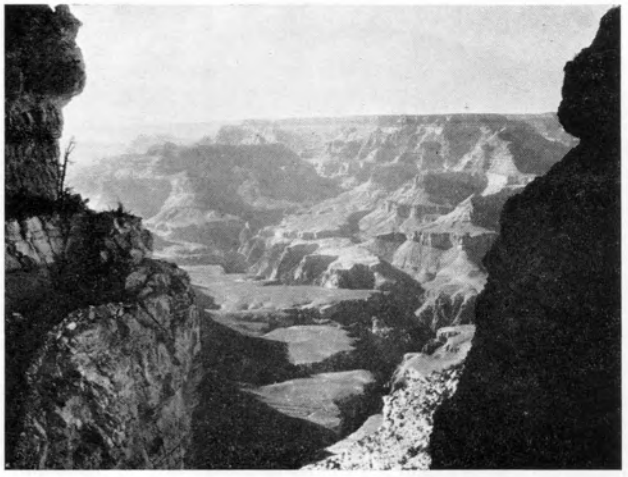
These investigators are studying the light which left distant bodies in space hundreds of thousands or millions of years ago, and so they also are intensely interested in the past. Their observatories have the great advantage of being close to universities, and it is only occasionally that the hardship of an expedition is necessary for such an event as an eclipse. The frontier of the outer universe is the field of their restless march, and their tools are the telescope, the spectroscope, and the electro-magnet.

A part of science, therefore, leaps from the university microscope or electroscope, to the observatory telescope, in studying pinpoints of light. It leaves the study of the earth, the study of the great rough frontier, of the mountains, the rivers, the ice, the sea-bottoms and the volcanoes, to the great rough corporations and their engineers, who handle great rough bodies of labor in tearing up the earth for raw materials and for power.

But what of the earth itself, and its great and small natural processes on the surface, where man dwells, at the present day? And what of the future results of those same processes, many of them quite within the range of man's prediction, that will sweep his cities with hurricane, flood, drought, dust, insect plague, famine, fire, earthquake, blizzard and tidal wave?

The mathematical quantitative study of a point of light under a lens, and the explanation of the past by its aid, is so much more orderly than fighting the battles of the earth frontier; that the pure sciences of the interaction of the atmosphere with the earth, are somewhat left to engineers, and governments, and commerce.

Loomis Memorial Mission, Lassen Volcanic National Park.



In relation to the looming bulk of those things in the economy of mankind, there is no adequate field science today of the inorganic processes, of oceans, rivers, shorelines, glaciers and earth movements.

The Hawaiian Volcano Observatory has stood for this field science of Experimental Geonomy from the time when it was first proposed in 1909. The object was to keep a diary of active volcanoes, and by patient effort to decipher their habits, to discover the swelling and shrinking of the land, the cycle of outbreaks, the location of centers of small localized earthquakes, and the peculiarities of lava when it pours forth. The island was treated as a working model of process. This followed a resolution of 1907 recommending the foundation of earthquake and volcano observatories, passed by the Geological Society of America.

In the same way the Mississippi might be treated as a model of river process, all the way from Yellowstone and Rocky Mountain National Parks to the delta in the Gulf of Mexico.

And the laboratory should be called an observatory, because its function is to observe and record forever.

The result of twenty-five years of work in Hawaii has been to show that the Hawaiian volcanoes are always predicting their own coming events. Sensitive instruments tell what is happening underground. Earth movements and earth chemis-

Grand Canyon, Arizona.

try never cease. There are some discovered emanations, in gases and wave movements; there are probably many undiscovered ones which are telling the times and places of future eruptions.

There is great importance to comparison with different places. Such different volcanic places are the Yellowstone and the northwestern volcanoes, the hot steam region north of San Francisco, the Aleutian Islands, and Arkansas Hot Springs. How do the undeciphered emanations there differ from the Hawaiian ones? And what difference do they predict for intrusion of lava underground, in contrast to the occasional and relatively rare extrusion, in places like Hawaii and Japan?

And so for the other processes of the earth, the making of new rock, the uplift of the land, the sweep of the waters, the rotting of the mountains, and the settling of the rubbish, we need never leave the National Park System to establish observatories of the behavior of the earth.

Glaciers are to be found in Glacier Park, Rainier and Mount McKinley. Mountains are rotting in different ways in the Great Smokies, the Grand Tetons and Yosemite. Rivers are telling their story in all of these, as well as at Platt, Hot Springs, Yellowstone and Grand Canyon. Volcanoes offer a variety at Lassen, Crater Lake, Rainier, Katmai, Craters of the Moon, Yellowstone and Hawaii. And sea-bottoms in great variety are close to Hawaii, Acadia, Katmai, Sitka and Olympus.

All of these places contain superb opportunity for establishment of permanent geonomical observatories. Here lie the mysteries of possible deciphering of the great powers that dwell in our own earth; which from second to second and minute to minute is being altered as man's habitation by the hot forces within it, and by both the hot and cold forces of its own interaction with water and air.

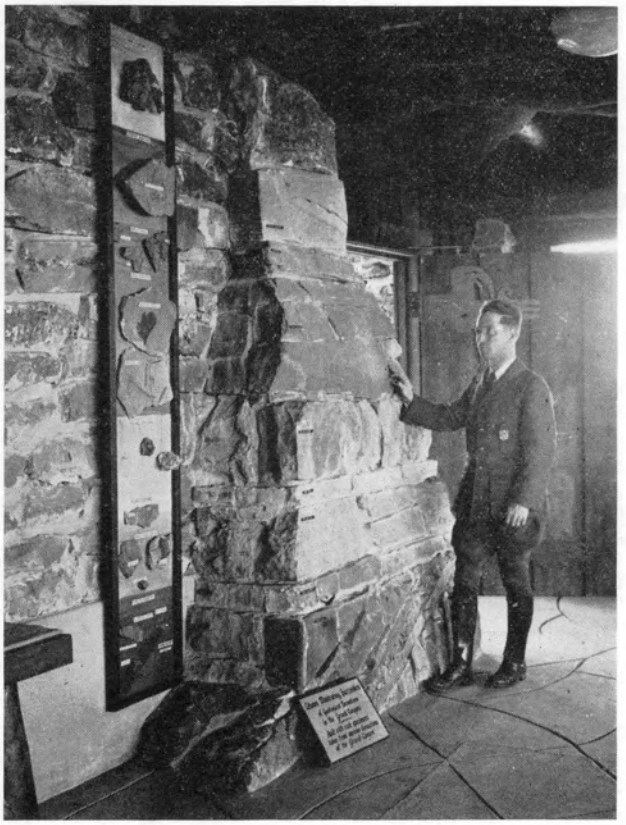
T. A. J.

Photographs herewith kindly supplied by Assistant Geologist H. H. Waesche.

VOLCANOLOGY

The month of August, at Halemaumau Pit of Kilauea Volcano, produced more slides and a widening of eastern cracks at the edge of the pit. Otherwise nothing of external happenings was conspicuous for the Hawaiian volcanoes during this month. The third week of the month was most active seismically and showed the highest weekly index per month, of local seismicity, since April, the sequence being for the weeks ending:

May	31,	Seismic	index	15.25
June	7,	"	"	11.25
July	19,	"	"	22.25
August	23,	"	"	45.50



In the main this index is made up of tremors, and this summer these tremors have been greatly affected by slides from the walls of the pit. The total number of slides for the month, however, counted during daily forenoon visits and by dust cloud at other times does not accord with the above table of seismicity maxima:

Number of slides May	12
June	6
July	26
August	6

Slides at Halemaumau

Slides from the wall of the pit have been noted as follows:

August 6. Dust on floor of pit seemed to concentrate around the floor crack.

Columnar Sections of Natural Rocks and Fossils of Grand Canyon in Yavapai Museum.

August 9. Moderate slide NE wall 9:25 a.m., apparently from gaping outcrop of Crack No. 29.

August 18. Moderate slides 9:35, 9:42 and 10:42 a.m. NE wall under Crack No. 29. A little farther north some dis-

tance back is Crack No. 46, which has been opening. Still farther north Crack No. 34 caved in completely on March 22. This high part of NE wall, between E and NNE taluses, was getting ready to fall.

August 31. Moderate slide 8:03 a.m. under Crack No. 29, sending up thick dust cloud, leaving fresh scar, and thin dust on floor beneath.

August 31. Small slide same place 12:18 p.m.

lava cascades NW. These places are on a diagonal of the pit at right angles to the rift belt.

Measurement of Halemaumau Rim Cracks

Weekly measurement of 32 marked places on rim cracks around the upper edge of Halemaumau Pit resulted as follows:

Week ending forenoon of:

August 8, 9 opened, 3 closed, aggregate opening 9.5 mm. Crack No. 46 opened 6.5 mm.

Mountain Lion. North Rim, Grand Canyon, Arizona.

Halemaumau Solfataras

There has been no notable change in the places at the edge of the floor, where yellow sulphur and white sulphates are depositing and blue fume rises, varying in visibility with the humidity of the air. The most conspicuous places are under the Tourists' Stand SE, and at the north end of the 1934

August 15, 6 opened, 4 closed, aggregate opening 8.5 mm. Crack No. 46 opened 7.0 mm.

August 22, 11 opened, 2 closed, aggregate opening 14.0 mm. Crack No. 46 opened 7.5 mm.

August 29, 8 opened, 2 closed, aggregate opening 12.0 mm. Crack No. 46 opened 8.0 mm.

T. A. J.

EARTHQUAKES

Table

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Slight Earthquakes	Distant Earthquakes	Local* Seismicity
August 9	84	5	0	0	23.50
" 16	17	6	0	0	7.25
" 23	140	19	1	1	45.50
" 30	47	7	0	1	15.25

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began at the times indicated and whenever possible, determinations of depth of focus have been made.

August 3, 10:36 pm, very feeble, probably located in Kilauea Crater.

August 7, 8:21 pm, very feeble, probably located near Puu Huluhulu, Chain of Craters Rift.

August 8, 7:13 pm, very feeble, probably located about 0.8 mile SW of center of Halemaumau.

August 8, 9:51 pm, very feeble, with location same as preceding quake.

August 10, 3:12 am, very feeble, probably located in SW rift zone of Kilauea, 0.9 mile W of Pit seismograph.

August 13, 12:25 pm, very feeble, probably located in vicinity of Kamakaia Hills about 10 miles SW of the Observatory.

August 16, 7:38 am, very feeble, probably located about 10 miles W of Hilo. Reported felt by several at Waimea Hotel.

August 18, 4:54 pm, very feeble, located 2.2 miles deep in Kilauea SW rift zone near Puu Koae. 19° 21' 8N; 155° 19' 3W.

August 18, 10:39 pm, very feeble, located 1.4 miles deep under Byron Ledge, SE portion of Kilauea Crater about half the distance between Keanakakoi and Kilauea Iki Craters. 19° 24' 5N; 155° 15' 6W.

August 19, 10:28 am, very feeble, located 1.9 miles deep in west portion of Kilauea Crater. 19° 25' 2N; 155° 17' 4W.

August 19, 11:05 am, very feeble, located 0.7 mile deep and 1.2 miles S of Pit Seismograph Station. 19° 23' 3N; 155° 17' 0W.

August 20, at 6:23 am, a slight earthquake occurred. It was probably of very shallow origin under SE rim of Kilauea Crater. The shock was not reported felt. 19° 24' 2N; 155° 16' 1W.

August 20, 9:41 am, very feeble, probably located under N rim of Kilauea Iki.

August 20, 6:04 pm, very feeble, located 2.4 miles deep in rifts 0.3 mile N of Ahua Kamokukolau. 19° 23' 2N; 155° 16' 3W.

August 21, 8:36 pm, very feeble, located 3.3 miles deep in rifts 0.9 mile SE of Ahua Kamokukolau. 19° 21' 5N; 155° 15' 4W.

August 24, 1:56 am, very feeble, located 6.2 miles deep in Chain of Craters rift near Devil's Throat. 19° 22' 8N; 155° 14' 5W.

August 24, 2:17 am, very feeble, located 2.3 miles deep and 0.3 mile NE of the Observatory. 155° 15' 5W; 19° 26' 1N.

There was a marked increase of seismic activity during the week of August 16-23. Many of the locations of the very feeble earthquakes of the month were difficult or impossible to make because of the lack of definite demarkation of phases. In most cases they waxed to maximum amplitude with little change from the initial type of movement. In this respect they resembled enlarged tremors.

At 8:34 pm, August 21, the preliminary waves of a teleseism began recording at 8h 33m 31s pm. Its reported location was in Formosa. 22° 3N; 121° 5E. The distance from Kilauea was 5,265 miles. Another teleseism registered its preliminary waves at the Volcano Observatory beginning at 10h 59m 6s am, August 26. Its estimated distance from Kilauea was 3,155 miles.

Periods of continuous tremor registered as follows: beginning at 9:32 am, August 4, 4 minutes; at 11:16 am, August 9, 30 minutes.

Microseismic motion of the ground at Kilauea was light for the entire month of August.

H. H. W.

TILTING OF THE GROUND

The following table shows tilt by weeks from seismograms at the Volcano Observatory NE rim of Kilauea Crater and at Halemaumau, the algebraic sum of radial tilts for two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending August 30, was 4" 67N and 0" 25E.

* For local Seismicity definition, see Volcano Letter 371.

CRATER ANGLES

Measurement of Horizontal angles across Kilauea Crater from the Observatory, August 18, compared with similar measurements July 24, showed a slight closing both across the Crater and Halemaumau. From July 24 to August 7, there was closing from the SE rim of Kilauea to Uwekahuna of 2".5 and across Halemaumau from the Pit seismograph to the NW BM, closing of 1".25. From August 7 to August 18, the Crater angle opened 1".00 and the Halemaumau angle opened 0".67.

THE VOLCANO LETTER

No. 439 monthly Department of the Interior National Park Service September 1936

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

The succession of numbers of this journal in the autumn of 1936 will deal with the sequence of special studies, by the Volcanologist, that led to the bombing operation on Mauna Loa during the great lava flow that reached South Hilo District in December 1935.

The present number describes the summit crater eruption, the like of which is always followed by a flow from the flank.

The October number will print the Annual Address of March 1934 that showed the reasons for expecting that flow within two years at the north: with more illustrations of the 1933 eruption.

The November number will describe the Kilauea eruption of September 1934, with illustrations of that extraordinary cascading eruption of Halemaumau, keeping up the precedent of averaging one eruption a year for the Hawaiian system in the recent eleven-year cycle 1924-1935.

The December number will reprint, by permission, an article from "The Military Engineer", describing concisely the exact facts concerning the 1935 eruption, the bombing, and the stoppage of the flow towards the city of Hilo, with illustrations.

SUMMIT OUTBREAK OF MAUNA LOA DECEMBER, 1933

T. A. Jaggar

Sequences Preceding 1933

Eruptive cycles of the Hawaiian volcanic system have indicated[1] that a complete eruption of Mauna Loa, and disregarding Kilauea, consists usually of one or more preliminary summit crater eruptions. These lead to one or more concluding lava outflows from an established rift that cuts across the mountain from southwest to northeast, with a slight bend at the summit crater.

The lava outflows so led up to, and occurring some years

after the crater outbreak, themselves begin with a summit gushing. This takes place a few days before the establishment of the flank outlet, which may be 6 to 12 miles (10 to 20 kilometers) from the central caldera.

The last complete cycle for Mauna Loa, preceding the one which is the subject of this paper, started in 1914. It began with an eruption of liquid lava, in the large summit sink-crater Mokuaweoweo, making a brilliant display at a fountaining cone, and flooding the crater floor from November 25, 1914, to January 11, 1915, a period of 48 days.

The later flank outflows, down the southwest rift of the mountain, were in 1916 and 1919; these came in May-June and September-November, and lasted respectively 17 days and 56 days.

The completion of a cycle for Mauna Loa may not be judged without taking account of Kilauea. Kilauea frothing lava spurted and subsided in sympathy with the two outbreaks of Mauna Loa 1914 and 1916. After the Hawaiian Observatory had plotted this sympathy, the 1919 outbreak induced us to publish the expectation of sudden subsidence of Kilauea, which was then flooding, as soon as the Mauna Loa outbreak was finished. This was verified and the lowering occurred in Halemaumau pit of Kilauea volcano 600 feet (180 meters) in one morning, November 28, 1919. The lava in the pit immediately recovered and rose nearly to the top in 24 days,[2] a lift of 560 feet (171 meters). Such sympathy appears in the Halemaumau pit only when the crateral pipe has free liquid lava in evidence within it. When it is plugged the sympathetic movements can only manifest themselves by seismic action.

As Kilauea proceeded during the four years following 1919 to make three flank outflows, while Mauna Loa stopped its action, the repose interval for Mauna Loa had evidently arrived. That an 11-year cycle for the Hawaiian system ended in May 1924, was proved by the unusual large steam-blasts and engulfments at Kilauea, with the collapse of the pit Halemaumau.

The platted curve of rise and fall of lava for both volcanoes[3] makes a complete 11-year cycle for the system, between 1913 and 1924.[4]

This brings us to the new cycle for Hawaii, which began with the return of a short-lived inflow of spurting liquid lava on the bottom of the cup of talus in Halemaumau pit, in July, 1924. Just as in the case of the last cycle when Kilauea had resumed vigorous activity in 1914 and was followed by the Mauna Loa eruption of 1916, so this inflow at Kilauea of 1924 was followed by the gushing of Mauna Loa in April, 1926. This began its outbreak at the south pit of the summit caldera Mokuaweoweo, then spread down the southern flank and the lava emerged at about 8,000 feet elevation, to pour into the sea at the village Hoopuloa. The eruption lasted 25 days.[5]

This eruption of Mauna Loa was followed by small gushings in the bottom of Halemaumau pit, each adding a layer 60 or more feet (about 18 meters) deep, in July 1927, January 1928 (thin), February 1929, July 1929, November 1930, and December 1931.

The Outbreak of Mauna Loa, 1933

The earthquakes associated with this eruption have been described by Jones in Journal Washington Academy of Sciences Vol. 24, No. 10, October 15, 1934. A cluster of notable shocks in October, 1933, felt strongly at Kapapala Ranch on the east side of the mountain, led to an investigation of the summit crater by E. G. Wingate and A. E. Jones, Nov. 1-2, 1933. The main crater showed puffing vapor from the 1914 cone[6] on the floor, fume was dense from the sunken area around it, and the western walls of the crater were dusty with fresh avalanche scars. There was nothing remarkable about sulphur fumes or vapors elsewhere. Later events proved that the dense fume and puffing vapor near the 1914 cone in the southern part of the main bowl of the big crater heralded at just that place the coming eruption of December 2.

The summit crater of Mauna Loa was split along the upper end of the southwest rift (see map of Hawaii November Volcano Letter 1935, and later), where frothy lava gushed up, at 5:43 a.m. December 2, 1933. The rift opened along a belt about two miles (three km.) long in the southwest part of the crater, trending south 27° west from the inner basin. The cracks crossed the south inner platform, extended up the cliff to the outside country, and then on to the south for a half mile (one km.), about 500 feet (150 meters) west of the lip of the South Pit. The breakage was then offset 500 feet (150 meters) to the east, a crack emerging from the west corner of this pit and continuing across the upland to the southwest, so that cascades of lava were poured both into the South Pit of the main crater, and into the next pit to the south, Lua Hohonu.[7] The gushings of these outside cracks were short-lived, and the main activity of the eruption which continued, was inside the main Mokuaweoweo basin, about 500 feet (150 meters) east of the cone of 1914. Here a line of gigantic fountains was formed, continued in action for 16 days and stopped gushing December 18.

The physical measurements at Kilauea crater, during the activity of Mauna Loa, were of considerable interest. Halemaumau pit had its bottom sealed with the lava plug of December-January, 1931-32, so that no liquid lava, to rise or fall, was observable at the time of the Mauna Loa eruptions of the last cycle. The weekly measurement of marked rim cracks around Halemaumau, and precise levellings during the week ended December 17, comparing Halemaumau rim with the southern gravel spit, and the readings of horizontal angles across the pit from the Observatory, measured twice during the month, revealed no unusual ground surface displacements.

The tremors, tilts both at the Observatory and Halemaumau, and the total local seismicity, showed striking changes accordant with the period of the Mauna Loa eruption.

The number of minutes of tremor for the week preceding the eruption, as measured at the Kilauea observatory, was 56, whereas for the week ending December 3, the day after the outbreak, the number was 1393. For the next two weeks, the weekly frequency of tremors dropped off to 345 and 580. Thereafter the figures were low and normal, the numbers of tremors per week being 20 and 34 for the last two weeks of December. It thus appears that the number of tremor spasms, or minutes of tremor, increased suddenly from figures counted in tens, to figures counted in hundreds, for the three weeks of the eruption.

[6] Effects in Mokuaweoweo of the Eruption of 1914, by H. O. Wood. Amer. Jour. Sci., May 1916.

[7] Geology of Kau District, Hawaii, by Stearns, Clark and Meinzer, Water Supply Paper 616, U. S. Geol. Surv., 1930, maps.

It is customary at the Hawaiian Volcano Observatory to compute local seismicity in terms of minutes of "tremor", feeble, slight, moderate and strong correspond to I, II, III, IV, of the Rossi-Forel scale. The local seismicity index for any

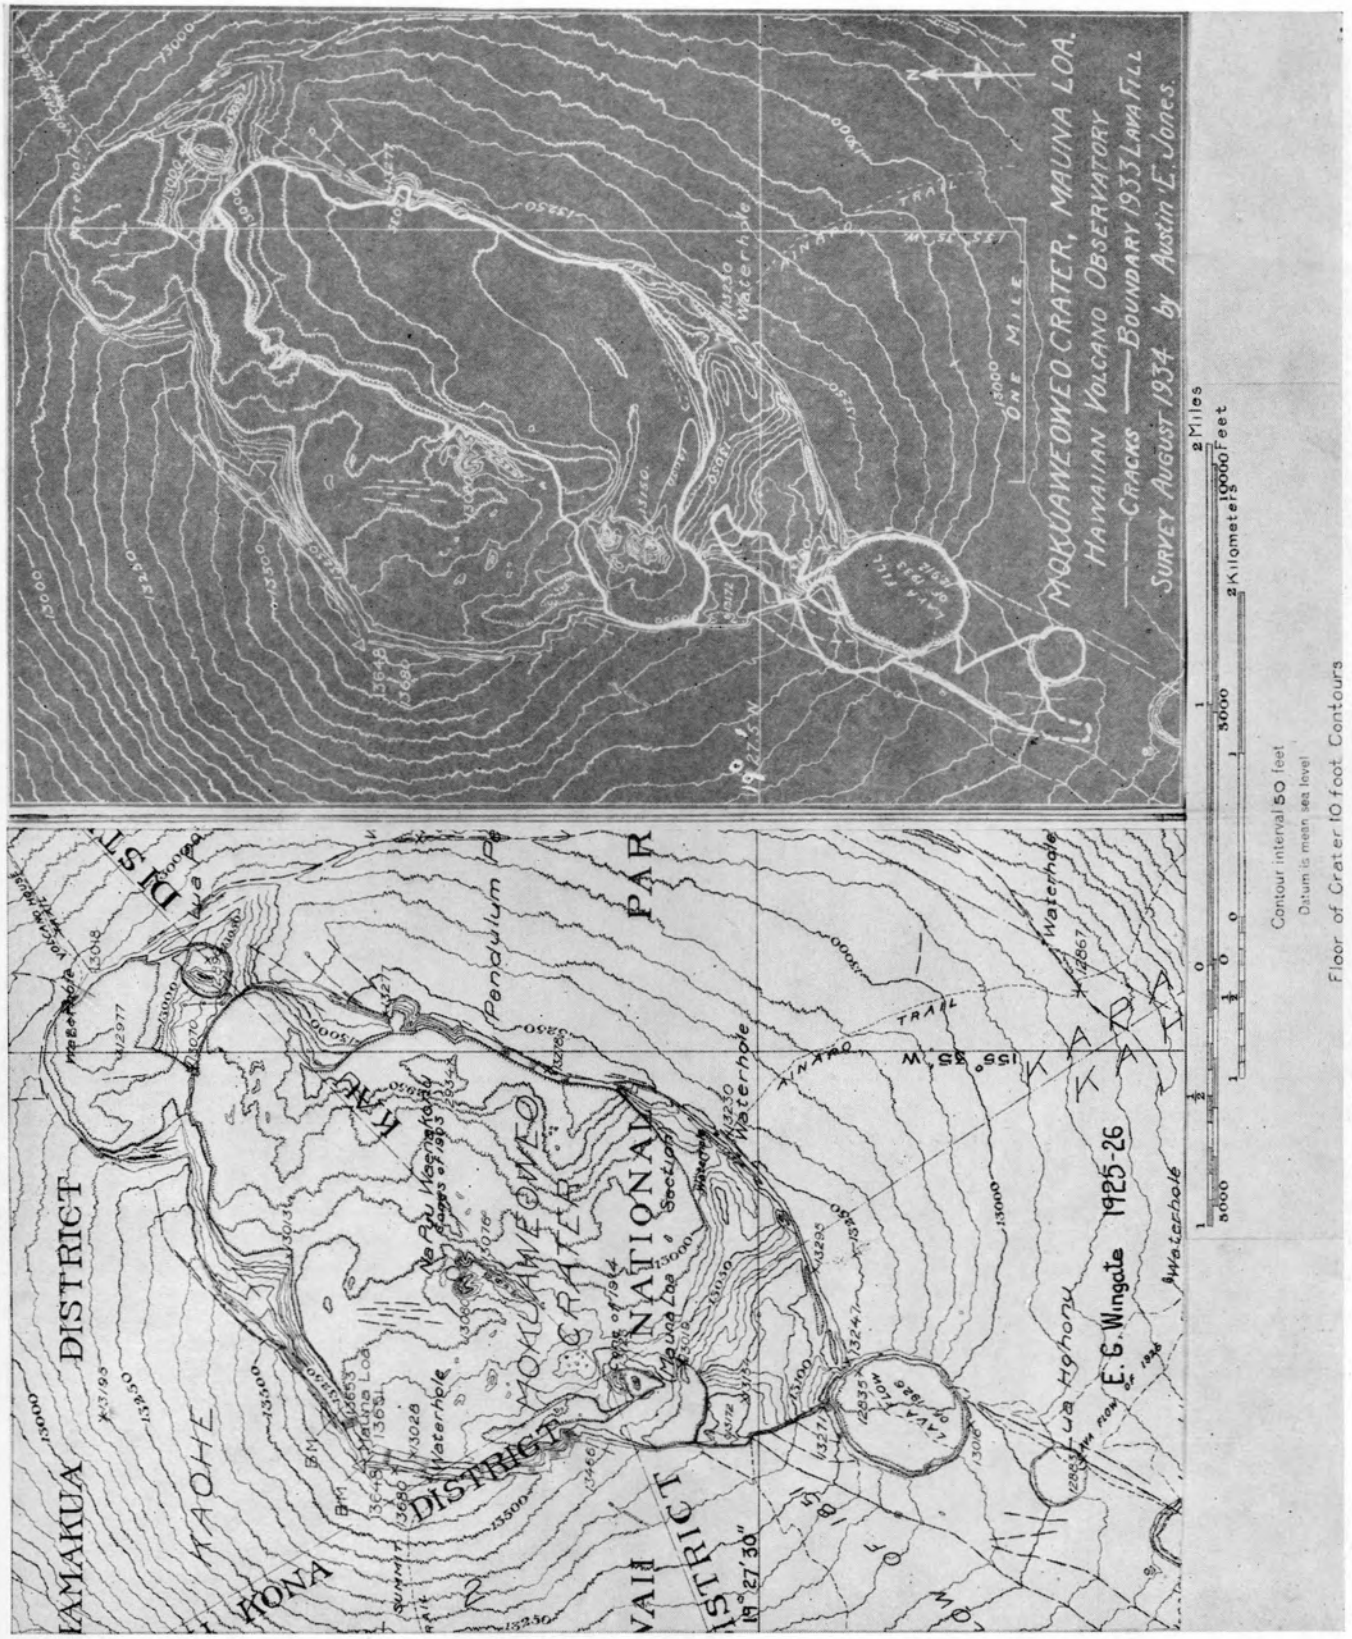

Figure 1. Maps of Mokuaweoweo before and after 1933 eruption.

unfelt or "very feeble" earthquakes, slightly felt or "feeble", felt or "slight", generally felt or "moderate", and "strong" representing earthquakes that are alarming. The grades

week is obtained by adding together the frequency numbers of arbitrary weights, corresponding each to one unit of each type of earthquake. The tremor unit is ¼, the very feeble shock is

½; feeble is 1, slight is 2, moderate is 3, and strong is 4. When a tremor lasts less than a minute it is evaluated as a single tremor unit; when it is continuous the unit is the minute of

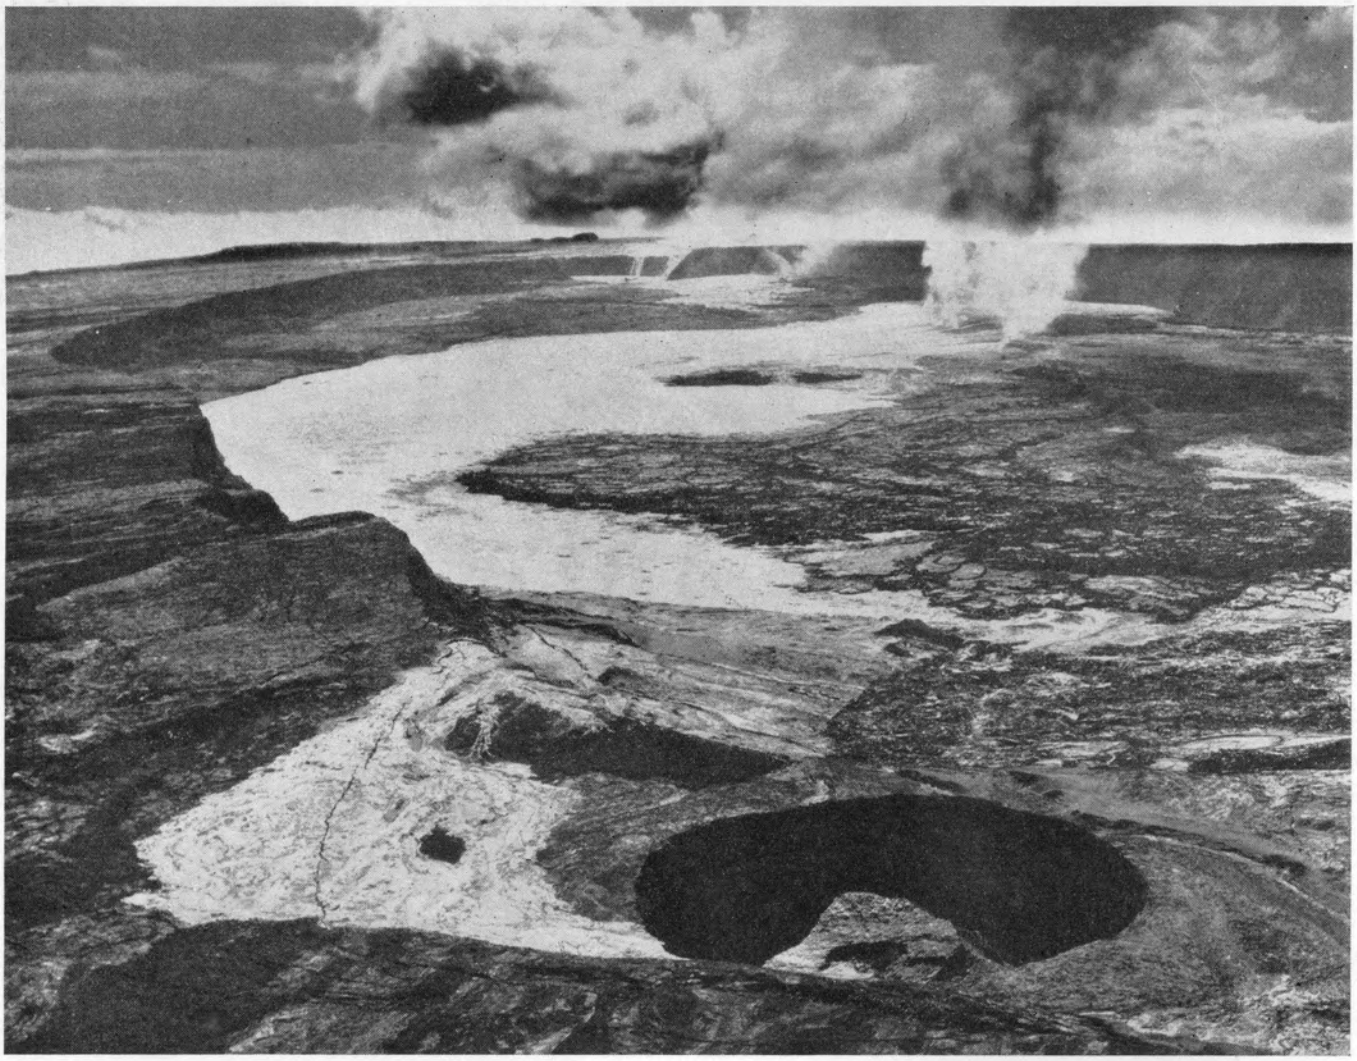

Figure 3. Mokuaweoweo eruption from 14,250 feet, 11 a.m. December 2, 1933, looking SW. North Pit in foreground, old lava gleaming to left of it. By permission Fleet Air Base, Pearl Harbor, U.S.N.

duration. If a week produced one of each of the six types the local seismic index, or summation of the weights would be 10¾. It will readily be seen that continuous tremor, measured in minutes, is a factor which greatly raises local seismicity values.

These values in 1933 were as follows, the eruption starting December 2:

	Seismicity
Week ending November 26	15.50
Week ending December 3	360.00
Week ending December 10	86.00
Week ending December 17	170.00
Week ending December 24	6.50
Week ending December 31	12.50

Tilting of the ground, measured at the Observatory on the northeast rim of Kilauea crater, was strong and northerly or easterly (away from the crater), before and after the Mauna Loa eruption, weaker and westerly during the eruption. The total tilt of the three clinoscope[8] cellars around Halemaumau pit, outward away from the pit, or inward toward the pit, measured on the radial lines from the center of the pit, and disregarding other directions of tilting, yielded interesting results. The aggregate tiliting at the pit had been notably inward for many months before the Mauna Loa eruption. The week of the outbreak it was strongly outward as though the Kilauea floor were swelling upward. After the outbreak it was **more** strongly inward, as though the sinking of the Kilauea floor followed the sinking back of lava under Mauna Loa. This sequence, for the lava fill, is just what happened at Kilauea, when the live lava in Halemaumau was visible during the Mauna Loa eruptions of 1914, 1916 and 1919; and the Mauna Loa crater is 22 miles (35 km.) away WNW.

[8] Volcano Letter, Nos. 382 and 392.

Maps of Mokuaweoweo Crater

In Figure 1 maps are shown of Mokuaweoweo crater before and after the 1933 eruption. The first is by E. G. Wingate, as mapped in the summer of 1926, after the eruption of that year. Contour intervals are 50 feet (15.24 m.) outside the crater, 10 feet (3.05 m.) within the crater floor. The lowest point of the main bowl showed elevation 12,934 feet (3942 m.) before the eruption, 13,035 feet (3973 m.) after the filling of 1933. The bottom of the South Pit showed elevation 12,835 feet (3912 m.) before the eruption, 12,912 feet

(3936 m.) after the filling. The eastern side of both bowls had been depressions before the eruption, but the fills made them relatively flat or level. The heavy outlines on the second map, a survey of August 1934 by A. E. Jones, indicate the two areas of fresh lava north and south. The northern area was fed by the north-south line of big cones approximately 100 feet (30 m.) high that built themselves up on a crack immediately east of the cone of 1914. This source made big floods of lava over the entire eastern side of the main bowl north of the southern lunate platform. These floods also filled the depression adjacent to the 1914 cone and made a new fill against the high western wall of the crater for a third of a mile (one-half kilometer).

The southern area of 1933 outbreak includes the two pits and the cracked upland west of them. A big fountain formed a cone at the foot of the bluff just north of the South Pit and sent a cascade for many hours into that pit. It is this cascade which produced and lies northeast of the small island mapped in the southern area of lava, shown on the northern side of the South Pit. The surface area of the southern lava tract is one square kilometer (0.39 sq. mi.) and of the northern tract three square kilometers (1.16 sq. mi.). The total volume produced in this eruption was of the order of 68 million cubic meters (2400 million cu. ft.).

1 sq. km. = 1 million sq. meters.

Max. thickness in pits southern area = 24 meters.

Mean thickness in south area = 8 meters—thin at the west.

Max. thickness in north area = 31 meters.

Mean thickness in north area = 20 meters counting the cones and west fill.

Area south = 1,000,000 sq. meters.
x 8 = 8,000,000 cu. meters.

Area north = 3,000,000 sq. meters.
x 20 = 60,000,000 cu. meters.

Add N & S = 68,000,000 cu. meters.

Progress of the Eruption

The estimated time of outbreak, 5:43 a.m., December 2, 1933, is that shown by the beginning of continuous volcanic tremor at the Kilauea seismographs. At 7:00 a.m. December 2 two dense white columns of vapor were rising, and by 9:00 a.m. there were three jets, the northern the largest and highest, the two southern ones each double. After the first two hours the white vapor columns became bluish and sulphurous, and these when seen in transmitted light were absinthe red. Filamentous glassy lava, or Pele's hair, fell in small amounts at Hookena 22 miles (35 km.) to leeward, west-southwest. There is reason to think that the division of the fume columns in three corresponded to the opening of three principal gashes on the rift belt. These are respectively the southern gash connecting the two outlying pits, the gash immediately west of the South Pit, and the gash inside the big crater offset still farther to the west and extended to the north. By 7:30 p.m. December 2, when the glow of the fountains at the base of each fume column could be seen, the glowing columns were three in number. The northern one was triple and very brilliant, representing three gigantic fountains east of the 1914 cone within the big crater. The second one was bright and stood over the big fountain at the southwestern border of the big crater, building a cone which vomited up a cascade that streamed down into the South Pit. The southern glow column was faint, and represented the last gushings of the southern gash after fourteen hours of action. The region near the southern pits went entirely out of action by the end of the first twenty-four hours.

Figure 2 shows a lengthwise view of Mokuaweoweo taken before the eruption from an army plane in 1925 at elevation 14,600 feet (4430 meters), looking from the region of the northeast rift towards the southwest rift cones in the distance.

The whole bowl of the caldera is exhibited for comparison with Figure 3, which shows the activity of the first forenoon of 1933 eruption. The line of fountains crosses the southern part of the large cauldron, cuts the northwest cliff-block of South Pit, and extends into the upland beyond, sending cascades of incandescent lava into the South Pit and the pit farther south. The three fume patches represent three principal fountaining areas, the first and largest just east of 1914 cone; the others north and west of South Pit, the floor of which has a new lava fill. Vast floods of pahoehoe in the picture are filling the depression near the cone of 1914, and also the basin of the east side of the main crater.

On the first day, December 2, there were about 35 fountains in the main basin, and 20 each at the two other localities. The basin fountains concentrated to a smaller number about built-up cones. These basin vents poured lava both east and west, but the eastern flows became the great feature. The western ones obliterated the pit of 1914, and made a fill against the western cliff of the south lunate platform. The South Pit outside of the main basin received a fill about 21 meters deep (70 feet) at the base of the cascade through the gap. The main flow area covered about 3 square kilometers (1.16 square miles) the second day, and the southern pits had received a quarter as much. The southernmost upland fissure made big fountains the first day, the lava cascading strongly into South Pit, and feebly into Lua Hohonu.

In the main crater there was liquid flooding of silvery sheets of lava the first day, but on the second day there were crusted floor flows, and flocculent skins appeared on the scarlet torrents of the main streams. On this day the outside southwestern cracks were steaming only. The flow lava of the crater was pahoehoe, but the cones were heaped with basaltic pumice, and Pele's hair lay on the ground to leeward. Milky-blue fume cirrus lay in belts across the sky during the next few days. There was glow over the crater at night, and a fume column by day. December 4 the southwest wall fountain stopped. December 5 the two central fountain groups were within throne-like conical heapings more than 100 feet (30 meters) high.

Figure 4 is a remarkable picture of lava-flow pattern. It shows a half-mile (0.6 kilometer) of the spouting rift inside Mokuaweoweo. It is the forenoon of December 3, when the fountains along the crack, about eighteen in the photograph, had built pumice cones. The jets were 100 to 400 feet (30 to 120 meters) high, and show indistinctly as light patches, for the camera was directed downward. The 1914 cone was smoking violently but still intact behind the second of the two larger fume columns. The left-hand or southern end of this particular fault-block rift crack, one of the echelon of cracks that erupted, is drowned under its own flood. This lake of lava spread to the western crater wall, in a local basin that had been left in 1914. The erupting crack is itself faulted down in the foreground, bounded by a higher block in the background west, and so building crescent half-cones on the step, and the lava flows away from the rise.

This last feature is highly significant of an age-long trend in the active rifts of Hawaii. They are breaking down in steps away from the summit. The same step-down to the east appeared in the 1926 eruption 3 kilometers (2 miles) south of here. The larger fault blocks of both Kilauea and Mauna Loa are sliding toward the southeastern bay of the island for the Kau district, and toward Kealakekua Bay for the Kona district. Something similar is going on in a northern embayment of Mauna Loa, on the Mauna Kea side. Probably dikes under-

ground form three hard ribs on the southwestern, northeastern and northwestern rifts, and between these, the weight of the flanks of the dome breaks it on slipping planes.

The foreground of the photograph shows the great rivers of golden pahoehoe which filled the eastern half of Mokuaweoweo with 30 meters' depth (100 feet) of new lava. The two main fume columns are over the two persistent fountaining heaps, destined to build up cones 80 to 100 feet (25 to 30 meters) high and to envelop the 1914 cone as shown on maps, Figure 1.

The peculiar flocculent pattern of the surface of the liquid rivers is occasioned by the forming and rending of skins of solidification. Each of these skin belts may be traced to its fountain source, the wider ones to the bigger cups, and the contact of skin against skin produces lines longitudinally like the medial moraines of a glacier. Each skin belt tends to wrinkle in festoons of ropes, with convexity down-stream, so that the lines are occasioned by the meeting of the curtains at the frictional drag, where each festooned crescent flows more slowly at the sides. The writer had opportunity to inspect this scene from an airplane, and this was the first time in the history of Mauna Loa when its summit eruption was repeatedly so inspected, by regular passenger planes. By this method far more could be determined in a few minutes, concerning the progress of the eruption, exploring from an airport 65 km. (40 miles) away, than through days and weeks of camping trips, wherein only a small part of the field could be seen at one time.

The flows within Mokuaweoweo proper continued to spread against the east wall; the eastern part of the cliff on the north side of the south lunate platform became obliterated (See Figure 2). Airplanes carried visitors day after day to watch the fan-like rush of lava pouring eastward from the two cone-filled gashes in the crater. The fountains of the northern gash, by December 12, had dwindled to two small ones. December 13 there was only one fountain, with occasional jets from other vents. The fume and glow as seen from Kilauea continued until December 17, becoming faint. The last fountain died down at 2 a.m., December 18, revived slightly after daylight, and thereafter went out of action. The Mokuaweoweo crater area remained very hot and fumy with many jar-rings and rumblings.

A party visiting the crater January 6 to 7, 1934, found that the new lava was somewhat broken up in places near the fronts of the flows. There was much heat about the new cones, rumbles and sharp cracking noises were heard during the night, coming at intervals of three or four minutes, and a few sharp earthquake shocks were felt.

During the mapping expedition, July 30 to August 3, 1934, the new summit resthouse of the national park was occupied by Mr. A. E. Jones and his men, and gave much protection against the cold. The temperature was 32° F. at sunset, and 20° F. at daylight. There were occasional sounds of falling rocks, much of the new shell-lava broke easily and was dangerous to walk on, the lava near the vents was hot enough to be uncomfortable, and sulphurous fume was locally strong.

The results of mapping show the new lava field in the eastern half of the main Mokuaweoweo bowl to be over three kilometers (nearly two miles) long, and something more than one kilometer (0.6 mile) wide, with a thickness of 30 meters (100 feet). The source cones are 30 meters (100 feet) high; the lower basins of the crater are now at the north and at the southeast. The new lava heap is an elongate dome, highest at the southwest in a ridge athwart the crater sink, with its longer axis northeast-southwest.

Hawaiian Volcano Observatory Report for September 1936

VOLCANOLOGY

During the month of September the number of slides from the ENE wall of Halemaumau Pit at Kilauea Volcano increased. Eighteen were reported as compared with six for August.

The following tabulation shows the relation for the month between local seismicity, number of reported slides, and aggregate opening in millimeters of the measured cracks:

Week	Seismicity	Number of slides	Aggregate crack openings
First	7.00	0	10.5 mm.
Second	12.50	3	13.5 mm.
Third	24.75	6	17.5 mm.
Fourth	20.25	5	14.5 mm.
Fifth	27.75	4	28.0 mm.

It is evident that these phenomena as a whole increased during this month that ended with the fortnight that followed the equinox. The crack opening was much larger than August, but not the seismicity.

Slides at Halemaumau

The NE rim of Halemaumau had been roped off, owing to the menace of crack opening and of slides, and the latter from the wall of the pit have been noted as follows:

September 7, Rocks were heard dribbling down the NE wall 9:12 a.m.

September 9, Moderate slide from E rim, near Crack No. 31, 9:50 a.m.

September 9, Rocks dribbling NE 9:58 a.m.

September 14, Large fresh scar over dust on floor, 150 feet below rim, under Crack No. 29. Rocks there were still in motion during forenoon visit.

September 15, Slide under NE rim 10:50 a.m.

September 16, Dribbling rocks NE 1:40 p.m.

September 19, Rocks in motion NE 9:30 to 11:00 a.m. Central part of NE talus had been increased with debris falls from fresh scar above.

September 25, Big noisy slide ENE at 9:42 a.m., and a new scar had appeared 100 feet below ENE rim near Crack No. 29. Rocks dribbled down wall throughout forenoon visit.

September 26, Small slide E wall 10:04 a.m.

September 26, Another at same place 10:24 a.m.

September 29, Small rocks fell WNW wall 9:40 a.m., and a larger slide had left a scar there 300 feet below rim.

October 1, Large dust cloud arose ENE rim, 2:20 p.m.

October 3, Small slide NE rim 11:00 a.m.

Halemaumau Solfataras

September 19 fume was rising from SE and NW Solfataras at edge of floor. This was not unusual.

Measurement of Halemaumau Rim Cracks

After the middle of the month, all along the ENE rim, the opening of cracks shown by the measurements was supplemented by breaks in the surface soil. At the NE flag the slumped slabs under the rim had moved down. By the end of the month the cracks ENE had widened and broken the soil extensively, with marked increase in rate of opening since the September equinox.

Weekly measurements of 32 marked places on rim cracks around the upper edge of Halemaumau Pit resulted as follows:

Week ending forenoon of:

September 5, 7 opened, 6 closed, aggregate opening 10.5 mm. Crack No. 46 opened 9.0 mm.

September 19, 6 opened, 0 closed, aggregate opening 7.5 mm. Crack No. 46 opened 11.0 mm., and Crack No. 31 opened 3.5 mm. Crack No. 31 is east, No. 46 northeast.

September 26, 3 opened, 4 closed, aggregate opening 14.5 mm. No. 46 opened 13.0 mm., No. 31, 3.5 mm.

October 3, 12 opened, 1 closed, aggregate opening 28.0 mm. No. 46 opened 17.0 mm., No. 31, 6.0 mm.

EARTHQUAKES

Table

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Distant Earthquakes	Local* Seismicity
Sept. 6	20	4	0	0	0	7.00
Sept. 13	40	3	0	1	0	12.50
Sept. 20	91	4	0	0	0	24.75
Sept. 27	73	4	0	0	1	20.25
Oct. 4	87	10	1	0	1	27.75

* For local seismicity definition, see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began at the times indicated and whenever possible, determinations of depth of focus have been made.

September 4, 6:06 am, very feeble, probable location under NE portion of Kilauea Crater.

September 4, 8:03 am, very feeble, probable location in Kilauea Crater about midway from the Pit to the Observatory.

September 4, 9:38 pm, very feeble, located 18 miles deep near the old Halfway House 13.0 miles SW of the Observatory. 19° 20′ 5N; 155° 26′ 0W.

September 6, 6:25 am, very feeble, probable location under NE rim of Kilauea Crater, 0.5 mile west of the Observatory.

September 7, 4:18 am, very feeble, located 0.8 mile deep, under NE edge of Kilauea Crater floor. 19° 25′ 4N; 155° 15′ 7W.

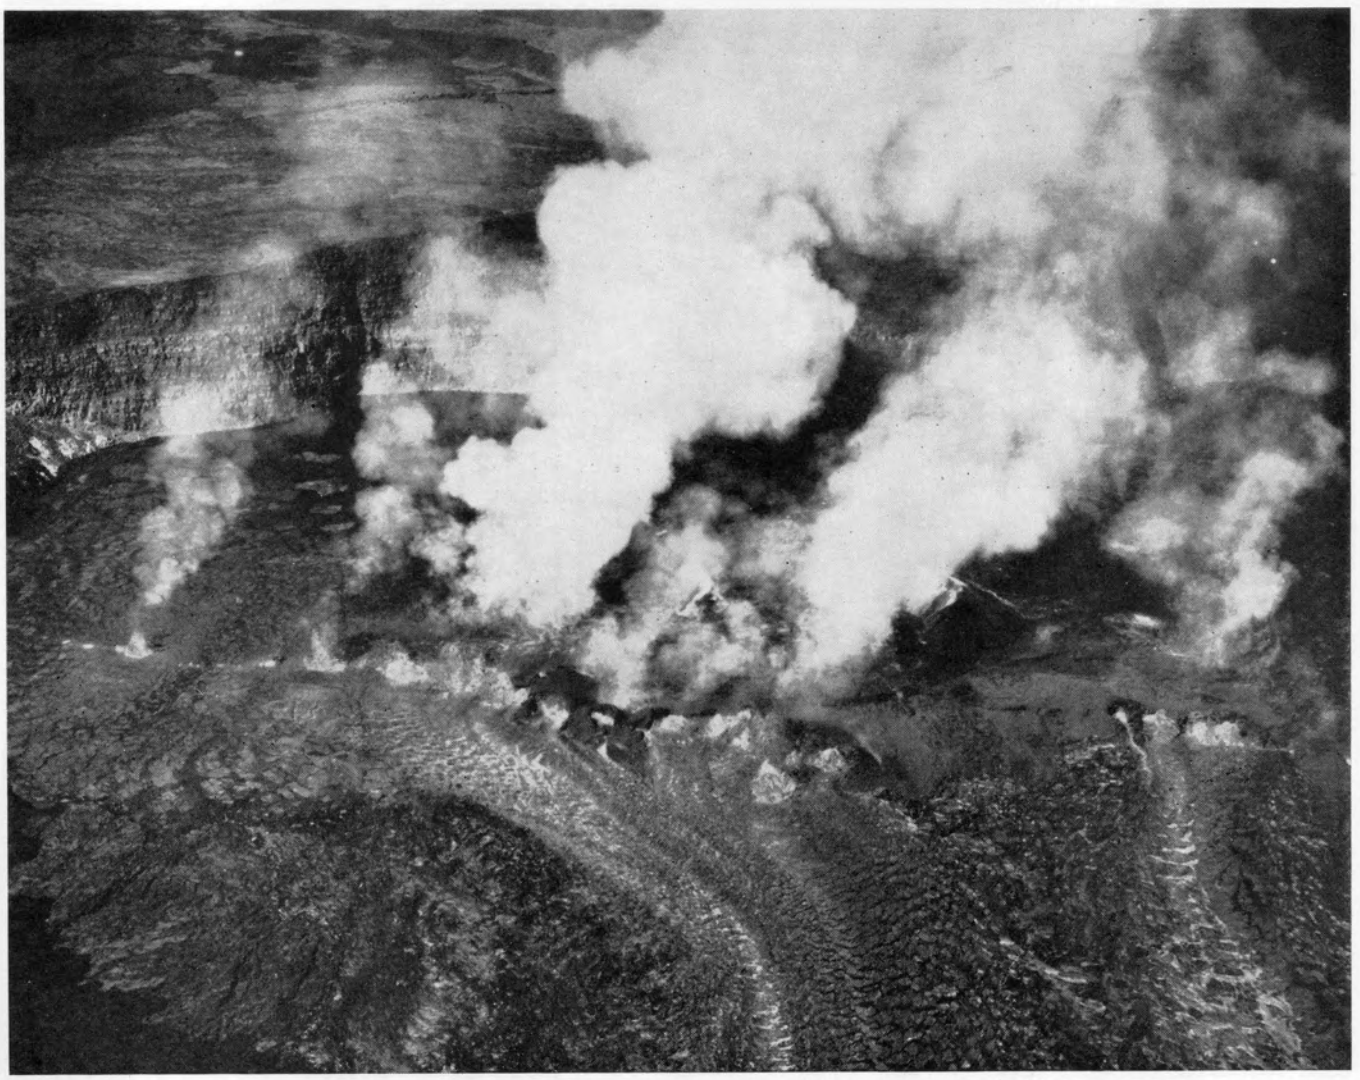

Figure 4. Line of main fountains inside Mokuaweoweo looking west, the second day December 3. The cone of 1914 is seen back of fume column. Lava-pattern, west cliff and outside Mauna Loa slope. From elevation 14,500 feet. By permission Fleet Air Base, U. S. Navy, Pearl Harbor.

September 8, 7:17 pm, very feeble, located 13.0 miles deep and 4.0 miles S of Makaopuhi Crater in the Hilina-Kapukapu Fault. 19° 18′ 8N; 155° 10′ 6W.

September 9, 5:46 pm, a slight shock felt by a few in Volcano district. Located 2.3 miles deep and 1.3 miles SE of the Pit Seismograph Station. 19° 23′ 4N; 155° 16′ 1W.

September 14, 3:39 pm, very feeble, located 4.0 miles deep and 2.0 miles NE of east entrance to Hawaii National Park. 19° 26′ 6N; 155° 12′ 9W.

September 15, 12:07 pm, very feeble, located 1.2 miles under NE portion of Halemaumau. 19° 24′ 7N; 155° 17′ 0W.

September 17, 1:37 am, very feeble, probably located under NE rim of Halemaumau.

September 20, 2:44 am, very feeble, located under SE rim of Kilauea Crater near Keanakakoi Crater. 19° 24′ 4N; 155° 16′ 2W.

September 21, 3:56 am, very feeble, located 5.5 miles deep under that portion of Kilauea Crater immediately to the east of Halemaumau and 0.4 miles N of Pit Seismograph. 19° 24′ 6N; 155° 16′ 9W.

September 23, 1:11 pm, very feeble, located 4.0 miles deep and 3.3 miles N of Uwekahuna. 19° 28′ 2N; 155° 17′ 4W.

September 24, 1:25 pm, very feeble, probably located in SE portion of Kilauea Crater.

September 28, 2:06 am, feeble, located 2.2 miles deep and 3.6 miles E of the Pit seismograph. 19° 24′ 1N; 155° 13′ 6W.

September 28, 3:08 am, very feeble, located 3.7 miles deep and 2.1 miles N by E of the Volcano Observatory. 19° 27′ 6N; 155° 15′ 1W.

September 29, 4.12 am, very feeble, probably located in NE rift of Mauna Loa near Puu Ulaula.

October 4, 12:02 pm, very feeble, probably located 1.0 mile NE of Kilauea Crater.

The surface (L) waves of a telesism began recording 2h 37m 41s, HST, September 25. Reported location was approximately 300 miles off W Coast of Southern Oregon, 2140 miles from Kilauea. 42° 5N; 131° 4W. Registration of the preliminary waves of another distant earthquake began at 11h 26m 25s, HST, October 4. It was 5340 miles SW by W of the Island of Hawaii and the reported location was the northern border of the Banda Sea east of Celebes Island. 3° N; 126° 4E.

Periods of continuous tremor registered as follows:

September 20, 3:49 am, 6 minutes and October 1, 12:33 pm, 4 minutes.

Microseismic motion of the ground at Kilauea was moderate September 16, 17 and 18, the remainder of the month it was light.

H. H. W.

CRATER ANGLES

Measurement of horizontal angles across Kilauea Crater from the Observatory on September 23, showed slight opening across Halemaumau and slight closing across the Crater as compared with similar measurements August 18. From Kilauea SE rim to Uwekahuna the angle closed 1″.92 August 18-September 1; September 1 to September 11 an opening of 2″.67; September 11 to September 23, an opening of 1″.25; total closing 0″.6. From the Pit seismograph to the NW Pit station there was a closing of 1″.00, August 18-September 1; September 1 to September 11, a closing of 1″.83 and September 11 to 23, an opening of 3″.33. Total opening 1″.50.

H. H. W.

SPIRIT LEVELLING

Spirit levelling across Halemaumau from the Spit SE edge of Kilauea Crater to the NW Pit BM showed a lowering of the NW Pit BM with reference to Spit of 5.5 centimeters between February 10 and September 3, 1936.

H. H. W.

TILTING OF THE GROUND

The following table shows tilt by weeks from seismograms at the Volcano Observatory NE rim of Kilauea Crater and at Halemaumau, the algebraic sum of radial tilts for two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending August 30, was 4.″23 N and 1″.1 E.

TABLE OF TILT

THE VOLCANO LETTER

No. 440 monthly Department of the Interior National Park Service October 1936

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

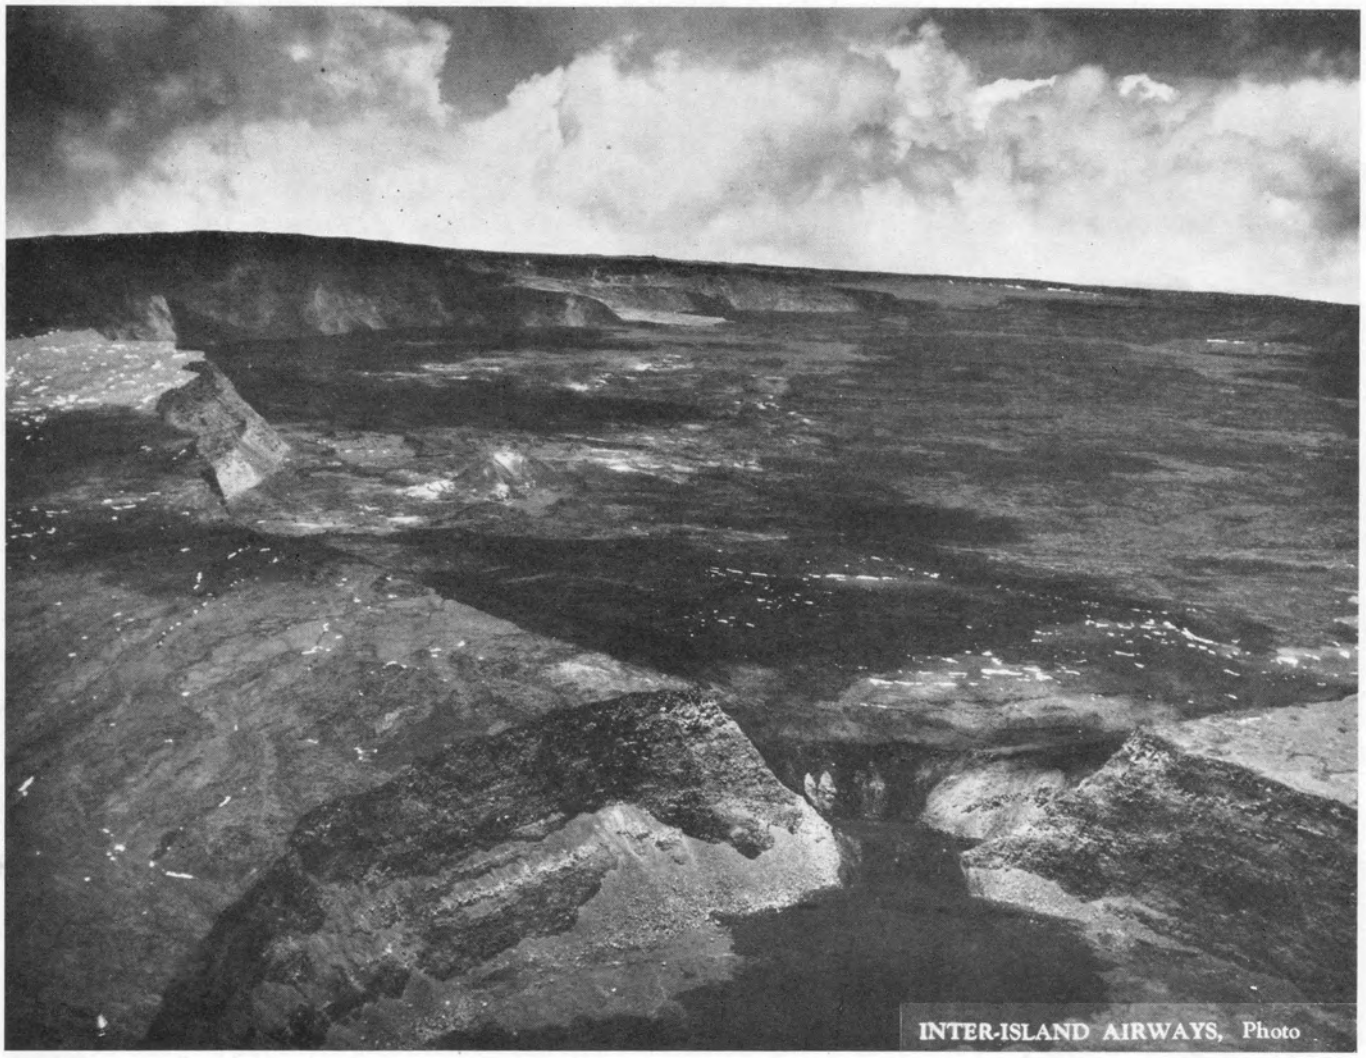

Figure 1. General view from plane of the Inter-Island Airways, Ltd., winter 1932-33 looking north. Mokuaweoweo, summit crater Mauna Loa, before December eruption of 1933. South Pit in foreground, 1914 cone on left, 1903 cones in center.

THE COMING LAVA FLOW

The Most Serious Responsibility in Our History

T. A. Jaggar

Annual Address, March 26, 1934, Hawaiian Volcano Research Association*

Mauna Loa at its summit crater has recently made a spectacular lava gushing December 2-18, 1933. This 17 days of summit activity should be followed by an outflow over somebody's land within a period of from 16 to 37 months.

This expectancy is the serious responsibility which rests on the shoulders of the Hawaiian Volcano Research Association. The words are not "the most serious lava flow in history." They are "serious responsibility." It is serious if we take our 22 years of volcano observing seriously, because we are called upon to make good, to make the forecast as careful as possible, and to advise the community soberly and preparedly.

* In sequence of dates to preceding and following Volcano Letters.

There is no call for fear. There is every appeal for an intellectual and practical victory over nature. Prediction and resulting preparation are what exhibit science at her best.

What are the Facts about the Past of Mauna Loa?

There are listed 23 summit crater eruptions of Mauna Loa, in 90 years, between 1843 and 1933. This is without counting some small summit effusions which may have gone unrecorded.

Between 1832 and 1899 there were nine NORTHERN and EASTERN flank outflows, with one source as low as 8500 feet elevation on this 14,000-foot mountain, namely 1852.

Between 1868 and 1926 there were eight SOUTHERN and WESTERN flows, with one source as low as 3500 feet elevation in 1868, and one below sea-level in 1877.

The districts invaded by Mauna Loa have been NORTH KONA, SOUTH KONA, KAU, SOUTH HILO, NORTH HILO INLAND, HAMAKUA INLAND, and even SOUTH KOHALA was touched by the prehistoric but recent Keamuku flow west of Humuula. The very voluminous 1843 flow at the same place might well have found its way to South Kohala. Puna and North Kohala are the only districts of the Island not visited by fiery lavas from Mauna Loa sources, and Puna has been abundantly invaded by flows from Kilauea volcano.

What are the Intervals between Crater Eruptions and Outflows?

There are two classes of Mauna Loa eruptions, those at or near the summit crater lasting days, weeks or months, and followed by a major lava flow, usually some years later; and secondly, those at or near the summit, but not necessarily in the crater, often making small preliminary flows on the upper rifts, always lasting only a few minutes, hours or days, and then followed immediately by an outflow from a vent farther down the mountain. This second class is the SOME YEARS LATER group of the first class.

In other words, all great lava flows are preceded immediately by high-level gushing, and some are preceded by a summit crater eruption a few years before which announces that a flow is coming; but this preliminary summit crater outbreak may announce that a GROUP OF SUCCESSIVE OUTFLOWS is coming.

In like manner, all eruptions exclusively in the summit crater, like our recent display of December, 1933, are followed eventually in a few years by one or more low-level outflows with their immediately accompanying summit gushings; but it is possible for such summit crater eruptions of the preliminary class to follow one another in a GROUP OF SUCCESSIVE SUMMIT CRATER ERUPTIONS, before the mountain breaks to emit an outflow lower down.

Applying these facts of history to December, 1933, for discovering what is to follow, we may expect either one or more additional summit crater extrusions, or one or more lava flow eruptions.

Eruptions wholly at the summit Crater

Year	Duration	Interval	Next Succeeding Outflow
1832	3 weeks	10½ years	1843
1849	3 weeks	2 years	1851
1865-66	4 months	2 years	1868
1870	2 weeks	7 years	1877
1872	2 months	5 years	1877
1873	10 months	4 years	1877
1874	10 months	3 years	1877
1875	2 months	2 years	1877
1876	1 week	1 year	1877
1880 (May)	6 days	6 months	1880 (Nov.)
1892	3 days	7 years	1899
1896	15 days	3 years	1899
1903	9 weeks	4 years	1907
1914	6 weeks	2 years	1916
1933	17 days		

Flank Outflow Eruptions with Near-Summit Beginnings

Year	Duration	Interval Between Near-Summit Start and Outflow	Elevation of Flow Source
1843	3 months	7 days	10,000 feet
1851	4 days	minutes?	13,000 feet
1852	4 months	3 days	8,500 feet
1855	16 months	hours?	11,000 feet
1859	10 months	minutes?	11,000 feet
1868	4 days	10 days	3,500 feet
1877	few days	10 days	30 fathoms submarine
1880 (Nov.)	9 months	5 days	10,500 feet
1887	10 days	2 days	6,250 feet
1899	26 days	5 days	10,800 feet
1907	14 days	4 hours	6,500 feet
1916	17 days	3 days	7,300 feet
1919	40 days	3 days	7,600 feet
1926	1 day	minutes?	13,000 feet
1926	19 days	3 days	8,000 feet

Summary of Frequency for Mauna Loa Eruptions

There were 30 summit or near-summit events on Mauna Loa between 1832 and 1933, within the period of 101 years. As all the lava outflows begin with a near-summit outburst, this number includes all the Mauna Loa eruptions recorded in the white man's occupancy of Hawaii.

There was probably an average of just as many Mauna Loa eruptions in the eighteenth century and the first quarter of the nineteenth, but the icy wastes of the high mountains were too remote to interest Hawaiians. Lava flows lower down were taken as a matter of course and were not recorded. White explorers like Captain Cook and Vancouver did not usually happen to arrive at eruptive dates. Captain Cook apparently never heard of Kilauea and records Mauna Loa as extinct.

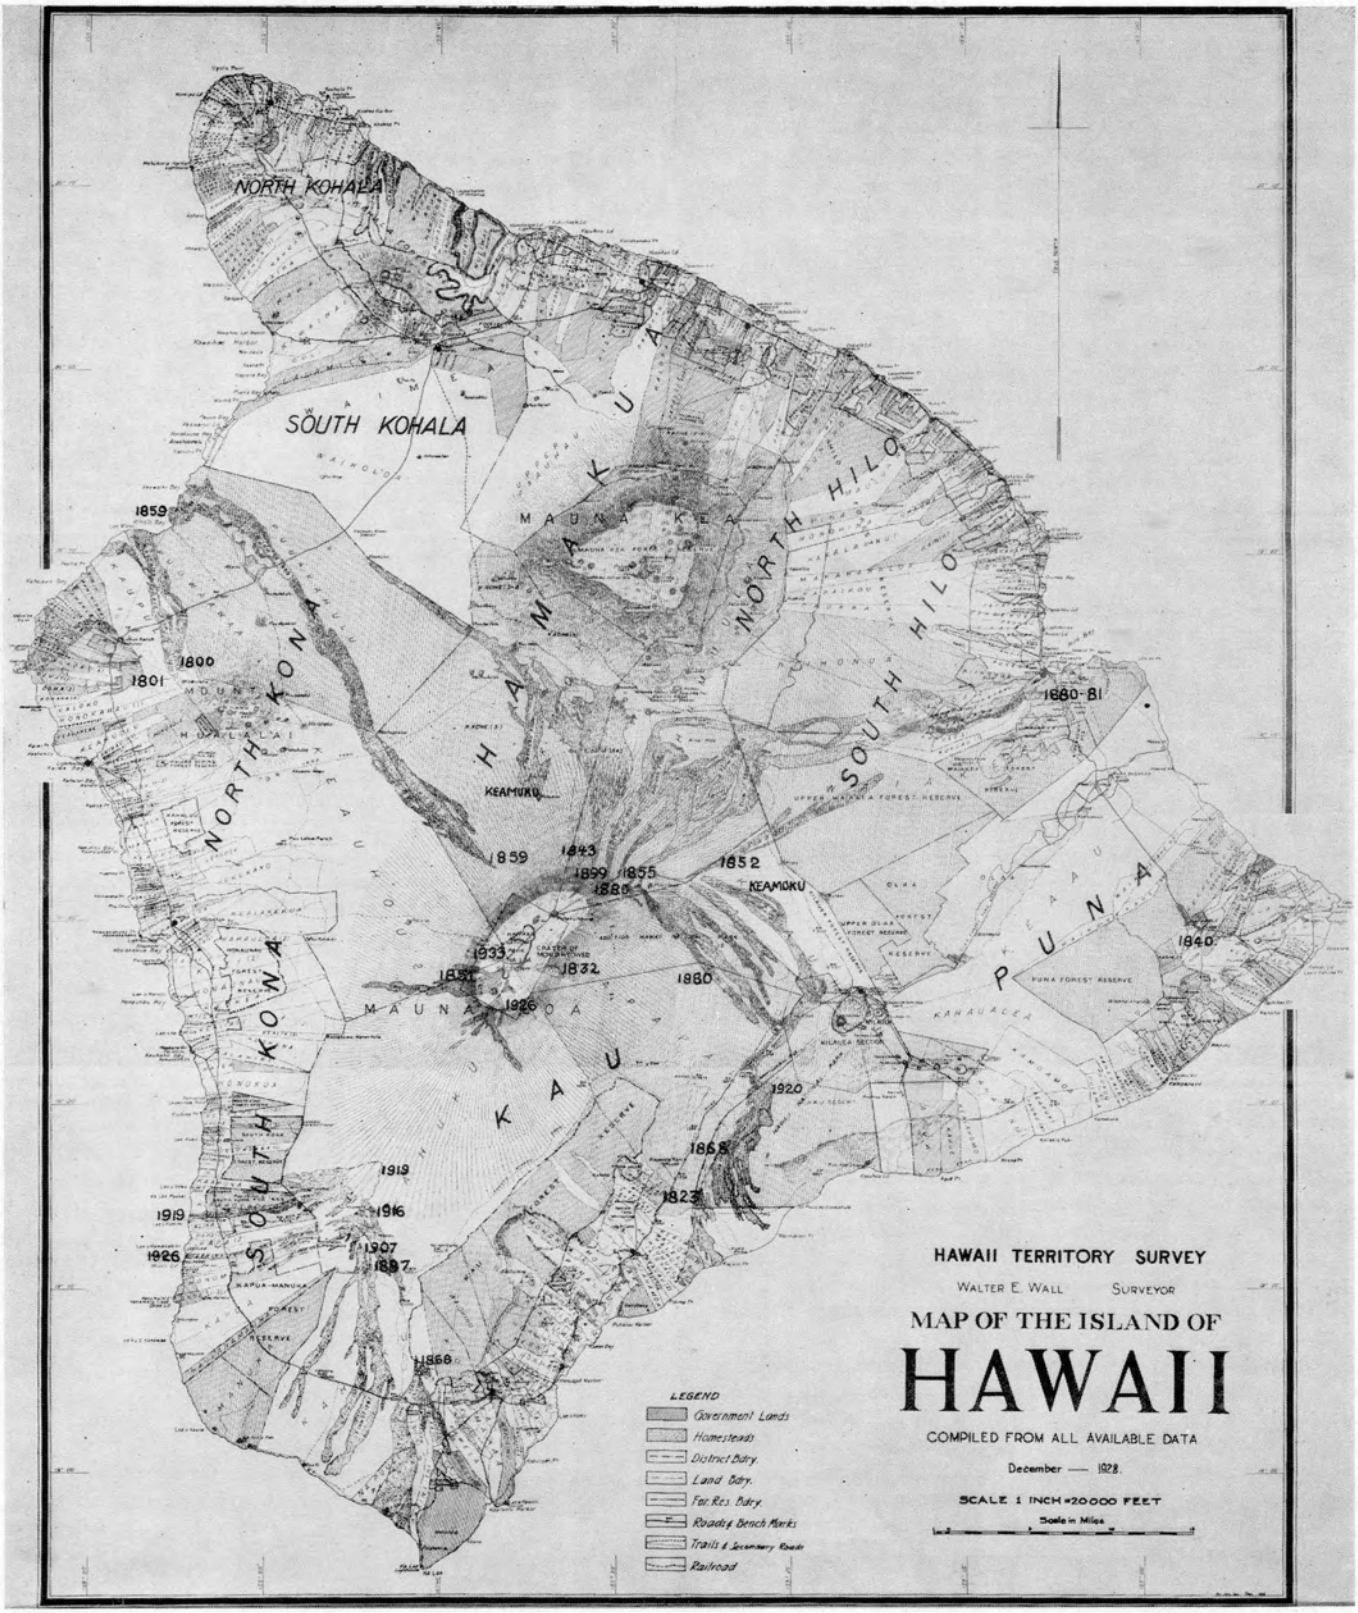
What are the Average Intervals for Mauna Loa?

The average is one outbreak in three and a third years near the Mauna Loa summit. There are 14 flows between 1843 and 1926, in the period of 83 years, averaging one outflow from the flank of Mauna Loa, as perceived by man, either above sea-level or close to sea-level under water, every six years. It must be remembered that commonest interval is by no means identical with average interval. Reviewing:

Intervals, SUMMIT AVERAGE, 3⅓ YEARS.

Intervals, FLOW AVERAGE 6 YEARS.

There were probably several submarine outflows under deep water, not perceptible to man, but indicated by extraordinary crater collapses, like those at Kilauea in 1790, 1894 and 1924. The reason for thinking this is that observed outflows close above sea-level caused similar collapses, as in 1823, 1840 and 1868. The submarine outflow in Kealakekua Bay in 1877, made very slight impression on mankind, but as it drained Mauna Loa of lava after seven years of summit activity, it may have been one of the greatest lava flows of history, down that cold, dark, wet slope, tipping away steeply 12,000 feet off Kona. The crater collapses of Mauna Loa have gone unnoticed, as nobody lives there. There is plenty of room in this globe for it to do colossally big things without informing mankind, until such time as it occurs to man to distribute and live in numerous observatories of the earth.



The frequency and continuity of lava activity at Kilauea have been even greater than on Mauna Loa, and there have been contributions within 200 years from Hualalai and Haleakala volcanoes, but this discussion is concerned only with Mauna Loa.

How the Lava Breaks the Dome

With summit eruptions of Mauna Loa every 3⅓ years, and outflows every 6 years, it appears to be nearly twice as easy for the lava and gas to squirt through the summit vents, as to break the flank of the great dome. We have to think of the expanding gas-charged paste swelling the mountain all the

time through hundreds of thousands of years, dammed back by its own accumulations which have built the mountain. An eruption is determined by the yielding of the heap to a never-ending force.

The breaking of the flank ranges from 180 feet below sea-level, to elevations on Kilauea mountain 700 feet (1840), on Hualalai mountain 1500 feet (1801), and on Mauna Loa slopes approximately 3,000, 8,000, 10,000, 11,000, and 13,000 feet above sea-level for the statistics of only one century.

What Class was the Recent Eruption in?

The outbreak in Mokuaweoweo crater of Mauna Loa volcano in December, 1933, was not in the Class II of the second list, where the outflow follows the summit gushing by a few hours or days. No outflow has appeared. Therefore, the flow is yet to come, and when it comes it will begin at the top.

This concentrates interest in the first list where the summit eruptions lasted from three days to ten months, and were followed each by one or several flows of the second list, after repose intervals of from six months to ten and a half years.

By analogy the 1933 outbreak lasted 17 days; other eruptions of one to three weeks at the summit were those of 1832, 1849, 1870, 1876, 1880 and 1896. Imagining 1933 to be like one of these, let us see what happened:

Samples of Eruptions like the 1933 Outbreak

After 1832, June, at the summit, the interval was 10½ years to January, 1843. The 1843 flow poured for more than six weeks, largely pahoehoe as mapped today, filling the Mauna Loa-Mauna Kea saddle, flowing north and northwest 14 miles, starting at an elevation of 10,000 feet.

After 1849, May, at the summit, the interval was two years and two months to August, 1851. The 1851 flow poured only four days, pahoehoe lava above and aa lava below. It went towards Honaunau, very high up on Mauna Loa, moving due west eight and a half miles, starting from the southern pits of Mokuaweoweo at an elevation of 13,000 feet.

After 1870, January, at the summit, "steam and smoke," introducing seven years of summit activities, the interval was seven years to February, 1877. The other summit gushings lasted two months in 1872, 10 months in 1873, 10 months in 1874, two months in 1875, one week in 1876 and 10 days in 1877 just before the outflow. What was seen of the 1877 flow lasted only half a day. It was frothy lumps of hot pahoehoe under the sea in Kealakekua Bay in 30 fathoms of water a half mile off Keei. The pieces bubbled up and floated while hot and were collected. No one knows how far the flow went under the sea, nor how long it may have pushed onward under its water-chilled skin.

After 1876, February, the interval was one year to the Kona submarine flow February, 1877.

After 1880, May, the interval was six months to the flow of November 5, 1880. The 1880-1881 flow poured for nine months in several branches, aa at first, pahoehoe afterwards. A first aa flow went to Ohaikea in Kapapala, 11½ miles, after four days of preliminary upland flowing. Then aa flows went towards Mauna Kea and towards Hilo. Always the vent lavas were pahoehoe, changing to aa a short distance away by stirring. Finally the source pahoehoe overrode the previous flows and pushed its way to Hilo town. The length of the flow was 30 miles. It stopped in August, 1881, in the outskirts of Waiakea, one mile from the city center (August 10). The source was on the northeast rift of Mauna Loa at an elevation of 10,500 feet. The lower extremity of the flow is about 100 feet above sea-level.

After 1896, April, the interval was 3 years 2 months to July 1, 1899. The 1899 flow poured ten to fifteen miles northeast for 26 days, starting at elevation 10,800 feet on the northeast rifts of Mauna Loa. It headed for the upper Wailuku drainage back of Hilo, but did not reach it. It was aa at first over most of its course, but pahoehoe as mapped, in a final stream, eight miles long. One account states that an early branch headed towards Kau, as in the case of 1880.

Is the Present Time like 1870-1877?

The 1870-1872 time was critical for comparison with 1933, if it should happen that 1933 is the prelude to a new shift of flow sources, from the southern vents of the last thirty years, to northern vents in the near future.

Seismic happenings now in 1934, and the location of earthquakes under the mountain at the north in 1933, point to activity under the northeast rift of Mauna Loa. The progressive higher elevations of flow sources in 1868, 1887, 1907, 1916, 1919, 1926 and 1933, all on the southwest rift, point strongly to the probability that the cracking open of vents will cross the summit to the northern rifts. For the 1933 eruption, though mostly in Mokuaweoweo ,crater, began along southern cracks, just outside the crater and where the 1926 eruption left off.

If we make this expected shift a basis for comparison with the 1870's, there may come numerous summit crater eruptions for some years. Thereafter the northern flank will split open. Compound eruptions, involving numerous vents, for Mauna Loa, have occurred not only in the seventies, but also in the fifties, the eighties, the nineties and after 1914. Something similar is to be expected at present, as the combination 1926-1933 is already compound, and not yet finished. There is an eleven-year cycle following the profound crisis of 1924, which has been discussed elsewhere (Thrum's Annual 1932) for the Kilauea-Mauna Loa volcanic system.

How can we use Average Intervals?

The average interval, between summit eruption and outflow, for these six selected occasions that resembled 1933 in duration, was 4.1 years. The average interval for all the summit eruptions of the first list was 3.8 years. The range between longest and shortest intervals for all was from one-half year to ten and a half years. If we leave out the exceptionally long intervals of 1832, 1870 and 1892, we get an average interval of 2.6 years, and a range from one-half year to five years. The Mauna Loa average for all flows, and the probability of a cycle, ending in 1935, make two years after 1933 a probable limit of time within which the next event should come.

The National Park rangers right now report increasing fumes of sulphur at the summit crater vents of last December. Earthquakes have almost ceased under the southern half of Mauna Loa, where until recently they were most abundant. The suggestion of a coming flow on the Hilo side is inescapable. Let us summarize the probabilities:

Summary of the Expectations

1. A lava flow from Mauna Loa, or else another summit eruption, is expected within two years.

2. If it is a lava flow, the history of sixty-six years indicates sealing of the southwest rift, and coming outbreak at the north.

3. The resulting flow may push in any direction between North Kona and Kilauea. A likely direction is towards Hilo.

4. The change from Kau flows to Hilo flows is likely to be accompanied by a severe earthquake. This is what happened when the change was from Hilo flows to Kau flows in the terrific earthquake of 1868.

5. Severe earthquakes on the northern Mauna Loa rifts have already begun, at Hualalai, in the autumn of 1929.

6. Opening of the northeast rift of Mauna Loa after its repose and solidification for thirty-five years may make a world-shaking earthquake, for the whole east side of the island Hawaii, just before the outflow starts. The earthquake of 1868 was felt all the way to the island Kauai, and strongly felt.

Responsibility for the Protection of Property

To point out these probabilities is not to set dates for the events. To fail to point them out would be to suppress truth.

Hilo knows all these things, is completely organized to meet them, and has been instructed about the relief committees of Napier, Long Beach and Sakurajima. A statement of the Mauna Loa problem for the Hilo Chamber of Commerce appeared in Volcano Letter No. 338.

New Zealand, California and Japan have taught us lessons in earthquake insurance. With us the local government, the National Park administration, the National Guard, the Ameri-

can Legion, the Coast Guard, the Navy and the Army all know what they will be called upon to do. On December 11, 1933, the superintendent of Hawaii National Park called a meeting

Figure 2. Similar view to Figure 1, during eruption December 3, 1933, from altitude 14,500 feet, airplane photograph by permission Fleet Air Base, Pearl Harbor, T. H. Note offset in active rift cracks, new floor of South Pit, new and old cascades, and in upper left corner the trace of rim of ancient caldera.

of an emergency committee of these organizations in Hilo to discuss Mauna Loa, and it was done quietly and efficiently. Honolulu is also organized.

The Volcano Observatory at Kilauea was founded in 1911 under the Whitney Fund of the Massachusetts Institute of Technology, with these words: "To be conducted with a view to the protection of human life and property."

That charge was accepted by the Hawaiian Volcano Research Association. A fire department, which in dry weather with high winds did not take special precautions, would neglect its duty.

This address definitely announces that volcano dwellers in Hawaii should now take precautions, for **Mauna Loa has definitely mobilized and declared war.**

What Precautions Can Be Taken?

The answer is as follows:

1. The northeast slope of Mauna Loa must be made accessible. The roadway proposed should be built at once, no matter how roughly. It should extend from the top of the mountain to Kilauea.

2. The Hawaiian Volcano Research Association should increase from 180 to 1000 members and patrons. Government funds for the Observatory have been cut 83 per cent since 1932. Twenty thousand dollars are needed when the lava flow comes, which might be this summer, if 1880 is repeated.

3. The staff is now two scientists, and not even a typist. With a suitable staff, the Hawaiian Volcano Observatory can resume its scientific publication, which amounted to 3500 pages prior to 1932. It can keep the community properly informed. It can organize more volunteer observers to report small earth movements. It can patrol Mauna Loa with more expeditions. It can man an observatory on Mauna Loa when the rough road is built. It can organize preliminary plans for volunteer assistance by airplane services and other public relief, and prepare special maps. It can improve everything it is doing now in concentrating on Mauna Loa, if it has the requisite man-power. You cannot make war without money and men. The patrolling of an area as large as Mauna Loa is not a small job.

4. The actual details of how a northern Mauna Loa flow will lap up Hilo's water supply, as it has done it in the past, is set forth on page 3, Volcano Letter 338, under the title "Preparedness against Disaster."

5. Japan has had her Earthquake Investigation Committee, and does not hush up anything. The most important precaution to be taken we may copy from Japan. It is to face the situation, and not cry about bad advertising, and cry of wolf, and fear of scaring tourists. Tourists come from Los Angeles and Santa Barbara and San Francisco, and they know the game, and that Hawaii is not more dangerous than their own homeland.

6. A foreseen Mauna Loa flow can be made the best advertisement Hawaii has ever had. The headlines will read "Hawaii meets lava flow with complete preparation." "First time in history when mankind has been prepared." "Everybody in Hawaii rejoices and goes to the flow." "Everyone in Hawaii a member of Volcano Association." "Hawaiian lava flow scares nobody."

The introduction said: "There is every appeal for an intellectual and practical victory over Nature."

If every firm, engineer, officer, doctor, teacher and homemaker, if every business man will turn to and join the association now, if those who can't afford it will take an interest and get behind the Observatory at Kilauea, if every educated person will help and not kick, then this Territory can laugh at the fiery fountains and make them an asset. They may gush and bubble as inflammably as they choose, and we shall rub our hands with glee. Our engineers and aviators and bombers will rejoice at the opportunity to show their prowess. And finally, a program of generalship will be laid down, with advice from all experts, which can be carried out as an object lesson to the world. The Volcano Observatory cannot do it, but we can unite and do it, using the motto of volcanology, "Be always ready, and never hysterical."

Hawaiian Volcano Observatory Report for October 1936

VOLCANOLOGY

The month of October at Halemaumau Pit of Kilauea Volcano produced the culmination of the landsliding and crack opening which has been disturbing the NE edge of Halemaumau for two years. This took the form of a large avalanche on October 22. The records of crack opening and wall sliding increased to a maximum at this time, but the local seismicity, while greater because of the many tremors generated by the slides did not vary directly with the figures for sliding and crack opening. The following is the abridged table of these movements:

Week	Seismicity	Number of Slides	Aggregate Crack Openings
First	8.00	13	42.5
Second	17.50	12	93.0
Third	39.00	50+	Infinite
Fourth	20.25	16	26.0

For the first week slides increased to 13 from 4 the week before and crack opening to 42.5 from 28. For this same week seismicity decreased from 27.75 to 8.00. It should be remembered that the number of slides is merely the record for a short period of observation, not a quantitative expression of the measurable number, which is uncountable with any present apparatus. The word "infinite" for the third week in crack opening means that the big avalanche carried away the cracks.

Sequence of Events by Weeks

The first week produced many slides from the E and NE walls and along with this went excessive opening of ENE rim cracks.

The second week increased the cracking open of the rim and the sliding of the NE walls, while fresh cracks in the soil opened in many places. It is evident from the map of the pit outline, that the breaking down of this wall was eliminating one of the straight parts of the circular outline of the pit. This straight part was a nearly vertical cliff between the peaks of the E and NNE talus cones. The form of stability that will result for the pit will extend the circular curve in plan, and make the inner slope more a funnel and less a cliff.

The third week produced the large avalanche at 5:54 a.m. October 22, along with many other slides. This extended peeling of the wall for months has removed a length of 1500 feet along the rim ENE, to a maximum distance back near Crack No. 46 of more than 100 feet. Following the collapse of the former Crack No. 34 in March 1936, there were now obliterated Cracks Nos. 29, 30, 31, 32 and 46. This reduced our marked crack locations from 32 to 27.

The beginning of this yawning open of the cracks can be traced to measurements two years ago when Halemaumau erupted in September 1934. A marked increase of the gaping open, however, began in October 1935 just when the premonitory earthquakes were heralding the coming November outbreak of Mauna Loa.

The many slides kept a dust cloud over Halemaumau for most of the week. The result was a very large new talus cone halfway up the wall, over the middle of the white ledge known as the Canoe Sill. The new break is adjacent to the dykes of the Rift Belt on their eastern side. The whole of this part of the wall has fallen to form the heap, overlapping the 1934 floor about a third of the distance to the center of the pit, and covering the ENE floor cracks, the depression that lay along the wall, and part of the 1934 lake-basin. Crack No. 46 lay N 57° E from the pit center, and this direction is along the line of the former cracks across the bottom that were mapped after the eruption of 1931-32. (See mapping, Volcano Letter 394). The limit of destruction of the rim was slightly beyond No. 46, and movement on the deep rift possibly stimulated this landslide.

During the fourth week smaller slides ENE continued, the surface cracks in the ground had opened to the Volcano House Trail, so that on November 1 this area had to be roped off, and the trail was established farther back. The new breakage of the ground is southward from the great avalanche of October 22. The opening of measured cracks was now near the E corner of the pit.

Slides at Halemaumau

Slides from the wall of the pit have been noted as follows, but these are only a part of what actually occurred:

October 6, 9:40 a.m., moderate NE near Crack No. 29; fresh scar near No. 31.

October 6, 3:00 p.m., numerous avalanches.

October 7, 7:56 a.m., small rock sliding NE near Crack No. 31.

October 8, 9:11 a.m., rocks moving under Crack No. 29: scar 150 feet below it, new rocks and dust on floor.

October 9, 12:30 p.m., avalanche dust arose.

October 10, 10:15 a.m., moderate slide below Crack No. 34 NE.

October 10, 12:50 p.m., moderate avalanche and dust cloud NE.

October 11, forenoon, rocks sliding, east talus enlarged, more rocks and dust on floor, and fresh mark under Crack No. 31 perhaps due to earthquake of 4:05 a.m. Much cracking of soil ENE.

October 11, 1:30 to 1:45 p.m., numerous slides S of Crack No. 46.

October 11, 4:15 p.m., slide under Crack No. 31.

October 12, 2:00 p.m., dust from slide E.

October 12, 3:50 p.m., dust from slide E.

October 15, 9:05 a.m., dust from large slide E: changes in walls E and NE.

October 15, 10:00 a.m., small slide in motion.

October 16, 9:44 a.m., noisy NE slide: new scar 200 feet below edge there.

October 17, 10:25 a.m., big avalanche NE: heavy sliding during forenoon measurement with continuous dribbling of rocks down wall.

October 17, 11:55 a.m., big avalanche NE.

October 18, 9:20 a.m., moderate slide E, starting 300 feet below edge.

October 19, 9:20 to 9:49 a.m., thirteen slides NE; of these one at 9:20 was moderate, those at 9:30 and 9:40 were noisy and started 150 to 400 feet below edge under Cracks Nos. 29 and 31.

October 20, 4:19 a.m., loud roar of slide.

October 20, 2:00 to 3:40 p.m., continuous dribble of rocks NE half-way down.

October 20, 2:40 p.m., moderate slide.

October 22, 5:54 a.m., the great avalanche.

October 22, 8:30 a.m. to 2:45 p.m., 18 slides listed, the larger ones at 8:55, 11:20, 11:30 a.m., and 2:05 p.m.

October 22, 5:00 p.m., large cloud of dust lasting 20 minutes.

October 23, 8:30 a.m. to afternoon, continuous rock falls, with occasional moderate slides. Slides diminished between 5:00 and 6:00 p.m.

October 26, 9:20 a.m., moderate slide ENE.

October 26, 9:24, 9:47, 9:49, 9:57, 10:00, 10:04, 10:09 and so on, showing intervals for this period between small or moderate slides.

October 27, 9:23 a.m., slide making dust cloud, followed by dribbling of rocks.

October 27, 10:00 a.m., moderate slide: followed by smaller ones 10:03, 10:11, 10:15 a.m., etc.

October 28, 9:33 a.m., slide making thick dust cloud.

October 31, 10:20 a.m., large slide near dyke NE.

November 1, 12:50 p.m., dust over pit: this period showed some tendency to increase of slides just after the noon hour.

Halemaumau Solfataras

Fume from the sulphurous vents from the floor was conspicuous during forenoon crack measurements October 17, but nothing during this period of avalanching indicated anything unusual about the fuming of the solfataric vents.

Measurement of Halemaumau Rim Cracks

Weekly measurement of the 32 marked rim crack localities, reduced to 27 after October 22, around the upper edge of Halemaumau Pit resulted as follows:

Week ending forenoon of:

October 10, 9 opened, 4 closed, aggregate opening 42.5 mm. No. 46 opened 24.0 mm. No. 31 opened 14.0 mm.

October 17, 7 opened, 2 closed, aggregate opening 93.0 mm. No. 46 opened 47.0 mm., No. 25 2.0 mm., No. 31 43.0 mm.

October 24, five cracks had gone. Of the remainder many of them not on the avalanching sector; 8 opened, 3 closed, aggregate opening 12.0 mm.

October 31, 8 opened, 3 closed, aggregate opening 26.0 mm. Cracks at E corner of pit partly opened, while others closed as the rim blocks tilted: No. 24 close to the rim closed 1.0 mm., No. 25 a little farther back opened 11.5 mm.; No. 28 in the same region closed 1.0 mm.; No. 45 farther north opened 7.0 mm.

T. A. J.

TOPOGRAPHIC DATA

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory on October 20, showed slight opening across the Crater and closing across Halemaumau as compared with similar measurements September 23. From Kilauea SE rim to Uwekahuna there was an opening of 0".5, September 23 to October 6 and an opening of 0".41, October 6 to October 20. Total opening—0".91. From the Pit Seismograph to the NW Pit Station there was an opening of 0".33, September 23 to October 6 and closing of 1".17 October 6 to 20. Total closing —0".84.

Spirit Leveling

Spirit levelling across Halemaumau from the Spit SE edge of Kilauea Crater to the NW Pit BM showed a lowering of the NW Pit BM with reference to the Spit of 6.4 centimeters between September 3 and October 23. H.H.W.

SEISMOLOGICAL DATA

EARTHQUAKES

Table

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Distant Earthquakes	Local* Seismicity
Oct. 11	26	3	0	0	0	8.00
Oct. 18	50	15	1	0	0	17.50
Oct. 25	134	7	0	1	1	39.00
Nov. 1	67	7	0	0	1	20.25

* For local seismicity definition, see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began recording at the times indicated and whenever possible, determinations of depth of focus have been made.

October 11, 4:05 am, very feeble, accompanying rock slide in Halemaumau.

October 11, 5:39 pm, very feeble, located 3.3 miles deep and 0.7 mile NW of Pit Seismograph Station. NW rim of Halemaumau. 19° 24' 8N; 155° 17' 3W.

October 12, 4:44 pm, very feeble, located 1.0 mile deep in Kilauea Crater, 0.6 mile SW of Volcano Observatory. 19° 25' 6N; 155° 16' 1W.

October 12, 4:59 pm, very feeble, of shallow focus SE portion of Kilauea Crater in immediate vicinity of Pit Seismograph.

October 14, 2:45 am, very feeble, 0.9 mile deep under fissures immediately W of Keanakakoi Crater. 19° 24' 1N; 155° 16' 3W.

October 15, 1:15 am, feeble, 2.3 miles deep under N rim of Kilauea Crater. 19° 26' 1N; 155° 16' 7W.

October 15, 8:15 am, very feeble, 3.5 miles deep and 1.0 mile SE of the Twin Craters. 19° 24' 5N; 155° 13' 7W.

October 15, 9:02 am, very feeble, 0.9 mile deep under fissures immediately W of Keanakakoi Crater. 19° 24' 1N; 155° 16' 3W.

October 15, 9:03 am, very feeble, probably located under Waldron Ledge E rim of Kilauea Crater.

October 15, 5:48 pm, very feeble, 1.1 miles deep under fissures 0.5 mile N of Puu Ohale. 19° 21' 8N; 155° 17' 3W. This quake was succeeded by one October 16, at 12:10 am and another at 6:41 am, both of latter very feeble and all three of same location.

October 16, 10:18 am, very feeble, 1.0 mile deep in E portion of Kilauea Crater adjacent to Kilauea Iki. 19° 24' 9N; 155° 15' 8W.

October 17, 5:17 pm, very feeble, 1.8 miles deep near Stone Corral, Kilauea Crater. 19° 24' 8N; 155° 16' 2W.

October 18, 7:15 pm, very feeble, 2.0 miles deep near center of Kilauea Crater, 1.2 miles SW of the Observatory. 19° 25' 1N; 155° 16' 4W.

October 19, 8:52 pm, very feeble, 1.4 miles deep under E rim of Kilauea Iki. 19° 25' 0N; 155° 14' 8W.

October 20, 4:19 am, very feeble, accompanying slide from NE rim and by roaring sound from Halemaumau heard on NE rim of Kilauea Crater.

October 21, 8:18 am, very feeble, 3.4 miles deep NW rim of Kilauea Crater 0.6 mile NE of Uwekahuna. 19° 25' 6N; 155° 17' 0W.

October 21, 5:53 am, very feeble, 5.0 miles deep near center of Kilauea Crater. 19° 25' 1N; 155° 16' 4W.

On October 22, at 5:54 am a slight earthquake occurred simultaneously with a large avalanche from the E and NE wall of Halemaumau. Lack of definite preliminary phases prevented exact location but a review of the seismograms from Halemaumau and Uwekahuna showed it to be of Kilauea origin and was possibly caused by the fall of the unusually large mass of material.

October 22, 8:55 am, very feeble, accompanying slide in Halemaumau.

October 29, 7:36 pm and 7:37 pm, very feeble, probably caused by slides in Halemaumau.

October 31, 6:11 am, very feeble, probably located in fissure zone immediately west of Keaankakoi Crater.

The preliminary waves of a distant earthquake began recording at 8h 02m 09s pm HST, October 22. It was located 2835 miles from Kilauea and was reported by radio to have occurred in Alaska. The preliminary waves of a teleseism began to register at 8h 18m 40.0s am HST, October 29. It occurred 3960 miles from Kilauea and reports indicated the location as the Marianas Trough south of the Island of Guam.

A period of harmonic tremor lasting twenty-two minutes began at 2:56 pm October 19.

Microseismic motion of the ground at Kilauea was strong October 25, moderate October 7, 11, 12, 13, 15, 16, 17, 21, 24, 26, 27, 29 and November 1, and was light the remainder of the month.

TILTING OF THE GROUND

The following table shows tilt by weeks from seismograms at the Volcano Observatory NE rim of Kilauea Crater and at Halemaumau, the algebraic sum of radial tilts for two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending November 1, was 4" 0N.

Table of Tilt

Week Ending	Observatory
October 11	0".00
October 18	0".35 S 15°E
October 25	0".89 N 78°E
November 1	0".38 S 77°E

	Halemaumau Clinoscope Stations		
	West	Southeast	Pit Resultant
Oct. 11	1".85 N 60°W	3".05 N 33°W	1".43 toward
Oct. 18	2".24 S 89°W	4".86 S 88°W	0".03 toward
Oct. 25	7".12 N 62°W	8".81 N 18°W	2".47 toward
Nov. 1	3".34 N 31°W	17".50 S 72°W	4".17 toward H.H.W.

THE VOLCANO LETTER

No. 441 monthly Department of the Interior National Park Service November 1936

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

Figure 1. "The line of people is like a concourse of fire worshippers. At the bottom is a pool of blood-red molten slag." Halemaumau September 6, 1934, 5 p.m. Photo, 11th Photo Section, A.C., Wheeler Field, T. H.

ERUPTION OF KILAUEA VOLCANO SEPTEMBER 1934

T. A. Jaggar

This will show first the dramatic aspects of such an eruption and its effect on people living in Hawaii. Then there will be presented the scientific data describing the phases of the eruption. Here are two broadcasts by the Honolulu Advertiser, the first September 10, for the Hawaiian Islands, from Hawaii National Park: the second September 11, in a thunderstorm on the actual edge of Halemaumau pit, a national broadcast that was heard distinctly by listeners from Canada to Mexico, along with the detonations of the lava bursts on the floor of the pit 800 feet below. The eruption had started in the very early morning of September 6.

"September 10, Volcano House. Tonight in presence of the fire-pit, with the glowing lava again gushing and pounding and shaking the seismographs, I am asked to tell you something of the scientific meaning of it.

"We have established here a very small observatory. The University is helping and has made some experiments with the blasts at Moiliili quarry. The Bishop Museum is studying all

the Polynesian islands. The plantations are trying to find more water underground, and want to prevent their soils from washing into the sea. The engineers were baffled by the ocean at Mala, when they found that steamers cannot tie up to the wharf.

"These volcano changes, and shakings, and the building of coral islands, and the movements of the waters, are forces either useful or antagonistic to ourselves. We use gasoline from the earth which fifty years ago was hardly dreamed of for anything but cleaning gloves. The earth is full of secrets like this new force of petroleum. Six miles from Kilauea in the Kau Desert, we can light a stick at a crack. Here is a mysterious volcanic force from the ground, where continuously for fourteen years just past, we could have boiled water for making steam at those cracks.

We know a lava-flow is coming out of Mauna Loa. Where and when? The answer is written on that big, round, formidable mountain, with its cracks and caverns and sulphur and fume.

"We feel sure that a lava flow of 1924 lies under the sea east of Hawaii. Nobody has yet tried to discover it by sounding. A clever exploration there, with sonic sounding, wire sounding, bottom sampling, experiments, would make one of the great mappings of science, and would set a new standard.

"There is a job for fifty trained men for fifty years in unravelling the tangles of sea and land that beset us right here in Hawaii. This science of the earth will take men away from the cities. That is what the science of forestry is doing in the great public works program. That is what the Tennessee power plant is doing. That is what Boulder Dam is doing.

"It is astonishing that people with power, people who can employ labor, people with imagination, people who want to make a name or honor a name, cannot see the vision of the earth, and all the wonders it will yield. They see visions of the stars, but they do not see visions of the earth.

"Here in the light of the fiery lava which has risen thirty miles through the crust of the earth, which makes earthquakes for our seismographs twenty miles underground, which pours out under the sea or spouts up colossally on top of Mauna Loa, ought we not to be reminded of earth power?

"An Institute of Earth Research at Hilo could make a name for its donor that would live forever if it discovered the source of that rock heat at Mauna Iki, and the use of the powers of the living earth.

"September 11, crater's edge. Smooth miles in a noiseless car through hibiscus and stately tree ferns and summer habitations of men. No trace of volcanoes or brimstone in all that Hawaiian loveliness. And then in a flash you come upon a smoking fire-hole.

"A thousand people at the active crater Kilauea in Hawaii are standing here, on the edge of a vast circular pit three quarters of a mile across. The line of motionless white faces, all turned towards the setting sun, is like a concourse of fire worshippers. Sulphur of the volcano is in their nostrils. All are looking down, over a ring of precipice 800 feet high.

"At the bottom is a pool of blood-red molten slag. Through it come bursting fountains, making slow surges outward of fiery melt. Away from the fountains radiate zigzag bright lines. They are brilliant orange color, they are cracks eternally splitting the dark crust.

"Between them is a pattern of watered silk, in the black satiny robe that clothes Pele' the fire goddess. This magnificent garment lies over a bowl of the earth's glowing substance, molten, glassy, basaltic foam.

"Before the outbreak, a week ago, there was a hard lava floor, black or rusty, with a conelet at one side. The conelet is nearly drowned. The whole floor was the top of a taper cork, over converging slopes of debris. The live lava beneath lifted the cork and tipped it, escaping violently at one side of the neck of the bottle crater. Along with it, it lifted an upright slab of the wall four hundred feet high, and the glowing stuff squirted up the crack behind the slab.

"The eruption was the result. It was a quiet, instantaneous and unexpected gushing, in the dark before dawn, September 6. The evening before, nothing. The week before, nothing. The month before, nothing. People woke up, rubbed their eyes at three a.m., saw a brilliant glow and a vast cloud at the big inner pit two miles away. No one is frightened. Everybody cheers in Hawaii. Pele' has come back!

"It was all arranged as though the tourist stand, on the southeast side of the fire-pit, had been laid out by Pele' herself. In twenty minutes people were standing there, within a thousand feet of the near side of the lava lake, and just where the President's car stood a month and a half ago. There was no danger, the air was clear, the tremendous fire fountains and cataracts were all on the opposite side, and so were the whirlwinds. The best photographs were all made right there.

"The most spectacular and unusual feature of this lava rising was what happened at the wall slab, an immense cascade of incandescent liquid rock. Ribbon cataracts four hundred feet high, about twenty-five of them side by side, along a horizontal crack nine hundred feet long, fell from half-way up the wall of the pit. The liquid coalesced into a Niagara of fire at the side of talus. These cascades stopped flowing about three hours after the beginning of the eruption.

"A short distance to the north, at the edge of the glowing lake, were brilliant jets squirting up as though from hose nozzles, and criss-crossing against another slide-rock slope. These were more noisy, with deep rumble, than any of the other phenomena of the eruption. This rumble is due to gases rushing and shakng the whole volcano.

"Still farther around out in the lake was a tremendous fountain, shooting up three hundred feet in huge ropy flings, which slopped down onto the surface of the lake. The lake itself was indescribably beautiful, a vast labyrinth of glowing cobweb pattern ever changing radial and concentric to the central fountain group. The fire surf pounds on the shore, and the shore itself changes in the course of a few days of activity. A beach rampart forms. Then as the lake rises, slabs of crust pile up higher and higher on this rampart. It is like an ocean barrier beach of big flakes of stone, only the sea is made of fireworks.

"The deep shaking was such that all our seismographic instruments were vibrating violently, in unison with the trembling of the fire goddess.

"One of these machines is an annunciator, which rings a bell in the room above. When on the second day of the eruption, the big fountain started banging away like a big gun, this bell would ring in the Observatory building. Every detonation two miles away completely announced itself, as though Pele' were pressing the button.

"The whirlwinds were set going by the very hot rush of gas on the side of the pit away from the people. A strong trade wind threw this into cyclonic motion. Fragments of pumice, red hot, were falling on the west floor of Kilauea the first day. Some of them were a foot long. The whirls merged together and swept up the gravel on the ground as though with a giant's broom. I walked through this region on the first morning, in the light of the glowing pit, in order to read the tilt-meter in our cellar on the west side. My assistant picked up a pumice fragment with enough glow inside to light his cigarette. Now and then we had to crouch down to keep from being blown over. The gas and flying sand were trying, but the mighty yellow clouds shooting up above us, full of light fragments that floated down, made a marvellous spectacle. And the great billows of cloud rolled away to leeward for fifty miles in a straight

battalion of brownish volutes, tinged with pink by the rising sun. Pele' had declared war!

"What does it all mean to science? Do you say? Eight eruptions in ten years have laid new layers of lava on the bottom of Halemaumau pit in Kilauea crater. The layers average about sixty feet each. The pit is now about 800 feet deep.

"We have three active volcanoes in Hawaii, Kilauea, Mauna Loa and Hualalai. Mauna Loa had an outflow to the sea and destroyed a village in 1926. It erupted gloriously at its summit crater last December, and the travellers visited it in airplanes. We had a steam-blast eruption from Kilauea in 1924, and probably a mighty lava-flow poured out under the ocean to the east, where the water is 18,000 feet deep. We had a great trembling and shaking, thousands of earthquakes in a few weeks, from the volcano Hualalai on the west side of Hawaii in 1929. Add these things to Kilauea and you get eleven events in ten years. Who shall say that the Goddess is dead?

"A lava flow is soon coming from Mauna Loa. The scientific observatory of Hawaii National Park has been accumulating records for twenty-two years. Hawaii is the most perfect natural laboratory in the world. Here new land is being made, wind and weather act upon it, ocean and rivers sweep down the rubbish, and under all the crust of the globe is lifted. The Observatory will measure everything for a century to come. The measurement of the living earth and its breathing is just as important to your state as to Hawaii. Volcanoes in the past erupted in the Carolinas, Virginia, Pennsylvania, New Jersey, New York—your Palisades are a mass of Hawaiian lava—and in Connecticut, Massachusetts and Nova Scotia. But here in Hawaii you can take the pulse and breath and temperature of new rock when it is a-borning, and when it is making earthquakes. All over the globe there is need for more explorers for the study of the living earth.

"And now, listen to the Fire Goddess Pele' herself in the throes of her birth-pangs, listen to the pounding of liquid lava, to the bursts of earth puffing, to the surging of the waves of molten rock on the shore, all carried to you on the wings of radio, 180,000 miles a second—"

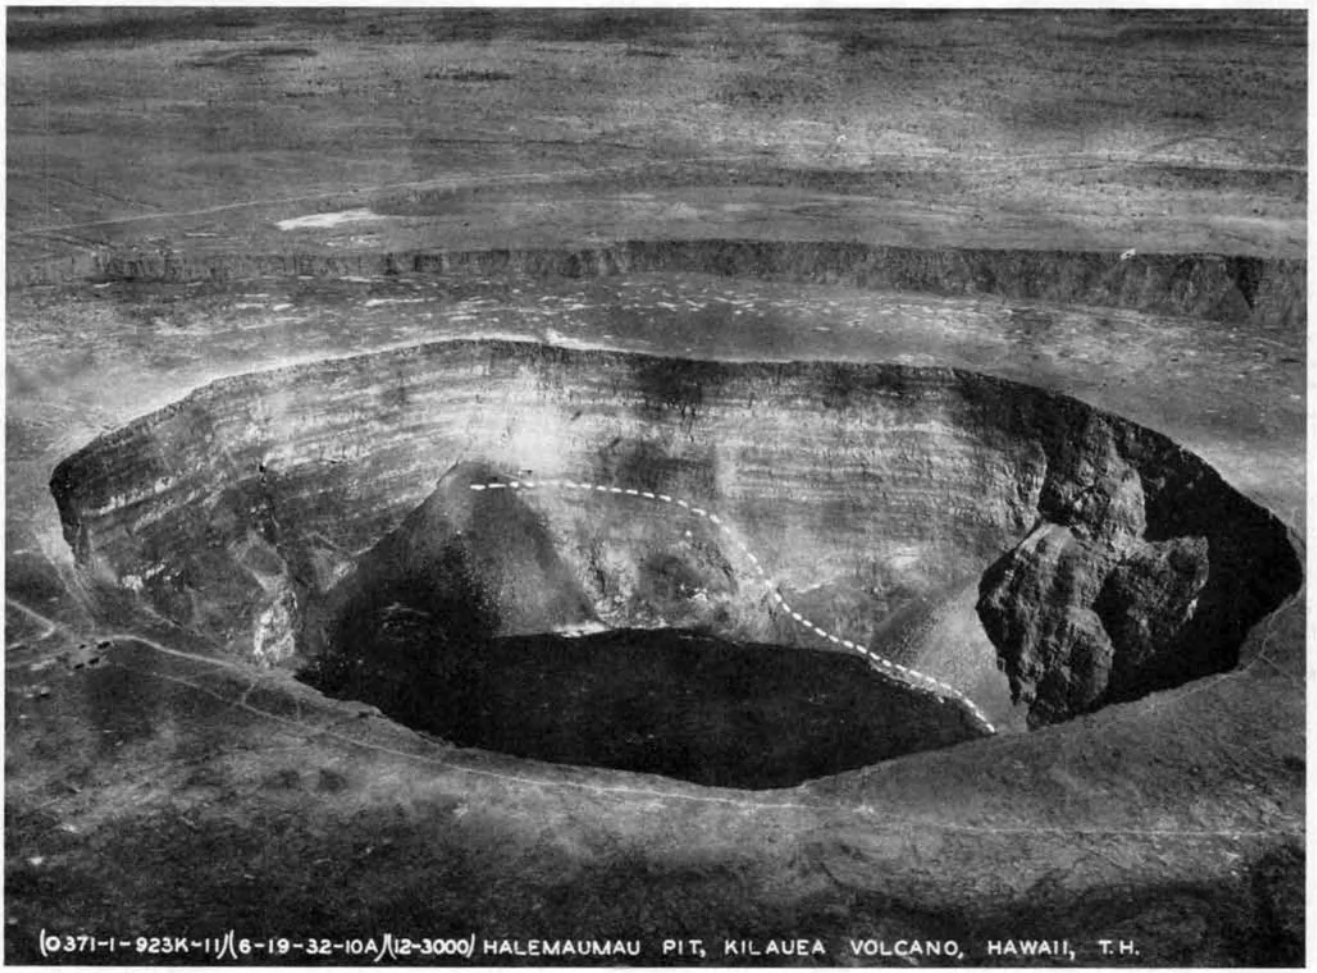


Figure 2. Halemaumau looking west from airplane June 19, 1932. Dotted line shows where the plug of 1931-32 lava lifted a wall slab to open the vent of 1934. Photo, 11th Photo Section, A.C., Luke Field, T. H.

ERUPTION OF KILAUEA VOLCANO, 1934

T. A. Jaggar

The seismic events in Hawaii that accompanied the outbreak of Mauna Loa in 1933 were reviewed by A. E. Jones in Journal Washington Academy Sciences for October 15, 1934, and those associated with the 1934 eruption of Kilauea in the number of October 15, 1935. In an earlier communication the writer has described and illustrated the 1933 eruption of Mauna Loa.

In Halemaumau pit there were slides before and after noon September 5, 1934, and the seimograph in a cellar near the southeast rim of the pit registered southwesterly tilt on the afternoon of this day. This was the first conspicuous premonitory symptom of the gushing up of lava in the bottom of the pit about 2:44 a.m. September 6.

Tremor spasms recorded seismometrically began at 1:07 a.m. and occured at intervals of a few minutes. Shocks close to the pit accompanied the outbreak, a feeble one at 2:44 a.m.

Figure 3. Halemaumau 4:30 a.m., September 6, 1934. Looking northwest, "twenty-five ribbon cataracts four hundred feet high, and brilliant jets squirting up below." Photo Maehara.

being followed by the continuous tremor which is characteristic of the rush of gas that accompanies fountaining. At the same time the bright glow of inpouring lava appeared, and clouds of fume arose. The fountaining places began at the edge of the lava floor at the bottom of Halemaumau on the north, northwest and west sides. The gush of gas bringing with it lava foam emerged through talus slopes at the first two places. The third was altogether different, and unique in the experience of the Observatory.

This was the gushing up of lava along an extensive fissure, forming a vertical crack back of a western buttress of the wall. The lava squirted up in 25 jets along a horizontal line half way up the wall of the pit. The frothy lava so ejected cascaded down the wall in ribbon cataracts. They poured over the large west talus between 3 a.m. and 6 a.m., and then went out of action. Ten main vents persisted until 6 a.m. along the cascade crack, the cascades being from 300 to 400 feet high, and there were two or three subordinate cascades, on an extension of the crack which opened on the northern side of the buttress. This buttress was in the nature of a fault slab, with the live dike fissure behind it. The wall of a pit of this kind is made up of several such imbricating fault blocks, produced by the caving away of the rim portions, and the leaving of a remnant buttress below. The vertical crack behind such a buttress is often not at all in evidence, and is frequently covered by talus.

The two photographs shown in Figures 3 and 4 are published by permission of K. Maehara for the night scene, and of the Eleventh Photo Section, Air Corps, Wheeler Field, U.S. Army, Territory of Hawaii, for the daylight view, which was made from an airplane. Both pictures were made from the southeastern side of the pit, the night scene about 4 a.m. September 6, while the cascades were in action, the daytime view at 9:30 a.m. September 7, the second day of the eruption, after the big western fountains had entirely ceased action. The two views show the contrast between the liquid flood of the first few hours of one of these pit eruptions, and the chilling around the borders which rapidly takes place afterward. The extraordinary feature of these photographs is the great western cascade. The upright fracture along the middle of the wall slope was 900 feet long and extended under the large west talus so that some of the fountains gushed through the talus along a horizontal belt, others poured over the rock buttress where there is an old intrusive body of irregular form, and still others cascaded out of the crack on the north side of the buttress, and it will be seen that the crack behind resisted the splitting effect for a quarter of its length. The most violent fountains were those at the northwest side of the pit shown at the right of the

night photograph. These were several hundred feet high, like jets from hose nozzles, covering the northwest wall and talus with pumiceous lava. The fragments of pumice were ejected several hundred feet above the rim of the pit the early morning of September 6, and fell in light spongy fragments as much as a foot long over the floor of Kilauea crater to the southwest. There was not much Pele's hair, but coarser needles of basaltic glass were common.

Phases of the Eruption

This eruption of Kilauea may be divided into four phases: (1) the large liquid pool of September 6; (2) the small lake heap and overflows which developed September 7 to 20; (3) border trickle flows from the wall-crack dike September 20 to 30 and (4) the period of subsidences, with detonations and intrusion from September 22 to October 8. These phases were more illuminating in revealing new explanations of some habits of Hawaiian lava, than anything which has happened here for many years.

Phase One: The Large Liquid Pool

This is the phase illustrated by the night photograph, and its decline is shown by the picture of September 7. Sulphurous fume of absinthe red color in transmitted light boiled up several thousand feet during the first 12 hours. The reflected fountain light was yellow-green to orange. The noise was a rumbling, and a rushing of gas, while hundreds of whirlwinds swept clouds of surface dust west and southwest of Halemaumau, and the odor was that of sulphur dioxide.

At 4 a.m. September 6 there were 30 jet fountains, and by 8 a.m. the new pool had covered the former floor 60 feet deep. Its area was 90 acres and its volume nine million cubic yards. Only the top of the 1933 border cone was still emergent. At noon the north fountains had dwindled, the northwestern ones were very violent, and the lava lake was covered with a bright-line pattern and black silky skins. A bench and rampart of crusts developed around the lake, wider at the talus slopes where the submerged slope was flatter. Between 3 and 4 p.m. the violent northwest fountaining stopped rather suddenly, and only thin blue fume was left rising from the north central fountains within the lake area itself.

Shrinkage of the lake now started in, so that by September 9 there was an inner lake 1100 feet in diameter surrounded by a floor which had shrunk and lowered beneath the border rampart 10 to 20 feet. The remnant lake was concentrating about the fountains at the NNE side of the floor. On all sides there was a slump scarp at the inner border of the rampart. The lake September 10 measured 1000 feet east-west by 400 feet north-south and became defined as an oval plateau on top of a terraced heap surrounded by a rim, over which went overflows. (See map). Within the lake spatter banks formed behind the two bigger fountains, showing that the lake was shallow, and that only the fountains were over source wells.

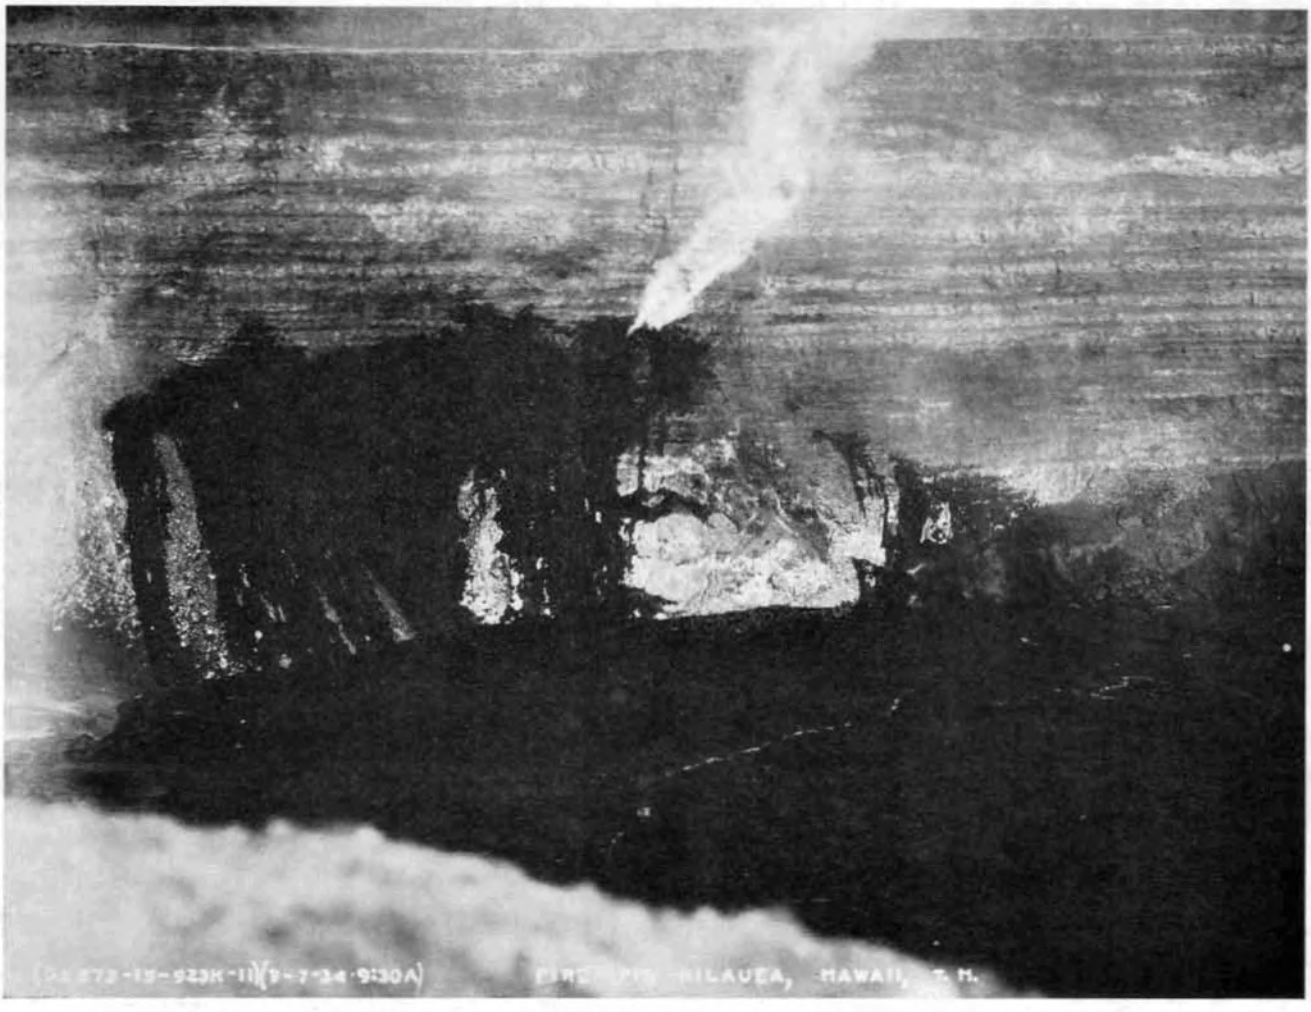

Figure 4. Halemaumau 9:30 a.m., September 7, 1934. Compare with Figures 2 and 3. Looking northwest. 11th Photo Section, A.C. Wheeler Field, T. H.

Phase Two: Small Lake Heap and Overflow

As early as September 7, temporary tremor increase rang the seismometric annunciator bell at the Observatory two miles

away. This meant that the larger fountain was making blast-like detonations, flinging up lava froth 300 feet, and emitting brown puffs. These detonations from the fountain wells increased as the vents clogged. September 15 there were five principal fountains, and a line of shoals across the lake. The reduced lake began to develop an interior topography, with a cone and crater around the large western fountain and nine other fountaining vents amid six islands and a peninsula.

By September 20 the floor measured 2700 by 2200 feet, and the lake oval was a detail within it at the north measuring 744 by 390 feet. The lake pool was on a heap 38 feet above the floor, and the highest grotto heap piled by the fountains stood 136 feet above the pre-eruption floor immediately under it. The average 1932 floor level was 2796 feet above sea-level, while the average 1934 new level was 2874 feet.

Overflows built up the new lake heap and 10 cracks developed in the outer floor radial to the lake, indicating that the lake heap was over a laccolithic swelling. Within the lake the streaming was from west fountains to east fountains, and sometimes the latter exhibited inward cascading downward. Evidently a convectional circulation was being established. Finally the sinkhole well tended to explode with detonations. Overflows were numerous from the lake so that it was being built up on a slag heap.

Phase Three: Lava Trickle up the Wall Crack

A new feature appeared September 20 around the extreme edges of the floor in the shape of a welling up of red lava, between the talus and the cake of 1934 fill, which constituted the floor. This was the first time any glowing lava had appeared from a source away from the fountaining wells. They began along the talus edges, but eventually extended to places where the floor made contact with the rock wall of the pit. In no case did they cascade over the slump scarp inward, but the lava rose as a dike between the floor cake and the containing funnel. The band of border extrusion was 20 feet wide in places, and it gradaully extended to all sides of the floor with the exception of the north edge that was closest to the lake. The marginal extrusion was always simultaneous with extra pressure at the lake, accompanied by overflow. It was evident that intrusive action was going on under the floor. Transit surveys in the course of the eruptive period showed that the outer floor rose, and the lake area gradually lost its relief.

Phase Four: Subsidence with Detonations

Detonation spells from both east and west wells, which had built cones within the lake, recurred from time to time during September 22. This usually happened when the east fountain had been transformed into a sinkhole grotto at the level of the lake, big bursts of gas and flame came up, and downpouring would last from 10 to 20 minutes. Then the pot would resume ordinary fountaining with outward flowing streams. During the detonation spells, tremor increased at the seismographs. By September 23 the west fountain had become a pool in a raised craterlet, from which a cascade poured into the lake. This craterlet also made noisy explosions, and four avalanches were noticed at the north wall of the pit close by.

About 2 p.m. September 23 the lake drained away through the eastern sinkhole leaving a saucer 20 feet deep, and then the liquid poured in again. These drainages increased in duration until October 1. Their violence also increased, they lasted from half an hour to two hours, and the intervals between them were notably about six hours. The detonations were finally heard three miles away.

It now appeared that the whole floor was swelling by intrusion, and a concentric ridge around the edge of the floor replaced the former slump scarp. Apparently the pulsations of lowering the lake basin were occasioned by inflow of the liquid under the shell of floor crust. The floor was lifted and the lake area went down. Gradually they were brought to a common level. The explosions were due to clogging of the gases in the increasingly viscous lava of the wells, and to the confinement of a small shaft. Failing to overflow the wells became gun-barrels. With each detonation an umbrella-shaped fling of stiff lava would shoot up, sometimes 400 feet, the roofs of the grottos would be blown to pieces, and fragments would clatter down all over the surrounding surfaces. Toward the end the explosive spells would be followed by complete quiet for a half hour. Then the liquid would quietly recover in the wells and restore the lake to a period of four or five hours of quiet streaming.

The detail of a sinking spell was as follows: At 9 a.m. the west fountain cone was cascading over its flank; at 11 a.m. the lake saucer was 25 feet deep, with shoals on its bottom, and both east and west wells were cannonading vertically, long squirts of viscous melt were sent up 200 feet or more, the intervals between detonations or hisses were from 5 to 10 seconds. The lava pooled in the wells and came back with quiet fountaining just after noon. The explosions gradually lessened, a fan-shaped flow on the lake bed from the west fountain encountered an expanding puddle from the east fountain in mid-lake, and the entire body of new liquid overrode the foundered crusts that formed the floor of the lake.

September 28 and 29, and again on October 1 occurred the last overflows of the lake margin. The extraordinary intrusion ridge at the edge of the floor at the foot of the east talus had become 25 feet high, crevassed along its crest, and the floor on the inner side of this ridge, which had been 15 feet below the slump scarp around the margins, was now 25 feet above it. The actual lift of the floor therefore, above its slumped position of three weeks before was of the order of 40 feet.

The lake area was gradually converted into several ponds. By October 3 three quarters of the lake basin had become a slag heap, with the northern pool a depression in its flank 300 feet long. There were evidently tunnels leading from the cone pots to the lakes. Several pots had developed and these became smoke holes. October 5 the lake area had collapsed, blowing noise was audible and some streaming was still visible. Thudding noise was heard in the western part of the swelling floor, and prolonged slides at the north wall of the pit showed that slumping of the lake area was in progress. The eruption ended October 8 and subsequent shrinkage caused numerous slides from the pit walls.

Level Changes

From time to time the Observatory runs levels from a bench mark on the gravel spit south of Kilauea crater as a base, so as to close a circuit around the rim of Halemaumau pit. After the eruption, October 17-25, A. E. Jones ran such a leveling circuit to discover changes since July 2, 1934. Treating "Spit" bench mark as stationary, results showed a stretch of the north rim of Halemaumau 1800 feet long to show positive elevation to a maximum of 1.28 feet; along 1000 feet of the rim on each side of the elevated tract, negative elevation to a maximum of 0.5 foot occurred northwest and northeast of Halemaumau. The remainder of the rim showed diminishing depression southward to a line of no change 400 feet SSE from the pit.

It should be observed that the north tilt cellar near the pit rim was much less disturbed by the eruption than the two other cellars southeast and west, as though the north were comparatively rigid ground. The rift belt of the mountain crosses the pit from southwest to northeast. The bench mark "Spit" lies within an old graben fault block on the side of downthrow relative to the north side of the rift belt. It seems likely that the evacuation of magma produced by the eruption undermined this fault block, that the northern country remained relatively stable, and that what is really represented by the level change

Figure 5. Halemaumau from Observatory September 6, 1934. Heavy fume column over lava fountains. Photo Jaggar.

is a lowering of the bench mark, rather than an elevation of the northern pit rim.

Hawaiian Volcano Observatory Report for November 1936

VOLCANOLOGY

The month of November at Halemaumau Pit of Kilauea Volcano continued the slides from the walls which have been so conspicuous of late.

The following is the abridged table of movements:

Week Ending	Seismicity	Number of Slides	Aggregate Crack Opening
November 8	15.50	20	518.5 mm.
November 15	19.75	14	20.0 mm.
November 22	11.75	14	5.5 mm.
November 29	7.50	16	0.5 mm.

Sequence of Events by Weeks

The first week slides and cracking of the NE rim continued with more debris added to the talus slopes, and much breaking of rim ground. Crack No. 34, a chasm close to the cliff edge, opened 501 mm.; this accounting for the excessive value above.

The second week kept up these processes, with a marked tendency to continuous dribbling of rocks down the E and NE walls about the noon hour.

The NE surveying station monument, the third week, was left unstable at the extreme edge of pit, undermined by slides.

The fourth week showed a change of habit, with much lower seismicity, much **closing** of cracks, so as to make the lowest record of weekly crack opening since September 20, 1935, and uplift instead of sinking for the levelling measurements of Kilauea floor at Halemaumau pit rim. The slides extended their operations to the north wall of the pit.

Slides at Halemaumau

Slides from the wall of the pit have been noted as follows, but these are only a part of what actually occurred:

November 2, 10:00 am., continuous sliding NE wall 12 to 1:30 p.m., dust from slides until 3:00 p.m., continuing slides N and NE.

November 3, 9:42 and 9:53 a.m., small slides.

November 5, 9:00, 9:40, 10:15 a.m., moderate slides. 9:55 a.m., small slide. 11:53 a.m., 12:55 p.m., slides. 2:20 p.m., 3:36 p.m., large slides NE station. 1:30, 5:00 p.m., continuous sliding. 3:18 p.m., earthquake rang No. 1 Annunciator Bell, dust cloud at pit NE. 3:46 p.m., No. 1 Bell again, dust continues. Below Crack No. 34, 200 feet, a dark spot in the wall was caving away.

November 6, 9:22, 9:30 a.m., moderate slides NE.

November 10, 9:02 a.m., a large slide had left a scar, and small rocks dribbled down the wall E, sending up light dust. 9:37 a.m., moderate slide NE, 100 feet below Crack No. 34. 9:51 a.m., large slide ENE.

November 11, 9:54 a.m., small slide sending up light dust E. The Volcano House trail near the pit ENE had now lost 100 feet of length by caving in, a new notch here indented the edge of the pit, and fresh cracks farther back had started to open.

November 12, 10 to 11 a.m., rocks falling continuously from E wall.

November 13, 8:50 a.m., rocks dribbling down wall. 11:55 a.m., 12:40 p.m., moderate slides send up dust.

November 14, 10:15 a.m., moderate slide E. 11:16 a.m., big noisy slide E.

November 15, 9:24 a.m., 9:55 a.m., moderate slides ENE with small slides in interim.

November 16, 9:45 a.m., moderate slide NE. 9:50 a.m., larger slide ENE, preceded for 15 minutes by dribbling stones. Slides during day undermining NNE wall and removing 100 feet of edge east of NE station.

November 17, 9:56 a.m., rocks dribbling at new scar NNE.

November 19, 10:12 a.m., rocks dribbling NNE.

November 21, 9:25 a.m., dust NE wall. 9:46 a.m., continuous small sliding ENE. 9:54 a.m., 10:17 a.m., moderate slides NE and ENE.

November 24, 9:00 a.m., NE dust cloud. 9:45, 9:47 a.m., small slides ENE. 9:50 a.m., large dust cloud. 10:15 a.m., moderate slide ENE and dust cloud under NE station. 10:22 a.m., large slide there leaving scar. 10:30 a.m., 10:45 a.m., large dust clouds N. 11:15 a.m., large dust cloud ENE. 2:50 p.m., dust cloud NE station. 4:00 p.m., moderate slide 400 feet west of NE station. 4:10 p.m., large slide same place. 3:00 to 4:00 p.m., continuous falling of rocks there, which ceased after the large slide.

November 25, 10:55 a.m., noise of moderate slide heard, followed by continuous dribble on wall 300 feet W of NE station.

November 27, 11:15 a.m., dust from slide NE.

Halemaumau Solfataras

Fume of bluish color continued to rise at the edge of floor of pit NW and SE. On November 13 it appeared dense at 8:50 a.m., and thinner at 9:40 a.m. It was reported "not conspicuous" the third week.

On November 19 a fresh slide was reported to have left a scar in the SE corner of Hiiaka Crater in the Chain of Craters east of Kilauea.

Measurement of Halemaumau Rim Cracks

Weekly measurement of 27 marked rim-crack localities, reduced to 26 the third week, resulted as follows. Some time before November 21 possibly during the earthquake of November 16, sliding carried away the southern ledge of Crack No. 34.

Week ending forenoon of:

November 7, 11 opened, 1 closed, aggregate opening 518.5 mm.

November 14, 9 opened, 2 closed, aggregate opening 20.0 mm.

November 21, 9 opened, 1 closed, aggregate opening 5.5 mm.

November 28, 6 opened, 8 closed, aggregate opening 0.5 mm.

Crack No. 34 on November 7 was found yawning excessively and collapsed in the middle of the month. It is a chasm over the NE extension of the Kau Desert rift which crosses Halemaumau. Omitting it the general opening November 7 was 17.5 mm.; No. 17 opened 2.5, No. 25 8.0, and No. 45 2.0 mm. No. 17 is SSE, the others E (See map of pit, rim figures).

On November 14, the opening of cracks was in gradations to a maximum of 9.0 mm. at No. 28, where the edge had broken back the most. No. 34 NE opened only 2.0 mm., in contrast to November 17, when it opened 510 mm.

November 21, the destruction of No. 34 over the deep rift made the sixth marked crack on the rim destroyed within a month. The rift belt crosses the pit (see map) from SW Pit Station to NE Pit Station.

SEISMOLOGICAL DATA

EARTHQUAKES

Table

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Distant† Earthquakes	Local* Seismicity
Nov. 8	22	15	1	0	2	15.50
Nov. 15	65	7	0	0	2	19.75
Nov. 22	21	8	0	1	0	11.75
Nov. 29	12	9	0	0	1	7.50

† Includes teleseisms or those shocks over 5000 kilometers distant.

* For local seismicity definition, see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began recording at the times indicated and whenever possible, determinations of depth of focus have been made.

November 3, 5:28 pm, very feeble, located in fissure zone 0.5 mile NE of Ahua Kamokukolau and 2.4 miles deep. 19° 23' 1N; 155° 17' 2W.

November 5, 3:18 pm, very feeble, in Kilauea SW Rift Zone near the Kamakaia Hills and 16.0 miles deep. 19° 19' 5N; 155° 21' 0W.

November 5, 11:26 pm, very feeble, probable location, Mauna Loa NE rift about 18 miles SW of Hilo.

November 7, 1:43 pm, very feeble, 1.8 miles deep and 0.6 mile N of Kalanaokuaiki Pali. 19° 21' 7N; 155° 15' 3W.

November 7, 2:19 pm, very feeble, 3.3 miles deep, 2.0 miles S of Halemaumau and 1.4 miles W of Ahua Kamokukolau. 19° 22' 8N; 155° 17' 4W.

November 7, 3:47 pm, feeble, located 4.8 miles deep and 0.6 mile E of Keanakakoi Crater. 19° 24' 3N; 155° 15' 4W.

November 12, 4:25 am, very feeble, located near center of Kilauea and of shallow depth.

November 16, 1:44 am, very feeble, located 1.0 mile NW of Kilauea Military Camp and 4.0 miles deep. 19° 27' 1N; 155° 17' 0W.

November 16, 4:42 am, very feeble, located 4.2 miles deep in vicinity of Kilauea Military Camp. 19° 26' 3N; 155° 16' 2W.

November 16, 8:33 am, very feeble, 1.0 mile deep under NE edge of Kilauea Crater. 19° 26' 0N; 155° 16' 2W.

November 16, 8:36 am, very feeble, 0.9 mile deep under western portion of Kilauea Iki. 19° 25' 1N; 155° 15' 2W.

November 16, 10:14 am, very feeble, 5.0 miles deep in Kilauea Crater adjacent E edge of Halemaumau. 19° 24' 7N; 155° 16' 9W.

November 16, at 1:08 pm a slight to moderate earthquake registered on all the Observatory seismographs. It was located immediately to the SE of Kilauea Iki Crater, 1.4 miles E of Byron Ledge E rim of Kilauea Crater. Reports indicated that it was felt slightly by many people in Hilo. The shock was felt by a few in the Kilauea Area and very strongly in the vicinity of Puu Koae on the Kau Desert SW of Kilauea Crater. 19° 24' 8N; 155° 14' 4W.

November 16, 5:11 pm, very feeble, 4.8 miles deep near juncture of Pali Lele o Kalihipao and Kalanaokuaiki Pali. 19° 21' 1N; 155° 16' 0W.

November 16, 5:52 pm, very feeble, 0.4 mile N of N edge of Kilauea Iki, 3.5 miles deep. 19° 25' 5N; 155° 14' 9W.

November 16, 7:36 pm, very feeble, located 3.4 miles deep under E portion of Kilauea Iki. 19° 24' 9N; 155° 14' 7W.

November 18, 1:51 pm, very feeble, located 9.0 miles deep and 5.0 miles E of Mauna Loa Summit Crater.

November 23, 5:48 am, very feeble, probably located in the vicinity of Ahua Kamokukolau, 2.0 miles SE of Halemaumau.

November 25, 1:02 pm, very feeble, probable location under center portion of Kilauea Crater.

November 27, 9:39 am, very feeble, probably located under SE rim of Kilauea Crater.

November 28, 10:06 am, very feeble, probably located in fissure zone 1.3 miles SE of Ahua Kamokukolau.

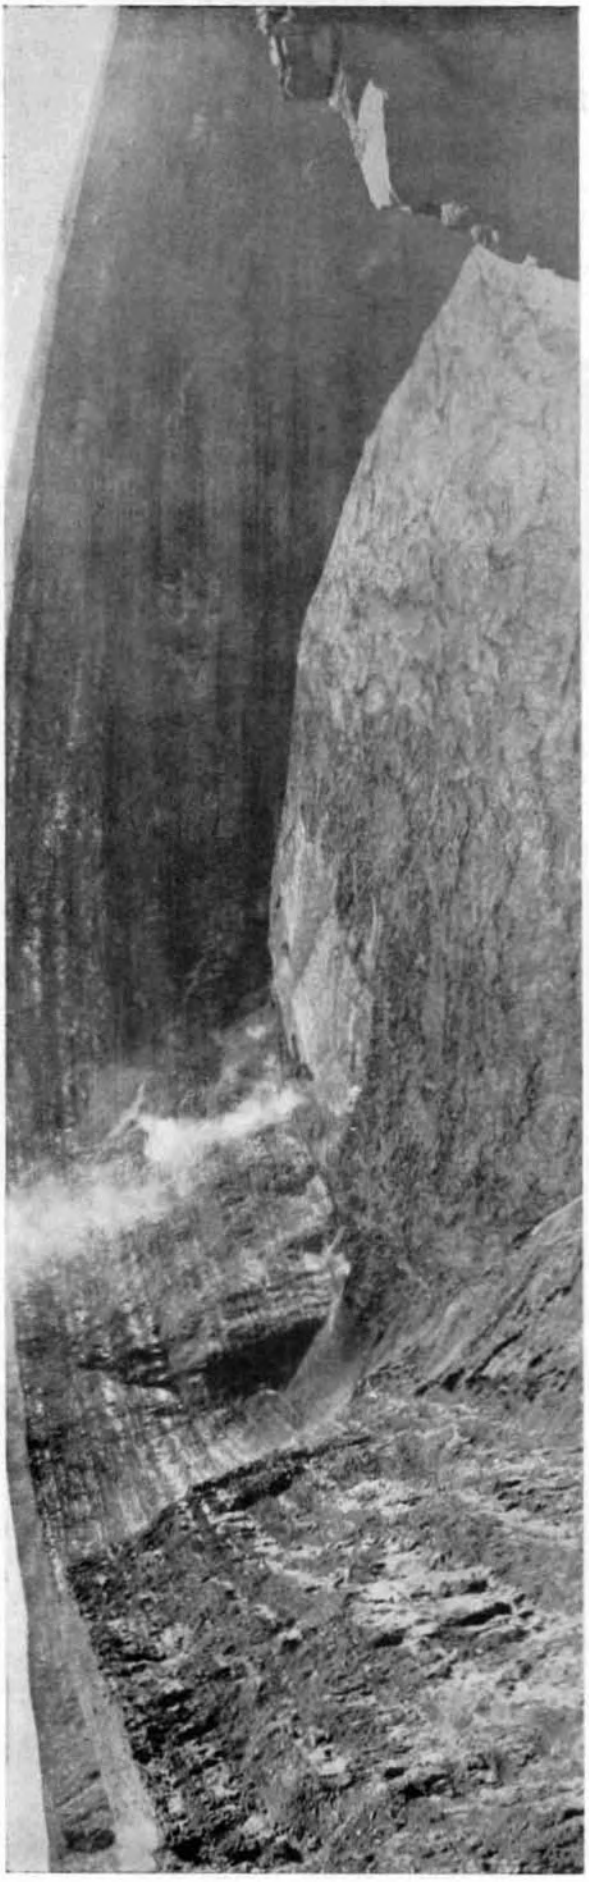

Figure 6. Halemaumau looking NE September 13, 1934, when the inner lake had formed at the top of a heap. Photo Jaggar.

The following very feeble earthquakes occurred simultaneously with, and are probably associated with rock slides from the E, NE or N walls of Halemaumau. November 5, at 2:03, 2:20, 2:28, 3:36, 4:40, 4:41 and 4:49 pm.

November 14, at 11:13 and 11:17 am.

November 24, at 2:13 and 4:08 pm.

Periods of continuous (harmonic) tremor registered during the month as follows: beginning at 5:41 am November 5, six (6) minutes; 6:54 pm, November 13, twenty-eight (28) minutes.

Microseismic motion of the ground at Kilauea was light November 4, 13 and 28; strong November 8, 9, 14 to 21 inclusive and 24; the remainder of the month it was moderate.

Teleseisms or Distant Earthquakes began registering on the Observatory seismograph as follows: November 2, the preliminary (P) waves at 4h 36m 39s H.S.T., thought to be located near Guam, 3485 miles from Kilauea. November 2, (P) waves at 10h 25m 48s H.S.T., 3850 miles from Kilauea, reported location off the coast of Honshu west edge of Japan Trough 38° N; 142° E (U.S.C.G.S.). November 12, (P) waves at 9h 43m 51s H.S.T., 3905 miles from Kilauea. November 13, (P) waves at 2h 10m 11s H.S.T., 3305 miles from Kilauea, reported location near Kamchatka Peninsula N of Japan Trough 57° N; 164° E (U.S.C.G.S.). November 25, (P) waves at 10h 10m 50s H.S.T., 2200 miles distant from the Volcano Observatory. November 28, Secondary waves (transverse) at 8h 21m 45s probably associated with news reports of disturbances in Alaska.

H. H. W.

TILTING OF THE GROUND

The following table shows tilt by weeks from seismograms at the Volcano Observatory NE rim of Kilauea Crater and at Halemaumau, the algebraic sum of radial tilts for two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending November 29, was 4" 85N and 3" 66W.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
November 8	1".90 N 30°E	1".82 S 35°W
November 15	1".18 S 70°W	2".59 N 38°W
November 22	0".50 N 12°W	5".78 N 88°W
November 29	0".33 S 61°W	5".22 S 52°W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
November 8	4".92 N 17°W	3".'50 toward
November 15	1".20 S 69°E	1".86 from
November 22	6".67 N 16°W	0".35 toward
November 29	5".12 N 19°W	3".39 toward

Crater Angles

Measurement of Horizontal Angles across Kilauea Crater from the Observatory November 23, showed closing across the Crater and slight opening across Halemaumau as compared with similar measurements October 20. From Kilauea SE rim to Uwekahuna there was closing 2".75, October 20 to November 2; closing of 0".66, November 2 to 13 and opening of 1".00, November 13 to 23. Total Closing 2".42. From the Pit Seismograph to the NW Pit B.M. there was opening 0".25, October 25 to November 2; closing of 0".58, November 2 to November 13 and opening of 0".67, November 13 to November 23. Total opening 0".34.

Spirit Levelling

Spirit levelling across Halemaumau from the Spit, SE edge of Kilauea Crater to the NW Pit B.M. showed elevation of the NW Pit B.M. with reference to the Spit of 6.4 centimeters. This is the first indication of elevation since before the 1934 eruption of Kilauea. H. H. W.

THE BOMBING OF MAUNA LOA, 1935*

T. A. Jaggar

Summit crater lava eruptions of Mauna Loa are always followed eventually by a breaking open of the mountain flank and emission of lava there. Mauna Loa crater filled with 100 feet of fresh lava December 2-18, 1933, and on March 26, 1934, the following statements were published: (1) A lava flow is expected within two years; (2) It should come at the north; (3) A likely direction is toward Hilo; (4) Several earthquakes, or one severe earthquake, may happen at Hilo.

Eight earthquakes came, one about every three months, close to equinox and solstice, some of them alarming shocks in Hilo. They occurred throughout the two years, and this relieved the city from any single cataclysm.

The lava flows came on the north side of the mountain, November 21, 1935. The near-summit gushing of fume, from the new rift which ejected the lava, continued into March. The

* Reprinted from the July-August 1936 issue of The Military Engineer, The Mills Building, Washington, D. C.

prolonged flow, which developed a vitreous cover, moved crookedly north, then, on December 22, bent east toward Hilo after pooling in the saddle between Mauna Loa and Mauna Kea. It was about 15 miles long including its meanders, and had 20 miles more to go to reach Hilo.

Expectancy and Policy for Emergencies

Apart from earthquake probability, above noted, the Hawaiian Volcano Observatory has experimented with preparation for emergencies for many years. The work is based on statistics and has been useful in many eruptions. Hilo is organized through its police and Red Cross systems, and these have the collaboration of the National Guard and the American Legion. A Conference of the Associated Engineers of Hawaii on January 16, 1918, was advised of the exact facts concerning Hawaiian volcanic blasts and lava flows, earthquakes and tidal waves. A Conference of the Chamber of Commerce, June 9, 1931, was advised of the Napier, New Zealand, unpreparedness. Organizations for discipline, communication, rescue, relief, funds, refugees, and rebuilding were considered.

Hilo understands that it is committed to future lava flows. The Volcanologist in the 1931 address stated: "A vitreous lava, flowing under crust in tunnels, but doing damage on lower mountain slopes, could be blown up at the source tunnel about the 9,000-foot level. This would open the tunnel, dam the lava stream with rocks, and force it to flow anew out of the blocked tunnel and channel over the surface of the upper country by a changed course. If the previous flow took 5 months to get near Hilo, the renewed flow 30 miles up the mountain would require as much, and the city would be given 5 months' respite."

The Crisis of December 22, 1935

The map shows the relation of the 1935 flow areas to earlier flows of definite years. The expectancy of a north flow was based on the succession of south flank outflows from 1868 to 1926, moving progressively up the mountain along the southwestern rift belt. The belt crosses the summit. Each flow on cooling seals the rift at its orifices. The next flow after 1933 was expected across the summit, and it so happened.

The expectation that 1935 would be the year was based on average intervals and past history. The expectation of northern earthquakes was based on a southward crossing of the summit in 1868 and southern earthquakes therewith. If there were a northward crossing of the summit now, northern earthquakes might be expected to accompany the rupture of the north rift. The likelihood of advance towards Hilo was based on the precedents of 1852, 1855, and 1881.

Without recounting all the detail of the 1935 eruption, it may be said that the first rapid flows, between November 21 and November 26, from a near-summit source, swept 8 miles northward and stopped. The loss of gas, heat, and energy of emission was very rapid the first day. The clinker slag cools from below upward, releases fixed gases that react exothermally to heat the top surface, and the stirring crystallizes the melt so that solidification is by crystalline frosting or sprouting. The Hawaiian name of this clinker lava is **aa** (pronounced ah-ah). The sprouts break up into boulders during viscous flow.

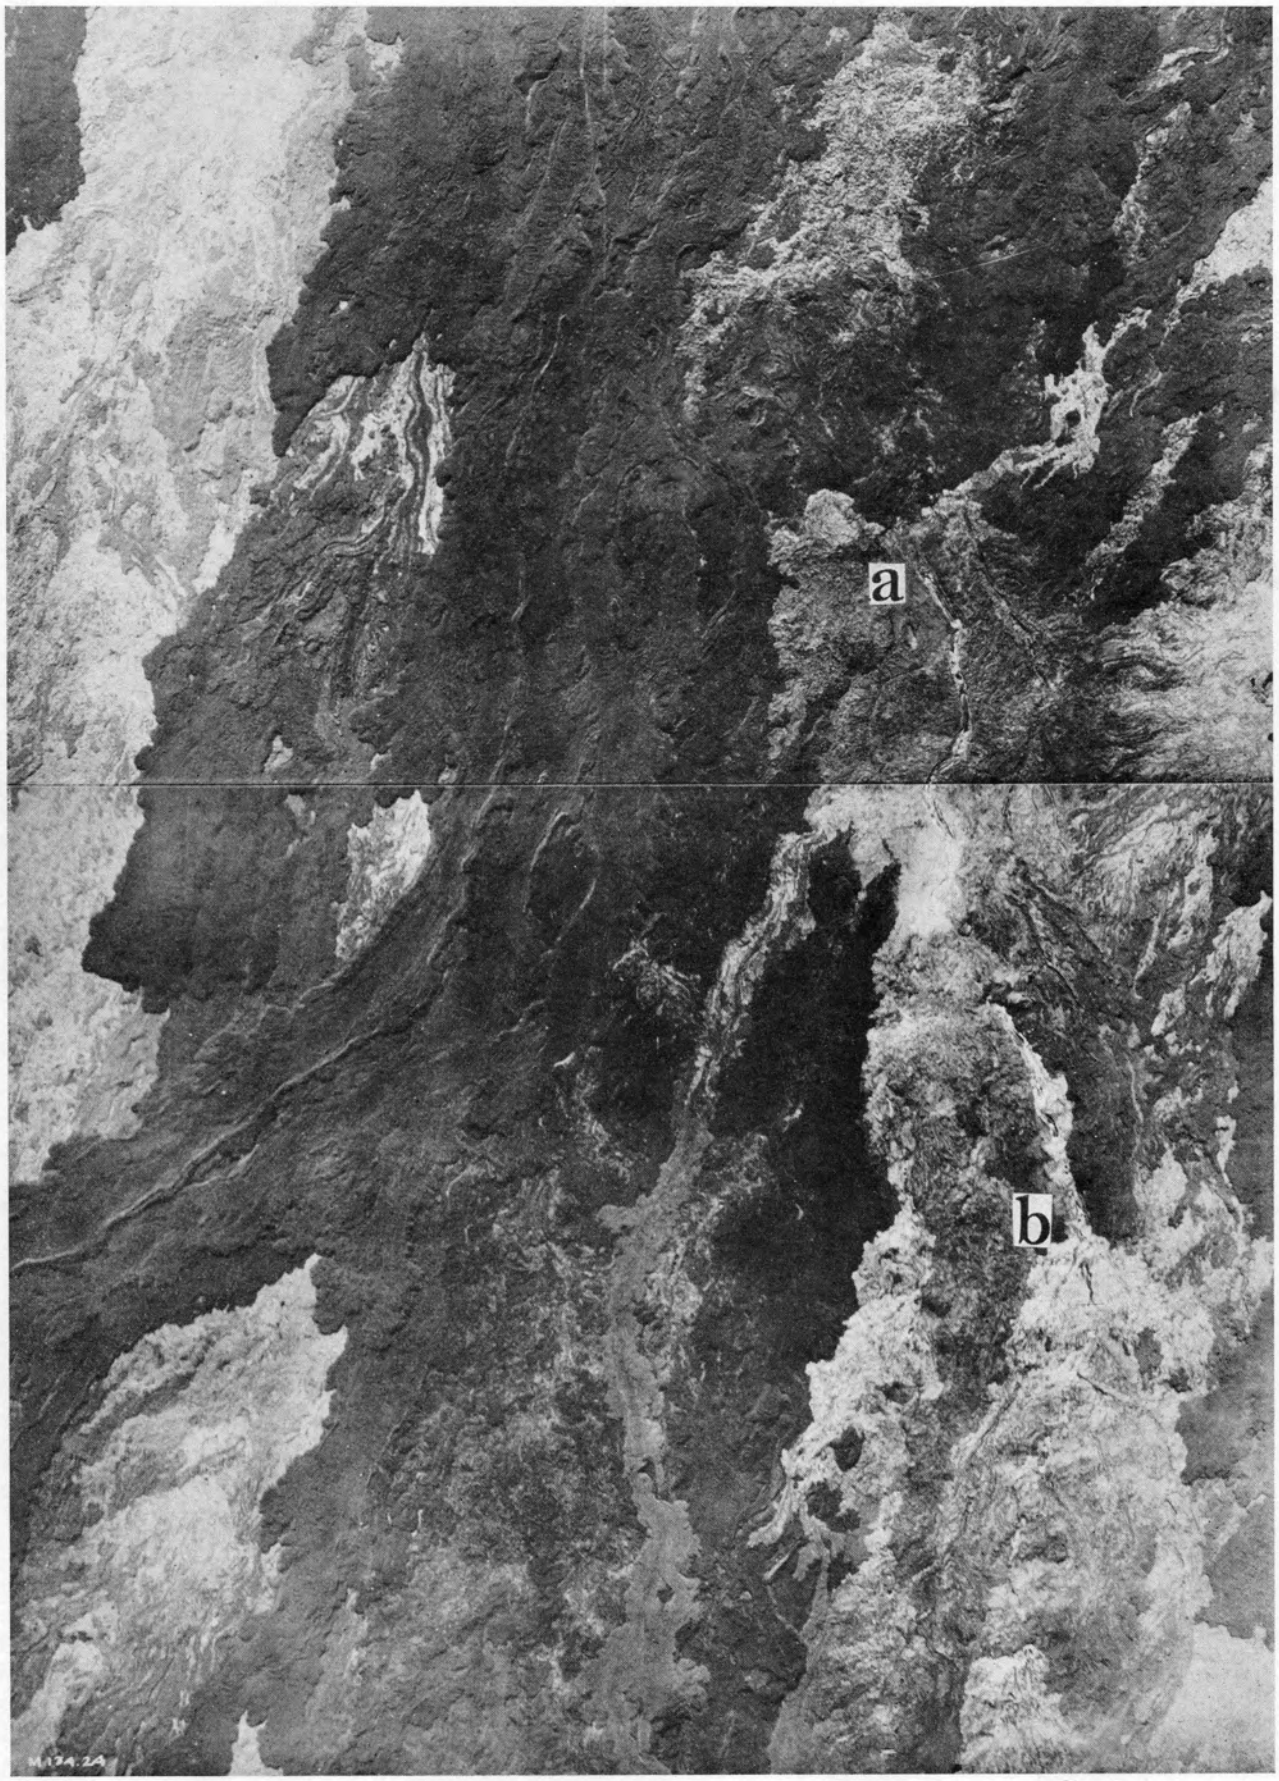
Beginning November 27, an entirely new flow vent appeared. This was 4,000 feet below the summit and 10 miles northeast from the top of Mauna Loa. An ancient tunnel or fissure was opened underground to drain the central well. From this orifice a new clinker-lava stream poured north toward Mauna Kea, between the 1899 and 1843 flows. The near-summit vent of the first outbreak clogged itself, and became noisy with gas bursts and viscous blobs. Then its lava subsided into the shaft, clouds of yellow smoke puffed up, and sulphur was deposited on the conelet. This upper vent was at about 12,000 feet elevation. The new lower vent was at 9,000 feet.

It was this lower flow that turned towards Hilo on December 22. Before that date there was doubt. The lava pooled in the saddle. It might have drained westward into waste lands, but the 1843 flow blocked it and it turned eastward a mile a day into valuable pastures, steeply sloping into the well-watered drainage of Wailuku River. This is part of the Hilo water supply. By December 26 it had flowed 5 miles of the 20 that would put it into Hilo.

During the month the lava had changed its character from clinker lava to vitreous, or glassy-skinned, lava. This the Hawaiians call **pahoehoe** (pah-hoy-hoy). It is exactly the same chemically as clinker lava, but is totally different physically. With less of stirred "sugaring," the glass may rise to the top of basaltic melt. It forms a gas-tight skin. The gas-making slag then pours onward under a heat-insulating crust of thickening membranes. This is the "ropy lava" of geology. It is silvery, smooth and vesicular, and unlike the clinker type, it cools and solidifies from the surface downward. The skins, ever reforming over bulbous toes which push down the hill, confine the heat and create a mechanism of tunnels. There is a single tunnel near the source, and there are distributary tunnels at the fronts. It is this vitreous-coated lava which may hold its heat and push forward for 40 miles. It is in sensitive equilibrium isothermally to its own evolution of self-heating gas bubbles, to the chill of the air, to the pressure on its pipe walls, and to the source pressure, which is both hydrostatic and effervescent—that is, the lava from inside the mountain is really a glassy foam.

The point of all this is that if the single source tunnel is broken open, a pressure-temperature adjustment of gas-in-slag is destroyed. Not only does this let the higher fluid escape and rob the lower distributary frontal tunnels, but also it lets loose the gas and heat, and solidifies the fluid **back into the source vent.** A lava filled shaft, after a month of violent release, is no longer a resistless mountain-breaker. The weight of the mountain and the cooling have reasserted themselves as dominant.

The Army Called In



Monday morning, December 23, the Volcanologist, Dr. T. A. Jaggar, consulted Maj. Hugh C. Gilchrist, commanding Kilauea Military Camp. Before that time bombing would have been dangerous, for it might have diverted the flow **toward** Hilo, but now the flow was definitely headed thither. Major Gilchrist sent a radio at once to the Chief of Staff, Col. Daniel Van Voorhis. The Commanding General, Hawaiian Department, sent a plane from Honolulu with three officers of the bombing squadron that afternoon to inspect the lava flow area. At noon the next day a conference was held in Hilo with Col. Delos C. Emmons, Department Air Officer; Lieut. Col. V. L. Peterson, Department Engineer; Capt. J. J. Ladd, bombing officer; Lieut. J. W. Cox, Third Engineers; Lieut. B. J. Webster; Major Gilchrist; Mr. Stanley Elmore, President of Hilo Chamber of Commerce; Superintendent E. G. Wingate of Hawaii National Park; and the Volcanologist.

Col. Delos C. Emmons, Air Officer of the Hawaiian Department, reported that he and Lieut. Col. Virgil L. Peterson, Corps of Engineers, examined the lava flow from the air December 24 and held the conference above recorded with the Volcanologist, and with other officials. They jointly reported:

a. That lava flow actually threatened the headwaters of Wailuku River, which provides water to Hilo. There also seemed to be a possibility that this flow might endanger the city of Hilo with its valuable harbor.

b. That public opinion demanded that something be done to divert or stop this lava flow.

c. We recommend that twenty 600-pound bombs be dropped in an effort to divert the lava flow.

Vertical airplane photo of Target a, the uppermost channel, and Target b, a mile downstream.
Photo, 11th Photo Section, U.S.A.

Dr. Jaggar stated that there was a strong probability that properly directed bombs would help the situation materially; that there was always the possibility in the future of a more serious eruption which might destroy Hilo unless preventive steps were taken, and that it should be found out now whether or not aerial bombs would stop or divert a lava flow. The Secretary of War, during a recent visit, had expressed great interest in the aerial bombing of a lava flow, and Dr. Jaggar had been assured that, if an emergency arose, the Department Commander would assist in protecting life and property threatened by lava.

Aa and pahoehoe lavas of 1935. Jaggar photo.

The Conduct of Operations

It was decided, after the Volcanologist had outlined the problem, to conduct the operation December 27. The Army Transport **Royal T. Frank** brought twenty 600-pound TNT bombs; and as many 300-pound pointer bombs were brought by the planes and were charged in Hilo with black powder and sand.

On December 26, the Volcanologist accompanied a group of Bombing Squadron officers over the target in a Douglas amphibian plane in order to point out the area to be bombed. They, in turn, took up other officers later in the day, so that all should be acquainted with the terrain. The Volcanologist recommended that the uppermost channel of the actual flow be bombarded at elevation approximately 8,500 feet on the north flank of Mauna Loa. The channel about a mile down the lava stream was indicated as a second target. This was to be demolished in the event that the upper target had been successfully hit, so that if any liquid still trickled through the tunnel, it would encounter a second obstacle. Both parts of the channel were crusted over, but glimpses of the liquid lava appeared in open parts of the tube where the crust had caved in. By demolishing the tunnel roof, the operation would block the tube with debris, force the liquid within to overflow, cool it and release gas, and thereby rob the tube system farther down the mountain where the front of the flow was being fed with lava through this tunnel.

Special Orders Number 304, December 26, 1935, sent twenty officers and thirty-seven men, including sixteen sergeants and corporals, by air from Luke Field, Honolulu, to the island of Hawaii, in command of Lieut. Col. Asa N. Duncan, Air Corps. They represented the 23d and 72d Bombardment Squadrons, a Signal Corps operator of Headquarters Detachment, four men from Wheeler Field, including photographers of the 11th Photo Section, and one each from the 4th and 50th Observation Squadrons.

The departure for Hilo from Honolulu was at 8:30 a.m., December 26, in ten bombing planes, two observation planes, and two amphibians. Upon arrival at Hilo, work was begun immediately in locating the targets with the aid of the Volcanologist. The Ordnance Department sent two civilian employees to supervise fusing and loading of bombs.

Colonel Duncan's report shows that, in the operation of December 27, the first bombing plane took off at 8:45 a.m. from Hilo and was followed by four others at twenty-minute intervals. Each plane was loaded with two 600-pound demolition bombs, armed with 0.1 second delayed-action fuse, and two 300-pound practice bombs for sighting shots. The bombs were dropped from an altitude of 12,000 feet, approximately 3,500 feet above the target. Two photographic airplanes accompanied the bombers and carried cameras for still and moving pictures. The first mission showed that individual bombing produced good results, so that the salvo method, using five planes in formation, was not used.

Observation of the Bombing

Colonel Duncan and staff at Hilo Airport maintained short-wave radio communication with the airplanes; and telephone communication with Dr. Jaggar, the Volcanologist, who had established a station at Puu Oo ranch high up on Mauna Kea mountainside, to observe the bombing. Twenty demolition bombs were dropped between 9:30 a.m. and 3:00 p.m.

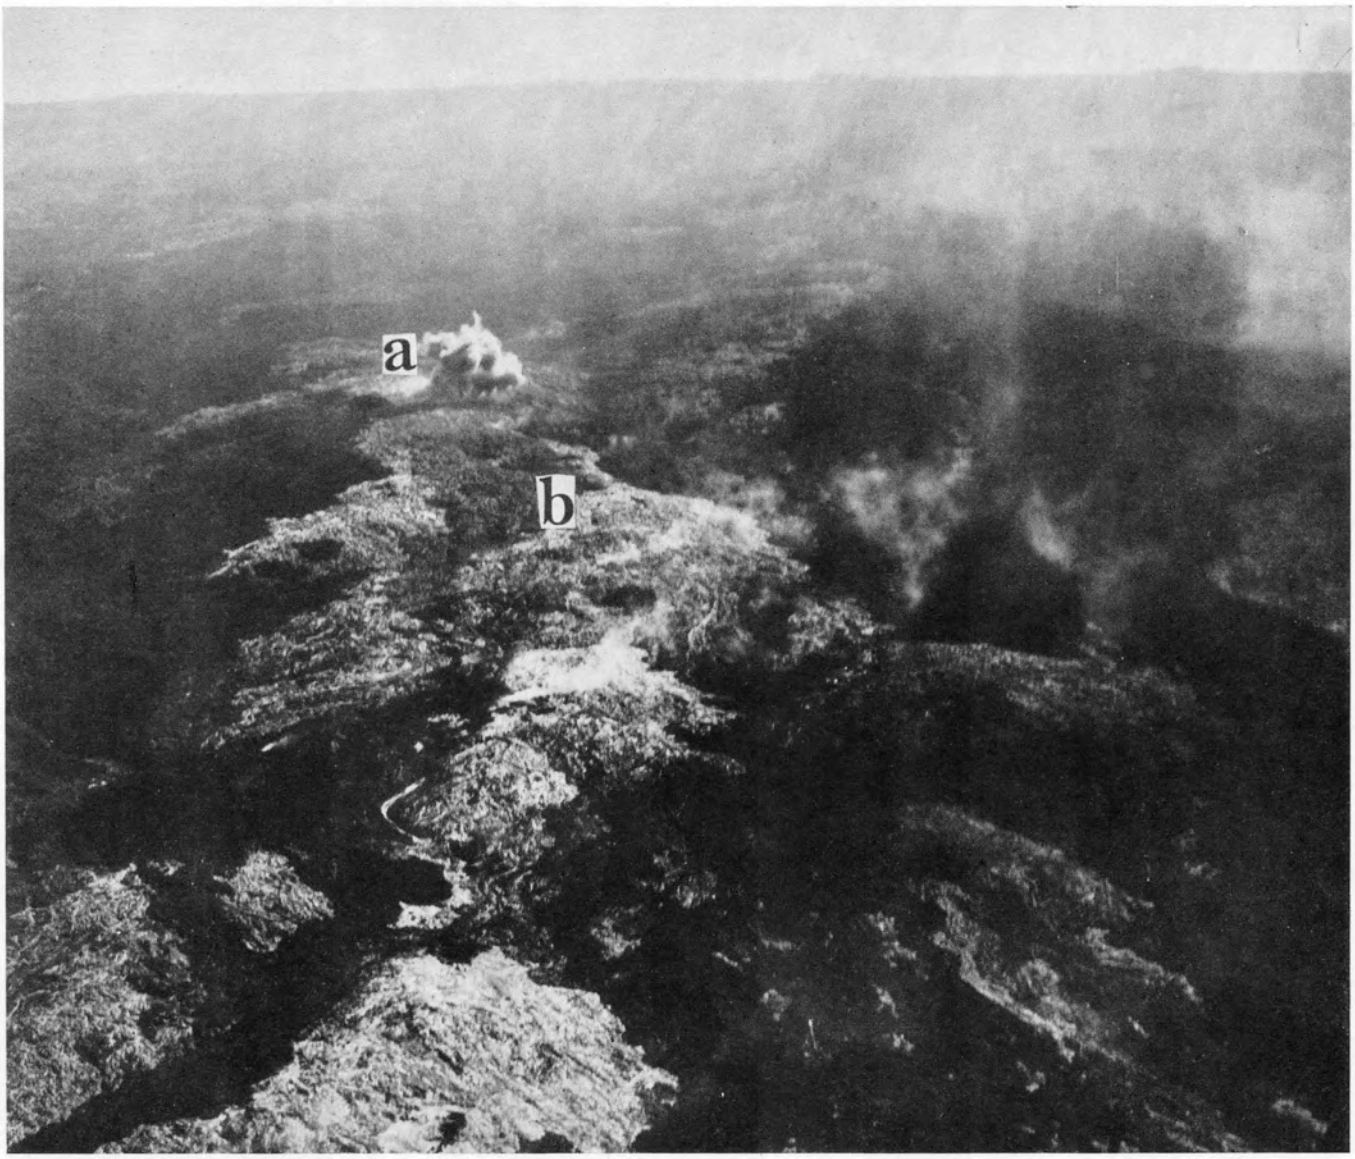
From the high post of the Volcanologist at Puu Oo ranch house, elevation 6,300 feet, the front of the flow was seen to be pushing through the valley 4 miles away in the foreground; Hilo airport was discernible with field glasses 23 miles away to the east; and the lava source targets were in full view up the mountain southwest, 12 miles in a bee line. The planes were moaning overhead all day long, and the bombers climbed high, poised, pitched forward, and a gray ball of smoke and dust boiled up from the upper lava channel.

The hits were noted at 9:43 a.m., there was a flash, 60 seconds interval, then a deep boom; at 9:49, a flash and a weak smoke column; at 10:15, a high column and noise after one minute; at 10:18, a soft column and the detonation; at 10:28, a high puff, interval, and booming; at 10:32, the same; and, at 10:59, a double puff, as though two bombs hit together. All the early shots were at the extreme upper tip of the gleaming silvery lava field, narrowing to a point at the source.

After 11 a.m. the lower target, the lava channel a mile below the source, was evidently the goal. One bomb exploded

The great bend of the flow towards Hilo, pahoehoe lava: a tunnel lies underneath. Jaggar photo.

with very deep penetration and heavy concussion in the depths of the incandescent stream, and great sheets of glowing melt shot hundreds of feet into the air, orange red, glistening, and spreading like a fan. When this was seen the Volcanologist knew that the single channel of the upper tunnel could not stand such punishment without damming itself, freezing, and spilling over. That tunnel lay at the bottom of a trench 10 feet wide and 40 feet deep in places; and a 600-pound bomb



crater might be blasted 20 feet wide and 5 feet deep in hard rock; hitting a trench of the size noted, it could hardly fail to wreck it. Hitting it in five places directly along the upper mile of its course (the 25 per cent of direct hits reported by Colonel Duncan) might be counted on to block the channels and leave the lower tube system to empty itself and collapse.

Other bombings were observed until 2:37 p.m. and notes were made of the soft black powder explosions, in contrast to the heavy puffs and thunder claps of the demolition shells.

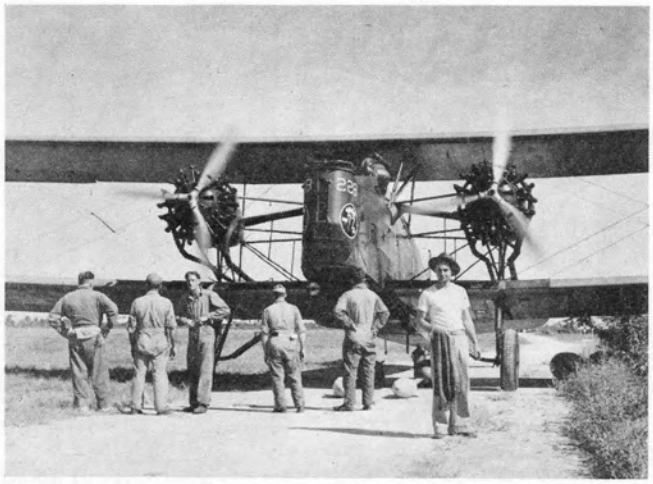
The Stoppage of the Flow

The evening of December 28 all motion at the front stopped temporarily. This was a totally new phenomenon, for the preceding week had shown the front making a mile a day; and the front lay on an increasingly steep slope, averaging 157 feet to the mile for the 7 miles of eastward flow from the lake of lava in the saddle.

The bombing thus smashed and dammed the source tunnel, released lava there, and beginning at the noon hour of the

The lava heaps of the flow source; a direct hit near upper source channel target a: and a collapsed tunnel near foreground showing a glowing stream inside. Photo, 11th Photo Section, U.S.A.

Meanwhile the front of the flow pushed ahead, passing successive tree markers which had been photographed. All day photographs were taken to show the changing progress. At 11:15 a.m. the front of the flow piled itself 30 feet high, entered woods, and sent up clouds of black dust and flames, while explosions of carbon gas made noisy detonations in old caverns. That night, December 27, the flow was more brilliant than ever, for oxygen had been admitted to the tunnel system by its collapse. Up at the bombed area, ten or twelve glow spots were visible where liquid lava was welling up bomb holes. A side branch of smooth lava made out from the main flow below the saddle.



bombing date, the speed of frontal motion was:

12:00	noon	December 27	800 feet per hour
4:00	p.m.	December 27	150 feet per hour
10:30	a.m.	December 28	44 feet per hour
6:00	p.m.	December 28	0 feet per hour

The release of liquid lava at the source tunnel was confirmed as follows: December 26 the Volcanologist flew over and could see no liquid on the surface. During the bombing, December 27, the pilots could see liquid in short stretches of collapsed tunnel roof. Next day air inspection showed a rapid glowing stream at the source itself, on the surface of the lava

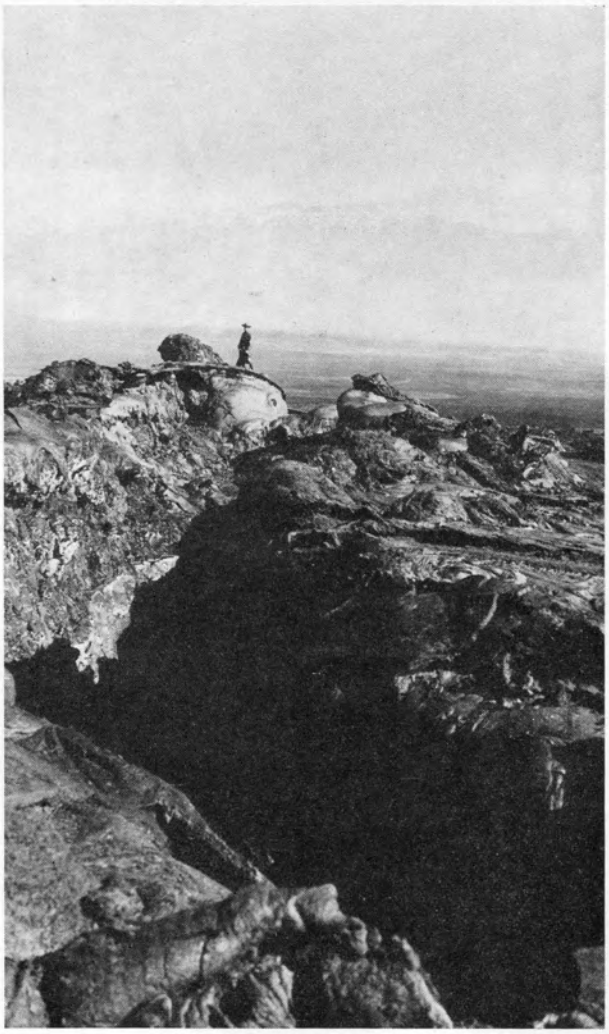
field. On December 31 all motion on the surface had ceased at the source.

This last fact was an unexpected development and was not the end of the eruption. But it was the end of the outflow. The inside eruption was manifest by clouds of sulphurous vapor from internal lava effervescing in the near-summit crater, showing that the well beneath was still charged with liquid;

A bombing plane with the bombs beneath. Maehara photo.

and this continued until March, 1936. An earthquake crisis in that month definitely ended the eruptive period.

That the bombing would end the source outflow was theoretically probable. The direct hits were sufficient in number to blast open the roofed channel and release to the air the vitreous froth called basaltic lava. The equilibrium of self-heating was destroyed and the slag, after spilling over for two days, stiffened, slowed down, and solidified into the source vent. Pilots who flew over on the second and third days after the shelling reported that the released liquid stream at the source had stopped.



The remainder of the activity of frontal flowing towards Hilo was a spilling of remnant lava from the tunnels and streamways. This was partly over the sides of the lava fields, partly lengthening of the front. There was a notable sudden gushing out of clinker lava at the front on December 30 for 1,000 feet. The final tongues became narrower, and one of these slightly passed the Forest Reserve fence east of Puu Oo ranch January 1 at 11 a.m. The last motion of the tip of this finger, only 100 yards wide, was at 2 a.m., January 2. The position of this final front was in the drainage basin, 8 miles east of the saddle, and 12 miles short of the Kaumana Road in Hilo. The total movement forward after the bombing was 1 mile in 6 days. If the flow rate of the Christmas season had continued, the front would have been in Hilo on January 9.

The following is quoted from a report of the operation: "After the bombing was completed, a reconnaissance was made of the shelled area. It was found that five bombs hit the stream itself, three in the flowing lava of the first target (source stream), and two directly above the tube of molten lava of the second target (one mile downhill). One of these caved in the tunnel and the other failed to penetrate. Three other craters were within 5 feet of the stream, the explosion throwing debris into the red lava. Two others were within 20 feet of the target. From the sensing of the pilots, seven other bombs fell within 50 feet of the stream. Those who witnessed the bombing declare that the execution of the mission was superb; that the bombs had been placed exactly where they should have been; and that this aerial bombing of a lava flow made history for science in performing a great geological experiment which was a success. From a military viewpoint of the bombing, Colonel Emmons says: 'Very valuable tactical training was received as a result of this mission, well worth the cost. Excellent co-operation was received from the Quartermaster Depot, the Ordnance Depot, and the commanding officer, Kilauea Military Camp'."

Hilo Chamber of Commerce furnishes the following minimum approximation of values, apart from life, good-will and natural assets like the harbor:

Sewers	$ 1,200,000
Streets	2,125,000
Schools and churches	2,883,804
Water supply	1,000,000
Piers, breakwater, dredging	7,500,000
Taxable land	10,387,824
Taxable improvements	12,408,300
Territorial property	2,224,395
Federal property	350,000
Personal property, growing crops, etc.	11,000,000
	$51,079,323

Supposing that the flying, transportation, ammunition, and payroll cost $25,000, the operation of December 27 appears to have been more than justified. An experiment pouring

Detail of collapsed tunnel near Target B, Mauna Kea in distance. Jaggar photo.

liquid clay on a scale model of Hawaii showed that this flow would have extended itself down Wailuku Canyon so as completely to fill Hilo breakwater and wipe out the second harbor of the Territory. Just such a flow in 1859 extended the land at Kiholo. As there will be more flows on the Hilo side, the bombing experiment has furnished a new weapon to civilization.

The Volcano Observatory at Kilauea was founded in 1911 by the Whitney Fund of the Massachusetts Institute of Technology with the words: "To be conducted with a view to protection of human life and property." That responsibility was accepted by the Hawaiian Volcano Research Association and the National Park Service. The 1934 address announced that "Mauna Loa has definitely mobilized and declared war, there is every appeal for an intellectual and practical victory over Nature, and a program can be laid down whereby our engineers and aviators and bombers will rejoice at the opportunity to show their prowess." All honor to the Army for an excellent peace-time achievement.

Hawaiian Volcano Observatory Report for December 1936

VOLCANOLOGY

The coming of December, and the elapse of a year since the last outbreak of the Mauna Loa-Kilauea system, are both reasons for expecting return of lava to Halemaumau. The winter solstice has produced more eruptions here than any other season. And the average of intervals has been one year. But nothing happened in December 1936 except a sudden quietness the last week of the month. This may mean uplift under Kilauea crater, following the slumping that caused the October avalanches.

All the movements were fewer than in November, as shown (see Volcano Letter 441) by the following tabulation, that indicates by weeks the local seismicity, the counted number of slides in Halemaumau pit when it was under routine observation, the amount of aggregate opening of marked rim cracks at Halemaumau by weeks, and the seimograph count of local tremors and quakes:

Week Ending	Seismicity	Slides	Cracks	Quakes
December 6	5.00	1	6.0 mm.	12
December 13	8.75	0	6.0 mm.	13
December 20	7.75	2	5.0 mm.	25
December 27	12.75	1	2.5 mm.	33
January 3	0.50	0	0.0 mm.	2

Sequence of Events by Weeks

The first week the pit was generally quiet, and the second week showed no slides at all, and remarkable constancy.

The third week slightly increased seismic motion and dust from a few slides. The shocks were mostly from Kilauea.

The fourth week tremors increased, and fume from the NW floor solfatara was notable.

The new year opened with unparalleled quiet, no slides, very slight crack movements, and seismic activity confined to two tremors in seven days.

Slides at Halemaumau

Slides from the wall of the Pit have been noted as follows, mostly from a distance, or at type periods of visitation:

December 6, 4:10 p.m., small dust clouds east edge.

December 17, 11:00 a.m., dust at NE wall, and scar from a recent slide there.

December 27, 4:00 p.m., dribbling of small rocks down NE wall.

Measurement of Halemaumau Rim Cracks

Weekly measurement of 26 rim crack locations resulted as follows:

Week ending forenoon of:

December 5, 10 opened, 0 closed, aggregate opening 6.0 mm.

December 12, 7 opened, 4 closed, aggregate opening 6.0 mm.

December 19, 11 opened, 4 closed, aggregate opening 5.0 mm.

December 26, 7 opened, 2 closed, aggregate opening 2.5 mm.

January 3, 4 opened, 2 closed, aggregate change 0.0 mm.

It is of interest as showing consistency among the subjects selected for measurement after years of experience at the Observatory, that crack widening, numbers of quakes, intensity of quakes, and number of slides all dwindled simultaneously the last week. This shows Halemaumau to be an index vent for all Hawaii, as some of the usual earthquakes originate under other parts of the Island, and those regions also were quiet the last week of the year. It would seem also, with seismicity suddenly lowering along with crater values, that all the island seismicity is clearly volcanic. T. A. J.

SEISMOLOGICAL DATA

EARTHQUAKES

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Distant† Earthquakes	Local* Seismicity
December 6	14	3	0	5.00
December 13	31	2	1	8.75
December 20	19	6	0	7.75
December 27	47	2	1	12.75
January 3	2	0	1	0.50

† Includes teleseisms or those shocks over 5000 kilometers distant.

* For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began recording at the times indicated and whenever possible, determinations of depths of focus have been made.

December 3, 11:17 pm, very feeble, located under SE rim of Kilauea Crater adjacent to Keanakakoi Crater and 1.5 miles deep. 19° 24' 4N; 155° 16' 2W.

December 4, 12:11 am, very feeble, located under N rim of Kilauea Crater 0.3 mile SW of Kilauea Military Camp and 2.0 miles deep. 19° 26' 1N; 155° 16' 7W.

December 11, 7:20 pm, very feeble, probably located under SE portion of Kilauea Crater.

December 16, 3:05 am, very feeble, located 0.7 mile NW of Ahua Kamukokulau S of Kilauea Crater and 0.8 mile deep. 19° 23' 4N; 155° 16' 6W.

December 16, 10:20 am, very feeble, located 1.1 miles SE of Pit Seismograph and 5.0 miles deep. 19° 23' 6N; 155° 16' 4W.

December 17, 5:52 pm, very feeble, located deep under SE slope of Mauna Loa. 19° 19' 0N; 155° 33' 2W. Reported felt at Hookena.

December 18, 3:22 pm, very feeble, probably located in SE portion of Kilauea Crater.

December 19, 5:56 am, very feeble, of Kilauea origin.

December 27, 12:06 am, very feeble, located deep under Kilauea SW Rift 5.0 miles SW of the Volcano Observatory. 19° 22' 0N; 155° 14' 5W.

Periods of continuous (harmonic) tremor registered on the Observatory seismograph as follows: beginning at 12:04 pm, December 1, six (6) minutes; 9:11 pm, December 13, twenty-one (21) minutes and 4:24 pm, December 26, seventeen (17) minutes.

Microseismic motion of the ground at Kilauea was light December 2, 3, and 5; moderate November 30 and December 1, 4, 6, 7 and strong the remainder of the month.

Registration of Distant Earthquakes at the Observatory was as follows: December 13, the preliminary waves at 11h 10m 37s am, HST, with 3020 miles as the distance of focus from Kilauea; probable location in the Kamchatka Peninsula as reported by newspapers. At 8h 50m 37s am, HST, December 21, the surface waves of a teleseism began recording. Its distance was undetermined. At 4h 27m 40s am, HST, December 29, the preliminary waves of a teleseism began recording. Its location was 3550 miles from Kilauea.

TILTING OF THE GROUND

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts for two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending January 3, 1937, was 3.60" N and 0.24" W.

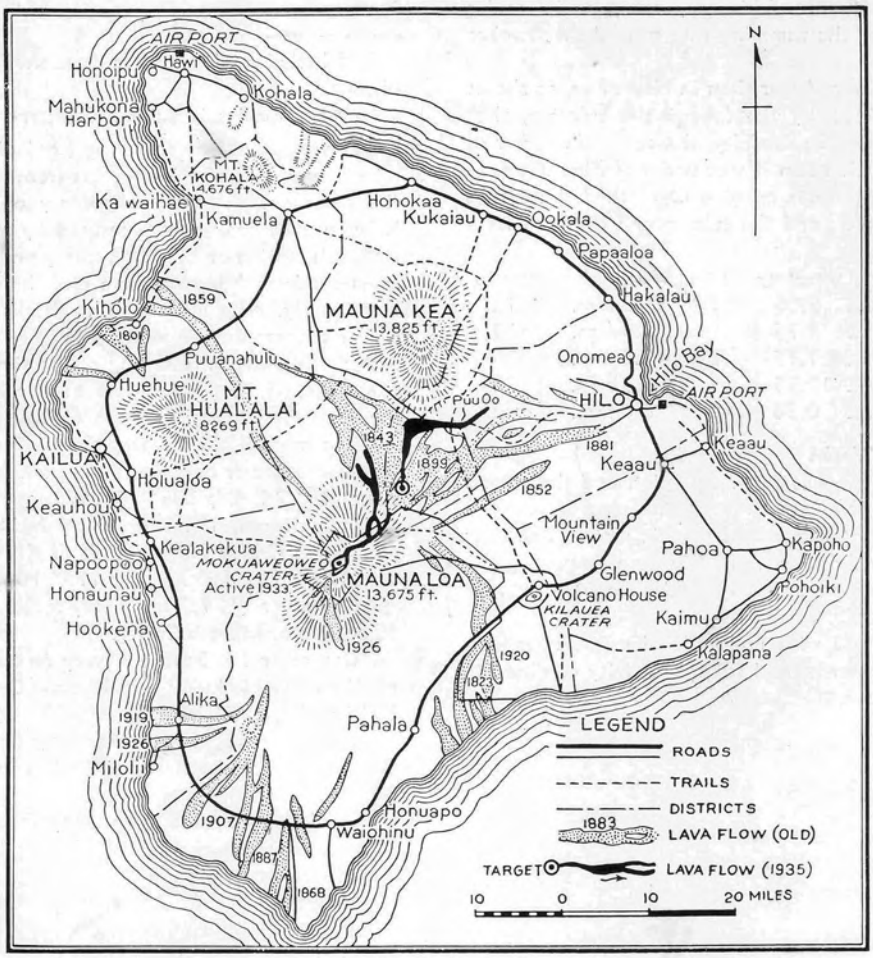


Table of Tilt

Week Ending	Observatory	Halemaumau West Station
December 6	0.62" S 78° E	3.19" N 57° W
December 13	1.10" N 43° E	2.15" S 65° W
December 20	0.74" N 38° W	9.86" W
December 27	1.05" S 33° W	3.75" S 61° W
January 3	1.18" S 02° E	5.13" N 64° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
December 6	3.79" N 11° E	0.26" from
December 13	1.46" N 34° W	0.63" from
December 20	2.20" N 61° W	7.75" from
December 27	3.11" S 21° W	5.05" from
January 3	5.61" S 81° W	2.04" from

Crater Angles

Measurement of Horizontal Angles across Kilauea Crater from the Observatory, December 26, showed a closing of the Halemaumau value and an opening of the crater value compared with similar measurements made November 23. From Kilauea SE rim to Uwekahuna there was opening 0.42" November 23 to December 11 and closing of 0.08" December 11 to December 26. Total opening 0.34". From the Pit Seismograph to the NW Pit B.M. there was a closing of 0.84" November 23 to December 11 and closing of 1.16" December 11 to 26. Total closing 2.00". H. H. W.

PROTECTION OF HILO FROM COMING LAVA FLOWS*

By T. A. Jaggar

Observatory Plans 1936

The following paragraphs are from the special report of December, 1936, from the Volcanologist to the Superintendent of Hawaii National Park. They concern, not a new and sudden alarm, but a serious project for safeguarding the industries of Hawaii from the lava flows of Mauna Loa. It has long been the intention of the Hawaiian Volcano Research Association to make Mauna Loa its principal center of study, and the time has come to do this.

"It is just one year since the Mauna Loa Flow of 1935, which seriously threatened Hilo, and ceased flowing in sequence upon artificial bombing. The law of cycle recurrence on Mauna Loa for 101 years is one crater outbreak every three and a third years, and one lava flow every six years. The north rift is open and smoking, and the next outbreak may threaten Hilo again, by analogy with nineteenth century sequences.

"The National Park with CCC labor has finished nine and nine-tenths miles of truck roadway up Mauna Loa east slope, going WNW from Bird Park. The resources of volcano research should be brought to bear on the engineering problem of protecting Hilo with the planning aided by 1935 experience. In like manner the 1933 crater eruption of Mauna Loa furnished data for forecasting the 1935 outflow of lava.

"There are four issues involved, namely: more Park land on Mauna Loa, an embankment to deflect lava flows near the source, other embankments lower down, and a survey of the rift land. Discussion of the project has the approval of the park superintendent, and is on the initiative of the Hawaiian Volcano Research Association.

"The embankment proposed is entirely distinct from the

* Address delivered at Annual Meeting of Chamber of Commerce of Hilo, Hawaii, January 19, 1937.

bombing method. The latter is a last resort measure, intended for lava flows of the tunnel-flowing variety called 'pahoehoe,' which appear in late stages of an eruption. The embankment-deflection is for the early and most dangerous liquid stage of an eruption, lava called 'aa,' which we saw naturally deflected November 22, 1935, by old lava banks. There is abundant loose rock on Mauna Loa for construction. There is no question but that an artificial embankment aligned downhill oblique to flowing slag would deflect it. A lava flow fills as a liquid. It does not push as a solid.

"The source belt, a mile wide, is a series of definite cracks trending N 70 deg. E from the summit crater for eleven miles. The distance to Hilo in the same direction is 35 miles. The divide between Puu Kipu, and Puu Ulaula called 'Red Hill,' is the parting line between old Hilo flows and southward flows, and the line trends N 85 deg. E.

"An embankment from Red Hill N 20 deg. W, five miles long, would steer any flows such as 1855, 1880, and 1899 to safety. An embankment north and south, with Puu Huluhulu of Humuula in its middle, about a half mile in each direction, would hold the flow pool steered into the Humuula lands by the Red Hill embankment, and send it west from the saddle between Mauna Loa and Mauna Kea.

"The short Puu Huluhulu embankment would be about 20 feet high; and the Red Hill embankment, oblique to the flows down a steep slope, need be only about 15 feet high.

"With reference to a line survey of the proposed embankments, and an aerial photographic mosaic of the entire northeast flow belt from the rift to Hilo, General Drum has expressed approval of the project.

"There the matter stands at the end of 1936. The volcanologist recommends that the establishment of Observatory volcanologic work on Mauna Loa at Red Hill shall be the main purpose of 1937 plans of the Hawaiian Volcano Observatory. The founding of Mauna Loa seismological measurement, and rift patrol, appear essential to the safety of the community."

Motive of the Work Proposed

From a small village threatened by numerous lava flows, with upper land destroyed by two of them, and the main water source invaded by three of them, Hilo has grown to a city, a port, and an airport.

These things have been improved at great expense from time to time, and the population has grown from a few hundred to 20,000 people. The harbor dredging and breakwater, the airport, wharfs and real estate will all be improved much more, and the adjacent plantations in health, labor, insect control, transport, agronomy, water supply, and milling are models of scientific advance in aggressiveness and in defense against evils. Hilo is their harbor.

The shadow of the lava menace is just as removable as the shadow of malaria, tuberculosis or yellow fever, the noxious mosquitoes, the leaf hopper, or the plague fleas and rats. It merely never occurred to anyone to remove it.

There is just one way to do this, and that is to face the exact facts, and then act with decision and unanimity at this present time of Government employment of labor. Remove the lava shadow, and watch Hilo go ahead by leaps and bounds.

Expectable Intervals and Flow Sources

Using the data of the 1934 article (Volcano Letter, October, 1936) for the history of Mauna Loa flows, the average of Mauna Loa eruptions is one summit outbreak every three and a third years between 1832 and 1933, and one flank outflow every six years.

There were six Mauna Loa eruptions between 1914 and 1935, making present average three and a half years. There were four flank flows, making outflow average 5.5 years. Thus the twentieth century holds up the general average.

The succession of newly opened vents since 1868 was from elevation 3,500 feet that year at the southern end of the Mauna Loa rift, progressively up the rift to 13,000 feet in 1926, 13,150 feet inside the crater in 1933; and 12,000 feet in 1935, on the northern extension of the rift down the Hilo slope.

This was approximately five miles north of the 1933 eruption, and if the next flank outflow comes out five miles farther north, the place will be a half-mile above Red Hill, close to the source of the 1881 flow, which entered the city of Hilo.

It should not be understood that the next eruption of Mauna Loa will be a flank outflow. Furthermore it may not come in three and a half years; that figure is merely an average. It may come in the summit crater or on some other flank, as alternations between the two sides of the mountain are common.

We know, however, that fume and steam are rising, that the ground is hot, and that sulphur is depositing at the line of source cracks of 1935. That means that the north rift of Mauna Loa in the Hilo direction is open and ready for action which was not the case between 1900 and 1926, when all the outflows were from the south rift.

Eruptions Now Expectable

On the basis, then, of the same historical data that the Hawaiian Volcano Observatory collected for the argument of 1934, we can state that a succession of eruptions is expectable now from the Hilo rift, some of them making outflows down the northeastern flank of the mountain, at intervals averaging three and a half years for all eruptions.

A change began with the great series of bad northern earthquakes of 1929, whereby the northern rifts were opened and the southern ones were closed.

The historical flow sources of the northern rifts may be thought of as lying in a semicircle around the north side of Mauna Loa all the way from Huehue to Nanawale, making a set of radial fractures from the summit of Mauna Loa northwest, north, northeast and east, the northwestern one being the Hualalai rift, and the eastern one the Kilauea rift.

The Huehue Flow at the west poured into the sea from elevation 2,000 feet in 1801, and the Nanawale Flow at the east poured into the sea from elevation 650 feet in 1840. Note what low sources are possible.

It is fortunate for Hilo that the northeast rift bends eastward at elevation 8,000 feet; and we have no historic record of a flow source, of Hilo flows, lower than 8,424 feet, at the head of the 1852 flow. But there were many pre-historic ones that formed the entire south side of Hilo bay, when the ancient shore line extended from Waiakea Kai to Olaa Mill. The range of speeds of sudden aa flows has been 1 to 20 miles a day.

The Lava Cycles of the Nineteenth Century

There is good evidence in recent history for eleven year cycles, 1903-1913, 1914-1924, 1925-1935. These include both Mauna Loa and Kilauea, each with at least two eruptions Mauna Loa; Kilauea pit variously spouting, fluctuating, or rising, and the lava as a whole effervescing strongly and sinking at the end of the cycle.

The cycle is terminated by a very quiet year or years. The quiet years were 1913, 1925, and 1936; we are now approaching the end of the 1936 lull. The distinctive character of this 1936-1937 repose period, leading to an assumed 1936-1946 cycle, is that it is the first repose period following Kau flows and leading to Hilo flows, since 1840.

Leaving aside theories about cycles for 1840, as structural resistance to breaking is the real control, the significant feature of that year, with reference to the structure of the island, was that it made an outflow into the ocean from the eastern Kilauea rift, and it followed southern outflows from both Kilauea and Mauna Loa of 1823 and 1832. A characteristic of 1840 was that it was followed in the next cycle by two northern

outflows of Mauna Loa, 1843 and 1852, both beginning just where our 1935 eruption began.

Disregarding intervals, as structural sequence is more important and comparing 1924 with 1840, we had the eastern Kilauea rift erupting 1922 to 1924, following after southern outflows from both Mauna Loa and Kilauea, respectively, 1916, 1919, and 1920. This was very much like the sequence 1823 to 1840.

The parallel is made still more remarkable by the fact that the 1916-1924 sequence of southern and eastern outflows for the whole island has been followed in 1935 by an outbreak at the north in the same place as the eruption of 1843 from Mauna Loa, with the flow in very nearly the same volume and filling the saddle between Mauna Kea and Mauna Loa in just the same way.

This parallelism to the first half of the nineteenth century leads one to suspect that the unrecorded period of Mauna Loa activity preceding 1932 produced flows in Kau just as did the twentieth century period preceding 1935.

Loa summit, and travelled for seven months 38 miles into the sea at Kiholo Bay. There it filled the northeastern half of the bay making new land two miles along shore and a mile out to sea. Its first gushing of aa reached the sea in seven days at Wainanalii.

The next north flow was 1881 starting in the northeast rift and travelling 29 miles for nine months towards Hilo, with a side branch at first to Kapapala that flowed ten miles in a day. It stopped one mile from the city center.

The Fortification of a Harbor

The first flows are always very liquid aa. They travel far in a few days, and are the most dangerous to property if they get into industrial lands. For such flows bombing would be wasteful and useless.

It was this kind of flowing which destroyed Bosco tre Case on Vesuvius in 1906, and also Mascali, a large town of 7,000 inhabitants, on the railroad east of Etna in 1928. In either of these cases it would have been possible to fortify the town, if suitable earthworks oblique to the course of an expected lava

Rapid Lava Flow Pouring Into Ocean Destroying Hoopuloa Village in 1926

We know that the middle of the nineteenth century, beginning with 1843 and continuing to 1881, produced a tremendous volume of flows to the north from Mauna Loa, those of 1852, 1855, and 1881 ending progressively closer and closer to Hilo; 1855 and 1881 might have been successfully bombed.

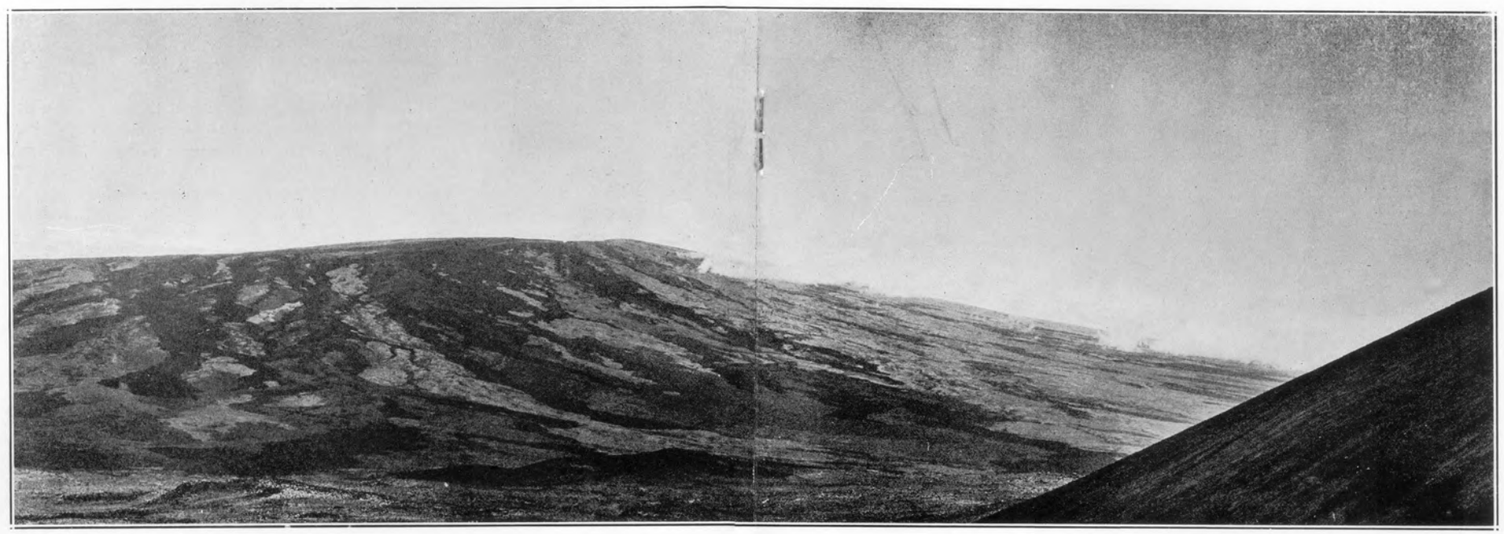
Add to these 1935, straight down the Wailuku River valley, which if it had not been bombed might have filled Hilo harbor, and we find indication that the threat to Hilo is increasing. We now in 1937 find ourselves with the island structure broken wide open for a succession of lava flows historically similar to the series 1852-1881.

Early Series

That series was 1849 at the summit crater; 1851 west of the summit for 10 miles towards Kona; 1852 from the northeast end of the Hilo rift for 15 miles in 20 days straight toward the city, ending 11 miles from the Federal building.

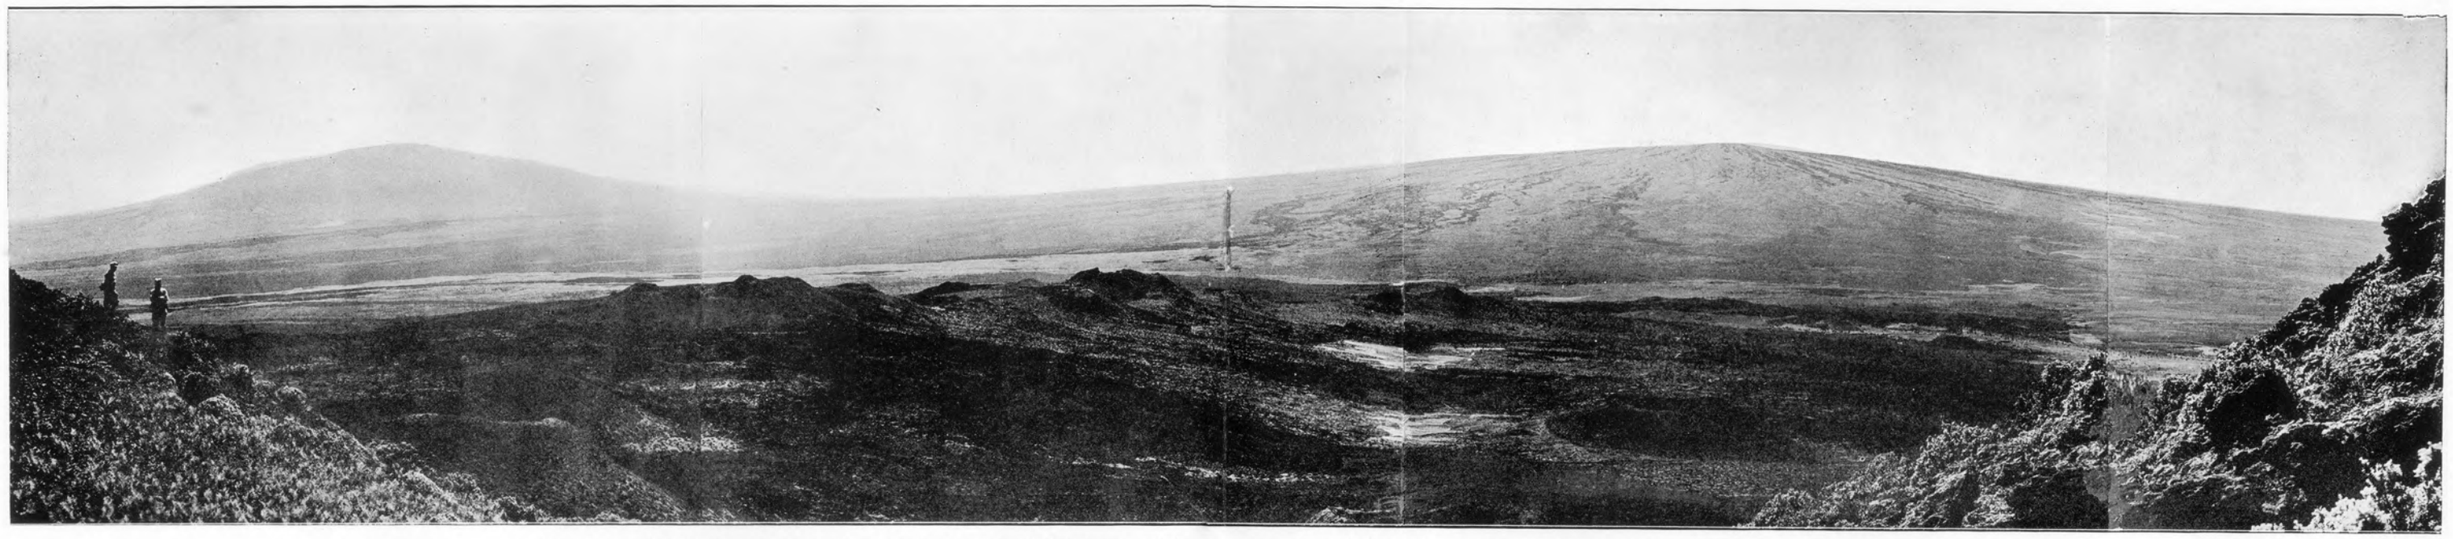
1855 started at the northeast rift farther west than 1852, and travelled 25 miles for 15 months in a curved course to the Wailuku drainage, ending seven miles from the city.

1859 started at elevation 11,000 feet northwest of Mauna



flow had been erected in advance, at a site selected to divert such a flow into a valley leading to agricultural or forest lands.

In neither of these cases was any harbor involved. A harbor is a national asset, it usually lies where a valley emerges on the ocean, and if a mass of new rock, a mile seaward and miles long, fills a developed port, the calamity cannot be reckoned in money. A harbor is vastly more valuable as a natural feature than all the millions spent on houses, roads, sewers, and public utilities.



The Situation of Hilo

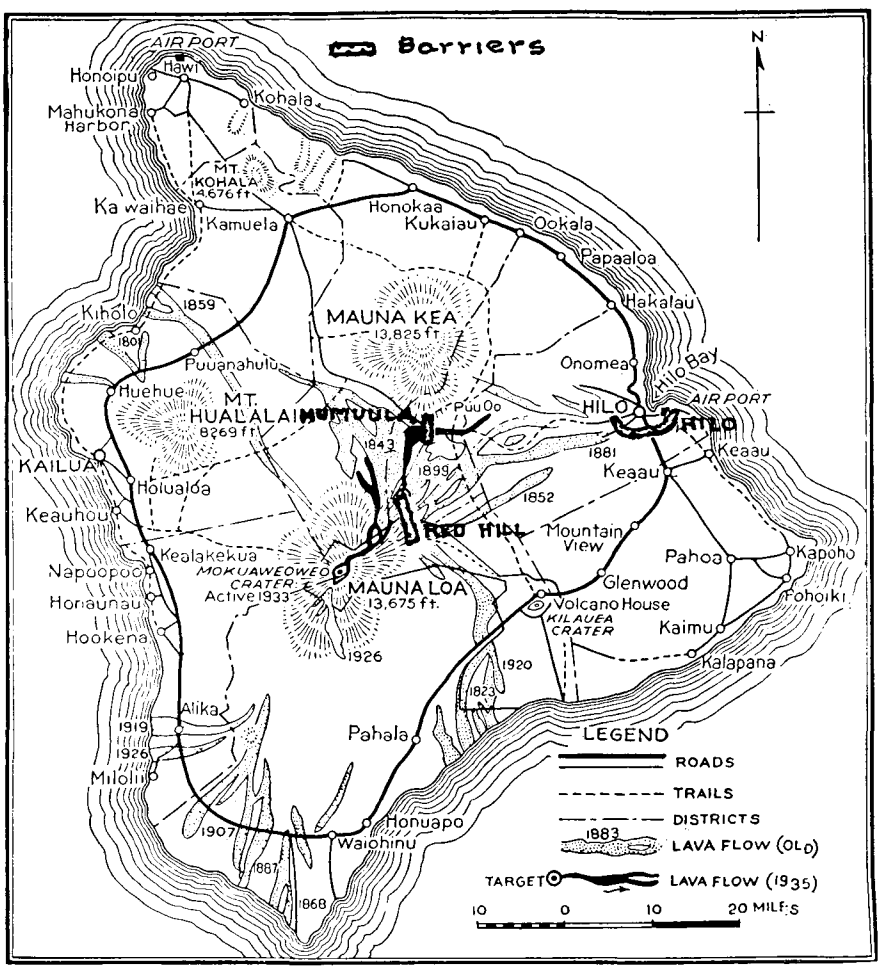
Hilo lies at the meeting place of three valleys all straight below the dangerous end of the Red Hill rift of Mauna Loa. These we may call the Wailuku Valley, the Kaumana Valley, and the Waiakea Valley. The first is the contact of lava flows against Mauna Kea drainage. The other two are seepage remnants of buried valleys on the east slope of Mauna Loa.

All three would lead a new rapid lava flow straight into the harbor. The distance is only 20 miles from the nearest possible lava source, Puu Kipu at Helipo Camp. Puu Kipu is right in the line of the east bend of the live rift. An existing heavy aa flow from it in the forest extends half way to Hilo.

North Face of Mauna Loa Volcano, Showing Net of Lava Flows Mutually Deflected; the Area of the Red Hill and Humuula Barriers

Mauna Loa (right) from Hualalai, Showing the Hualalai Rift Belt Line of Cones in Foreground: Behind Them aa Lava of 1859 (dark), and Pahoehoe Lava (light).

A new flow on its north side would sweep about 24 miles to Waiakea Fishpond, and at the rate of the 1859 flow would reach the sea in five days.



A flow from the 1852 source at the same rate would travel 26 miles, take six days, follow the southeast side of the 1881 flow and Alenaio stream, and enter the sea at Mooheau Park.

A flow from an old cone at elevation 8,750 feet 2¾ miles north of Red Hill, at the same rate, would flow 27 miles between the 1881 and 1855 flows, reach the Wailuku River by Kahoama stream and the gorge above Waiale Falls, pass Piihonua and reach the railway bridge over the Wailuku River in something like six days.

All these distances are shorter than the 1859 flow, which travelled 38 miles in seven days from a point 11,000 feet up.

There are three elements in the Hilo problem. One is to steer lava flows with obstacles, near their sources, into safe places like Humuula while they are liquid. The second is to build an obstacle at the Humuula pass that will protect Hilo's water supply. The third is to build a final protection for the harbor in Hilo itself in case of (1) an unexpected low vent or orifice in the mountain; (2) a vent too far east for the obstacles constructed; (3) the failure of all upper obstacles.

The first two obstacles have been mentioned in the preamble. One is the Red Hill embankment, which, along with natural features, will extend about five miles N 20 deg. W from near Red Hill, will steer such flows at 1855, 1881 and 1899 to Humuula, will be about 15 feet high down a relatively steep slope, and may take 300 men two years to finish.

Map of Hawaii 1937, Showing Proposed Barriers Exaggerated

If the 1859 flow had come out at Puu Kipu with the same energy, it probably would have done the 24 miles to Hilo Bay in four days and piled up the material of its remaining 14 miles of first gushing in Hilo breakwaster. The breakwater would probably hold it and tongues of aa like the Laupahoehoe flat would spread out in a leaf delta to the north of Hilo harbor, after the harbor was transformed into the same kind of land as Keaukaha.

Defense of Hilo

The foregoing is a legitimate picture of what we have to fortify against. Fortification in war consists of two elements, protection and obstacle. Lava flows are the enemy. Protection will shield Hilo from a lava flow when it comes. Obstacle will prevent the lava flow from coming to close quarters if possible.

This is partially prepared for by the CCC camp at Hawaii National Park, which has built 9 9/10 miles of truck roadway up Mauna Loa, and has about eight miles more to go to reach Red Hill. The work of laying a 15-foot bank down natural grade, with double track for dump trucks on top, and using loose aa blocks, without much grading and almost no cutting, taking advantage of natural spurs, is simpler than building a road. It will be necessary to extend the present road as a rough track as fast as possible to Red Hill. A volcano observatory will be established there this year.

At Puu Huluhulu, the forested hill in front of Humuula sheep station, a bank 20 feet high will be built north against Mauna Kea about a half mile long. A similar one will be built south against Mauna Loa for the same distance until its top is

at grade. These, with the hill, will be at a height where a lava pool in the saddle will spill west over the top of the 1843 flow. The Red Hill bank will steer flows near the 1935 and 1843 flows. Such flows will pool in the saddle and spill west. The combined obstacles will protect the projected Kaumana-Kona road, the water supply of Wailuku River, and stave off 80% of expectable flows, including a low northern or Humuula vent. This steers flows to Keamuku, not to Puuwaawaa.

The Puu Huluhulu bank is prepared for by the improvement in the Humuula road made by the Pohakuloa CCC camp, and by the camp itself as a nucleus for labor, and as a shelter for laborers. The work will take a year, with perhaps 200 men.

The Hilo Causeway, or Lava Guard

At first it was thought that to construct a fortress against lava attack in Hilo would be impossible. So it would be if we threw up earthworks in a wide circle around the outer city limits. But a study of the topographic map has revealed a strategic line for a Hilo Causeway, or Lava Guard Embankment, which will not be excessively expensive, and may be used (1) as a parkway drive, (2) for possible impounding of water, (3) as a cross-connection for existing roads and (4) as a possible start for the Kaumana-Kona driveway.

As no lava flow on a slope is likely to be more than 12 feet high here, this embankment will average 18 feet in height, being higher where it has to cross low ground. It will start at Wailuku valley above Piihonua over the head of Waiale Falls, with a culvert or arch for the river. This is above the big Mauna Kea tributaries, so that it will not get maximum floods. The culvert construction will have to provide a steel gate capable of closing the arch to small dimensions in case of lava flow.

The line will start about South 70 deg. East for a mile from the river and then run east; the grade downhill to Lanikaula Street is 200 feet to the mile, and obliquely crosses all the valleys. The bank will cross only the Kaumana and Volcano roads, and will make a smooth curve northeast before reaching the railway near the quarries. It will then cross the railway fork, may be lowered to 15 feet, and carry far enough on the Keaukaha spur to guard the harbor as far as Keokea Point.

The roads and railways will pass under bridges in the embankment, and there also the uphill face of the causeway will hold rolling steel gates inclined at the natural slope of the bank. These will be kept rolled to one side. Remember that the lands outside the guard are protected by the upper two obstacles.

The total length of the Lava Guard will be seven miles to the top of the Keaukaha spur. The fundamental object of the guard is to protect Hilo and Hilo harbor, the second harbor of the Territory. If everything fails in the upper obstacles, if the water of one or the other valleys were buried, Hilo could still find water. But if a quick flow comes into Hilo itself and the harbor, there will be no motive left to find any water. There will be no Hilo. Remember what we watched as the 1926 flow swallowed Hoopuloa.

The Lava Guard will require heavy quarrying on the uphill side of the bank, the places being chosen to create a channel across obstacles.

I estimate roughly the Hilo job will occupy two years, and give work to 600 men.

The costs for the three jobs may be:

Red Hill	$300,000
Humuula	100,000
Hilo	400,000
Total	$800,000

If any of these embankments has a lava flow piled up against it, it will be more an obstacle than ever, strengthened for its work.

The Hilo Causeway will be the Hindenburg Line, the final protection. It should be begun first and it is most important. It is near labor and a base of supplies and subsistence. On that account it is much easier than the Red Hill job. The first thing to do is to run the line surveys. The second is for all organizations to pull together to get all three jobs done, for they completely interlock.

The Parallel With Kiholo Bay

In 1800 the Kaupulehu Flow poured from Hualalai into the south end of Kiholo Bay. It filled three miles of shoreline, and out to sea one mile. In 1859 the flow from Mauna Loa poured into the north end of Kiholo Bay. It filled the harbor a mile out, along two miles of shoreline.

The Puuwaawaa valley may well have been like the Hilo valleys centuries ago, ending in a deep indentation. Here were only 60 years of the nineteenth century, and the harbor that on the west side of the island corresponds exactly to Hilo, had five miles of length filled one mile wide.

From Mauna Loa Kiholo was protected by Puuwaawaa hill, Hualalai Mountain, and Puu Anahulu. The 1859 flow was not stopped at all by Puu Anahulu flats. The whole South Kohala shore as far as Puako is a filling of Mauna Loa flows. The early 18th century filled west. Seventy-five per cent of present-day flows are to the east.

Hilo has no hills whatever between it and the most dangerous present active rifts of Mauna Loa. It is on a valley which Mauna Loa is perfectly certain to fill up in time. It is 34 per cent nearer to the active vents than Kiholo is to the 1859 source. It has been attacked five times in 83 years, mostly when it was a small village. Last year it was attacked in its urban maturity, and it was saved by bombing pahoehoe. The next flow may be of different kind, when nothing will save Hilo but fortification.

The lava surface equal to the Kiholo fill would be five square miles. This would fill Hilo harbor from a point a mile north of Wainaku across to a place in the sea a half-mile north of Keaukaha. There would be no city, no Iron Works, no Canec, no Waiakea, no railway yards, no airport, no wharves, no electric works, no telephone center.

The city is worth $51,000,000; the harbor possibly $500,000,000 to the Territory, to commerce, and to the Nation. There are only two real harbors on Hawaii Island, Kealakekua and Hilo.

The river would find a new channel in one of the northern gulches. The people would sit on the Halai Hills and watch another layer added north from Reeds Bay and Onekahakaha, both of which are Mauna Loa lava flows. The Oil Tanks would blow up, the sugar in Kuhio wharf would be buried, and the lumber mills would burn, just as we watched the Hoopuloa wharf burn.

If a foreign Hobson were going to scuttle Merrimac hulks in the breakwater entrance, we would ask the Government to line up a blockading fleet. That is exactly what we are called upon to do against Mauna Loa. You have created an intelligence service, the Observatory. It is making its report soberly and conservatively. This is not alarmist sensationalism.

Conclusion

The thing I would suggest that the Hilo Chamber of Commerce do, is to have a meeting, for discussion of this question, with representative engineers, business men and the supervisors. At that meeting may be decided whether or how to approach the Governor.

I would suggest having representatives of the National Park, the Army, Navy, Parker Ranch, Shipman Ranch, and the Bishop Estate; with the Land Commissioner to represent the Governor. I have discussed the matter with Mr. Whitehouse, and with several of these administrators of Mauna Loa lands,

and also General Drum, and the presidents of the Hawaiian Volcano Research Association and the University. The protection of Hilo needs no argument, and these gentlemen have great respect for Mauna Loa.

The things to do are:

1. Extend the Mauna Loa road.
2. Equip a Red Hill Observatory and patrol.
3. Acquire the upper Mauna Loa waste lands.
4. Design and start the Hilo Lava-guard Causeway.
5. Design and start the Humuula Obstacle.
6. Design and start the Red Hill Embankment.

For all of these the appeal, started by myself as volcanologist of Hawaii National Park and the Hawaiian Volcano Research Association, for which I take full responsibility, should probably proceed through the Hilo Chamber to the Governor, who will take whatever action seems wise.

If we do these things you can sleep in Hilo and feel jubilant for your future and your business. Read the pathetic letters of Mrs. Severance to Miss Gordon-Cumming in 1881, when the flow was in Hilo, if you want to know the depression of it (book called "Fire Fountains," Gordon-Cumming). Or see the volcano film of Etna at the National Park museum. And after the embankments are built we still have bombing in reserve for the slow smooth flows.

More than all else, you will set an example to the world. Italy, Japan, the Philippines, Java and Central America will all watch Hilo. Hilo has not said "Manana" (tomorrow), nor "Shikata ga nai" (it can't be helped). The trails of the Hawaiians go straight to the goal with the motto "Eternal is the life of the land in righteousness." Righteousness means straightness. Let us perpetuate the life of the land in Hilo.

Hawaiian Volcano Observatory Report for January 1937

VOLCANOLOGY

The month of January indicated continuance of the quiet conditions which had begun rather suddenly the last week of December. The winter proved exceptionally rainy, with much stormy weather and high winds, occasioning deep ground swells that broke on the rocky cliffs of the island. As a result microseismic motion has been strong, and appears to vary with the impact of waves on the shore.

Observation of Mauna Loa

On January 2 a party from the Observatory, S. Sato and A. Okuda, accompanied soldiers from the Red Hill Resthouse up the Mauna Loa trail, encountering fresh snow from a point a mile and a half above the house. The old steam crack east of the trail was making vapor with snow close to its edge. The 1935 cones at about 12,000 feet elevation showed sulphur coatings that were too hot to hold the snow, and both vapor and blue fume were noted there. After exposure to snow glare from seven to ten hours, some of the party were snowblinded, and had to be led down the trail on the return. This experience of snowblindness has been repeated by other parties on Mauna Kea, where a new trail built by Civil Conservation Relief Workers has induced many to go skiing.

From the Observatory at Kilauea the 1935 cone on Mauna Loa, 18 miles away, was seen to make visible fume the hour before noon on January 6.

Observations of Kilauea

The following tabulation for January shows somewhat higher values for the Kilauea Volcano Observatory data than in the week ending January 3, but mostly lower values than December. There are indicated by weeks the local seismicity, the counted number of slides in Halemaumau pit when it happened to be observed, the amount at Halemaumau of aggregate opening of marked rim cracks by weeks and the Observatory count of local seismographic tremors and quakes:

Week Ending	Seismicity	Slides	Cracks	Quakes
January 10	7.25	3	2.5 mm.	11
" 17	2.75	4	3.0 mm.	9
" 24	3.00	3	6.0 mm.	8
" 31	7.00	0	3.0 mm.	14

Sequence of Events by Weeks

The first week produced two felt earthquakes and some sliding from the Halemaumau wall.

The second week had lower seismicity and small slides continued.

The third week produced occasional dust from slides and no change in the seismicity.

The fourth week of heavy rains filled the pit with large clouds of water vapor, surmounted by cauliflower clouds caused by convectional displacement, and the nucleation due to fume issuing from vents on the floor of the pit. There were some felt earthquakes, and southerly tilt was strong.

Slides at Halemaumau

Slides from the wall of the pit have been noted as follows, either from a distance or at typical times of visitation:

January 6, 12:45 p.m., dust rose from a small slide NE, while blue fume was seen at E and W Solfataras.

January 7, 9:30 a.m., small rocks dribbled down west wall, and at 1:30 p.m. dust arose NE.

January 8, at 2:18 p.m., a moderate slide fell from NNW wall.

January 15, 9:33 a.m., a small slide fell N.

January 17, 12:03, 12:27, and 12:35, dust clouds from slides arose NW; all were small.

January 22, 12:45 p.m., dust arose N rim.

January 23, A scar on the west wall indicated new sliding, and small rocks were in process of dribbling down there.

The last week was too stormy for observation of slides.

Measurement of Halemaumau Rim Cracks

Weekly measurement of 26 rim crack locations resulted in aggregate movement as follows: week ending forenoon of

January 8, 5 opened, 2 closed, opening 2.5 mm.
" 15, 7 opened, 4 closed, opening 3.0 mm.
" 22, 6 opened, 1 closed, opening 6.0 mm.
" 29, 9 opened, 4 closed, opening 3.0 mm.

T. A. J.

Crater Angles

Measurement of Horizontal Angles across Kilauea Crater from the Observatory, January 21, showed an opening of the Halemaumau value and an opening of the Crater value compared with similar measurements made December 26, 1936. From Kilauea SE rim to Uwekahuna there was closing of 0.17", December 26 to January 8 and opening of 0.84", January 8 to January 21. Total opening, 0.67". From the Pit Seismograph to the NW Pit B.M. there was an opening of 0.17", December 26 to January 8, and an opening of 0.83", January 8 to January 21. Total opening, 1.00".

H. H. W.

Spirit Levelling

A recheck of levels run in Kilauea Crater after February, 1936, indicates that values reported for elevation changes are erroneous. Improper corrections and poor instrumental adjustments have been responsible for the discrepancies. Proper corrections will be made and results reported in a later edition of the Volcano Letter.

H. H. W.

Note: Seismological Data for January, 1937, will appear in February issue.

THE VOLCANO LETTER

No. 444 monthly Department of the Interior National Park Service February 1937

Hawaii National Park

EARTHQUAKES*

By Hugh H. Waesche, Asst. Geologist, H.N.P.,
Hawaiian Volcano Observatory

A very commonplace phrase or question in Hawaii is, "Did you feel the earthquake last night?" Sometimes there was one, more often imagination has played someone a trick and there was none. We are all earthquake conscious here on this island, and justifiably so, as fairly frequent earthquake shocks are as much a part of the region as are the volcanoes of Hawaii National Park, the City of Refuge at Honaunau or the Black Sands of Kalapana. Hawaii being volcanic, is at the same time an active earthquake center. This condition is true of other parts of the world. It has been discovered that earthquakes occur most commonly in two zones or belts on the earth's surface. One of these zones starts at the southern tip of South America and runs northward following the course of the Andes, passes through Central America, continues through Mexico and the U. S., following the Rocky Mountains, Sierra Nevada and Cascade Ranges to Alaska from where it follows the Aleutian Chain to Japan, passes on to Java and Sumatra of the Dutch East Indies and finally swings back eastward across the South Pacific. The other belt runs diagonally across this one and includes the Caribbean, the Mediterranean Sea, the Caucasus and Himalaya Mountains and the East Indies. It is interesting to note that these two zones also roughly indicate regions of volcanic activity. However, from that relation it must not be inferred that the one is the cause of the other. It would be better to think that both earthquakes and volcanoes are the resulting effects of disturbances or movements in zones of evident crustal weakness. Earthquakes can and do occur in these regions without volcanic activity. Volcanoes can and do erupt without being accompanied by major earthquakes although they usually occur simultaneously with local earthquake shocks, or are preceded by the latter. In Hawaii we often have earthquakes of various intensities without any sign of activity. They are usually located near features of structural importance such as under one of the five volcanic masses of the island or rifts associated with them. How these locations are determined will be described later.

The exact cause of earthquakes is still open to question but is always an interesting point. When a person feels the so-called ground under him shaking violently or possibly rocking like a ship at sea he wants to know what is causing the disturbance. This is a natural reaction and the early Greeks and Romans of the Mediterranean areas who were quite familiar with both volcanoes and earthquakes asked that question just as do their successors. They were contented though with a much more simple, and to them, logical explanation. Some of these explanations, connected with gigantic underground explosions, wind blowing through tunnels in the earth and the caving-in of subterranean caves would not fit in too well with modern concepts along those lines. Today three possible general causes are suspected. The first and generally accepted one is the most important and goes by the rather high sounding name of elastic rebound theory. This type is associated with the making of new fractures in the earth's crust or remaking of old ones such as the making of earthquake cracks in Hawaii in 1868 or a split along the Mauna Loa Northeast rift in 1935. In spite of the name of this theory, it is simple to understand. Most everyone has had the experience of breaking a piece of kindling wood over his knee. When the wood partially breaks with a snap there is a jar in the hand and knee. This jar is in reality a small hand-made earthquake and was felt by the rebound of the pieces of wood to their former position as they snapped back from the bent position across the knee. The bending is the elastic part of the theory name and the snapping back of the wood is the rebound. The same thing happens in most natural earthquakes, large or small, depending on the strength and snap of the material concerned. Stresses tend to build up on either side of a rift or crack in the earth's crust and so continue accumulating until like in the case of the stick of wood—it gives and the ends snap back into position and then everybody says "Oh! did you feel the earthquake?" and the telephone starts ringing at the Volcano Observatory. The second type of earthquake is spoken of as volcanic. Many of these occur around any active volcano and their originating cause is somewhat doubtful. They may be of the same origin as the first-mentioned group, caused by lava and gas pressure changes on the rocks composing the volcano. Explosive volcanic activity likewise results in earthquake movements. Another possibility would be the sudden stopping of a lava column with the same general effect as the jar in a hydraulic ram or the stopping of a weight in a pile driver. Rapidly flowing lava or gas produces earth vibration just as water flowing from the end of a hose nozzle will vibrate one's hand. In any event, although volcanic earthquakes as we all know here, can be quite strong locally, they are seldom felt at a great distance. This is characteristic of such disturbances. An exception was in the case of the great shock in Hawaii in 1868 which was classed as one of world-shaking variety. The elastic rebound type of earthquake first discussed is given the credit for causing practically all major disturbances. Typical examples of this great class are the Charleston earthquake of 1886, the Yakutat Bay earthquake of 1898 when a good-sized mountain range raised itself forty-two feet, the San Francisco earthquake of 1906 where in places the ground slipped as much as twenty feet sideways along the San Andreas rift, and the Tokyo earthquake of 1923 which practically destroyed Yokohama and Tokyo. Most any of the great world-shaking earthquakes one might mention belong to this class. A third and very minor cause of earthquakes is still listed in most textbooks. This theory is concerned with the caving-in of underground openings or caverns. The strong shocks of the New Madrid, Missouri region in 1812 were thought by some to have originated in this fashion. Subsidence of the ground certainly did occur but it would be hard to conceive of underground spaces of sufficient size to produce such disturbances.

From time to time one reads in the newspapers that an earthquake occurred at such and such a place and that its distance was a number of miles from some given locality. Sometimes these reports are based on someone reporting having felt the shock at the point where it occurred or on the basis of its destruction but more often the detection of the quake and its location is based on instrumental evidence. That is, scattered over the world at more or less strategic points are instruments known as seismographs which make a record of the earthquake at that locality. At first this all seems a little mystic until one knows more about the activity generated in the earth's crust by the shock. When an earthquake occurs, waves are set up radiating out from the center of disturbance in all directions much as the waves go out from where a stone or fly strikes the surface of a pond of still water. In the case of the earthquake, three different kinds of waves are started simultaneously. The fastest of these goes through the earth and vibrates back and forth in the same direction in which it moves. A second and slower wave follows the same path as the first type and vibrates crossways to the direction in which it moves just as do the waves on a tight clothesline which is struck sideways. A third and the slowest type of wave follows the earth's surface and makes the biggest movement of all. It, too, vibrates crossways. By means of experiments and mathematical calculations the respective speeds of these types of waves are known and it is this knowledge that makes distances from the earthquake to

* Radio talk, KHBC, Hilo, Hawaii, February 23, 1937.

seismograph stations determinable. Since the first group or longitudinal waves and the second group or transverse waves start together but travel at different speeds they must arrive at some other point at different times with the longitudinal waves arriving first. Tables have been made which show directly the distance a shock is from a station for any given time difference in time of arrivals of these waves. That means that it is only necessary to have some method of detecting and recording the wave movements and then for one experienced to identify the specified waves on the record which must have some time control. The first-mentioned wave travels moderate distances at about seven miles per second. However, as the distance increases the rate also increases. The waves that travel around the surface travel at a constant rate of about two and a half miles per second regardless of distance.

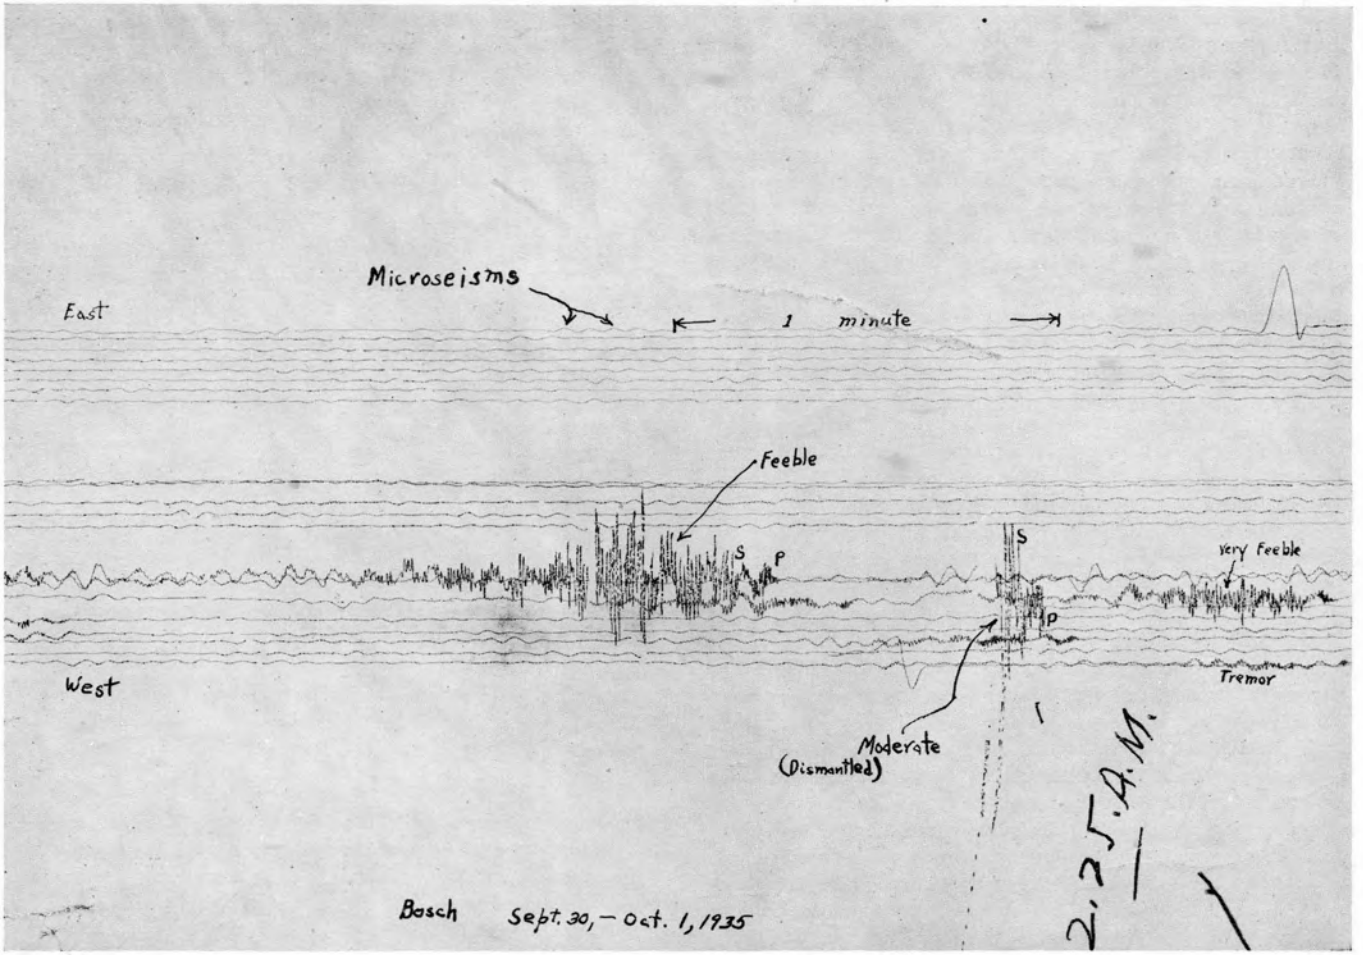

Figure 2.—East-West component of part of earthquake series of September 30-October 1, 1935. Observatory Bosch-Omori instrument, static magnification 115.

Now to return to the seismograph which is the instrument that records the earth's movements, we find a comparatively simple apparatus which nevertheless must be well constructed for proper results. It is a well-known fact that if a heavy object is at rest a lot of extra force is necessary to move it. When a fast-moving car stops suddenly the people are thrown forward, when the car starts the passengers are jerked backward. This is the same property and is known as inertia. No doubt you have all heard that word applied to some people with reason—and for the same reason. Anyhow, it is this property which makes the seismograph work. In these instruments a weight is suspended from a support which is attached solidly to the earth much as is the pendulum in a clock only in this case the earth swings in an earthquake and the weight stays still. Now, if the weight is connected properly to some device which will trace the record of the earthquake on a piece of paper then we have a seismograph. Since earth motions even of strong quakes seldom exceed, at most, a quarter of an inch the motion must be magnified so that the waves may be large enough on the record to study. This is accomplished by either of three methods, first, by mechanical levers, second, by electrical magnification and, third, by light beams as levers. Usually in the most sensitive instruments a combination of the last two is used for distant quakes. At the Volcano Observatory, mechanical levers are used, with magnification of the actual earth movement of about one hundred. Two common methods of registering are used. The first uses a sheet of paper which has been smoked with a kerosene flame, revolving on a drum at a known constant speed and in which a very light steel point attached to the pendulum through the levers draws a line. When nothing happens this mark is straight but zigzags when an earthquake occurs. The other type of recording uses a sheet of photographic paper and a beam of light takes the place of the steel pen of the first type. Magnification in the second type sometimes is as high as one thousand. The movement of the ground in Hawaiian earthquakes ranges between about one one-thousandth of an inch and a tenth of an inch. Remember the one of June 28, 1935, which knocked down a few chimneys and cracked several walls in Hilo? The ground movement at the Volcano Observatory was only slightly more than a tenth of an inch and the earthquake was centered as close to the Park as it was to Hilo. Yes, when mother earth moves even a little bit —and does it rapidly—you are going to know it. That earth-

quake was probably the first official herald of the Mauna Loa eruption in November.

A completely equipped seismograph station has three separate pendulums or instruments. They are usually so arranged that one records only earth movements north and south, another only east and west and the third, up and down. The advantage to this arrangement is that under favorable conditions an earthquake can be located from the one station. This is possible because the first longitudinal wave to arrive will move the pen east or west, another north or south and the third up or down on the record exactly proportional to the direction and intensity. The best recent example was the case of the earthquake of November 21, 1935 (Figure 1) which occurred at one-eleven a.m. and was pretty strongly felt all over the island. At the Observatory the east-west pen moved east one-half millimeter; the north-south pen moved south three millimeters. That meant the earthquake was a little south of east of us, or a little north of west. The time space between the first waves and the second waves showed it to be about nineteen miles away. Inspection of the up-down record showed that the ground had gone down at the Observatory, meaning that the wave was contracting and therefore the earthquake was nineteen miles, slightly north of west from the Observatory right on the Mauna Loa northeast rift about five miles below the summit. Seventeen hours later Mauna Loa was pouring streams of lava from around that spot. But don't be misled—they do not all come out that well.

The Volcano Observatory operates other stations than the one mentioned. It has one at Kealakekua, one at Hilo, one on the southeast edge of Halemaumau and one at Uwekahuna Museum at the Park Naturalist's headquarters. In locating the general run of shocks all of these stations are used. Distances are determined from each and laid off as circles on a map. Lines are drawn connecting the circle intersections and the point where these lines cross shows the earthquake center. But that is not all—by a little descriptive geometry the earthquake is ferreted up to the surface and the distance it was under ground is determined. Preceding the Mauna Loa eruption, the heavy shocks of September-October, 1935 (Figures 2, 3 and 4), ranged as deep as twenty-five miles. The shock of November 21 was not over five miles deep and those which occurred with the outbreak were so shallow that depths could not be determined. By no means are all the earthquakes which occur on this island located. Roughly, forty per cent are located within reason and half of this number are located with comparative accuracy and the large remainder are located only in a general sort of way as a Kilauea shock, a Mauna Loa shock a Hualalai shock, and so on. There is good reason for this deficiency. A large per cent of the shocks do not oblige by having nicely defined wave groups; many are close to only one station so cannot be checked on the others, because they are too weak to record that far away. Sometimes clockworks which rotate drums get stuck, time marks interfere and portions of the quake are lost and if the earthquake is strong and close by, dismantles the instrument before it can make a clear record—and some earthquakes just go by the name of "Maud" and both stubbornly and impudently defy you to locate them, but it makes a reasonably exciting chase at that.

At the Observatory some five different sizes of shocks are recognized as earthquakes. These are very feeble, feeble, slight, moderate and strong. By far the greatest per cent of them are very feeble with feeble a poor second. Both of these are only instrumental and are only felt where they are some distance from the instrument and near an observer. Slight earthquakes are usually felt by many people slightly near their origin. Moderate earthquakes are generally felt all over the island and produce visible effects such as moving objects, rattling doors and the like. A strong quake is anything resulting in some damage and many people frightened. The only really strong shock of the last two years was the one which was previously mentioned, June 28, 1935. Moderate shocks occurred frequently in 1935 averaging about one a month. Outstanding ones were January 2, June 25, a whole series of them, some of which bordered on strong the night of September 30, October 1 and November 21 (see Figures 2, 3 and 4). A still smaller vibration than the very feeble earthquake is one known as a tremor. Some of these last several minutes and always continuously accompany the play of fountains during eruptions. During 1935, 296 earthquakes of all sizes registered at the Volcano Observatory and besides these there were 6,227 tremors. In 1936 332 earthquakes of all sizes registered and only 2,078 tremors. That is an average of almost one earthquake a day—if we assume that the earth rests on Sundays and holidays it looks as though there may be a better average than one a day. I shall leave that for the individual to work out, meanwhile most of the strong earthquakes of 1935 were under Mauna Loa and it erupted; most of the strong ones of 1936 were under or near Kilauea and nothing happened. Let's all watch the earthquakes of 1937 and—what's next?

Hawaiian Volcano Observatory Report for February 1937

VOLCANOLOGY

The month of February showed marked increase of seismic activity, and of opening of cracks around the rim of Halemaumau pit in Kilauea Crater. Microseismic motion continued strong. The cold, rainy weather continued. The winter rainfall has been as follows:

December, 18.93 in., maximum day December 30, 5.12 in.
January, 22.01 in., maximum day January 14, 6.12 in.
February, 20.46 in., maximum day February 18, 4.87 in.

Total 61.40 inches.

The following are the monthly data for observations at the Observatory near Kilauea Crater:

Week Ending	Seismicity	Slides	Crack Openings mm.	Local Quakes
February 7	7.75	3	16.5	24
" 14	9.00	0	23.5	28
" 21	10.25	2	19.5	32
" 28	5.50	3	16.0	12

Sequence of Events by Weeks

The first week showed dense vapor from Halemaumau lava floor, due to rainfall and some sliding there.

The second week showed increase of seismicity and of crack opening.

The third week continued the increase in tremor and slides were small.

The fourth week showed less quaking and crack opening.

Slides at Halemaumau

Slides from the walls of the pit have been noted as follows:

February 2, 10:03 am, a small slide S; 10:08 am, rocks dribbling down NE wall.

February 3, 8:58 am, rocks falling NE wall.

February 19, 10:45 am, small slide NE wall; 5:23 pm, noisy slide N wall.

February 27, 10:08 am, slides NW and N walls.

Measurement of Halemaumau Rim Cracks

Weekly measurement of 26 rim crack locations resulted in aggregate movement as follows: week ending forenoon of—

February 5, 14 opened, 1 closed, opening 16.5 mm.
" 12, 19 opened, 2 closed, opening 23.5 mm.
" 19, 13 opened, 1 closed, opening 19.5 mm.
" 26, 10 opened, 0 closed, opening 16.0 mm.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Distant† Earthquakes	Local* Seismicity
January 10.....	5	4	0	2	1	7.25
" 17.....	7	2	0	0	0	2.75
" 24.....	4	4	0	0	2	3.00
" 31.....	8	4	1	1	0	7.00

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna Museum and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from stations at Hilo and Kealakekua. The disturbances began recording at the times indicated and whenever possible determinations of depths of focus have been made:

January 6, 9:13 am, very feeble, located 0.5 mile S of Bird Park area and 4.1 miles deep. 19° 26.2′ N; 155° 18.7′ W.

January 7, 11:35 pm, very feeble, probably located in vicinity of Ahua Kamokukolau.

January 8, 6:53 am, slight, probably located in Hilina Fault system S of Puu O hale.

January 8, 10:56 am, very feeble, probably located in vicinity of Kilauea Iki.

† Includes teleseisms or those shocks over 5,000 kilometers distant.
* For local seismicity definition see Volcano Letter 371.

January 10, 10:50 pm, slight, located in Kilauea SE rift zone 2.5 miles SE of Makaopuhi Crater and 7.0 miles deep. Reported felt in Hawaii National Park, in Hilo and at Honomu. 19° 20.5′ N; 155° 9.2′ W.

January 11, 9:06 pm, very feeble, located 1.8 miles NW of the Volcano Observatory and 4.1 miles deep. 19° 26.9′ N; 155° 18.7′ W.

January 13, 9:40 am, very feeble, located 4.1 miles deep under Bird Park area. 19° 26.5′ N; 155° 18.3′ W.

January 20, 9:56 am, very feeble, located 1.1 miles deep near center of Kilauea Crater. 19° 24.8′ N; 155° 16.3′ W.

January 24, 7:31 pm, very feeble, probable location in ocean 20 miles N of Upolu Point. Reported felt at Hilo, Hakalau and Puu Waawaa.

January 24, 9:38 pm, very feeble, located 2.8 miles deep, Kilauea SE rift near Hiiaki Crater. 19° 22.6′ N; 155° 14.0′ W.

At 3:39 am, January 25, a disturbance which recorded as a tremor at the Observatory was reported felt at Puu Waawaa.

January 25, 5:37 pm, very feeble, located 13.0 miles deep off coast near Keauhou Point, 4 miles S of Hilina Pali. 19° 15.1′ N; 155° 16.2′ W.

January 28, 6:05 pm, feeble, located 0.5 mile deep in E portion of Kilauea Crater near Byron Ledge. 19° 24.9′ N; 155° 16.0′ W.

January 29, 4:38 pm, very feeble, probably located in Kilauea Crater.

January 30, 4:00 am, very feeble, probably located in Kilauea Crater.

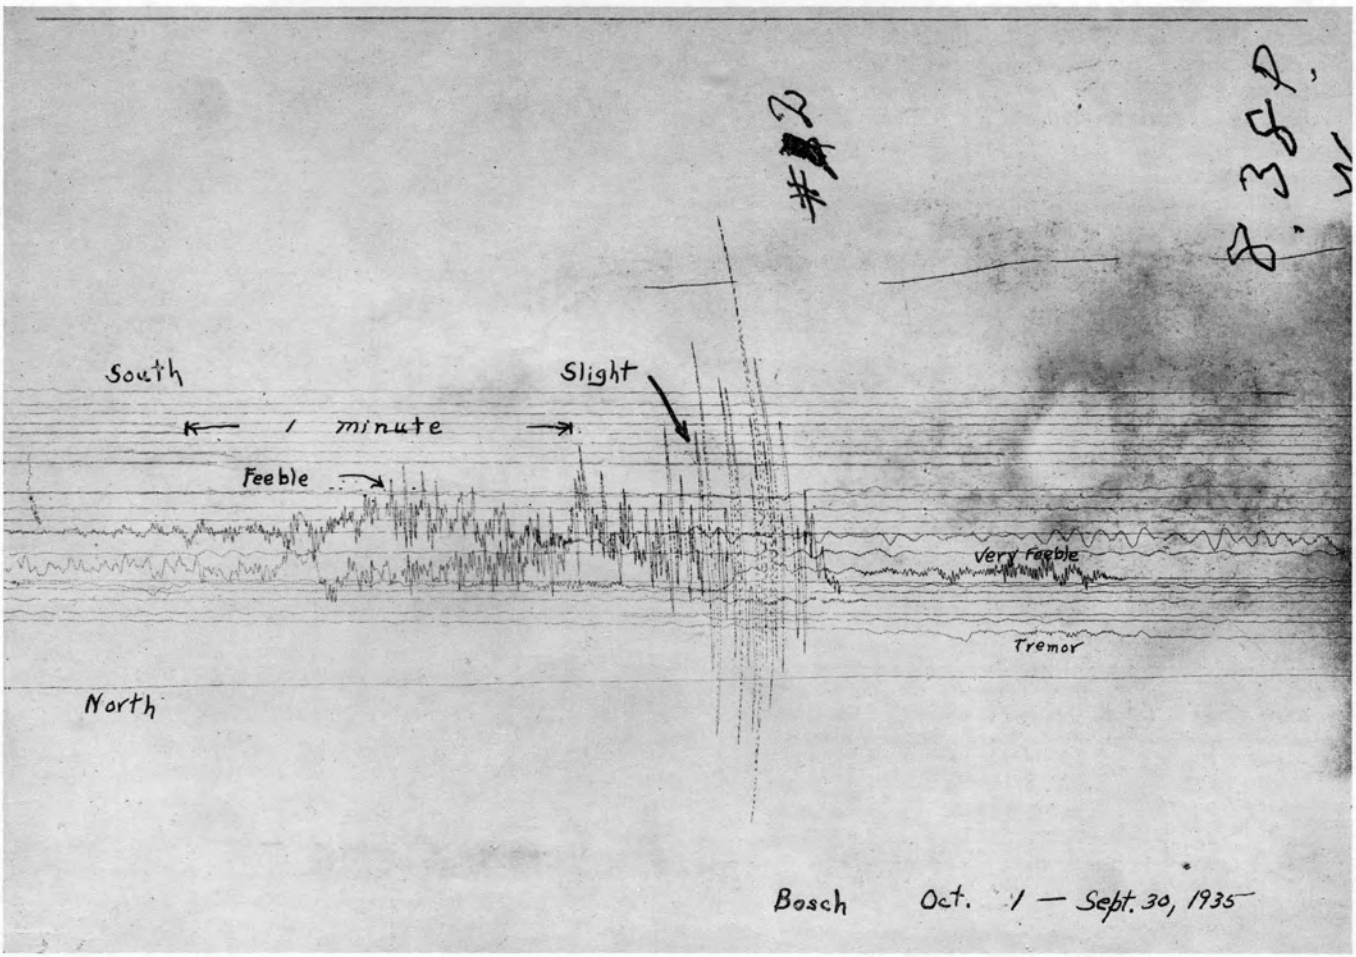

Figure 3.—North-South component of same series illustrated in Figure 2.

January 30, 11:26 am, very feeble, probable location 14 miles deep in marine extension of Kilauea SW Rift Zone, 5.0 miles E of Palima Point. 19° 9.3′ N; 155° 22.7′ W.

January 31, 7:33 am, slight, located 18 miles deep and 6.0 miles NW of summit of Mt. Hualalai. Reported felt at Hookena and at Kamuela. 19° 45.5′ N; 155° 55.3′ W.

Microseismic motion of the ground at Kilauea was strong throughout the month.

Registration of distant earthquakes at the Observatory was as follows:

January 7, the preliminary waves at 3h 04m 12s am, H.S.T., with a probable focal distance from Kilauea of about 6,100 miles. Radio reports indicated this disturbance as contemporaneous with a strong earthquake in Central Asia. The preliminary waves of a teleseism began recording at 12h 35m 38s am, H.S.T., January 23; estimated distance from Kilauea was 3,720 miles. The preliminary waves of a teleseism began recording at 8h 13m 23s, pm, H.S.T., January 24. Its estimated distance from Kilauea was 3,400 miles.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts for two clinoscope stations towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending January 31 was 2.05″ S. and 1.57″ W.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
January 10	0.44″ S 58° E	5.81″ N 70° W
" 17	1.22″ S 14° E	6.29″ N 78° W
" 24	1.36″ S 8° W	5.96″ N 88° W
" 31	3.92″ S 23° W	6.85″ N 62° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
January 10	6.84″ N 47° W	1.57″ toward
" 17	5.22″ S 75° W	4.01″ from
" 24	3.73″ S 74° W	3.18″ from

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began recording at the times indicated and whenever possible, a determination of depth of focus has been made.

† Includes teleseisms or those shocks over 5,000 kilometers distant.
* For local seismicity definition see Volcano Letter 371.

At 12:23 am, February 1, a tremor was recorded at the Observatory corresponding in time with a recorded Feeble earthquake at Kealakekua. It was reported felt in the Kona district.

February 2, 2:05 pm, very feeble, located 0.5 mile deep, E portion of Kilauea Crater, near Byron Ledge. 19° 24.9′ N; 155° 16.0′ W.

February 2, 8:59 pm, very feeble, a shallow quake located

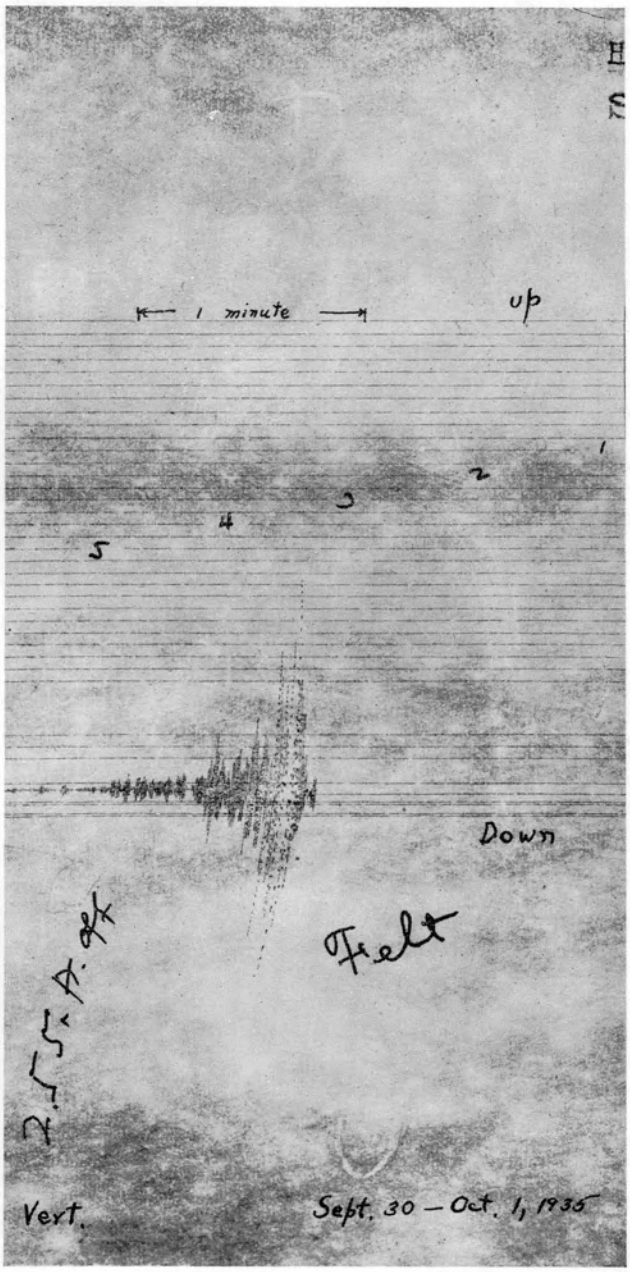

Figure 4.—Illustrates undamped vertical component of largest earthquake shown in Figures 2 and 3.

immediately south of Keanakakoi Crater. 19° 23.9′ N; 155° 16.0′ W.

February 3, 7:13 am, very feeble, located 1 mile deep and 0.4 mile NE Pit Seismograph. 19° 24.7′ N; 155° 16.7′ W.

February 3, 6:06 pm, very feeble, located in Kilauea Rim Crack Zone immediately north of Keanakakoi Crater. 1.2 miles deep. 19° 24.5′ N; 155° 15.9′ W.

February 3, 6:10 pm, very feeble, located 1.5 miles deep in NW portion of Kilauea Crater. 19° 24.7′ N; 155° 16.7′ W.

February 7, 4:22 pm, very feeble, probably located 0.8 mile NW of Kilauea Crater.

February 8, 10:47 am, very feeble, located 1.4 miles deep under SE rim section of Kilauea Crater. 19° 24.4′ N; 155° 16.1′ W.

February 9, 5:45 am, very feeble, located 4.0 miles deep and 12 miles S of Volcano Observatory at Keauhou Point. 19° 15.8′ N; 155° 13.7′ W.

February 10, 12:49 am, very feeble, probably located in Kilauea Crater.

February 10, 6:50 am, very feeble, located 1.2 miles under NW rim of Kilauea Crater in vicinity of Uwekahuna. 19° 25.5′ N; 155° 17.2′ W.

February 10, 12:40 pm, very feeble, located 0.5 mile deep under E rim of Kilauea Crater. 19° 15.8′ N; 155° 24.7′ W.

February 15, 5:09 am, very feeble, located 6.0 miles SE of Puu Ulaula, SE slope of Mauna Loa and 18 miles deep. 19° 29.3′ N; 155° 24.6′ W.

February 16, 3:50 pm, very feeble, probably located at shallow depth near center of Kilauea Crater.

February 16, 4:06 pm, very feeble, located 1.6 miles deep and 3.0 miles E of Kilauea Crater. 19° 25.5′ N; 155° 11.9′ W.

February 18, 2:38 am, very feeble, probably of moderate depth under SW portion of Mokuaweoweo Crater, summit of Mauna Loa.

February 18, 5:20 am, very feeble, located 2.0 miles deep in Chain of Craters Rift Zone, near Devil's Throat. 19° 22.6′ N; 155° 14.0′ W.

February 23, 6:20 am, very feeble, probably located in SE portion of Kilauea Crater.

February 26, 8:04 pm, slight, located 8.0 miles SE of Halemaumau near Hilina Pali and 10.0 miles deep. 19° 20.0′ N; 155° 23.3′ W. This shock was reported felt by many in Hilo and in Hawaii National Park.

February 28, 7:34 am, very feeble, probable location in E portion of Kilauea Crater.

Microseismic motion of the ground at Kilauea was strong throughout the month.

The preliminary waves of a teleseism began recording at Kilauea at 8h 42m 01s pm, H.S.T., February 20. Estimated distance was 3,430 miles.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau, the algebraic sum of radial tilts towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending February 28 was 5.56″ S and 0.60″ W.

Week Ending	Observatory	Halemaumau West Station
February 7	3.80″ S 32° W	3.81″ N 62° W
" 14	0.85″ S 69° E	5.10″ S 77° W

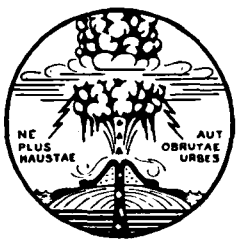
" 28	8.26″ N 68° W	0.54″ from

H. H. W.

Crater Angles



Measurement of Horizontal Angles across Kilauea Crater from the Observatory, February 25, showed closing of the Halemaumau value and an opening of the Crater value compared with similar measurements made January 21. From Kilauea SE rim to Uwekahuna there was closing of 0.84″, January 21 to February 3; opening of 4.59″, February 3 to February 12, and closing of 1.08″, February 12 to 25. Total opening 2.67″. From the Pit Seismograph to the NW Pit B.M. there was opening of 0.83″, January 21 to February 3; closing of 2.08″, February 3 to February 12, and closing of 2.25″, February 12 to February 25. Total closing 3.50″. H. H. W.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

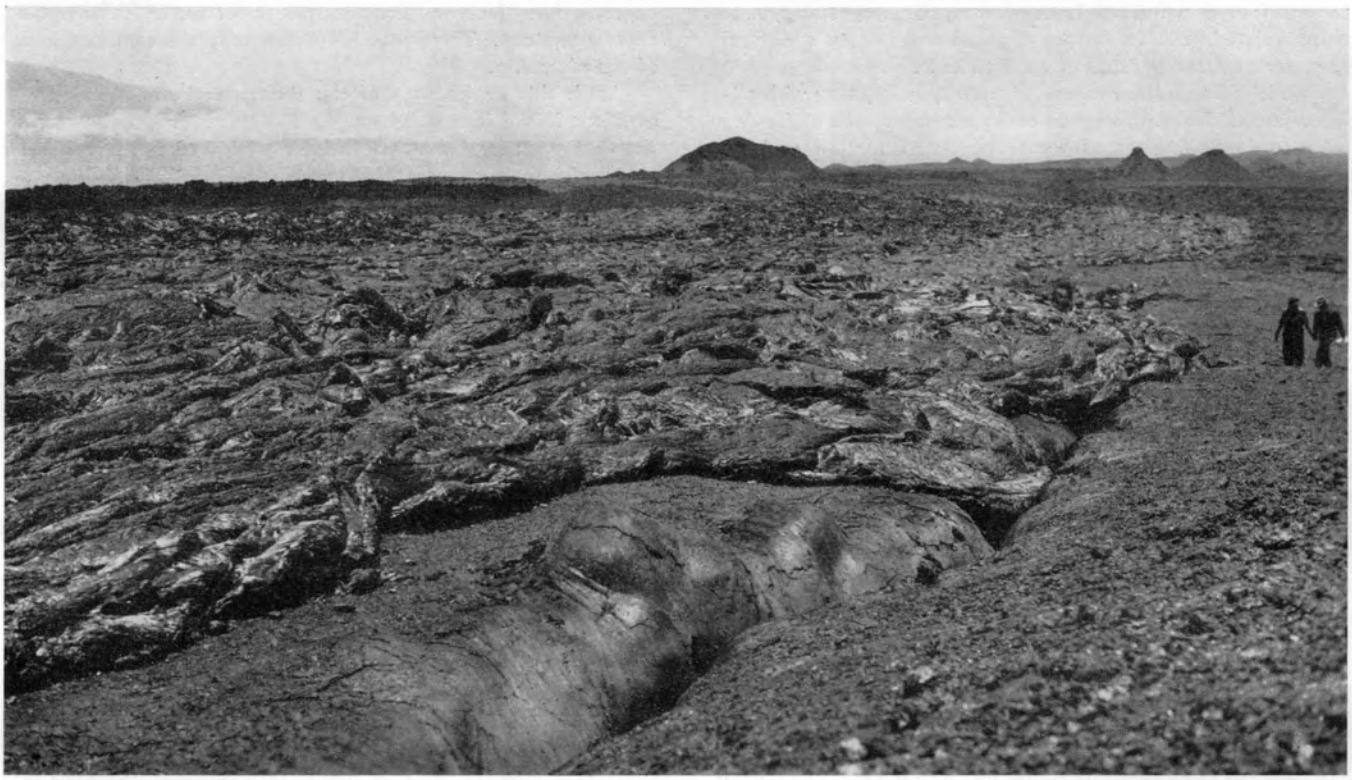

Figure 1. 1935 lava covering trail below summit crater.

MAUNA LOA*

We went up Mauna Loa from Kilauea on March 1st. The party included Mr. Coffman, chief forester of the Park Service, and Mr. Tillett, Superintendent of Territorial Emergency Conservation Work. The Red Hill resthouse was occupied as base.

We walked west two miles and studied the mountain slope towards Humuula. It is an even slope, interrupted by a few cones. In detail it is very rough where aa flows alternate with smooth ones of pahoehoe.

The proposed bank or wall to protect Hilo, across the Red Hill rift, where the flows emerge, will extend obliquely down the mountain north, when it is built. It will take advantage of existing depressions, where they are in the right direction. It will block them where they are not, diverting the stream.

This will create a channel towards Mauna Kea. The barrier would force any new flow obliquely down the slope towards the Hilo-Kona saddle.

There at the saddle the flow would make a lake. East of it on the Hilo side there would be a short high dam constructed. This would be between Puu Huluhulu and Mauna Kea, and it would extend south from Puu Huluhulu to Mauna Loa. It would block off the lava from Hilo.

It would be high enough to hold the lake until it spilled west towards Keamuku. This would protect the Ainahou and Puu Oo pasture land, and the Hilo drainage that supplies water to the city. Damming is practicable only where lava is a flat pool.

* Radio talk, KHBC, Hilo, Hawaii, March 9, 1937, and KGU, Honolulu, April 1, by T. A. Jaggar, Volcanologist, Hawaiian Volcano Observatory.

After the party had looked over this slope, and sized up the possibilities for a roadway from the Rest House down the rift northeast to some large cones, where the wall, five miles long, might start—there is smooth 1881 lava along this route —we spent the night in the Rest House, and the temperature was mild.

Next day against a bitter cold wind we rode up the rift five miles to the upper 1935 cone. This is yellow with sulphur, and steaming. It is one of many in a line. Here on November 21, 1935, the great eruption began.

At that time fountains of golden yellow slaggy foam shot up 500 feet. The whole crack for six miles from the summit crater was gushing. The torrents from it swept in many ribbons down the steep north slope away from the rift.

The liquid so bubbled and stirred itself as to crystallize in sugary lumps and sprouts. This is what is meant by aa lava. Near the actual vents the liquid that congeals is like candy or toffee. This is pahoehoe lava. It may be very stringy like coarse worsted. But its surface of ropes and folds is a natural glass, dark colored because of the iron in it.

The lava inside the mountain is mostly glassy slag with olivine crystals. The transition to aa in a quarter-mile of flowing is due to the boiling out of gases, the violent motion, and the rapid crystallization such as takes place in the centrifugals of a sugar mill.

Accompanying these changes there is great loss of heat. In the first 12 hours of an eruption there is enormous expenditure of energy. The gases are heat makers. Much more gas escapes than lava. The ebullition of gas comes from profound depths. The eruption pulls the cork. The opening of the mountain produces violent gas fizzing due to foaming up. The gas comes from whatever underground lava is relieved of pressure. Probably a big piece of mountain is lifted by the sudden frothing. The effervescence makes the inside lava swell. If you loosen the cork in a beer bottle, and start all the gas, and then try to put the cork back, you must make all that gas dissolve again, or else let it out. The volcano gases are heaters and liquefiers of the slag.

Probably some big force like the settling of the shell of the globe is always forcing the stiff inside lava up these volcano cracks. When the mountain gives way we get an eruption. Right now the lava is pressing up under Kilauea Volcano, the cork will lift, and the lava gas will spout up around the edges of the bottom of the pit.

What made the flow start out of the north flank in 1935? This came a week later than the big initial fountains. And the flow lava emerged from a crack 3,000 feet lower down the mountain slope. The answer appears to be that the internal swelling spreads down a rift belt, an old zone of vertical cracks that extend deep and are full of lava.

The top of the mountain is very heavy. The rift belt goes across the top. When splitting of the rift starts, the swelling lava inside acts as a wedge. The rapid foaming on top shrinks the lava inside as it loses heat and gas. Possibly the plug inside the top crater settles a little. The heavy summit squeezes together.

Down at the 9,000-foot level small cracks can still open in brittle old rock and let out the lowered liquid. It requires an enormous force to lift heavy slag to 12,000 feet elevation. The shrunken lava that has partly cooled glues together the top cracks. This hot paste is very tough like red-hot iron, and old places break more easily. The lower lava escaping at 9,000 feet still has gases heating and expanding it. It quietly welled forth and pushed down to lower places on the mountain. The smooth pahoehoe catches up with the aa, and finally passes the aa front. The movement is slow enough to let the glassy candy float to the top and make skin.

Then a strange and sudden change happens. Where the front that people visit had been a tumbling bed of coals, there quickly appears a gleaming glossy stream covered with beautiful membranes. These skins wrinkle, and festoon and tear and belch out glowing porridge. They puff into elephant toes. The top is silvery or opalescent, smooth and bulbous, flaming with the gas of burning sod below. Inside this crust the liquid has formed a tunnel for itself.

It was this tunnel that made the bombing effective. Let us imagine the water supply to a house under a cliff. The liquid enters the house from a hillside to the third floor. The inside pipe is broken and making a flood in the cellar. If you smash the source pipe and let out the water on the hillside, there will be no more flood in the cellar except for what liquid remains in the house plumbing.

The crusted flow on the mountain was the house. The top story inlet pipe was at 9,000 feet. The aviators of the Army bombed that place and smashed the upper tunnel. The liquid there came out. There was left below only the remnant lava of the plumbing.

With this explanation of the difference between the tremendous initial lava floods of the November, 1935, fountains the first week, and the smooth later flow, let us return to the proposed walls for protecting Hilo.

No bombing could have altered those first voluminous gushings of 1935. They travelled eight miles in a half day! If the lower vent had not opened they might have reached the sea in South Kohala in a week. Just this happened in 1859, a little farther west, for a very long and rapid aa flow.

Suppose such a flood were to burst out at the eastern or Hilo end of the northeast rift. This would be somewhere below Red Hill. It would enter Hilo Harbor in a week. It would burst forth with terrific fountains and might average five miles a day. The distance to Hilo is twenty-six miles. Mr. W. H. Shipman is among the people who can remember back to 1859.

Such lava would be intensely liquid and if it met barricades aligned down hill oblique to its natural course it would follow them. There is no question of damming across it. That is only for flat lakes. The plan is to create an artificial channel in the general direction of the natural slope. There are many natural channels. By taking advantage of them the cost of construction can be reduced.

The final Hilo Wall from Piihonua to Keaukaha is to be on such a natural slope. Its object is to give final protection to the harbor. It must be high enough to catch any flow in the Wailuku or Wailoa drainage valleys and deflect it eastward to the flat lauhala land of the cape south of Hilo Bay.

That land is all old Mauna Loa flows.

This Hilo project takes precedence of the Red Hill and Humuula projects for first construction. But it will not do to trust to the Hilo wall only. There are all the water supplies to protect, and the farms and suburbs and forest reserves. It is never good strategy to trust to one fortress for winning a battle.

The three projects interlock. They should all be started in the next three years. By average intervals, the next Mauna Loa eruption should be ready for outburst any year after 1939. Let us hope that it will be in the summit crater or at some other harmless location!

Mauna Loa in the textbooks is called the most active and bulkiest volcano on earth. Mauna Loa is the center of present-day activity in the Hawaiian Islands. Insurance against Mauna Loa eruptions and earthquakes, and consequent fires and floods, agitates the companies to know what rate to charge. If Hilo is safe the rate will be low. Marine insurance is equally important. Federal dredging to accommodate the biggest ships in Hilo harbor will be influenced by the harbor's safety. If they think it possible Hilo commerce will have to move to Kealake-

kua, the harbor will be less important. The army, the navy and shipping are all concerned. The Volcano Observatory has plans for a seismograph cellar on the Mauna Loa road soon to be constructed by C.C.C. labor. New instruments will be placed around Mauna Loa. Mauna Loa is just now the most interesting of world volcanoes. Hilo cannot afford to join the ranks of the world's disasters.

THE ILLUSTRATIONS

These photographs illustrate conditions at the north end of the summit region of Mauna Loa, as photographed by Ranger P. F. Murray June 15, 1936. At that time the upper cone at the 12,000-foot elevation was still emitting much hot sulphurous fume and yellow sulphur stained the cone. In Figure 1 this cone is beyond the large cone shown, this being a view close to the summit looking down the northeast rift. The trail here was covered for about a half mile with a new 1935 flow of thin shell pahoehoe shown in the foreground. A typical old crack of the rift belt is in the extreme foreground. The source of this flow was about three hundred yards northwest of the summit resthouse, from a crack that was probably the outlet for the 1935 lava lake that occupied the North Bay of Mokuaweoweo. Part of the flow poured down the open crack like the one in the foreground and the trail was covered within the area shown.

Figure 2 shows the 1935 fill of the North Bay, from the summit resthouse. The pahoehoe lava cascaded from a rim crack into the bay.

Figure 3 shows this rim crack in the foreground on the shelf where the resthouse is seated. A new small lava cone about ten feet high was built up only two hundred feet from the old stable of the resthouse. Some of this lava flowed toward the resthouse along the crater wall and disappeared through an upright crack in the wall; the remainder flowed to the right into the North Bay. The filling of the bay had been to a depth of some forty feet, and the pahoehoe surface stands within fifteen feet of the resthouse level. As shown by Figure 3, thin slabs of lava about four inches thick can be seen slumping down the wall crack completely around the north side of the bay from a level approximately fifteen feet below the house. This plainly marked rim crack extends around to the opening from the bay into the main bowl of Mokuaweoweo, according to Ranger Murray.

Figure 4 shows the summit resthouse of Mauna Loa, photographed in May, 1935, of iron and stone construction, and built with Hui o Pele funds.

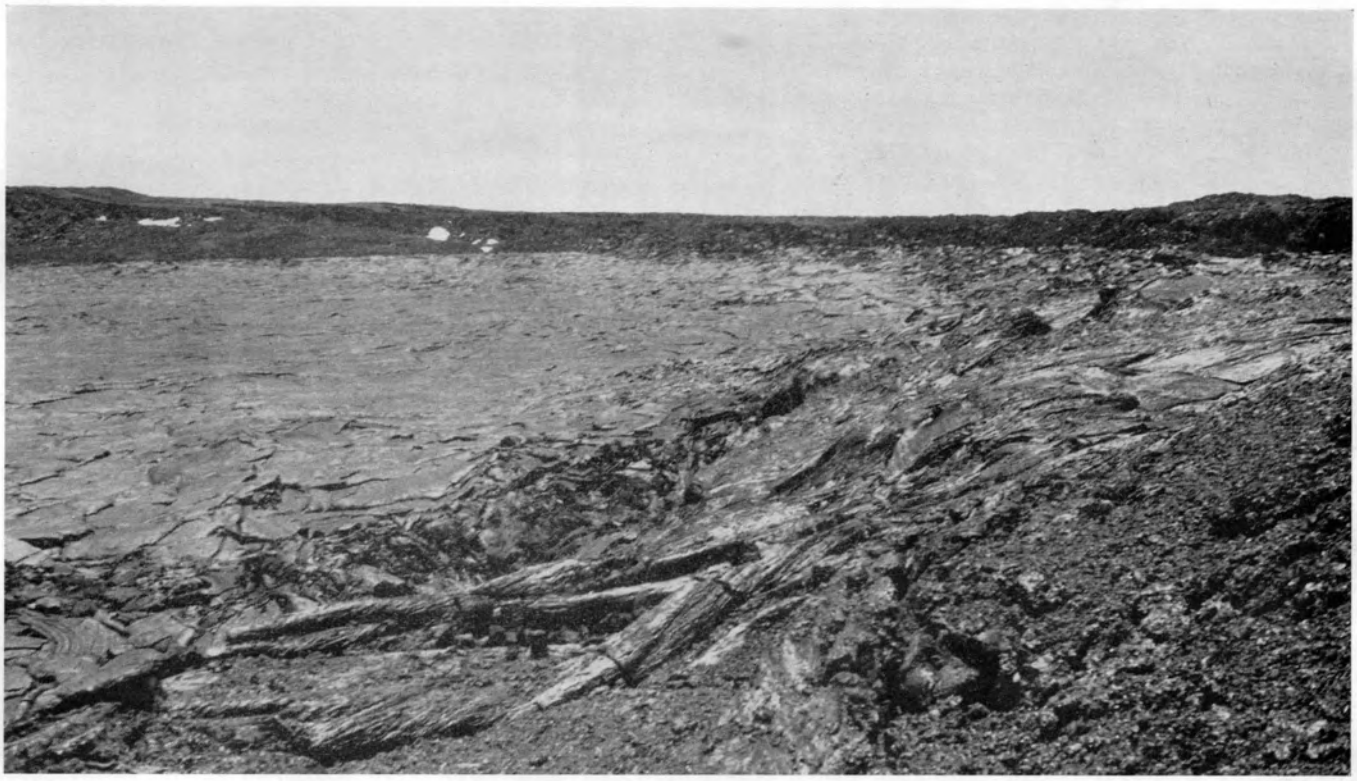

Figure 2. North Bay of Mokuaweoweo from resthouse region. New 1935 lava.

Hawaiian Volcano Observatory Report for March 1937

VOLCANOLOGY

The northeast rift of Mauna Loa was inspected March 2, the upper cones of 1935 were steaming mildly and one of them was stained with sulphur.

The following are the weekly data for observations of the Observatory near Kilauea Crater:

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Quakes
March 7	11.25	0	23.0	37
" 14	9.50	0	23.5	30
" 21	26.25	5	16.5	69
" 28	13.00	0	14.5	39

There were light earthquakes during the month perceptible at Kilauea and of Kilauea origin. There were three at Mauna Loa distances, and one felt strongly at Kailua, believed to originate east of Hualalai.

Sequence of Events by Weeks

The first week showed quiet conditions at Halemaumau.

The second week no slides were noticed, and blue fumes from the sulphurous patches at the bottom of pit were only slightly in evidence.

The third week, which had the most earthquakes, produced several slides.

The fourth week produced no reports of slides and there was fuming from SE and NW bottom solfataras.

Slides at Halemaumau

Slides from the wall of the pit have been noted as follows:

March 16, a fresh scar appeared on NE wall 300 feet below edge.

March 17, slides fell from the end buttress, 10:30 a.m. and 3:40 p.m. The earthquake 12:30 p.m. set going a slide NE, followed by dribbling of rocks more than an hour.

March 21, 5:20 p.m. slide started at NE rim.

Measurement of Halemaumau Rim Cracks

Weekly measurement of 26 rim crack locations resulted in aggregate movement as follows: week ending forenoon of—

March 5, 15 opened, 2 closed, opening 23.0 mm.
" 12, 16 opened, 0 closed, opening 16.5 mm.
" 19, 12 opened, 0 closed, opening 16.5 mm.
" 26, 6 opened, 4 closed, opening 14.5 mm.

12 mm. of this was contributed by Crack No. 25, at the east end of the pit. This crack has opened continuously since the heavy sliding of October-November, 1936.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Distant† Earthquakes	Weekly* Seismicity
March 7	29	6	0	0	0	11.25
" 14	24	5	1	0	0	9.50
" 21	49	16	2	2	0	26.25
" 28	36	2	3	0	1	13.00

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began recording at the times indicated and whenever possible a determination of depth of focus has been made.

March 1, 7:28 pm, very feeble, probably originated in NE portion of Kilauea Crater.

March 2, 1:26 am, very feeble, located 18.0 miles deep under Mauna Loa NE rift zone in vicinity of Puu Ulaula. 19° 32.5′ N; 155° 26.6′ W.

March 3, 8:42 am, very feeble, located deep under SE portion of Mauna Loa 13.0 miles W of the Observatory. 19° 26.0′ N; 155° 27.5′ W.

March 4, 1:24 pm, very feeble, probably originated in NE portion of Kilauea Crater.

March 8, 12:17 pm, very feeble, located 1.0 mile deep near center of Kilauea Crater, 1.4 miles from the Observatory. 19° 25.1′ N; 155° 16.6′ W.

March 9, 6:56 am, very feeble, probable origin under NE rim of Kilauea Crater.

March 10, 3:04 am, very feeble, located in N portion of Kilauea Crater, 0.9 mile deep. 19° 25.7′ N; 155° 16.7′ W.

March 10, 6:05 pm, very feeble, located in fissures at SE rim of Kilauea Crater immediately west of Keanakakoi. 19° 24.2′ N; 155° 16.1′ W.

March 10, 10:09 pm, very feeble, located 12 miles deep, 6.0 miles NE of Puu Ulaula, Mauna Loa NE rift. 19° 35.0′ N; 155° 23.0′ W.

March 11, 7:10 pm, feeble, located 5.0 miles deep under shoreline at Apua Point, 13.0 miles SSE of the Observatory. Reported felt in Hawaii National Park and at Mountain View. 19° 15.8′ N; 155° 11.0′ W.

March 15, 12:41 pm, very feeble, located 1.0 mile deep, SE rim of Kilauea Crater and 0.5 mile SE of Pit seismograph station. 19° 24.0′ N; 155° 16.6′ W.

March 15, 12:50 pm, feeble, located 0.6 mile NE of Pit seismograph station in Kilauea Crater. 0.4 mile deep. Reported felt strongly by many in Hawaii National Park with particular strength at Kilauea Military Camp, N rim of Kilauea Crater. 19° 24.8′ N; 155° 16.7′ W.

March 16, 11:00 am, very feeble, located 1.0 mile deep under SE rim area of Halemaumau. 19° 24.5′ N; 155° 16.9′ W.

March 16, 1:13 pm, very feeble, located under S portion of Halemaumau, 1.6 miles deep. 19° 24.5′ N; 155° 17.2′ W.

March 17, 3:05 am, very feeble, located under NE rim fault zone, Kilauea Crater, 1.0 mile deep. 19° 25.4′ N; 155° 15.8′ W.

March 17, 12:29 pm, slight, located 1.0 mile deep, 0.6 mile E of E rim of Halemaumau in Kilauea Crater. Felt by many persons in Volcano area and to a point 2.0 miles E of the crater. 19° 24.5′ N; 155° 16.6′ W.

March 18, 2:36 am, very feeble, same location as preceding shock.

March 18, 12:10 pm, very feeble, located 16.0 miles deep and 8.0 miles E of summit of Hualalai. Reported felt strongly at Puuwaawaa Ranch and at Kailua, Kona. Dismantled Kona seismograph. 19° 41.0′ N; 155° 44.5′ W.

March 19, 8:39 am, slight, located 1.4 miles deep in fissure zone SE rim of Kilauea Crater and 0.9 mile E of Halemaumau. Reported felt at CCC Camp. 19° 24.4′ N; 155° 16.2′ W.

March 20, 12:15 pm, feeble, located 1.8 miles deep near the Old Stone Corral in Kilauea Crater. 19° 24.8′ N; 155° 16.3′ W.

March 20, 7:13 pm, very feeble, located 1.6 miles deep and 1.2 miles SE of Pit seismograph station. 19° 23.6′ N; 155° 16.2′ W.

March 20, 7:14 pm, very feeble, probably originated in Kilauea Crater about 1.0 mile SE of the Observatory.

March 21, 6:10 am, very feeble, located 4.6 miles deep and 0.9 mile northwest of Cone Peak, Kilauea SW rift zone. 19° 24.0′ N; 155° 19.3′ W.

March 21, 3:37 pm, very feeble, probably located under Halemaumau.

March 22, 10:50 am, feeble, located 1.4 miles deep, 0.4 mile S of Kilauea Iki. 19° 24.5′ N; 155° 15.1′ W.

March 22, 11:12 am, feeble, located 0.4 mile N of Ahua Kamakokulau, 2.0 miles deep. 19° 23.3′ N; 155° 16.2′ W.

March 24, 7:11 pm, very feeble, located in Kilauea SW rift zone, 4.3 miles deep and 2.5 miles SW of Halemaumau. 19° 23.0′ N; 155° 19.0′ W.

March 24, 9:35 pm, very feeble, located 10.0 miles E of summit Crater of Mauna Loa, 7.0 miles deep. 19° 24.4′ N; 155° 32.0′ W.

March 26, 8:29 pm, feeble, located 8.0 miles deep and 7.0 miles S of Kilauea Crater in Hilina Pali Fault System. 19° 19.0′ N; 155° 16.0′ W.

Three minutes of continuous tremor registered March 26, beginning at 5:12 pm.

Microseismic motion of the ground at the Observatory was strong the entire month with the exception of March 25 when it was moderate.

The maximum wave of a teleseism recorded at 6h 37m 39s

† Includes teleseisms or those shocks over 5000 kilometers distant.
* For local seismicity definition see Volcano Letter 371.

am, H.S.T., March 25. It was probably associated with reported shocks in California of that time and date.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts towards or away from the Pit.

Figure 3. Mokuaweoweo Resthouse.

At the Observatory the total accumulated tilt for the year ending March 28 was 7.83" S and 2.6" W.

Week Ending	Observatory	Halemaumau West Station
March 7	1.23" S 71° E	4.77" N 77° W
" 14	0.94" N 35° E	6.29" N 73° W
" 21	3.33" S 49° W	6.88" N 4° W
" 28	1.42" S 45° W	4.29" S 78° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
March 7	4:15" N 60° W	0.58" from
" 14	7.06" N 51° W	0.99" toward
" 21	13.22" S 35° W	3.90" from
" 28	5.90" N 22° W	1.35" toward

Crater Angles

Measurement of Horizontal Angles across Kilauea Crater from the Observatory, March 24, compared with similar measurements of February 25, showed opening of 2.5" across Halemaumau and an opening of 0:41 across the Crater from the SE rim to Uwekahuna.

H. H. W.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
REPORT OF THE SECRETARY
ANNUAL MEETING, HONOLULU, 31st MARCH, 1937

To the Members of the
Hawaiian Volcano Research Association*

I have the honor to report upon the work of your association for the year ending at this date.

A year ago it was announced that a plan was being initiated for cooperation with the University of Hawaii. This plan was carried out and has proved to be helpful and advantageous. The services of Dr. Ballard—an expert physicist—were made available to us through its operation and important work in gas collection and spectroscopic analyses was undertaken. We were also able to add a permanent member to the clerical staff at Kilauea with a resultant saving to the Director of much necessary but time-occupying detail work in the sorting and classifying of documents and correct indexing of the very large number of exchange publications.

This saving of time has made it possible to devote proper attention to our monthly publication, The Volcano Letter, which has now been brought up to date—while the transferring of the detail work of editing and publication to Honolulu office has enabled it to be issued and distributed at the proper intervals.

The Volcano Letter in its enlarged and illustrated format has aroused considerable interest in many parts of the world and it has been gratifying to receive very many most favorable comments upon it. The now historic period, ending with the bombing of Mauna Loa in 1935, has been exhaustively dealt

* At this meeting an address by Dr. Jaggar dealt with the "Protection of Hilo Harbor."

with in this medium—no less than four successive issues having been required thoroughly to cover the subject.

Other publication work has been undertaken, such as an illustrated article upon the "Bombing of Mauna Loa," in the American Military Engineer, and "The Life of Bundjiro Kato" in the Bulletin of the Geological Society of America—both by Dr. Jaggar. A request story of the Mauna Loa incident has been completed by your Secretary in French, for a French-Canadian Journal of international circulation.

ciation of Volcanology which next meets in Washington in 1939.

While at the moment it may be said that the publications and the Observatory plant have been restored to their pre-depression efficiency—it is increasingly evident from the now-existing situation with respect to Mauna Loa that greater responsibilities than ever before are devolving upon this Association. We cannot escape the fact that it is we—as an agency, distinctively Hawaiian but recognized by the world of science

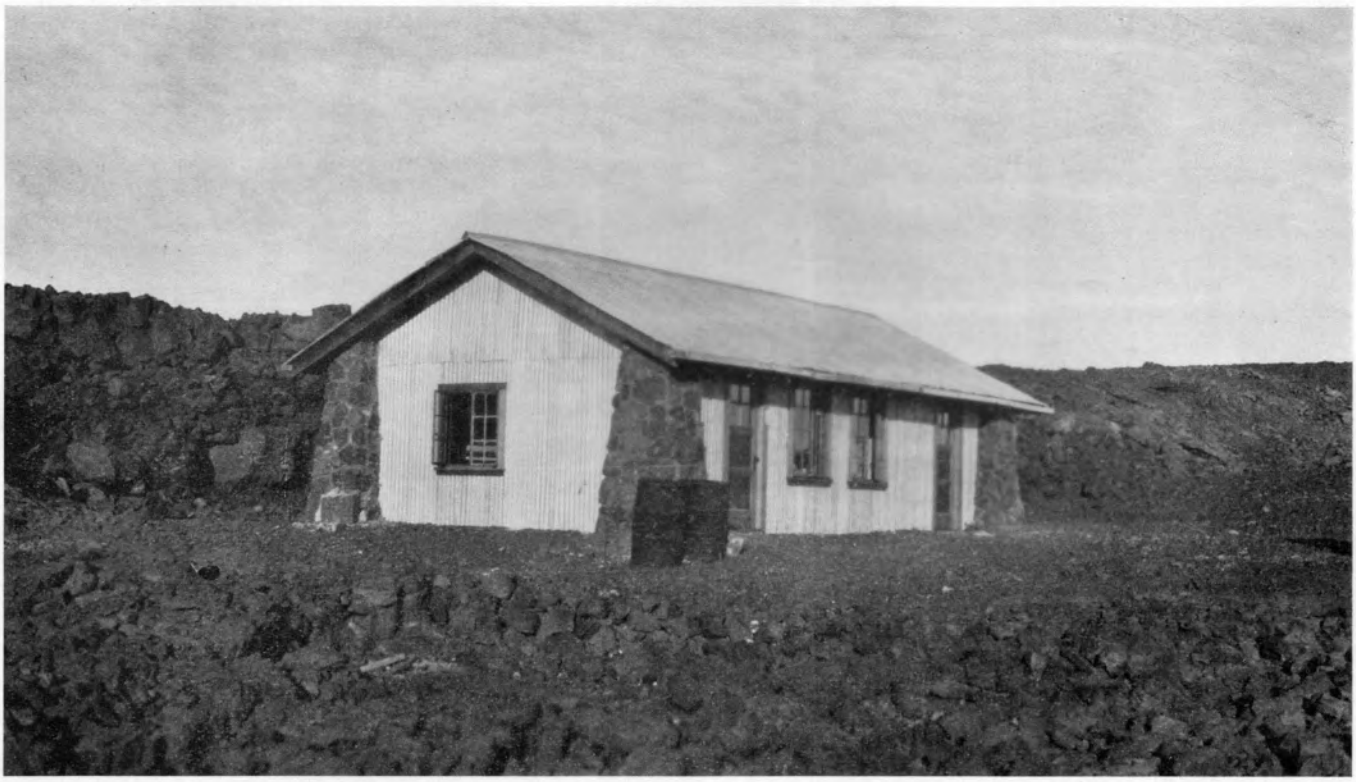

Figure 4. Resthouse, summit of Mauna Loa, constructed with Hui o Pele funds. May, 1935.

While on the subject of Mauna Loa, it may be mentioned that the great lava flow ended on January 2nd, 1936: summit emission of gas dwindled in March, but fuming and deposit of sulphur continued throughout the year. One of the most valuable lessons learned from this eruption by the people of Hawaii was that of the serious menace to Hilo and its nationally important harbor. It is upon this subject that Dr. Jaggar will address you tonight.*

In the spring of the year came an urgent request from the Royal Society of London for Dr. Jaggar to visit Montserrat in the British West Indies to help and advise in a serious seismic crisis that seemed to presage the possibility of a disaster comparable to that of St. Pierre in Martinique in 1902. Accordingly, Dr. Jaggar proceeded thither in April and, after thoroughly examining the situation, formulated a comprehensive program that—should disaster eventually occur—may be the means of saving very many valuable lives. It is of interest to recall that upon arrival in Montserrat, he found a number of Jaggar Shock Recorders were in use by the British authorities —having been made in the Kew Observatory near London. It should also be mentioned that the cost of this expedition was refunded to us by the Royal Society.

Your Association is honored by the election in Edinburgh of Dr. Jaggar as first vice-president of the International Asso-

as a pioneer—who are permanently called upon to direct and foster the progress of volcano research in Hawaii. It is not, as soom seem to think, a function of the Federal Government to educate our community here in Hawaii to an awareness of inimical forces close at hand. It is our function to do all that we can through our publications—and to take the initiative in matters of public safety. We have only to look back to as recent a time as December, 1935, to realize that, had we during the depression shirked this responsibility and been unprepared—a great disaster might have come upon the Territory; and the Federal Government might have been deprived of a harbor that may well prove vital in both war and commerce. It was this Association that saved the Volcano Observatory from extinction in 1934.

The whole question of safety for Hilo and its harbor, which looms large at this very moment, is one that—as we shall presently hear—is already receiving much serious thought in the Department of the Interior; in Hilo, and in Honolulu through the Territorial and other organizations whose interests are concerned.

It is our duty to undertake the initiative, to plan and to direct, and this is being done. Already, under the direction of the National Park Service—the Mauna Loa road—of supreme importance as a means of access to the mountain, is being extended towards Red Hill—a vital, strategic point for future operations—and has been completed by C.C.C. labor for nearly

* See Volcano Letter, January 1937.

ten miles at $5000 per mile. This is probably one of the most economical applications of labor on record in Hawaii.

A Mauna Loa Observatory is of paramount importance to the near future. It will entail staff additions to the Kilauea Station and we must promote the means to take care of it. We are extremely fortunate at the moment in the hearty cooperation extended to us by the National Park Service in Hawaii. Its work during the critical period at the end of 1935 was beyond all praise, and we are hopeful that this cooperation may long continue.

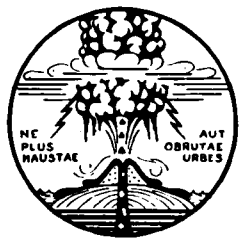
But the lesson of that time has taught us that there is very much to be done and we have but little money with which to do it. We depend entirely upon a continuance of the support which has been so loyally given to us in the past and for which we are profoundly grateful.

A year ago an appeal was made to our members to help us by interesting their friends. While our membership has increased steadily during the year it is noticeable that most of the increase has come from the mainland and from foreign countries. It takes a lot of members at $5.00 a year to produce an income sufficient to enable us to undertake important projects—and it is possible that the very nearness of the people of these islands to all that we are trying to do—blinds them to its real importance. That we have been able to carry on for a quarter of a century, however, is a tribute to the generosity of our community leaders who have done so much to make Hawaii one of America's chief assets.

It is appropriate here to state, for libraries and institutions at a distance, that their memberships in this Association are supporting unique scientific research and publication. They are not merely subscribing to a magazine. The Volcano Letter and technical papers—for numerous recent ones we are indebted to the University cooperation—are efforts to make this research known. The Government through the National Park Service is not financed to publish technical articles. The Association in Hawaii assumes this task. It has been difficult to combine interesting the general public as well as the scientific reader, along with prompt report upon volcanic activity. These three motives have been wrestled with for twenty-five years, with very feeble sinews of war.

This Volcano Research Association in the central Pacific stands for a world study of world processes of nature. Its publications and their indexing are limited by the money available for printing. May our generous leaders in Hawaii soon receive the support that will pay for the printing of numerous manuscripts now filed away, awaiting suitable publication, and the indexing of the serial ones.

Respectfully submitted,



L. W. de VIS-NORTON,
Secretary and Assistant Treasurer.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

CRACK MEASUREMENT AND TILT AT THE HAWAIIAN VOLCANO OBSERVATORY*

On February twenty-third of this year I had the pleasure of telling you something about the earthquakes on this island, their relation to the volcanoes, how they are detected and how located. It was a long subject to cover in fifteen minutes—in fact, I did not cover the subject in that time but went four minutes over the allotted amount. One might suspect from that state of affairs that earthquake studies took up about all of the time available to the personnel at the Observatory. It is true that the earthquake studies do consume a lot of time and energy, and they are a very important part of volcanologic research but they are by no means the only source of current information concerning the welfare of the volcano. There are other means of feeling out underground movements—not so spectacular but none-the-less important and probably even less ambiguous than earthshakings.

Each week there appears in the local newspapers a report of conditions for the preceding week, ending at twelve midnight Sunday. Among other things, the movement of cracks around Halemaumau and the tilt at the Observatory are reported. Not reported in the papers, but of great interest as significant observations are the results of triangulation and leveling determinations.

On the floor of Kilauea Crater and surrounding the rim of Halemaumau and roughly concentric to it, are a series of cracks. These cracks vary in width and depth from a few inches to several feet, and from some there issue considerable heat and steam. Every Friday morning two members of the

* Radio talk, KHBC, Hilo, Hawaii, April 6, 1937, by Hugh H. Waesche, Asst. Geologist, Hawaiian Volcano Observatory.

Observatory staff make a round of the pit and measure with a millimeter steel tape certain selected, marked localities along these cracks. The marks are copper studs on which are cut crosses for accurate reference. These studs are either cemented to or driven into the solid rock forming the respective sides of the crack toward or away from the pit. Thus, by regular measurement every appreciable movement may be and is detected. Gases and lava pressing up under the crater floor should open the cracks whereas a recession of lava and lowering of gas pressures should cause the cracks to close. It is possible also that tidal forces in the earth caused by moon and sun relationships may cause some changes in the cracks. Another factor, near the rim of Halemaumau, is undoubtedly the force of gravity ever tending to pull the large rim blocks bounded by these cracks, into the pit. Because of regular measurement of cracks indicating comparative movement the likelihood of material sliding in large amounts from certain localities around Halemaumau rim is known well in advance. The large slide of October twenty-second of last year was heralded by excessive crack opening, and a month before this occurred, the northeast area of the pit rim was wired off and warning signs were put up. The results of the crack measurements are plotted up on the basis of percentage opening for the total which makes an irregular curve and on the basis of actual amounts of opening for individual cracks. The latter curves are comparatively smooth and show that as the time approaches for a section of the rim to give away and fall into the depths below, the rate of opening increases more and more rapidly, or is accelerated.

In March, 1936, thirty-two crack localities were being measured. In March of this year only twenty-six were being measured. One crack at the northeast triangulation station gave way during the latter part of March last year. A new one was established twenty feet further back. This one was doomed to a short life. It disappeared with five others along the northeast and east rim of the pit last October and November. One crack, the famous number forty-six, began to show movement of a definitely progressive nature over a year before it fell in with the other just referred to. It opened by ever-increasing amounts, a total of thirty-six centimeters or approximately a foot and a half in about twenty-two months. In the last month alone, it opened ten centimeters, or about four inches, and this crack was nearly two hundred feet back from the rim. On Tuesday afternoon Naturalist Lamb and myself were taking pictures of the region. Thursday morning, October twenty-second, the ground where we had been was at the bottom of Halemaumau and the north side of crack forty-six was the rim of the pit.

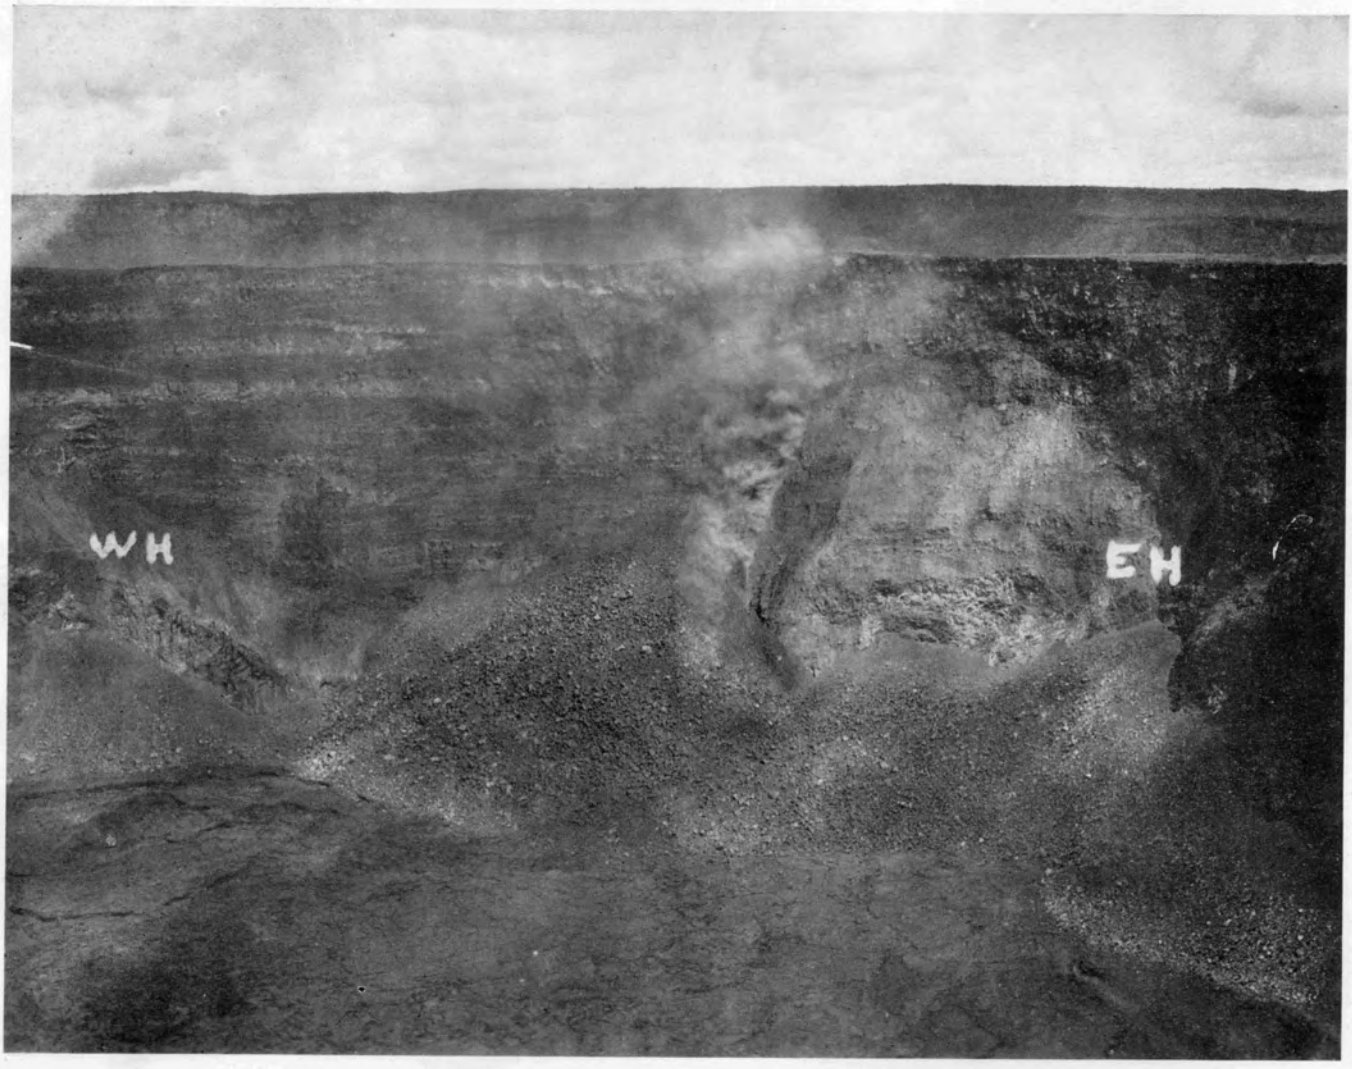

Figure 2. After collapse, October 22, 1936.

Generally speaking, all of the measured cracks have opened

by varying amounts continuously during the period following the Halemaumau eruption of 1934. One exception is number forty-one, about eight hundred feet southwest of the pit. It has shown no change in the same time period. At present, crack number twenty-five on the east rim is moving most rapidly and some large rock falls from that portion of the pit should be imminent and are anticipated.

One of the earliest established and probably one of the most significant branches of routine research at the Hawaiian Volcano Observatory is that related to what is referred to in reports as tilt or tilting of the ground. This action, although well identified, is by no means too easy to measure. At the Observatory and at Halemaumau tilt is measured by the wanderings of the seismograph pens, with relation to a fixed value recorded on the smoked seismograph drum. Also, tilt around Halemaumau is measured by a special apparatus known as a clinoscope. Two of these are now in operation, one on the southeast rim, and one to the west of Halemaumau. A third instrument was located northeast of the pit but was disrupted by an earthquake. It is the earthquake situation which makes tilt measuring difficult here. The problem is to have an instrument as sensitive as a seismograph, of high magnification, which would be inexpensive but accurate, and earthquake proof. In Japan a partial solution, at least, seems to be a sealed horizontal pipe, about half full of water with means of measuring changes of level of the water at the ends of the tube.

Tilt has been defined by Dr. Jaggar and R. H. Finch as "a change in angular relation between a portion of the earth's surface and the plumb line." A plumb bob suspended from an arm on a tall flagpole should illustrate this by the bob swinging to or from the pole, or sideways as the ground tilted, thus changing the angle of the pole with relation to the horizontal. If it were possible to attach a pen to the top of the flagpole and this pen wrote on a sheet of paper which was permanently fixed to the sky in its position, then the pen would trace a picture of the tilt graphically on the sheet of paper, the size of the drawing depending upon the height of the pole, the taller the pole the larger the drawing.

Figure 3. Crack No. 46 looking north before landslip.

Something of this nature is done at the Observatory. No flagpole is used but measured daily tilt on the Bosch-Omori seismograph is transcribed to a sheet of coordinate paper. Since the two pendulums of the seismograph are oriented north-south and east-west, these directions are used and all component directions resolved therefrom and a picture of what the top of the flagpole would have done is shown. It has been discovered that the ground on the northeast rim of Kilauea makes an

Figure 4. Crack No. 46 looking south after landslip (man in Figure 3 would be in air beyond A).

annual loop as much as twenty seconds of rotational arc for the greater diameter which runs northeast, southwest. Minor irregularities and loops occur in the major annual loop. Marked directional tilts have occurred preceding eruptions both of Kilauea and Mauna Loa. In the first week of October, 1935, tilt at the Observatory began to move, following the vigorous earthquakes of September thirty-October one, in a southeasterly direction and continued to do so until November seventeenth, when the tilt direction changed back to the northeast and on November twenty-one Mauna Loa erupted, thus relieving the pressure which had tilted the ground some two or three seconds at the Observatory. The tilt resumed its normal trend and made its usual annual loop in 1936. So far this year the tilt has moved slightly west of south very rapidly, necessitating adjustment of the seismograph to take care of the change quite frequently. However, this movement seems to have slacked up now and little tilt of any kind has occurred in the past week or ten days. What this may mean is a little uncertain but may mean considerable lowering of downward pressure under the crater.

The clinoscopes previously referred to as located around Halemaumau are quite different from seismographs. They consist of a circular heavy mass of iron suspended from a tripod frame supported by piano wires. The mass is damped by a tank of oil in which it moves. Thus, the arrangement is that of a plumb bob or pendulum attached to delicate levers and pivots which extend up in the tripodal frame. At the end of the light lever or boom is a point which approaches the face of a target-like indicator. This target indicator is graduated into concentric circles with a separation of two millimeters. From the center point are radiating lines corresponding to the cardinal points of the compass. The migration of the lever pointer indicates tilt by amount and direction. The magnification of the clinoscope has been previously calculated so that actual angular and directional daily tilts of the ground may be plotted graphically just as in the case of the seismograph at the Observatory. Since the clinoscopes are on widely separated portions of the pit rim, and the direction of the center of the pit is known with reference to the tilt stations, it becomes possible to resolve the components in such a way as to determine the radial tilt to or from the pit. Tilt toward the pit should indicate lowering in that direction accompanying decreased pressures with the reverse being true of tilting from the pit.

Dr. Jaggar and Mr. Finch in 1929 described tilt records and results for the thirteen years from 1913 to 1925 inclusive. Their very interesting conclusions will bear repeating and are as follows:

"1. Seasonal tilts of twenty seconds or more in a half-year

Figure 5. Before notch caved in 5:54 a.m. October 22 (taken October 20).

vary with air temperature, easterly tilts corresponding to cold months, westerly tilts to hot months.

"2. The range of angular tilting per half-year is greater when measured gushing up of lava is greater. The gushing up of lava and easterly tilting have been regularly greater in autumn and winter.

"3. There is practically no correlation between tilt and rainfall.

"4. Between 1913 and 1920 there was a northeasterly tilt of about eighty seconds accumulated at Kilauea, and an elevation of about 0.6 meters in the central part of the mountain, diminishing apparently to zero in a radius of ten kilometers. This was a partial eruptive cycle, characterized by rising lava.

"5. Between 1920 and 1926 there was a southwesterly tilt of about ninety-three seconds, accumulated at Kilauea and a depression at the central part of the mountain (distinct from collapse at the pit) of about four meters, diminishing in a radius of twenty-two kilometers to 0.09 meters. This was an extraordinary half-cycle of lava subsidence plus explosive eruption with engulfment.

"6. The total void computed from the engulfment and subsidence data is approximately 757 million cubic meters, of form suggesting the evacuation left by an intrusive sill of about thirty kilometers radius, swollen in the center.

"7. Local earthquake frequency and centripetal tilt accompany lava subsidence, otherwise there is little correlation between tilt and earthquakes.

"8. There is perfect correlation between Kilauea lava movement and Mauna Loa lava movement, whenever the Kilauea lava pit is not sealed. The east-west tilt curve exhibited accumulation of easterly tilt preceding every Mauna Loa eruption. The north-south tilt curve followed consistently the overflow and subsidence phases of Kilauea. These facts agree with the position of the instruments, north of Kilauea and east of Mauna Loa.

"9. Explanation of the correspondence between easterly tilt and lava gushing, on the one hand, and winter atmospheric mean lower temperature, on the other, is difficult. Two possible explanations are: (a) that solar heating in the summer checks volcanic radiation, whereas outward conduction is stimulated by the winter cold; (b) that a winter solstice tidal effect acts on the east-west fissure of the Hawaiian ridge, owing to a solar pull southward on the great mass of the ridge and on the equatorial protuberance. this might produce trigger stress for winter effervescence and tumescence, if the lava sponge below were in nice adjustment for gas-pressure release. Possibly both (a) and (b) work in concert."

If I may talk to you again at some future date, I should like to tell about level and triangulation values in the vicinity of the local volcanoes with corroboration of their action by volcanoes in other parts of the world.

Meanwhile, don't lose patience with Pele—Kilauea is going to erupt. However, I am glad this is a radio, so no one can ask me "when". Thank you.

Hawaiian Volcano Observatory Report for April, 1937

VOLCANOLOGY

The following are weekly data for observations of the Observatory near Kilauea Crater, including slides and rim-crack openings of Halemaumau Pit, the center of expected eruptions of the crater:

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Quakes
April 4	25.00	1	25.0 mm.	75
" 11	30.75	6	34.0 mm.	89
" 25	15.50	5	44.5 mm.	42
" 28	13.25	10	28.0 mm.	42
May 2	12.50	2	47.0 mm.	46

Slides continued the third week, 7 quakes were from Kilauea, 2 probably Mauna Loa, 1 at Hualalai.

The fourth week continued noisy slides and increased opening of eastern cracks, 4 quakes including a perceptible one were at Kilauea, 2 were probably at Mauna Loa.

The fifth week ending May 2 showed fewer slides but increased opening of an eastern crack, indicating approaching collapse of that rim. A distant earthquake released a prolonged local tremor April 29. Eight quakes were from Kilauea, two probably Mauna Loa.

Slides at Halemaumau, and fumes

Slides from the wall of the pit have been noted as follows:
April 4, 2:50 pm, small slide made dust east.

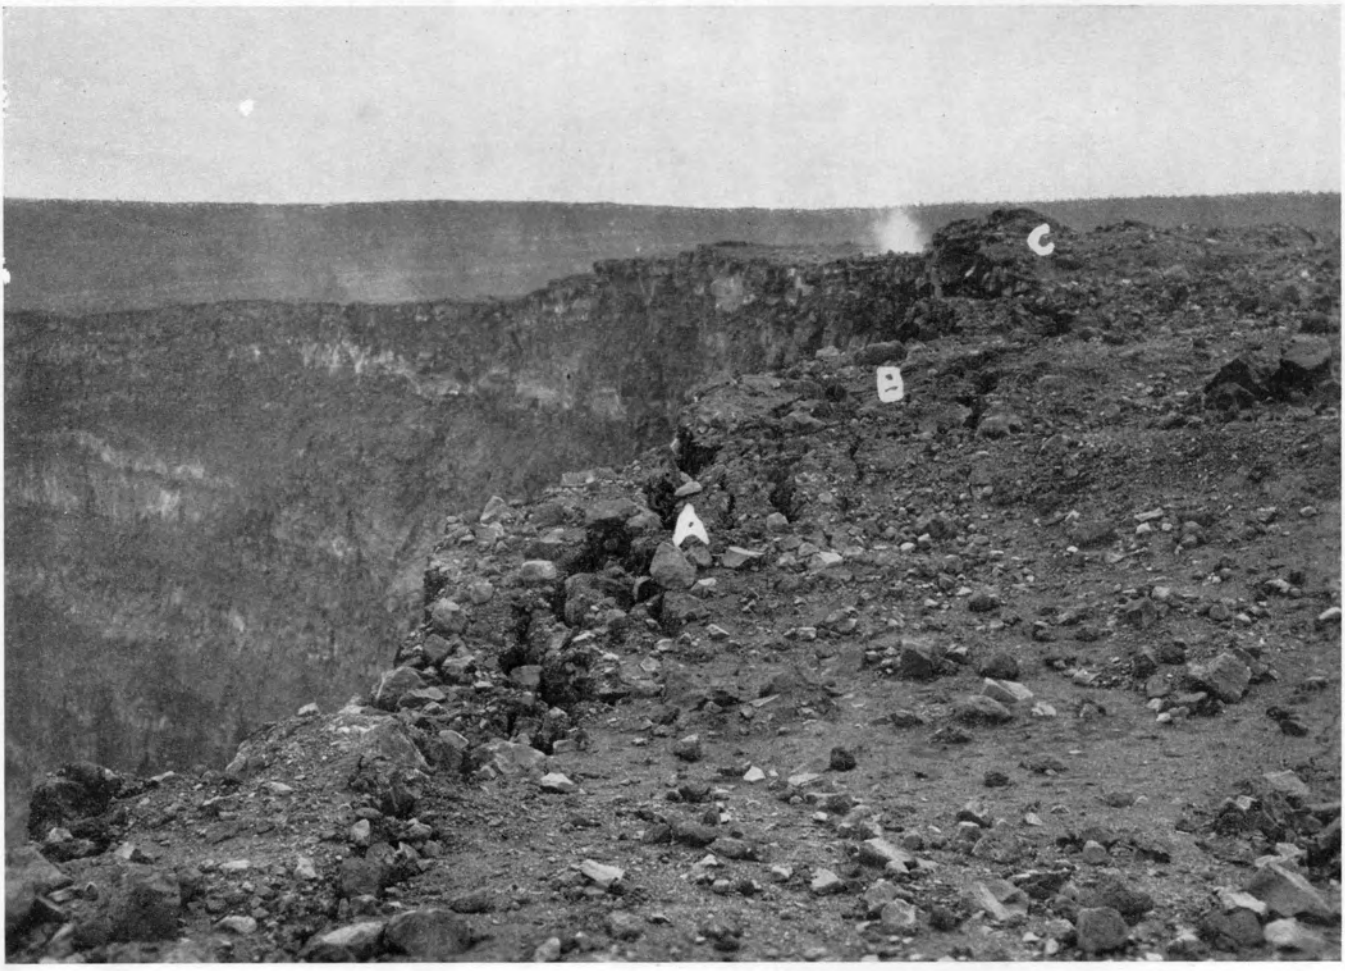

Figure 6. After the caving in, taken October 22.

Of felt earthquakes there were two in the feeble class, April 1 under Pahala (felt at Hookena), and Kau Desert, one under Hualalai felt strongly at Puuwaawaa ranch and otherwise generally felt April 18, and two April 30 at Kilauea.

Sequence of Events by Weeks

The first week ending April 4 had the Pahala shock and one reported slide at Halemaumau. There were 13 Kilauea quakes, four at northeast Mauna Loa rift, and one at southwest rift Mauna Loa.

The second week had numerous slides at east wall of Halemaumau, 15 quakes at Kilauea, 7 at Mauna Loa, including 2 stronger ones.

April 7, morning showed small slides had left scars on wall 400 feet under east cliff.

April 8, slides making dust NNE and E 12:38 pm, 1:05 pm, 1:10 pm, with rumbling heard at Uwekahuna, dust continuing to 1:20 pm. Intermittent dribbling of rocks 2:00 to 3:30 pm.

April 10, similar dribbling east 9:57 am. Fuming from solfataras at edges of floor was slight, becoming visible after April 9.

April 12, 3:20 pm, slide made dust cloud NE.

April 14, 3:25 pm, another at same place.

April 15, 11:47 am, slide made loud rumble, no dust.

April 16, all day 9 am to 5 pm, rock slides N and E, a noisy one sending up dust 11:30 am.

April 18, SE solfatara sent up conspicuous blue fume along with vapor of excessive humidity, noted 3 to 4 pm.

April 21, 9:57 am, small noisy slide NE.

April 25, 9:49 am, moderate slide NE after two small earlier ones, and followed by a large noisy slide 9:54 am, making dust cloud.

April 26, scars showed recent slides, and a small slide made the sound of falling rocks heard at Uwekahuna 11:30 am, and sent up dust.

Measurement of Halemaumau Rim Cracks

Weekly measurement of 26 rim crack locations resulted in aggregate movement as follows: week ending forenoon of—

April 2, 12 opened, 2 closed, opening 25.0 mm.
" 9, 14 opened, 0 closed, opening 34.0 mm.
" 16, 10 opened, 3 closed, opening 28.0 mm.
" 23, 8 opened, 1 closed, opening 44.5 mm.
" 30 9 opened, 3 closed, opening 47.0 mm.

On April 23 two cracks close to the east edge contributed most of the opening: No. 24 5.5 mm., No. 25 36.0 mm., and these are behind rim blocks of rock extending southward the edge that collapsed in October, 1936; they are going to fall soon. On April 30, crack No. 25 contributed 42 mm.

T. A. J.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Moderate Earthquakes	Distant† Earthquakes	Weekly* Seismicity
April 4	56	16	3	0	0	0	25.00
" 11	67	20	1	0	1	0	30.75
" 18	31	9	1	0	0	1	13.25
" 25	36	5	1	0	0	0	12.50
May 2	35	8	1	1	0	1	15.75

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the times indicated and whenever possible, a determination of depth of focus has been made.

March 29, 7:53 am, very feeble, probably located in Mauna Loa NE rift near Puu Ulaula.

March 29, 9:15 am, very feeble, located in Kilauea Crater.

March 29, 6:52 pm, very feeble, located in Kilauea Crater.

April 1, 5:31 pm, feeble, located in the vicinity of Pahala near the Kaapao Pali, and 20.0 miles deep. Reported felt in Hookena, where buildings creaked and hanging objects moved. 19° 13.3' N; 155° 30.2' W.

April 1, 6:49 pm, feeble, located 3.7 miles deep under Kalanaokuaiki Pali 1.3 miles SW of Puu Ohale. 19° 20.7' N; 155° 17.8' W.

April 3, 9:30 am, very feeble, located in vicinity of Kipuka Puaulu (Bird Park), 3.8 miles deep. 19° 26.5' N; 155° 18.3' W.

April 3, 10:55 am, very feeble, probably located under N rim of Kilauea Crater.

April 4, 1:52 am, feeble, located 0.5 mile west of Puhimau Crater 1.5 miles deep. 19° 23.7' N; 155° 15.5' W.

April 4, 8:10 am, very feeble, located 4.5 miles NW of the Observatory 1.4 miles deep. 19° 28.6' N; 155° 18.9' W.

April 4, 11:59 am, very feeble, thought to have been located in Chain of Craters area SE of Kilauea near Hiiaka Crater.

April 4, 5:11 pm, very feeble, probably located in SE portion of Kilauea Crater near Keanakakoi.

April 4, 11:41 pm, very feeble, of Mauna Loa origin.

April 5, 6:18 am, very feeble, probable location, Kilauea SW rift 0.7 miles NE of Cone Peak.

April 5, 9:47 am, very feeble, thought to have been located in Chain of Craters area, near Devil's Throat.

April 5, 10:57 pm, very feeble, located in Mauna Loa NE rift near Puu Ulaula and 18.0 miles deep. 19° 30.5' N; 155° 29.0' W.

April 6, 12:37 am, very feeble, located 1.5 miles W of Puhimau Crater and 0.5 mile SW of Kilauea Crater, 4.2 miles deep. 19° 23.7' N; 155° 16.5' W.

April 6, 11:15 am, very feeble, located 5.1 miles deep and 1.2 miles east of Kilauea Iki Crater. 19° 24.8' N; 155° 13.5' W.

April 6, 4:46 pm, very feeble, located 4.2 miles deep and 2.0 miles W by N of Uwekahuna. 19° 26.0' N; 155° 19.8' W.

April 7, 12:18 am, very feeble, located in vicinity of Lua Manu Crater 2.4 miles deep. 19° 24.1' N; 155° 15.6' W.

April 7, 9:51 am, very feeble. Probably located 2.3 miles SE of pit seismograph.

April 7, 11:02 pm, very feeble, located 4.2 miles deep in Kilauea SW rift zone near Cone Peak. 19° 21.9' N; 155° 19.3' W.

April 9, 12:18 am, very feeble, thought to have been located under Halemaumau.

April 9, 7:29 am, moderate, located near seacoast at Apua Point 3.0 miles S of Hilina Fault system and 7.0 miles deep. 19° 16.3' N; 155° 12.2' W.

April 9, 5:46 pm, very feeble, probably located in Kilauea SW rift, 3.8 miles from Halemaumau.

April 10, 9:24 am, very feeble, probably located 0.5 mile NE of Kilauea Crater.

April 10, 1:21 pm, very feeble, located 2.8 miles deep in Chain of Craters area near Hiiaka Crater. 19° 22.6' N; 155° 14.0' W.

April 11, 2:52 am, feeble, located near Mauna Loa NE rift 3.5 miles S of Puu Ulaula, 13.0 miles deep. 19° 29.4' N; 155° 29.3' W.

April 12, 7:38 pm, very feeble, located 2.4 miles deep near Lua Manu Crater. 19° 24.1' N; 155° 15.6' W.

April 13, 7:03 am, very feeble, located in rifts 0.4 mile N of Puu o Hale, 1.5 miles deep. 19° 21.5' N; 155° 16.6' W.

April 13, 8:33 am, very feeble, probably located 1.5 miles NE of Kilauea Crater.

April 15, 6:28 am, very feeble, located in cracks near NE rim of Keanakakoi Crater, SE portion of Kilauea Crater. 19° 24.2' N; 155° 15.1' W.

April 15, 6:21 am, very feeble, thought to have originated in Kaapo Pali near Pahala.

April 17, 12:14 am, very feeble, of Kilauea Crater origin.

April 17, 2:17 pm, very feeble, of Kilauea Crater origin.

April 18, 2:44 am, very feeble, located 1.2 miles deep under Byron Ledge, SE rim of Kilauea Crater and 1.0 mile east of Halemaumau. 19° 24.6' N; 155° 15.9' W.

April 18, 4:10 am, feeble, originated under Hualalai Volcano. Reported felt at 29.0 miles on Volcano Road, Hilo, Kamuela, and very strongly at Puu Waawaa Ranch House.

April 18, 8:50 pm, very feeble, probably located 1.5 miles E of Kilauea Crater and 1.0 mile S of Kilauea Iki.

April 19, 5:59 am, feeble, located under SE rim of Kilauea Crater, 1.2 miles deep. 19° 24.5' N; 155° 15.5' W.

April 20, 4:08 pm, very feeble, probably located in Hilina Fault zone N of Apua Point.

April 21, 11:59 pm, very feeble, probably located in Mauna Loa NE rift about 5.0 miles NE of Puu Ulaula.

† Includes teleseisms or those shocks over 5000 kilometers distant.
* For local seismicity definition see Volcano Letter 371.

April 23, 4:08 am, very feeble, probably located in Chain of Craters area near Devil's Throat.

April 30, 3:08 am, very feeble, located 0.7 mile deep near center of Kilauea Crater 19° 24.9' N; 155° 16.3' W.

April 30, 3:40 am, slight, located 0.8 mile deep near E edge of Keanakakoi Crater SE portion of Kilauea Crater. Reported strongly felt at the CCC Camp, felt at 29.0 miles on Volcano Hilo Road and dismantled pit seismograph. 19° 24.2' N; 155° 15.9' W.

April 30, 9:29 am, feeble, probably same location as preceding.

April 30, 12:35 pm, very feeble, thought to be of Kilauea origin.

May 2, 5:26 pm, very feeble, 5:27 pm, very feeble, and 5:29 pm, very feeble, all thought to be of Kilauea Crater origin.

Four minutes of continuous tremor began recording at the Observatory at 9:06 am, April 29.

Microseismic motion of the ground at the Observatory was strong throughout the month except from April 25 to 30 inclusive and April 18, when it was moderate.

The preliminary waves of a distant earthquake began to register at Kilauea at 4 hr. 39 min. 25 sec. pm, H.S.T., April 15. It was estimated to have occurred 2,700 miles distant, probably in Alaska. The preliminary waves of a teleseism began recording at Kilauea at 8 hr. 29 min. 41 sec. am, H.S.T., April 29. It was estimated to have been 3,560 miles distant.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending May 2, was 8.47" S and 0.76" W.

Week Ending	Observatory	Halemaumau West Station
April 4	1.64" N 45° E	3.37" N 60° W
" 11	0.73" N 51° W	6.05" S 76° W
" 18	1.11" S 37° W	5.54" N 67° W
" 25	0.17" S 44° E	5.22" S 73° W
May 2	1.17" S 31° W	4.32" N 71° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
April 4	7.23" N 3° W	3.32" Toward
" 11	4.47" N 27° W	1.59" From
" 18	4.99" N 3° E	1.04" From
" 25	6.48" N 53° W	1.90" From
May 2	3.95" S 42° W	4.68" From

Crater Angles

Measurement of Horizontal Angles across Kilauea Crater from the Observatory, April 21, showed slight closing of both Halemaumau and Crater values compared with similar measurements March 24. From Kilauea SE rim to Uwekahuna there was closing of 1.75", March 24 to April 8, and opening of 1.67", April 8 to April 21. Total closing 0.08". From the Pit Seismograph to NW Pit B.M. there was closing of 2.00", March 24 to April 8, and opening of 1.66" April 8 to April 21. Total closing 0.33".

H. H. W.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

THE VOLCANO LETTER

No. 447 monthly **Department of the Interior** **National Park Service** **May 1937**

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

TRENDS IN THE PHILOSOPHY OF SCIENCE

T. A. Jaggar*

By the philosophy of science is meant the definition of its motives. What has a group of scientists in common? How has the motive of their labors changed in a hundred years since Darwin and Faraday worked? Whither are we bound, and what are the boundaries, in the professions called scientific?

Science is said to be any knowledge that appraises data with logic and care, and uses the method of classifying, generalizing, induction and deduction. But this would apply in some measure to literature, education, languages, history and economics.

The modern meaning of science is limited to the nature sciences, for which the earth is the chief subject, with its kinsfolk the stars, and its products and processes including man himself.

Language is the chief instrument of science, including mathematics, which Willard Gibbs defined as a language. Observation and experiment are the chief activities. Application to human service, and the reform of that service to man's benefit, are the chief goals of science.

Language, the chief promoter of science

It is curious there is no chapter on "language" in Karl Pearson's "Grammar of Science". We learn much of the unreality of matter, force, space and time, "intellectual concepts describing our perceptual routine". We learn about constructs, ejects, contingency and correlation. We are told that science lives upon inference and is a classification and analysis of the contents of the mind. But not a word appears to show that those contents, in the form of thinking, are what Watson calls "sub-vocal talking". An important eject is "other-consciousness", which must agree that two normal perceptive faculties construct practically the same universe. But do we always agree to this? Similarity of perceptive and reasoning faculties depends on a common thought-language.

This point appears frequently missed. Language, mathematics, and logic are not science. But they are the stuff without which science could neither be conceived nor conveyed. Clearly written and spoken language is at the root of accuracy. If you cannot say what you think, you cannot think what you think you cannot say.

Take the subject of forecast. Science is the study of nature; **natural** universe, earth, force, life; origin, progress and future of each of these. Do not omit the future. Science is the first human craft to treat prophecy without superstition. Prophecy based on measured accuracy is the supreme test of science. Astronomy can understand a Babylonian eclipse in the light of mathematical forecast, a new language. Truthful history by its cycles may illumine prophecy. Language by its structure is itself history. What is "prophecy" but the Greek for "speaking before"? It is important to know the history of mother-tongue, and to talk and think foreign tongues.

If we say "inevitable" we are using a French word. Our word "passenger" is not identical with "voyageur". We have no word to connote "geschwister", meaning either brother or sister. We have no word such as an imaginary "menwo", meaning either men or women; "persons" or "people" is not an identical sense. "Onto" is not good English, but is a needed word. We have "widen", but we have no "smallen". "Scientist" hardly includes the ladies, and "men of science" certainly leaves them out. Such are the limitations of thinking.

One can be scientific in speech without language being a science. One can be mathematical in business without business being mathematical. One can be either qualitative or quantitative in science, without science being mathematics. So in the scientific laboratory one can be humanistic, artistic, businesslike or religious. But language is supreme in reasoning, and needs history and all scholarship for scientific use.

"The American Language" by Mencken shows how Americans are remodeling the thinking of the British empire by their straight-shooting lingo. Such language remodels thought and science. Illustrations of vividness are the phrases "What is your reaction?" and "That is not in the picture". The pencil or blackboard chalk illustrates the incessant use of pictographic language in science: we cannot explain without a map, curve, section, formula or sketch as we talk or think.

It may seem strange to stress the importance of words. The diplomats have an expression, "finding a formula". If they had "found a formula" August 1, 1914, the difference might have been to avoid the Great War. Writing science that is understood by the people may get suggestions for progress from a hundred minds; illustrations are the camera, telescope, and radio hobbies. How different this is from the jealousy for priority in Europe. "The best test of the truth", wrote Mr. Justice Holmes, "is the power of the thought to get itself accepted in the competition of the market".

Does science spend as much effort over its phrases as it does over its differential equations? Does it consider the comparative value for progress, of writing a sound newspaper editorial rather than a technical paper? Does it compare the outreach, in selling the goods, of spoken thought compared with the printed word? Spoken speech is creating classes for adults all over the world, because of the realization of our slovenly voices and use of words that people get from listening to radio. Radio is itself a means for propagation of the gospel of science.

Our technical memoirs are long, boresome and addressed to specialists. Difficulties of reading and abstracting, and photographic methods of filing, mean that the short paper has come to stay. The scientist counts on these to sell his goods, but technical terms hide scientists even from each other. Even school teachers have a jargon of technicalities, ratings and curves along with I.Q., P.Q., Hi/Y and as many alphabets as a British army corps. The passion for abbreviation in America is only exceeded by invention of words; realtor, cosmetician, groceteria, mortician, and lubritorium. Non-mathematical scientific papers might sometimes, in the same space, be made intelligible. Remember that mathematics is a different language.

University teachers, in my own experience of Munich, Heidelberg, and Harvard, defeated their own sciences for me as a budding student. Rosenbusch set me to work on one felspar crystal all summer, when I wanted petrography of field rocks. Groth fascinated me with mounted crystals, but I ought to have had association of minerals in nature. Germanized, I returned to Harvard and wrote a doctor's thesis designed to test the abrasion hardness of a large number of crystalline minerals measured with a microscopical instrument that I invented. Result, my Harvard professors said "a mere instrument would not be enough for a doctor's degree", and dissipated my efforts on a double thesis adding a field subject in geology. Here everything turned on the wrong interpretation of three words, "a mere instrument". It all threw me out of mineral collections, and into volcanic craters.

Science is learning the power of speech on the public. Commerce, engineering and industry employ all our sciences in advertising: right there by clear and forceful speech science may educate commerce, engineering and industry.

Experiment, the chief activity of science

In my youth Audubon was my ideal as a scientist, motionless for hours watching wild turkeys in the forest, sketching and painting them, and combining system and art in large

* Address at Hawaiian Academy of Science, Honolulu, May 6, 1937.

volumes of colored plates. Darwin extended this idea to breeding experiments with domestic turkeys. Faraday, Darwin and Pasteur established experiment as the final arbiter of science.

Probably ninety per cent of my audience are laboratory people. Even when your constructive work is in the field, as in the innumerable branches of engineering that have grown up since Audubon's time, you make laboratory tests before you act. Engineering is the most important scientific application in the world today. Vital sciences have been taken in as the soul and body of commerce, including industrial psychology, physical chemistry, biology, preventive medicine and public health, meteorology and radio. Even experimental ethics and social service are commercial sciences. This is a far cry from the lonely impoverished French artist watching the bird in the wet jungles of Louisiana.

Science holds men and women because today it is interested in people and action. It produces results. Engineers are interested in designs, professors in research, merchants in growth of service, sea-captains in increased efficiency, doctors in visible cures.

The old geology, zoology, botany, chemistry, physics and astronomy are being replaced by geophysics, biometry, experimental physiology, electro-chemistry, atomic physics and astrophysics.

Medieval science mingled art, religion and science. We have learned to separate the compartments, the experimental field today is unlimited, and the method involves a quest of objective proof in America, started by Benjamin Franklin using common sense, and willing to tackle any subject from thunderstorms to volcanoes.

Just a word about the old physics of the nineteenth century, which considered solids, liquids and gases in motion, at controllable room temperature and pressure as the subjects of investigation. We human beings, and the soil we dwell upon, are solids, liquids and gases in motion. We are constantly told that the old physics thought it had nothing more to discover. We are practically told by the atomists that, as organic human subjects of bio-physics, unless we can be agitated at high voltage as a rarefied gas, we are not interesting.

This appears to me to be pure hokum. The nineteenth century never had such complacency. There was never a time of such immense foresight and development as from Faraday, through Clerk Maxwell, Elihu Thomson, Hertz, Kelvin, Helmholtz, Roentgen, the Curie Family, and J. J. Thomson. Look at the other sciences, Humboldt, Lyell, Darwin, Haeckel, Huxley, and Bergson the philosopher: Virchow, Koch, Pasteur, and Osler: and in America, Rumford, Gray, Newcomb, Dana, Rowland, Agassiz, father and son, and Welch. The twentieth cen-

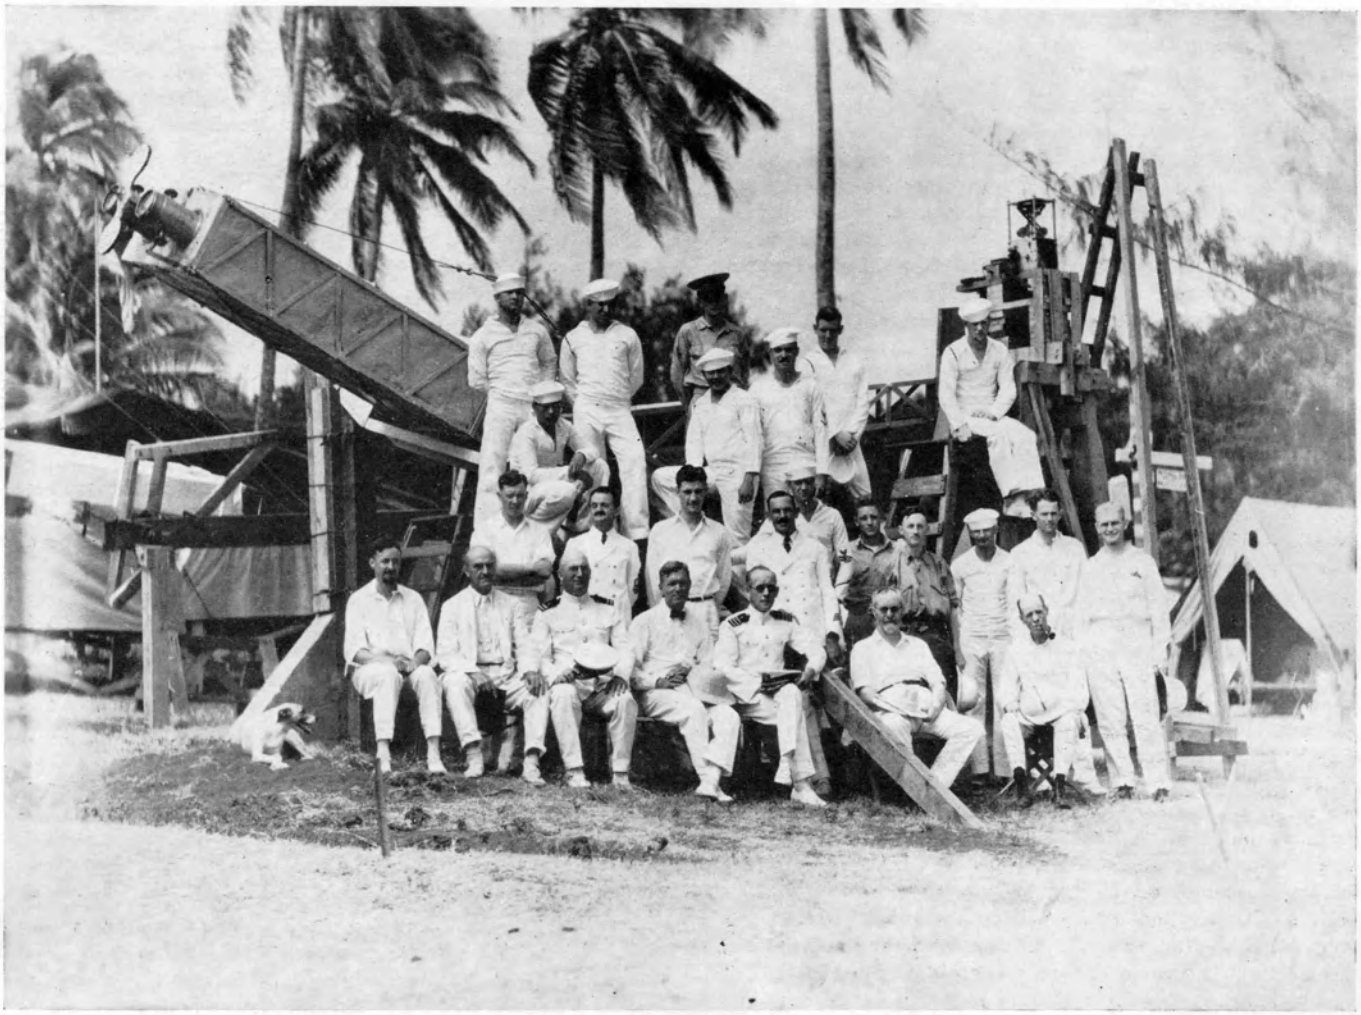

Figure 2. An expedition travels 12,000 miles for a single earth event—to photograph an eclipse of the sun—Navy Expedition, 1930, Niuafoou Island.

tury has barely scratched the surface with a few mathematical philosophers who are primarily linguists groping for ultimates. Otherwise we are working through corporate laboratories rather than individuals. This is good, but there is no sense in decrying the nineteenth century, nor in forgetting that our own seventy kilograms of flesh on solid rock has a problem apart from high voltage.

Reform, the chief goal of science

As science has become increasingly serviceable, so has it become less selfish. Stoddard has said "those peoples who first grasp and act upon the basic principles of the new knowledge will rightfully be the heirs of the future". Who will do it, the Germans, Italians, Russians or Americans? Reform has been disguised as research.

The twentieth century outlook on science has been jolted by the War and the Depression into seeing the need for more practical results, and the conquest of the world by extroversion. Here is a case of a new **word** for successful personality, the soul that opens outward instead of inward. We may have extrovert people, laboratories, cities, factories and nations. In this century the Wrights, the General Electric and Eastman Laboratories, the Peking Medical Center, Henry Ford, the Carnegie Institution, Rockefeller Medical Research, the Mayos, the Cancer Research Laboratories, and the Brookings Institute are all working on a theory of competitive donation. The Nobel and Cecil Rhodes Foundations and others are doing the same in Europe, Africa, Asia and South America.

Our government is extrovert, following upon the vague beginnings of the Monroe Doctrine, our missionary wars, the Open Door, and the Bryan and Kellogg Pacts. The South American pact and the Neutrality Law are a direct heritage of Woodrow Wilson. His League of Nations may seem eclipsed for the moment, but its scientific commissions are at work all over the world, and youth is arrayed against the armament trust. The present employment agencies and large engineering enterprises of the American government are extrovert science. Look over the list, and remember it is not confined to America. Public health, engineering, social security, public housing, slum clearance, agricultural relief, flood control, economic sciences, eugenics, home economics, home workshops, and adult education; add to this forestry, the great irrigation projects, the Tennessee Valley Authority, and the proposal to change the name of the Department of the Interior, which originally exploited our land in Audubon's time, to the Department of Conservation; and you have a world that would certainly astonish Andrew Jackson. Our extrovert government is opposed by the ancient acquisitive society of business. But science is responsible for our social consciousness of our kind. If psychology does what insurance has done, it may develop a cooperation of all science to higher accuracy, and higher truth than physics and mathematics.

The three fundamental concepts of all science are uniformity, evolution and value. Possibly evolution, uniformity, symmetry and rhythm are in Nature herself. Probably value and number are wholly human.

A tremendous gain over the nineteenth century is that physics, psychology and biology have all learned to distrust mechanism and to welcome positive liberalism. The intuitive of emotion, art, religion and philosophy, the elegance, symmetry, rhythm and universality of these cultures are more and more welcomed by science. Cosmopolitan demands will no longer allow science to dwell in a monastic cell.

Glenn Frank says that all laboratories have socially usable ideas that would lift the tone and temper of modern life. Our universities must dig up and put out the usable social ideas buried in each laboratory. Social science explores human nature for truth, searches for new ways, studies the "how", tests and "sees if", and finds out "whether". If your laboratory has an utterly new and usable idea, some island council should make you extrovert about it.

The Earth, the chief subject of science.

If you are studying the tonsils or teeth of school children or measuring binary stars, you may wonder what the earth has to do with it. This philosophy of science will be a success if it raises more questions than it answers. Science means the cooperation of all specialties. If they deal with human beings, they are concerned with civilization. The Polish Corridor, the Pyrenees, and Gibraltar are affecting the blood of future school children today. Civilization in America will be greatly affected by the eighty chemical plants in thirty different states of the DuPont de Nemours Company. They are placed in part for what the ground produces to make the earth yield up her increase.

Laboratory science likes to experiment with something like the fruit fly or white mice that will yield repetitions and controls. The earth, in explosive eruptions where lava flows drain out at the bottom of the sea (Figure 1), or in others capable of being bombed to save a city; the earth, in receiving the shadow of the moon (Figures 2 and 3) enduring seven minutes, does not admit of ten repetitions and ten experimental controls. But very important laws may be discovered from a single event.

The insurance man has the same problem; in life insurance he has hundreds of repetitions, and hundreds of controls. In disaster earthquake insurance, or in conflagrations, he has very few. Nevertheless, he learned something for his science in San Francisco, Tokyo and Napier. Henry Cabot Lodge, in spite of his opposition to Woodrow Wilson, said in a commencement address, "it is through the search for Utopias that the real advances have been made". Whatever your specialty in science, something about it may directly serve mankind out on the surface of the earth, and away from the congestion of cities. Science works either to discover the internal mind of nature, like Isaac Newton, or for a humanist love of nature like Audubon. The earth is a middle ground out of which we came ourselves; out of it comes all our food as well as the petroleum, iron and power that frame our civilization. The love of ultimates, describing something we cannot see in language which we do not understand, has tied science to cities.

But the age of infinite electric power is just across the threshold. Science is entering that door. The thing that created America was the frontier where man with axe and plow and rifle robbed nature and won freedom. The science of power is creating a new frontier that sees no limit to the materials and the arts that will build with the rock of the hill and the mud of the sea bottom. This is what is meant by the assertion that the earth is the chief subject of science.

It is the earth that affects our drinking water and our glands. It is the earth that produces a Utopia like the T.V.A. It is the earth that yields the atmosphere through which our airplanes fly. Seventy-two per cent of the earth's surface is a gigantic unexplored wilderness of fascinating possibilities possibly containing radium and all the rare earths and only just scratched for the first time by a recent invention that has taken a core six feet long from the mud covering this mysterious land. The core was obtained by shooting a tube straight down into the ground with a high-powered submarine gun (Figure 4). This wilderness is the bottom of the ocean.

The earth is necessarily the chief subject of science. It is conclusively so because science serves man. And man as the object of scientific effort is earthly, he is not celestial or electro-magnetic. It is in part science that is to blame, for

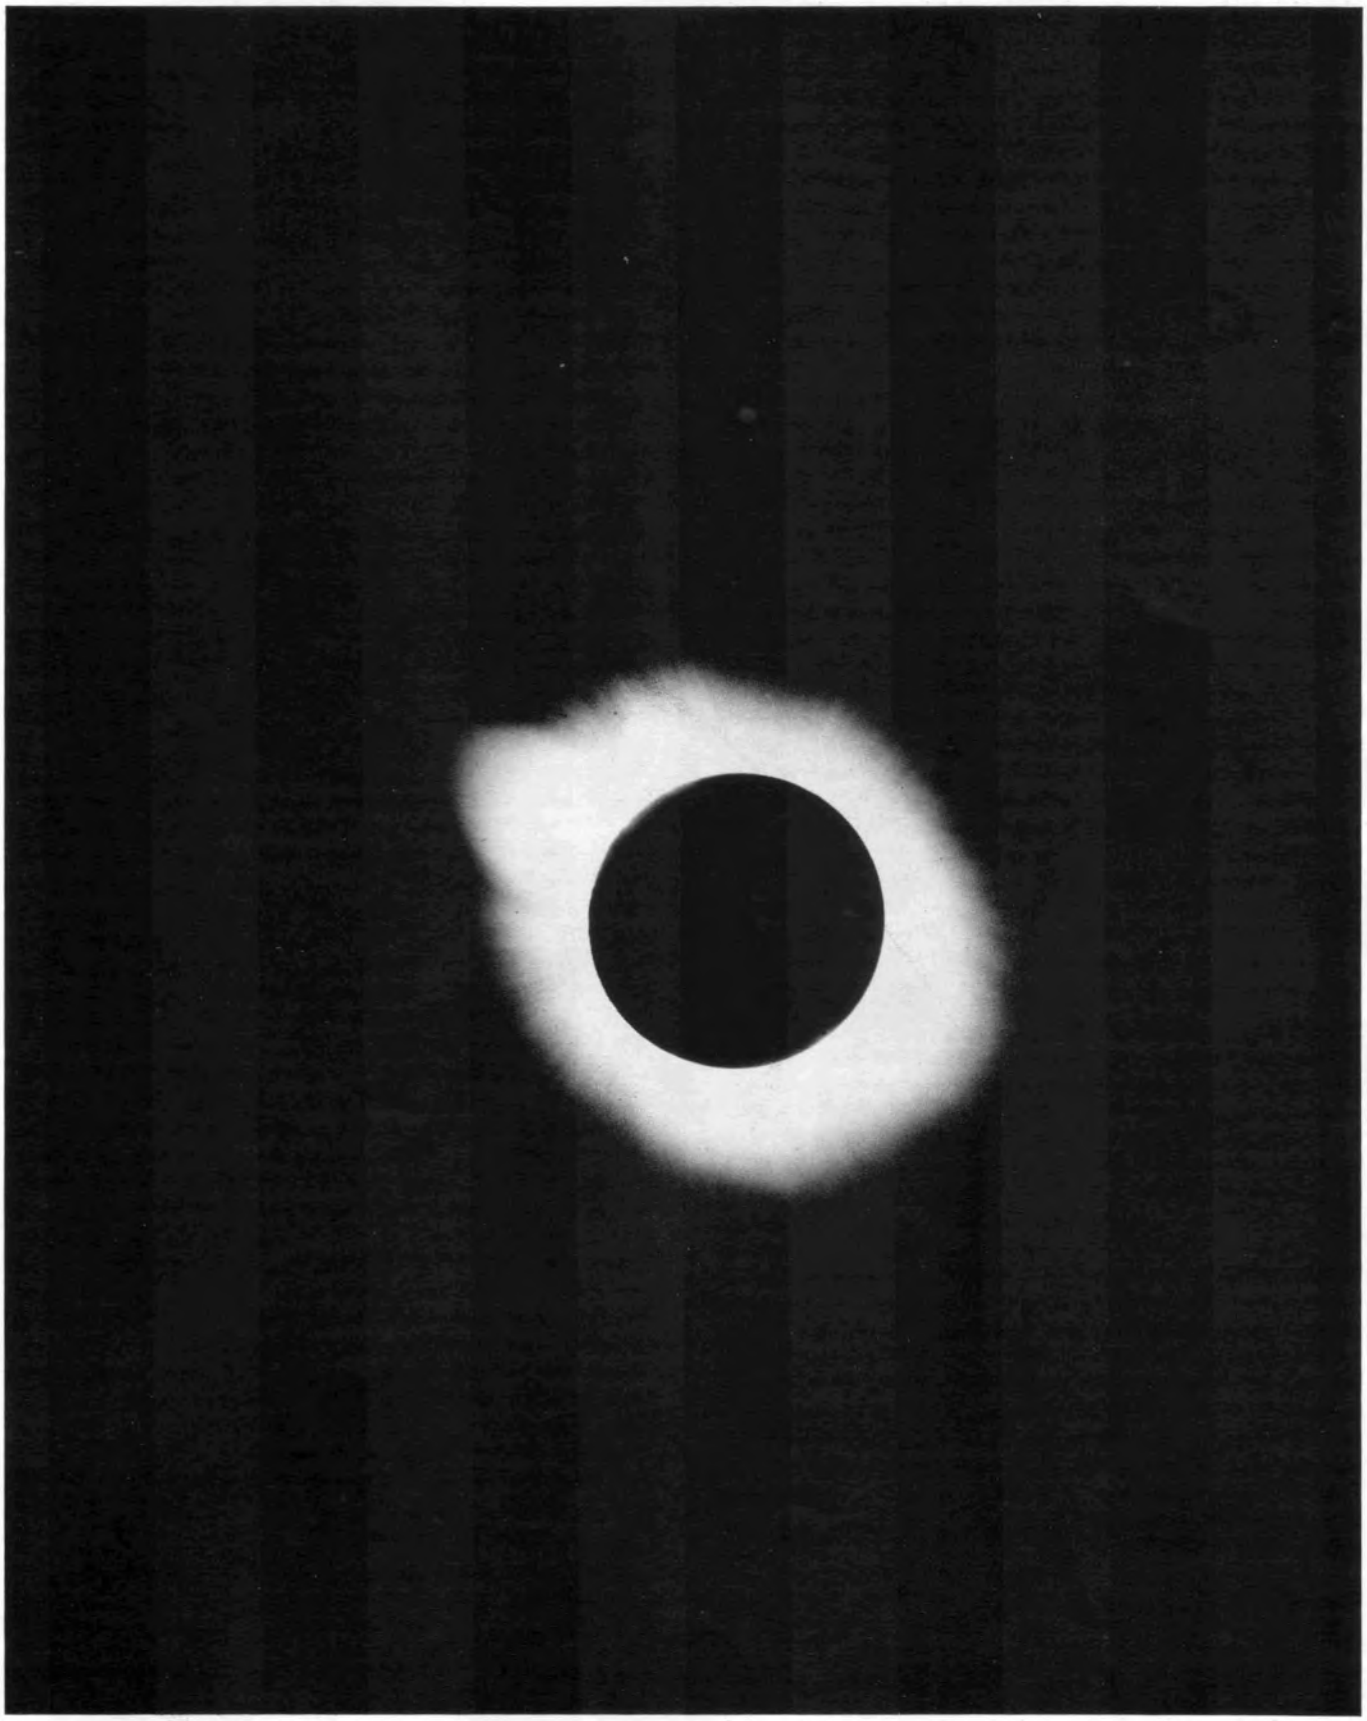

Figure 3. Photograph of the moon covering the sun's face. Niuafoou Island, October 21, 1930. Seventy men work three months for this photograph of an event lasting ninety-four seconds.

the misuse of science, that does not sufficiently consider man's happiness. Science agrees without protest to raising children in the sky-scraping gear wheels of a high stone-crusher like New York City, when there are thousands of square miles of country available with babbling brooks, grassy glades and sweet mountain air.

Science and education agree to an acquisitive society without protest, when every instinct of hygiene, sociality, uplift, public interest and experiment in the anthropometric laboratory suggests that human happiness lies in freedom, and in extroversion rather than acquisition. Science knows that an extrovert society will be more successful than an acquisitive one. Science has conquered distance and sluggishness, storm and savagery, famine and dearth.

But science shrugs its shoulder at the demand upon it to decentralize, to distribute and to invent a system of extrovert markets. Science knows it controls business, but it shrinks from reformation.

The terrestrial globe, the subject of the middle ground, producing the materials of physics and humanity intermediate between the electron and the germ cell, is pretty much left by the scientist to the rough and ready experiments of the prospector and pioneer, to the mountaineer and explorer, to the construction engineer and the navigator.

Laboratory science does not like to live in wild places. When we populate Howland, Jarvis and Wake Islands with a view to precise experiments in radio engineering and navigation of the air, we pick a group of Polynesian natives. If we were doing it in Antarctica we would pick a group of Eskimos or Icelanders. The suggestion is implied that no man or woman of European origin could reasonably be expected to live in a different climate. We are told that the Japanese have had similar difficulty in transporting their nationals to a colder belt. The earth is awaiting exploration by means of the new implements of modern science, but if modern laboratory science is afraid to dwell where the weather is hot, cold, dry or wet, the globe will remain undeveloped for the service of humanity.

Summary of trends in science

An attempt has been made in this essay for the speaker to review what fifty years of observation of natural history have impressed him as remaining unsaid and neglected in such general journals as "Nature" and "Science". The subject has been divided into four parts, in reviewing what seem to be the trends of scientific work in relation to human life for a century.

(1) First comes the overpowering importance of **Language,** both for thinking, and for arriving at agreement. Many scientists seem not to have realized with Willard Gibbs that logic, which comes from a Greek root meaning words, and mathematics, are languages and not sciences. It is not fair to say **mere** languages, because language itself, in the sense of the spoken tongue, is historically and constructively the most important implement in the whole range of all the sciences.

(2) Secondly, **Experiment** has been brought forward as the chief activity of science today. This is a great change from the time of Francis Bacon, who proposed categories, and extensions of science, which required observation rather than the invention of inductive tests.

A group of geologists, botanists, zoologists, and anatomists, meeting with natural philosophers and chemists at the Royal Society in 1845, was startled and delighted when Faraday sent in his nineteenth series of "experimental researches", to show that magnetic force produced an effect on polarized light. Medicine knew observational anatomy, and botany knew a systematic flora, but experimental physiology, phytometry, and phyto-chemistry had never been heard of.

There is of course nothing new nowadays in recognition of experimental work as a first essential of science. In my own science geology, however, the idea of experimental work in the field is decidedly new as a branch of pure science, and description of such work is notably lacking in the scientific journals.

(3) The third topic here considered, **Reformation** of the habits of mankind as the chief goal of science, is recognized by the gigantic efforts of special laboratories that the wealth of nations has produced, but is very little spoken of as an ethical ideal. The ethics of science emerges in the medical profession, and in some government activities actuated by political reform. In too many laboratories, however, science considers itself free, monastic, and privileged, or else it is frankly subservient to mercenary despotism.

The timidity of science in a bellicose world of overpowering industrialism and politics has had something to do with the two great catastrophies of the twentieth century.

(4) The last topic here considered, the **Earth** as the chief subject of science, involves a philosophical consideration, that few of you have ever thought of. Your own compartment was enough, and the earth could be left to the geologists.

What is the result? Thousands of men are at work building sensitive instruments, elaborating closed spaces for every possible temperature, pressure, and electrical condition, breeding insects, birds, animals, plants and bacteria for every possible service, and creating instruments of superlative grandeur, for evaluating the physical and chemical conditions of the universe of the stars. But all of this has preserved the habit of inertia in dwelling close to congestion centers, that existed in London in 1845.

It is only recently that the surface of the globe begins to be encased in a human net, demanding knowledge of the matter in outer atmosphere, mountain and plain, river and shoreline, sea-bottom and island; it is only recently that volcano and earthquake, simoon and flood, forest conflagration and drought, insect plague and blight, erosion and silt, have assumed proportions, where the interlocking of nations has made the misfortune of one a catastrophe for all.

Thus have sprung up geophysics, climatology, ecology, comparative anthropology, epidemiology, critical quarantine, and remedial construction in the service of insurance.

The people of London who looked upon Humboldt, Darwin and Livingstone as great explorers, have today barely begun to realize that travel is no longer a scientific virtue.

The discovery of the natural history of the earth by science can only be done by distributed laboratories that take pride in leading human enterprise to wealth that now is unsuspected. That wealth is partly materials, partly power, partly education. In metals China owns most of the tungsten, Canada the nickel, Peru the vanadium, South Africa the chromium, and America the molybdenum. The now precious xenon and krypton of the atmosphere are exercising the electric industry. The power of the sunshine and the tides is coming. **Science** it will be who shall educate the world to sheathe the sword, because happiness lies in experiments with mutual giving by men.

Hawaiian Volcano Observatory Report for May, 1937

VOLCANOLOGY

At Kilauea volcano the inner pit of the crater called "Halemaumau" went through another crisis of rim cracking on May 7, the east edge caving in, and carrying away a marked measurement-crack. This was an extension of the rim-breaking northeast that happened in October-November, 1936. Later in May the opening of eastern cracks diminished. There were two slight earthquakes, May 15 and May 30, the first of doubtful origin, the second about the Hilo end of the northeast rift of Mauna Loa. Thirteen very feeble shocks appeared to originate under Kilauea.

The following are the weekly Observatory totals for Halemaumau and the seismographs:

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Quakes
May 9	6.75	1	65.0	22
" 16	10.75	2	46.0	31
" 23	4.25	3	19.0	13
" 30	10.50	1	16.5	29

Sequence of Events by weeks

The first week produced the crisis of rim breakage at Halemaumau on the east side, just south of the notch which caved in last October. The description and photographs of that collapse appeared in Volcano Letter 446. The cracks there for several weeks have exhibited excessive opening. The index fissure was Crack No. 25, which expanded its opening 36, 42 and 57 millimeters respectively April 23, April 30 and May 7. On the last date came the falling in.

The second week showed eastern cracks continuing to widen and break the soil, and to make hot vapor.

The third week produced less widening of cracks and a few slides. New measurement marks back of northeast rim were established by placing copper studs on opposite sides of cracks. Seismicity declined.

The fourth week continued the lessening of crack-opening. In the wall of Halemaumau below the edge east an upright chasm was uncovered by a slide.

Slides at Halemaumau

Slides, and their effects, from the wall of the pit have been noted as follows:

May 7, evening, a length of about 40 feet along the rim caved in, probably 15 feet wide at the place of maximum breakage. Within this piece Crack No. 28 was destroyed and removed; this crack had not been opening, but was rigid with the rock that fell.

May 15, 2:35 p.m., a slide east, dust cloud and noise of falling rocks.

May 16, 8:30 a.m., a moderate slide sent up a dust cloud north.

May 18, 4:30 p.m., dust cloud from a slide northeast.

May 20, 11:05 a.m., a slide east sent a cloud of dust floating away westward.

May 21, 3:50 p.m., an east-northeast slide occurred.

May 25-26, night, a slide from the east wall uncovered an upright chasm, in the area of recent active caving fenced off from the Volcano House trail.

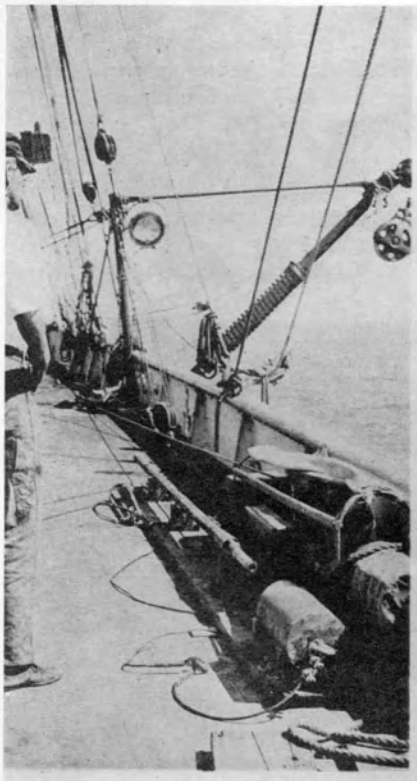

Figure 1. Apparatus in chocks on deck

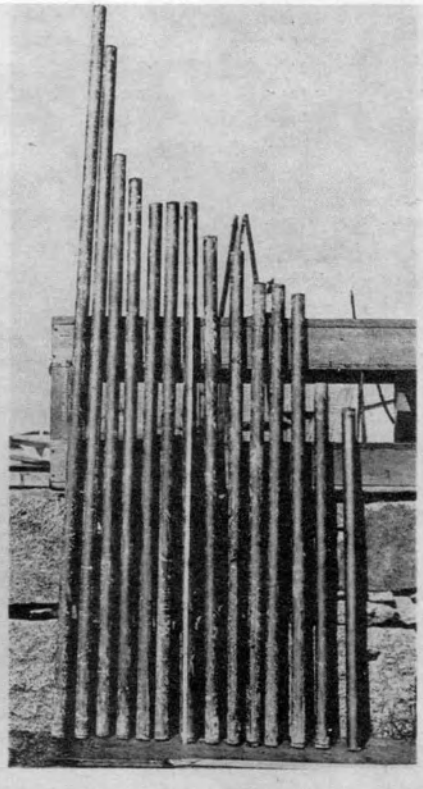

Figure 2. Cores taken August 1935 from depths of 200 to 1250 fathoms

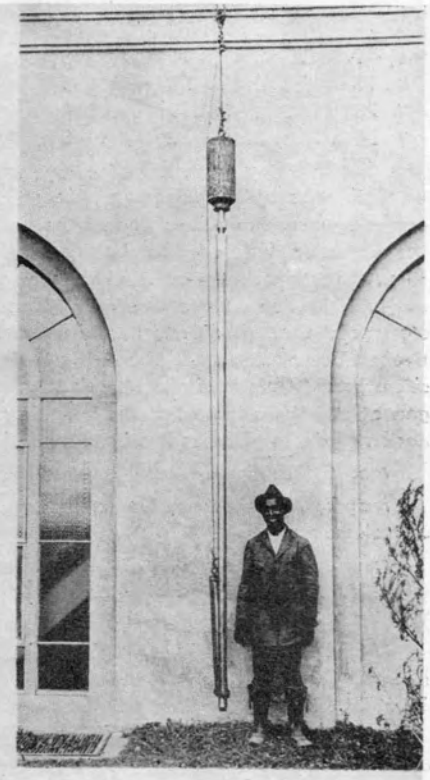

Figure 3. Core sounding apparatus ready for use

Figure 4. Core-drilling harpoon of Dr. Piggot. (Bull. Geol. Soc. Amer.—1936.) To sample the seventy-two per cent of unknown land—the sea-bottom. The gun takes cores 6 to 8 feet long in 200 to 1,250 fathoms of water.

Measurement of Halemaumau Rim Cracks

Weekly measurement of a varying number of rim crack locations destroyed and reconstructed during the month of May, resulted in aggregate movement as follows: week ending forenoon of—

May 7, 26 locations, 9 opened, 1 closed, opening 65.0 mm. collapse in evening destroyed No. 28.

May 14, 25 locations, 9 opened, 1 closed, opening 46.0 mm., to which Crack No. 25 contributed 40 mm. A new location, No. 37a, was established east of the road on an extension of Crack No. 37.

May 21, 26 locations, 7 opened, 1 closed, opening 19.0 mm., to which No. 25 contributed 14.0 mm. Four new measurement marks were established at northeast rim.

May 28, 30 locations, 13 opened, 1 closed, opening 16.5

mm., to which Crack No. 25 contributed 9.0 mm., showing marked decrease of rate. The ground extending the lost cracks of the east notch, after May 7, to the south of the notch, was broken and hot, with the soil ruptured and weeds browned with new vapor. Measurement with thermometer May 11 of the cracks south of Nos. 24 and 25, at 10:00 a.m., air 24°C., showed maximum crack temperature 64°C.

The break across the road southeast of Halemaumau, on the eastern extension of Crack No. 37, recently repaired, is moving again. Slowly this crack has opened: it is over the old sulphur beds on the Kilauea floor margin. The extension of the crack east of the road gave maximum temperature 50°C.

T. A. J.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Slight Earthquakes	Weekly* Seismicity
May 9	17	5	0	6.75
" 16	25	5	1	10.75
" 23	9	4	0	4.25
" 30	22	6	1	10.50

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the times indicated and whenever possible, a determination of depth of focus has been made.

May 6, 10:06 am, very feeble, of Kilauea origin.

May 7, 7:44 pm, very feeble, accompanied a slide at E rim of Halemaumau.

May 8, 12:22 am, very feeble, located 2.7 miles deep 0.4 mile NW of Kilauea Military Camp. 19° 26.4′ N; 155° 16.7′ W.

May 14, 3:13 pm, very feeble, located 0.6 mile deep in Kilauea Crater adjacent to Kilauea Iki. 19° 25.3′ N; 155° 15.9′ W.

May 14, 3:29 pm, very feeble, located 1.3 miles deep under E rim of Kilauea Crater. 19° 24.9′ N; 155° 15.8′ W.

May 14, 3:56 pm, very feeble, same epicenter as preceding except 0.9 mile deep.

May 14, 5:37 pm, very feeble, of shallow depth in cracks immediately east of Keanakakoi Crater. 19° 25.4′ N; 155° 15.6′ W.

May 15, 1:18 am, a slight earthquake was recorded at the Observatory, Uwekahuna and the Pit. It registered as very feeble in Hilo and as a tremor in Kealakekua. Because of lack of definite phases its location was not determined although it is thought to have been of Kilauea origin.

* For local seismicity definition see Volcano Letter 371.

May 16, 7:42 am, very feeble, probably located 0.7 mile NE of Kilauea Crater.

May 21, 1:20 pm, very feeble, tentative location in Kilauea SW Rift about 10 miles from Halemaumau.

May 28, 12:09 am, very feeble, located in cracks east of Keanakakoi, SE portion of Kilauea Crater, 0.9 mile deep. 19° 24.1′ N; 155° 16.4′ W.

May 28, 6:12 am, very feeble, located 1.3 miles deep under east rim of Kilauea Crater near Kilauea Iki. 19° 24.9′ N; 155° 15.8′ W.

May 28, 8:50 am, very feeble, located 0.8 mile deep and 0.5 mile S of Kilauea Iki. 19° 24.6′ N; 155° 15.3′ W.

May 30, 2:53 am, very feeble, probably located under N rim of Kilauea Crater and near Kilauea Military Camp.

May 30, 3:03 am, slight, tentative location Mauna Loa NE Rift about 10 miles from Hilo. Reported felt one mile east of Hawaii National Park entrance.

Microseismic motion of the ground was strong May 3 to 16, May 22 to 24 inclusive, and was moderate the remainder of the month with the exception of May 30 when it was light.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau the algebraic sum of radial tilts towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending May 30 was 8.98″ S and 1.35″ E.

Week Ending	Observatory	Halemaumau West Station
May 9	0.83″ N 77° E	4.50″ S
" 16	1.03″ N 48° E	2.86″ N 37° W
" 23	0.45″ N 60° W	1.73″ N 71° W
" 30	0.62″ N 3.5° E	0.75″ S 12° E

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant

Crater Angles

Measurement of Horizontal angles across Kilauea Crater from the Observatory, May 27, showed slight closing of both Halemaumau and Crater values compared with similar measurements April 21. From Kilauea NE rim to Uwekahuna there was closing of 2.50″, April 21 to May 11, and opening of 0.84″ May 11 to May 27. Total closing 1.66″. From the Pit seismograph to NW Pit B.M. there was closing of 2.50″, April 21 to May 11, and closing of 0.42″ May 11 to May 27. Total closing 2.92″.

THE VOLCANO LETTER

No. 448 monthly **Department of the Interior** **National Park Service** **June 1937**

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

Volcanic eruptions that caused a temporary evacuation of Rabaul: Clouds of steam rising from the craters of Matupi (on the right) and Vulcan Island, the more violent of the two.

ERUPTIONS AT RABAUL, NEW GUINEA

Volcanoes of New Britain

At the northeast end of New Britain (formerly New Pommern), the middle larger island of the three that constitute the British mandated territory of New Guinea, the capital town in that tropical land of missions, mines and copra (Lat. 5° South, Long. 152° East) is called Rabaul.

It is on a protected harbor. An east-west arcuate belt of active volcanoes encloses the Bismark Archipelago to the north, and the middle of the bow, bellied southward, contains the volcano "Ritter Island". This island cone threw up flames and lava fountains in March, 1700, poured lava cascades in June, 1793, and made explosive eruption in March, 1888 (west of Mt. Nangila on map) that caused a tidal wave and ejected more than a third of a cubic mile of dust, gravel and rocks.

Ten years earlier two volcanoes erupted at the north end of the Gazelle peninsula where Rabaul now is; they were called "Ghaie" or Matupi, and "Raluan" or Vulcan. Matupi, 800 feet high, is a solfataric hill southeast of and close to Rabaul on the northeastern tip of the volcanic arc. The rift crosses Blanche Bay (Rabaul harbor) from southwest to northeast, and Vulcan island on the southwest side of the bay appeared above the waves in the 1878 eruption.

This eruption included both Vulcan and Matupi along a steam-blast rupture; it started February 4 and lasted four days for Vulcan and three weeks for Matupi. It made two tidal waves, and built at Vulcan a flat cone 70 feet high and 900 feet across; from a new crater on Matupi smoke, flames and pumice were ejected, piling dust and pumice on the country and blocking the channel.

Thus Matupi was the more violent in 1878, but it appears that Vulcan was the culprit in 1937. Vulcan had subsided to half its height by 1897; Matupi is a subsidiary crater to "Mount Mother", a mountain back of the town, and is visited for its steaming hot spring.

We are indebted to the Sydney "Mail" of June 9 for the following data about the town, the Papuan natives, and the eruptions:

With a northeast wind the fumes from Matupi start the natives talking about earthuakes, and about the memories of the terrifying eruption of sixty years ago; when the Beehive Islands at the entrance to the harbor lowered to their present height; and Vulcan Island was built up next to the southwestern shore of the bay, so that their banana plantations were weighted down with heavy ash; and fish and turtles were found cooked in the steaming waters.

About twenty years ago an "eruption" is reported whereby the Matupi Peninsula sank about eighteen inches, and rose to its former level within a few hours. One wonders whether this story might not refer to tidal wave effects of the "Father" eruption of 1912.

The natives of course attribute very feeble earthquakes, which are frequent in Rabaul, to "debbil-debbils", and just as the Hawaiian legend of Pele migrating from Kauai to Hawaii agrees with geology, so the shrewd Papuan observations tally with science.

Folklore has it that the active volcano "Father" (see Map) or "Ulawun" to the southwest, with two other hills known as "South Son" and "North Son", alternates in "smoking" with the Rabaul volcanoes known as "Mother", with her two offspring "North Daughter" and "South Daughter". It is of course the subsidiary crater of Matupi that does the smoking.

Geologists know that the "Father" group and the "Mother" group are on the northeast-southwest rift line of New Britain, and the alternation of activity is probable, just as between Mauna Loa and Kilauea.

Rabaul is built over volcanic ash and it is said to be extremely difficult sometimes to get an earth terminal for an electric circuit.

Vulcan Island after the nineteenth century was left about 100 acres in size, some 5 miles from Rabaul, a cone unconnected with the shore. It was 900 feet in diameter, 30 feet high, and fuming from solfataric vents.

The mission stations of Walour and Taviji were on the southwest shore of the bay close to this island, along the driveway leading from Rabaul around the bay. This leads to Kokopo, a village on the eastern point of New Britain, facing the strait that separates New Britain from New Ireland.

The 1937 Eruptions

During the past year earthquakes have been unusually numerous in Rabaul. Vulcan Island began to show signs of volcanic activity Friday morning, May 28, 1937, when the mission stations experienced severe earthquakes, and landslips were observed on the island. The earthquakes increased in violence during that day and the next.

On the afternoon of May 29 Vulcan Island broke forth into explosive eruption, throwing up clouds of fume, dust, ash, gravel and bowlders so thickly that day was turned into night.

An observer at one of the missions thought that the dusk was coming a few hours earlier than usual. Then he noticed that Vulcan Island was throwing bowlders many hundred feet into the air, and pumice was falling everywhere. He described seeing a ball of fire running along the top of the cone, this being followed by a terrific explosion.

Then Matupi Volcano broke out in sympathy, sending up sulphurous steam, cauliflower clouds, ash and pumice, but the main eruption that darkened the entire landscape was from Vulcan Island.

The water became violently agitated. The succession of explosive steam blasts came from the side of Vulcan Island apparently on a rift line extending in the direction of the Beehive Islands and Matupi Crater to the northeast. A dome-shaped jet of water was seen to shoot up about 50 feet, followed by another explosion hurling sea water up 100 feet. Then many explosions occurred at Vulcan Island itself, flinging up rocks and debris, the cauliflower clouds rising 4,000 to 5,000 feet.

Some of the longshore roads developed crater depressions and all were blocked with gravel and ashes. Plantations were damaged for many miles, crops of coffee and bananas were ruined and the coconut trees had their leaves broken down with heavy gray ash.

The dense black cloud appeared to descend from above on some of the mission villages, earthquakes were numerous, thunderstorms developed, trees were struck by lightning and were seen falling in earthquakes, heavy rains fell, and motor cars were choked with the dust and had to be abandoned in the mud.

Volcanologic evidence

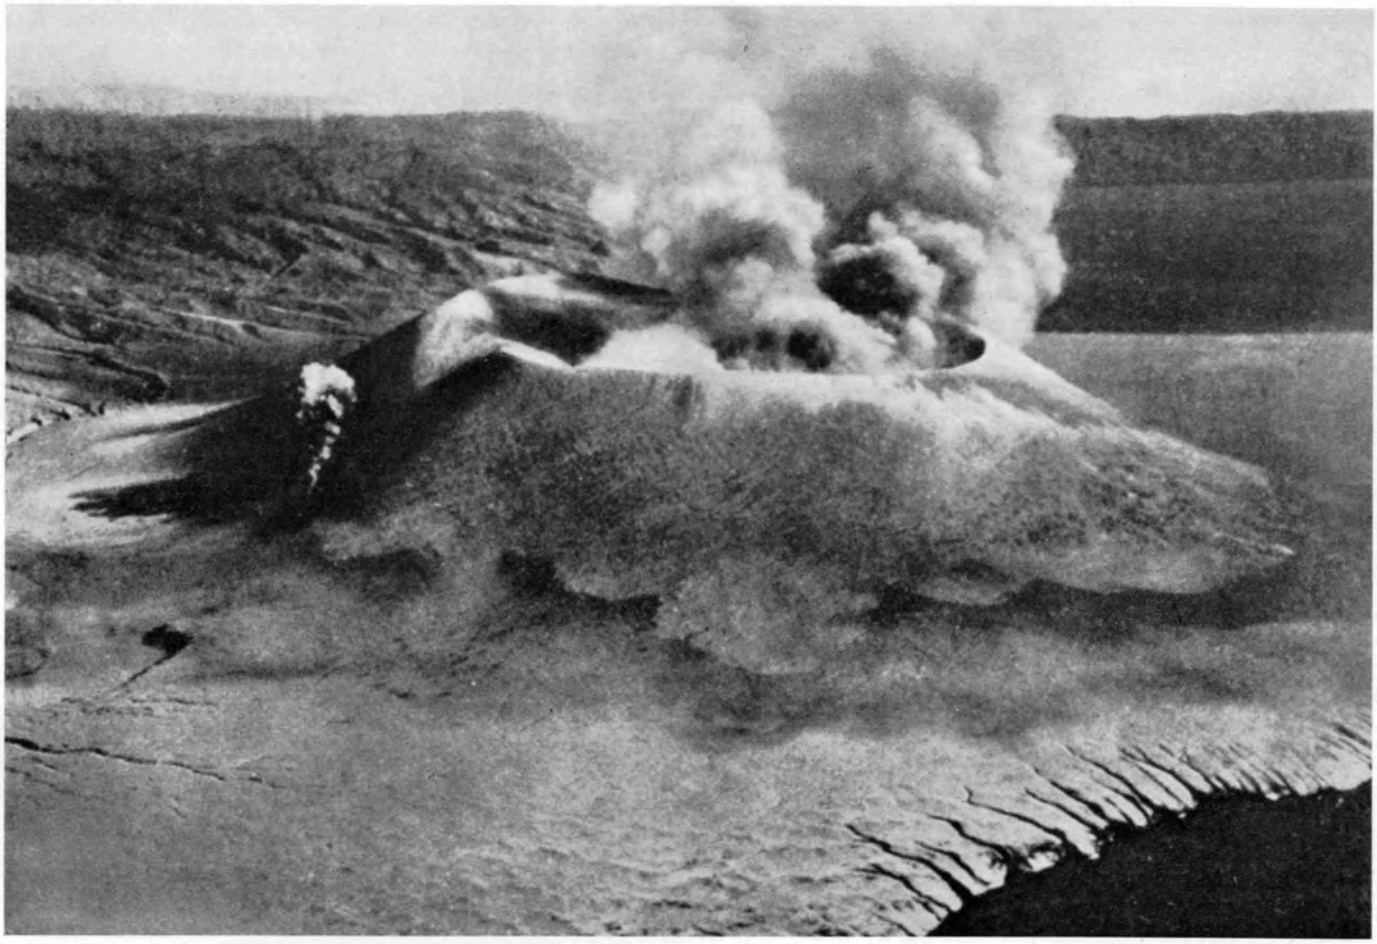
We shall have to await scientific statements for an account of what happened in changes of the sea-bottom. The sea-bed is said to have changed in elevation so as to make a new survey necessary.

As usual with explosive eruptions great quantities of floating pumice appeared on the surface of Blanche Bay, and some of this was thought to be a new bank of sand and mud blocking the outer entrance to Rabaul Harbor. The ocean currents swept this out to sea within a week, and it was found that the outer channel was still navigable. Shipping could enter Blanche Bay and reach the wharves with safety.

What happened to Vulcan Island itself may well have been a rising of stiff magma along with the building up of a symmetrical cone and cup, as shown in the pictures. We learn from the accounts that the island has been raised from 30 feet to a large hill more than 700 feet high, and from an island 900 feet across, to a peninsula three-quarters of a mile in diameter connected with the mainland by the new accumulations.

There is no evidence nor probability that liquid lava flow occurred. The worst of the eruption was on Sunday, May 30. The eruption died away very rapidly. When Vulcan Island was enveloped in smoke, the first impression of the onlookers was that it had disappeared.

One observer described a sudden lift of the island when the water waves occurred which played havoc with many of the smaller vessels, some of them being beached high and dry on the foreshores. Soundings were taken by a survey ship on Saturday, June 5, showing plenty of depth in the main channel.



like "Anak Krakatoa", of a constructive effort of rising magma acting through the ages, and reacting with groundwater.

We may conclude that the nature of this eruption was not particularly different from other eruptions of this volcanic belt, and to judge from Sapper's report concerning Father Volcano in 1912, and Ritter Island in 1793, this belt of volcanoes is quite capable of pouring out lava occasionally.

Von Wolff reports the recorded specimens of lava from this bay to be pyroxene andesite, and of pumice from New Britain to be andesite pumice. The minerals are plagioclase, angite, hypersthene and magnetite. Silica varies from 57% to 62%, and iron oxides from 6% to 8%. Specific gravity is 2.36 to 2.51.

Effects on the People

The evacuation of Rabaul was ordered, and was carried out efficiently with the aid of ships that moved the people from Nodup (a village close to Rabaul), to Kokopo, twenty miles south. Some 4,500 people were moved, and about 20

The erupting crater of Vulcan Island (normally low-lying) seen from the air: a view showing molten pumice building the cone hundreds of feet high and flowing into the sea.

The observer in question reported that Vulcan Island rose rapidly at the time of the tidal crisis so that where there had been water and a few rocks, solid land appeared. The interpretation of the airplane photographs was that "flowing pumice" spread down the sides of the cone.

There was the usual reddish glow seen in the reflections from the crater on the clouds. This and the presence of pumice show that frothing magma took part in the groundwater explosions, and it is probable that this is just one more example,

stayed to guard the place. The rain of ashes and mud was the principal cause of damage in the town, the heavy weight breaking down structures and destroying vegetation. Food supplies were transported from Nodup to Kokopo by schooners, and a large camp was made at Kokopo with sanitation directed by the government. The refugees included 3,000 natives, 800 Chinese, and 700 whites.

Within a week the harbor was clear, and progress had been made in cleaning the town. The island superintendent of one

trading firm suggested moving his headquarters to Madang, on the coast of New Guinea. This company's wharves at Rabaul were valued at $150,000, and could not be shifted. Moreover, the harbor is better at Rabaul than at Madang.

However, the trading firms had grave doubts about building and expanding on a place between two active volcanoes.

Ship Reports

Two larger steamers were in harbor, the "Golden Bear" of the Matson Line, and the "Montoro" of the Burns Philp Line. These were not injured and were instrumental in evacuating the population. Two steamers and a schooner were swamped.

At 1:00 P.M., May 28, the "Montoro" passengers, with ship moored to the pier at Rabaul, suddenly felt violent earthquakes and saw buildings rocking and palm trees falling, so that the roadways were blocked with fallen timber. Quakes continued throughout the afternoon and at 5:00 P.M. the "Montoro" sailed.

The "Golden Bear" was loading copra at a pier in the harbor when the eruption started the next afternoon, May 29, and a radio was sent to ask the "Montoro", then 120 miles at sea, to return. The land radio station was put out of commission by the eruption. The "Montoro" was showered with dust 100 miles away and in approaching the harbor found the ocean surface covered with pumice.

The columns of steam above the volcano rose white and fluffy, with an inky black inner column that exhibited rocketing bowlders falling back into the crater. With every new jet lightning and thunder occurred.

The explosion of Matupi came at 12:45 A.M., May 30, and large pieces of rock were flung up from its crater.

Captain Olsen of the "Golden Bear" had been doing heroic work, taking on board at Nodup hysterical women and children, hospital patients, and the Chinese population.

"The "Golden Bear" had at first been tied up at the wharf in Rabaul right in the path of the dust from Vulcan Island, and the falling pumice, heat and gasses were such that the danger was great, while the tidal waves chafed the lines, and grounded the ship. The water was covered with pumice and the outward channel looked as though new sand-bars had risen.

There might not be any channel and the course out involved passing close to the spouting volcano. The captain did not hesitate, but let go his moorings, ordered his crew below decks, cleared the channel and reached the open sea in a magnificent performance of seamanship. Then he turned about and anchored off Nodup.

The natives were loaded ten deep on the decks of both ships along with their dogs, cats and parrots. There was no panic. The launches pulled three boats at a time. The mission at Kokopo did splendid work in housing and feeding refugees.

The "Montoro" left on June 9, Captain Mitchie of that ship clearing for Sydney with some 200 refugees.

Some details of the eruptions

Rabaul was covered in places with dust four feet deep, and boats had been washed up into the streets. The tropical trees and shrubs were all broken and not a green or living thing was in sight. The water, light, and telephone systems were broken down, hardly a roof was intact, the roads were a mass of ruts, and the health commissioner could not allow any one to live there until the place was cleaned up.

Captain Olsen himself described the detail of the eruption as follows:

The ship was tied up at a dock near Rabaul at the time. Before doors or portholes could be closed a foot of pumice dust had settled in every nook and cranny of the ship, destroying clothes and other property. Most of the crew were ashore at the time of the terrific outburst of Vulcan Island. All returned to the ship, however, except Radio Operator V. M. Costner, who in the darkness may have fallen into the sea from the wharf, when attempting to grope his way back through the blinding, choking gaseous smoke which enveloped the town.

Captain Olsen is quoted as follows (Honolulu Star-Bulletin, July 12):

"About 4:10 P.M., May 29, I was outside on the starboard side of the lower bridge deck. Looking toward Vulcan Island, I saw a small white speck on the water near the island which swelled and rolled over, with the appearance of a large, fluffy cotton ball.

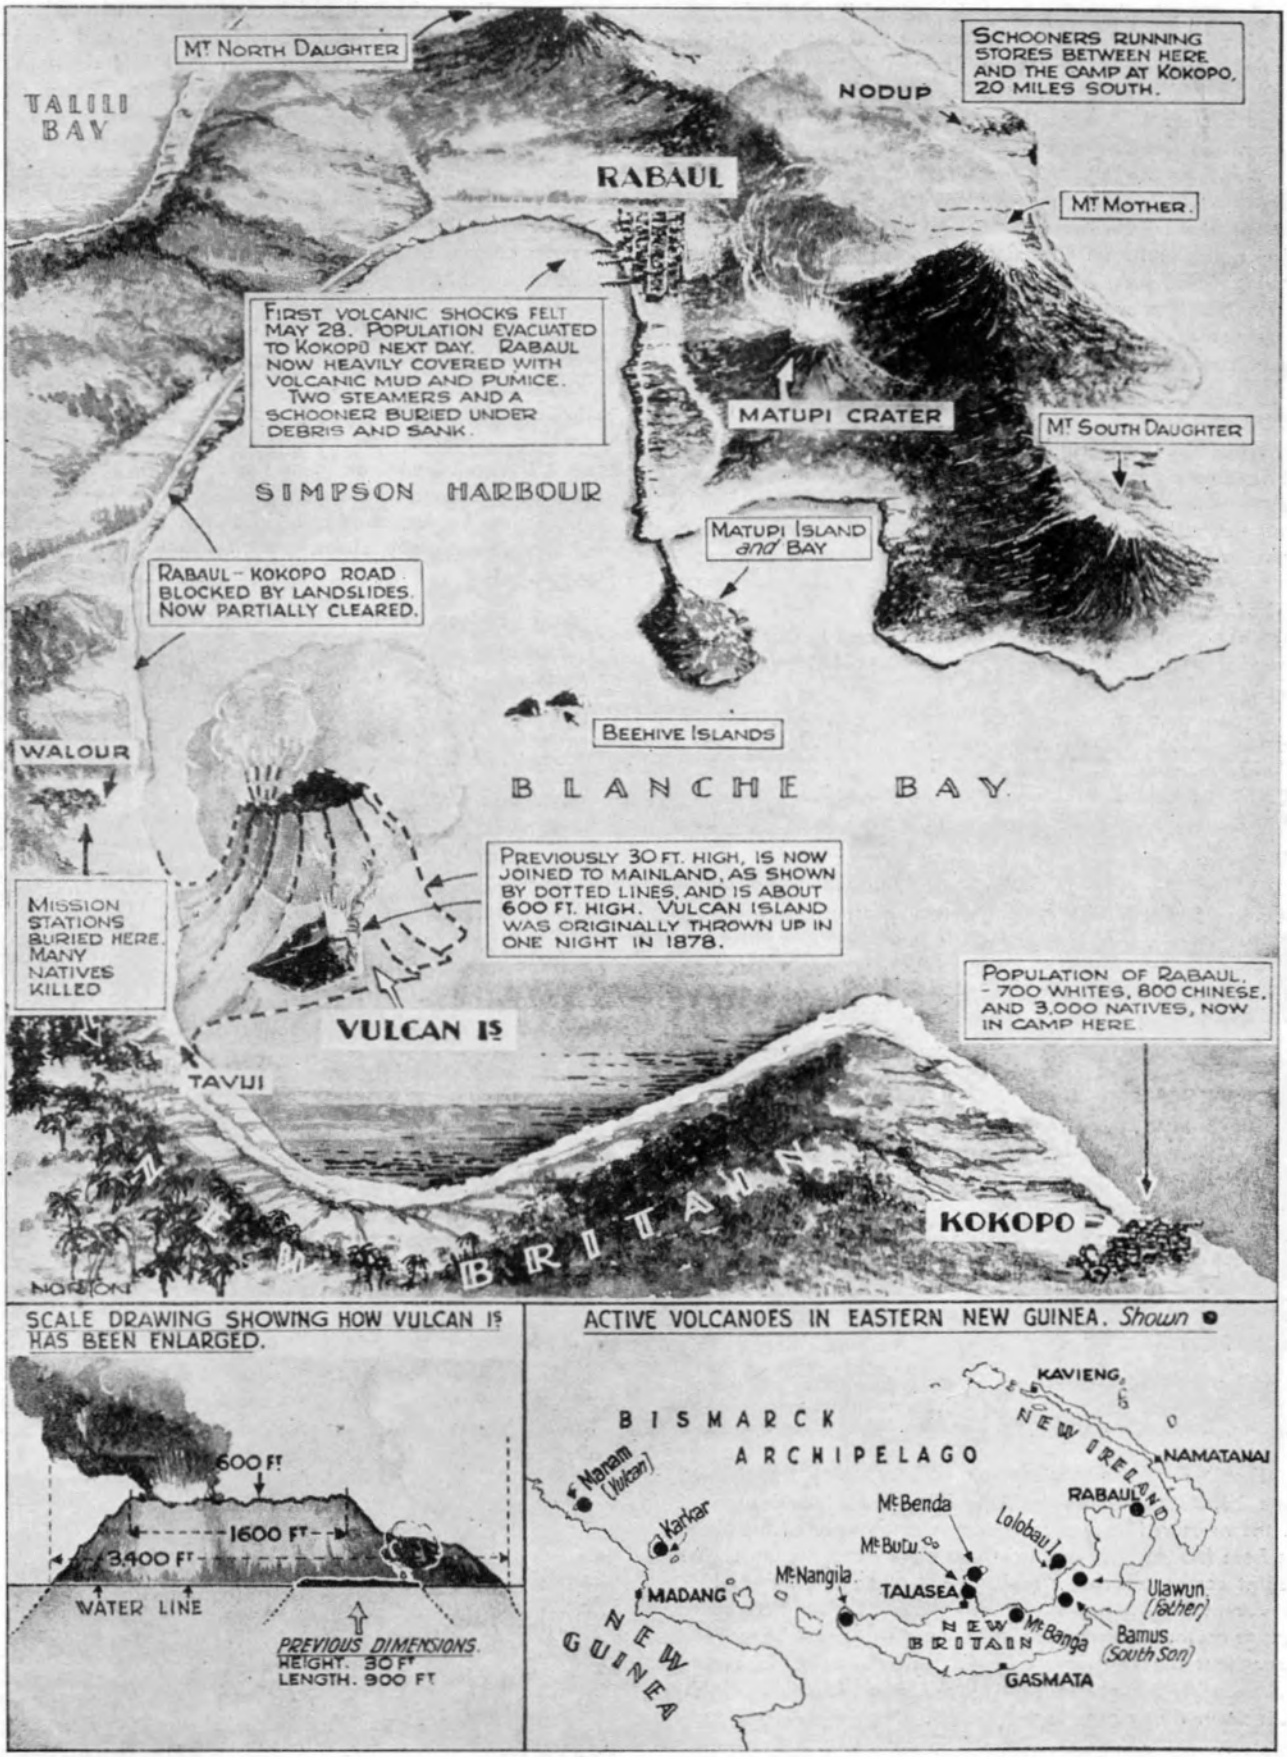
"It was only when the ball began to ascend into the air that I realized it was a volcanic eruption. After three or four minutes the island suddenly burst wide open, and with a tremendous roar sent a column of white steam and black lava smoke thousands of feet into the air.

"The mixture of gas and lava enveloped Vulcan Island and drifted in a northwesterly direction over the mainland, but after the first outburst the wind suddenly switched and sent the cloud of black smoke and debris in the direction of the "Golden Bear".

"The ship was enveloped in a cloud of gaseous ashes. All visibility was completely obscured. We left the ship under conditions difficult to describe. We crawled along on the wharf on our hands and knees. We felt our way along the car-tracks. We nearly suffocated. Fortunately, the wharf office door was unlocked and we all took shelter there against the heavy downpour of ashes."

A check of the men revealed Mr. Costner missing. In the late afternoon the Captain and the crew returned to the "Golden Bear" and succeeded in keeping her from being materially damaged by a series of minor tidal waves.

After reaching the Kokopo anchorage, May 30, Captain Olsen had a view looking northwest of the two volcanoes in action. Two great columns of white and black smoke ascended for thousands of feet. Spreading out and coming together at the top, they formed a gigantic archway over the entrance to the harbor.



Vulcan Island, the largest and heaviest of the two eruptions, was a magnificent sight during the night. Great masses of fire would be thrown into the air for distances of 4,000 feet, measured by sextant. The barrage would curve over and outwards and, exploding, fall back to the earth in a rain of fire.

J. W. Faulkner took the place of the lost radio operator on the "Golden Bear" in Rabaul. His ship, the "Durour", was on a marine railway close to Vulcan Island when the outbreak occurred. He and his companion barely succeeded in escaping to Rabaul in a motor boat. His ship, with the natives on board, was completely engulfed and sank out of sight.

Faulkner described the rising of a reef some 10 feet above water near Vulcan Island. This happened during the earthquakes that occurred in the 24 hours before the eruption.

Conditions at first in Rabaul were terrible during the eruption. While refugees were being transferred to outside plantations, it was necessary to erect temporary dormitories for the sick and injured. Rescue parties went from house to house searching for any who might be trapped.

In Kokopo there was an acute shortage of food and water, bad sanitary conditions prevailed and anxiety was expressed over the possibility of dysentery and typhoid. The mosquitoes were bad and the people were destitute. The swimming pools were thrown open to the women and children, many of whom maintained a stoic calm throughout the ordeal. The casualty cases were attended by one doctor and numerous nurses.

The tragic course of events in stricken Rabaul.

Captain Olsen's estimate of the loss of life caused by the eruption was reported as approximately 250 natives, 10 Chinese children, and 1 European. In the Sydney account the losses of life were known to be two white men, and in the missions close to Vulcan Island not less than thirty native women and children, overwhelmed by mud and ash.

Whatever the fact, this small loss of life in a harbor populated by 5,000, with an active pair of volcanoes athwart it, is a splendid tribute to the efficiency of the sailormen, traders, missionaries and local authorities in facing a sudden crisis and moving 4,500 people. They were assisted by ships, airplanes and radio. It seems likely that a volcanologic observatory and a system of earthquake stations might learn the cycles of recurrence, and greatly assist the New Guinea government.

T. A. J.

VOLCANOLOGY

After the May crisis of caving in of the eastern rim of Halemaumau pit, Kilauea Crater entered upon a period of comparative quiet. The establishment of thirty marked crack locations around the rim of Halemaumau, which had been renovated in May, exhibited in June only a quarter of the aggregate crack opening of May. The numbers of quakes, tremors and slides remained about the same.

The following are the weekly Observatory totals for Halemaumau and the seismographs:

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Quakes
June 6	15.00	0	11.0	20
" 13	11.25	1	10.0	35
" 20	12.75	4	10.5	36
" 27	5.50	2	9.5	16

A car covered with six inches of volcanic ash, which stopped the engine and compelled its owner, who was leaving for Kopoko, to abandon it: a typical scene of desolation in Rabaul.

Feeble shocks somewhat felt occurred May 31, June 3, June 13, June 16, two on June 20, June 21 and June 25. Of the measured local earthquakes, sixteen were from Kilauea, six from Mauna Loa, and two from more distant sources. Two distant earthquakes were registered June 21 and June 24.

A remarkable slow horizontally-moving fireball from southwest to northeast, with flaming tail, and without noise was seen throughout the Territory of Hawaii at 9:50 p.m., June 4. It was probably seventy or eighty miles away to the southward from the middle of the larger islands.

Sequence of Events by Weeks

The first week produced nothing important at Halemaumau. Crack widening, seismic frequency and sliding had all lessened. The yellow sulphur heap at the northwest margin of Halemaumau floor continued to fume hotly, and there was much cracking and sulphurous stain that had developed at the S.S.E. and N.N.W. edges of the floor. These places steamed occasionally, especially during wet weather. The northeast edge of the floor was now completely covered by new overlapping talus heaps from the north to the east sides of the pit. These have all been added to between October, 1936, and May, 1937. The wall above is raw and freshly scarred, and the rim of the pit is considerably changed by notches which have enlarged its circumference.

The second week produced a lessening of seismicity and widening of cracks, and one slide was noticed.

The third week there were more slides, characterized by location on three sides of the pit, a new feature in that nearly all slides during the previous years had been from the east and northeast walls. Seismicity and crack widening continued about the same, with much of the latter limited to a single crack at the east rim.

The last week showed notable decline in all the measured features of seismicity, slides, crack openings, and numbers of quakes.

Slides at Halemaumau

Slides from the wall of the pit Halemaumau have been noted as follows:

June 9, 8:57 a.m., a slide at the northeast wall.
June 14, 2:07 p.m., rocks fell from the east wall.
June 17, 9:57 a.m., a slide started from about half-way down the south wall.
4:35 p.m., a slide occurred at the east.
June 19, 10:45 a.m., a large slide occurred on the west side of the pit.
June 22, 11:25 a.m., a slide at the east wall made a small dust cloud.
June 23, 8:30 a.m., a slide at the northwest wall made a fairly large dust cloud. Slides south, west and northwest have been very unusual for the last year.

Measurement of Halemaumau Rim Cracks

Weekly measurement of a constant number of rim crack locations as reconstructed during the month of May, resulted during June in aggregate movements as follows:

Week ending forenoon of:

June 4, 30 locations, 8 opened, 3 closed, opening 11.0 mm.

June 11, 30 locations, 7 opened, 4 closed, opening 10.0 mm.

June 18, 30 locations, 10 opened, 5 closed, opening 10.5 mm., of which 6 mm. was accounted for by Crack No. 25 at east rim.

June 25, 30 locations, 10 opened, 2 closed, opening 9.5 mm., of which Crack No. 25 accounted for 5.0 mm. Crack No. 25 is one of the steaming extensions of the caved-in cracks of the east notch that collapsed May 7.

T. A. J.

SEISMOLOGICAL DATA

TABLE

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Distant* Earthquakes	Weekly§ Seismicity
June 6	46	3	2	0	15.00
June 13	27	7	1	0	11.25
June 20	27	6	3	0	12.75
June 27	14	0	2	2	5.50

§ For local seismicity definition see Volcano Letter 371.
* Including teleseisms or those shocks over 5000 km. distant.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory, and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the times indicated and, whenever possible, a determination of depth of focus has been made.

May 31, 6:18 am, very feeble, located 1.2 miles deep in Kilauea Crater near the old Stone Corral. 19° 24.8′ N; 155° 16.3′ W.

May 31, 6:29 am, feeble, located in N portion of Kilauea Crater 1.0 mile E of Uwekahuna. 19° 25.5′ N; 155° 16.5′ W.

May 31, 7:32 am, very feeble, probably located in SE portion of Kilauea Crater.

June 3, 3:07 am, feeble, located in Hilina Pali Fault system 9.0 miles S of Halemaumau 10 miles deep. 19° 17.2′ N; 155° 18.5′ W.

June 4, 10:40 am, very feeble, probable location in Kilauea Crater.

June 7, 6:46 am, very feeble, located 25.0 miles deep in Kohala District 5.0 miles east of Mahukona. 20° 10.3′ N; 155° 49.0′ W. Reported strongly felt in Kohala and at Kamuela.

June 9, 9:12 am, very feeble, of Kilauea origin.

June 12, 11:29 pm, very feeble, located 0.8 mile deep in E portion of Kilauea Crater. 19° 24.9′ N; 155° 16.1′ W.

June 13, 9:21 pm, very feble, located 3.8 miles deep in vicinity of the old Prison Camp 1.2 miles NW of Uwekahuna. 19° 25.8′ N; 155° 18.3′ W.

June 14, 7:01 am, very feeble, located 4.3 miles deep under N rim of Kilauea Crater 0.5 mile NW of Volcano House. 19° 26.2′ N; 155° 15.9′ W.

June 16, 4:52 am, feeble, located 0.5 mile E of center of Halemaumau in Kilauea Crater 1.0 mile deep. 19° 24.5′ N; 155° 16.7′ W. Reported felt rather strongly at CCC Camp on SE rim of Kilauea Crater and moderately felt near Park Headquarters.

June 16, 10:35 pm, very feeble, located in Kilauea Crater.

June 17, 11:27 am, very feble, thought to have been located in SE portion of Kilauea Crater near Keanakakoi.

June 21, 2:16 pm, feeble, probably located in Chain of Craters rift near Puhimau Crater.

June 25, 6:20 am, feeble, probably located 9.0 miles S of the Volcano Observatory in the Hilina Pali fault zone.

Seventeen minutes of continuous tremor began recording at the Observatory at 12:13 pm, June 5 and sixteen minutes of continuous tremor began recording at 9:22 am, June 6.

Trees stripped of foliage and their broken branches strewn on the ground: havoc caused by volcanic showers during the eruptions near Rabaul, the capital of New Britain.

Microseismic motion of the ground at the Observatory was light May 31, strong June 5, 6, 8, 15, 16, 17 and 19 and moderate the remainder of the month.

The preliminary waves of a teleseism began to register at Kilauea at 4h 55m 8s, am H.S.T., June 21. It was estimated to have occurred 5450 miles away. There was a partial trace of a teleseism recording at the Observatory June 24, 3:18 am H.S.T.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending June 27 was 8.8" S. and 1.35" E.

TABLE OF TILT

Week Ending	Observatory	Halemaumau West Station
June 6	0.60" N 4° E	1.49" N 79° W
June 13	0.60" S 4° W	2.24" N 87° W
June 20	0.60" N 4° E	1.49" N 80° W
June 27	0.50" N 4° E	1.40" S 70° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
June 6	1.75" N 55° E	1.16" from
June 13	4.01" N 72° W	1.16" toward
June 20	4.18" S 71° E	5.06" from
June 27	7.65" N 28° W	6.12" toward

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory June 19, slight closing of the Halemaumau value and opening of the crater value as compared with similar measurements May 27. From Kilauea SE rim to Uwekahuna there was opening of 0.82" and from the Pit seismograph to NW Pit B.M. there was closing of 2.01".

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Ascsociation was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

THE VOLCANO LETTER

WORK OF F. A. PERRET ON MONTSERRAT

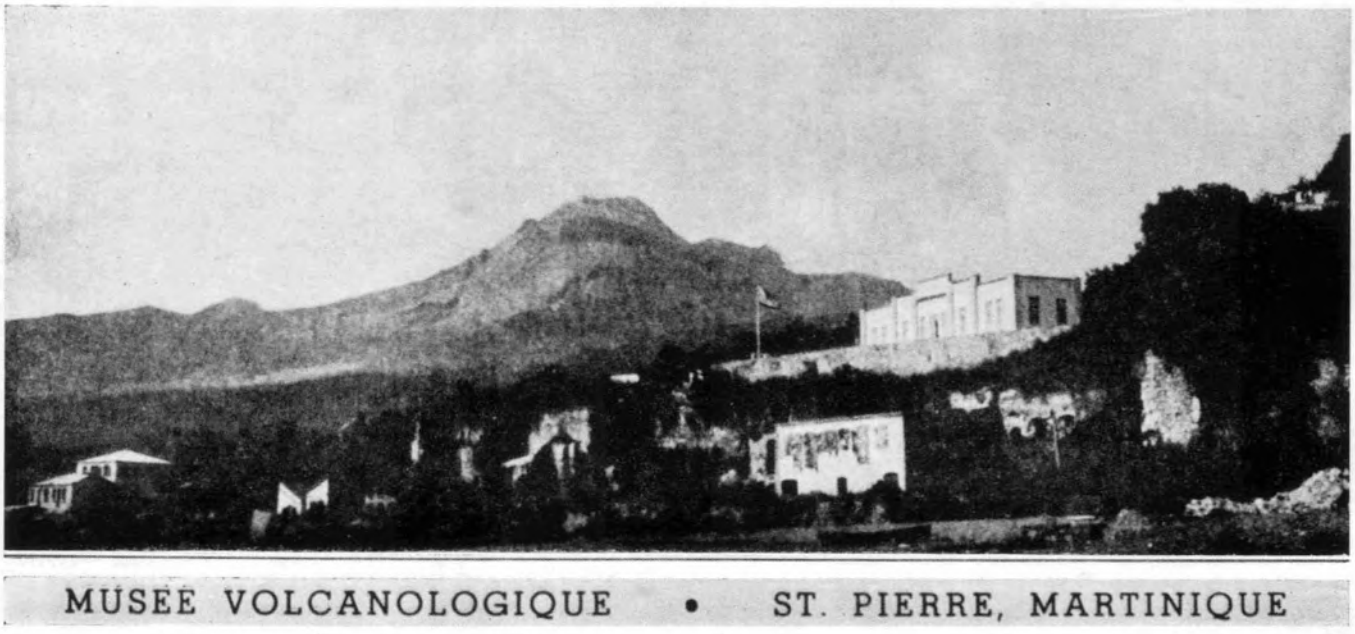

Figure 1. Museum at the ruins of St. Pierre, Martinique.

The Monserrat earthquake crisis of 1933-1936 was described in Volcano Letter No. 437, July 1936. Frank A. Perret, the volcanologist whose museum at St. Pierre, Martinique, is shown in Figure 1 (with the great new andesite dome of Mont Pele in the background) was called in to help by the governor of the Leeward Islands Presidency. Perret helped us in Hawaii in 1911, and his whole career has been devoted, as a volcanologist, to helping people in stricken volcanic lands. It may be of interest to show how such a man works. The Montserrat crisis was an apt illustration of such work, an island suddenly rushed into earthquake disaster in 1934, and its administration instinctively summoning the nearest expert for assistance.

The course of development of the Montserrat earthquake crisis, and its decline, are shown in the accompanying diagram, Figure 2. The columns are monthly seismicity. The four high ones May and December 1934, May and November 1935, were all times when churches and other masonry buildings fell, landslips occurred, and people were injured. These were earthquakes of grade VIII to IX Rossi-Forel. Frequency varied with intensity, and the sequence was from several and small shocks in 1933, itself a most unusual spell, to hundreds and severe earthquakes in summer and winter of the next two years. A terrifying feature of the crisis was the centering of these quakes at Gage's Soufriere, a crater gorge directly above the town Plymouth and only two miles away.

E. O. Hovey in revisiting the West Indies in 1903, after

careful work on Mont Pele in 1902, described these "principal craters of Montserrat as appearing to be in almost exactly the same condition as that of Pele, before the 1902 series of eruptions began."

Along with the coming of the quakes, the Montserrat solfatara gorge started vomiting up noxious odors of hydrogen sulphide, whose "rotten-egg" smell penetrated the town, and the gas actually darkened the white paint of steamers lying at anchor in Plymouth harbor. (Map, Figure 3.)

A striking feature of the map is the 100-fathom dotted line at the north. This contour under the sea is a half-circle. It outlines an ancient big volcano. The volcanic activity of recent ages has migrated to the south end at the Soufriere Hills. These hills have hot solfataras steaming and depositing sulphur on three sides. The ancient northern volcano is mostly eroded away by the ocean, leaving a platform 20 to 30 fathoms beneath the waves.

The new gas development was noted in April 1933 and earthquakes that year were most frequent at St. George's north of Soufriere Hills. They increased in force and number to April, 1934 and the government commissioner sent telegrams to inquire about volcanic conditions, which were found not to have changed in St. Vincent, Martinique, Guadeloupe and Dominica.

New sulphur vents were opening at the Montserrat solfataras. The hospital and private buildings were damaged by a sharp shock April 9, 1934. Revising the whole method of building was suggested.

Vague reports were at hand of a volcano scientist camped

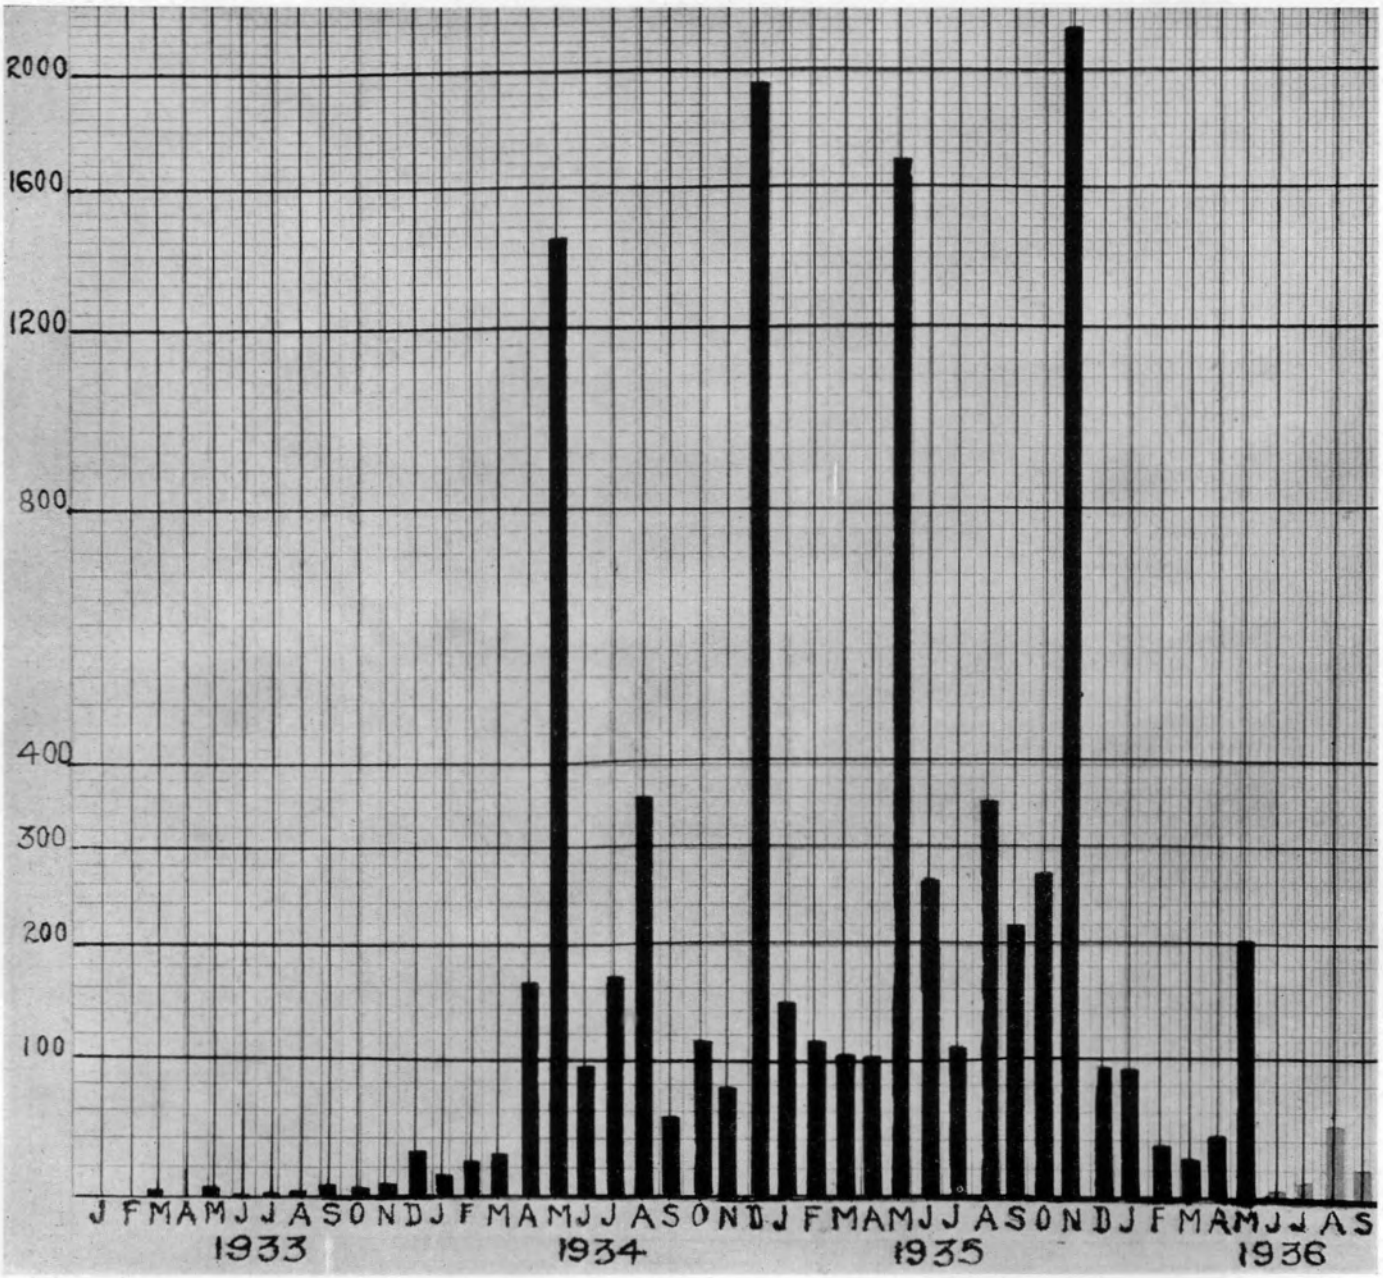

Figure 2. Chart of the rise and fall of earthquake activity in Montserrat.

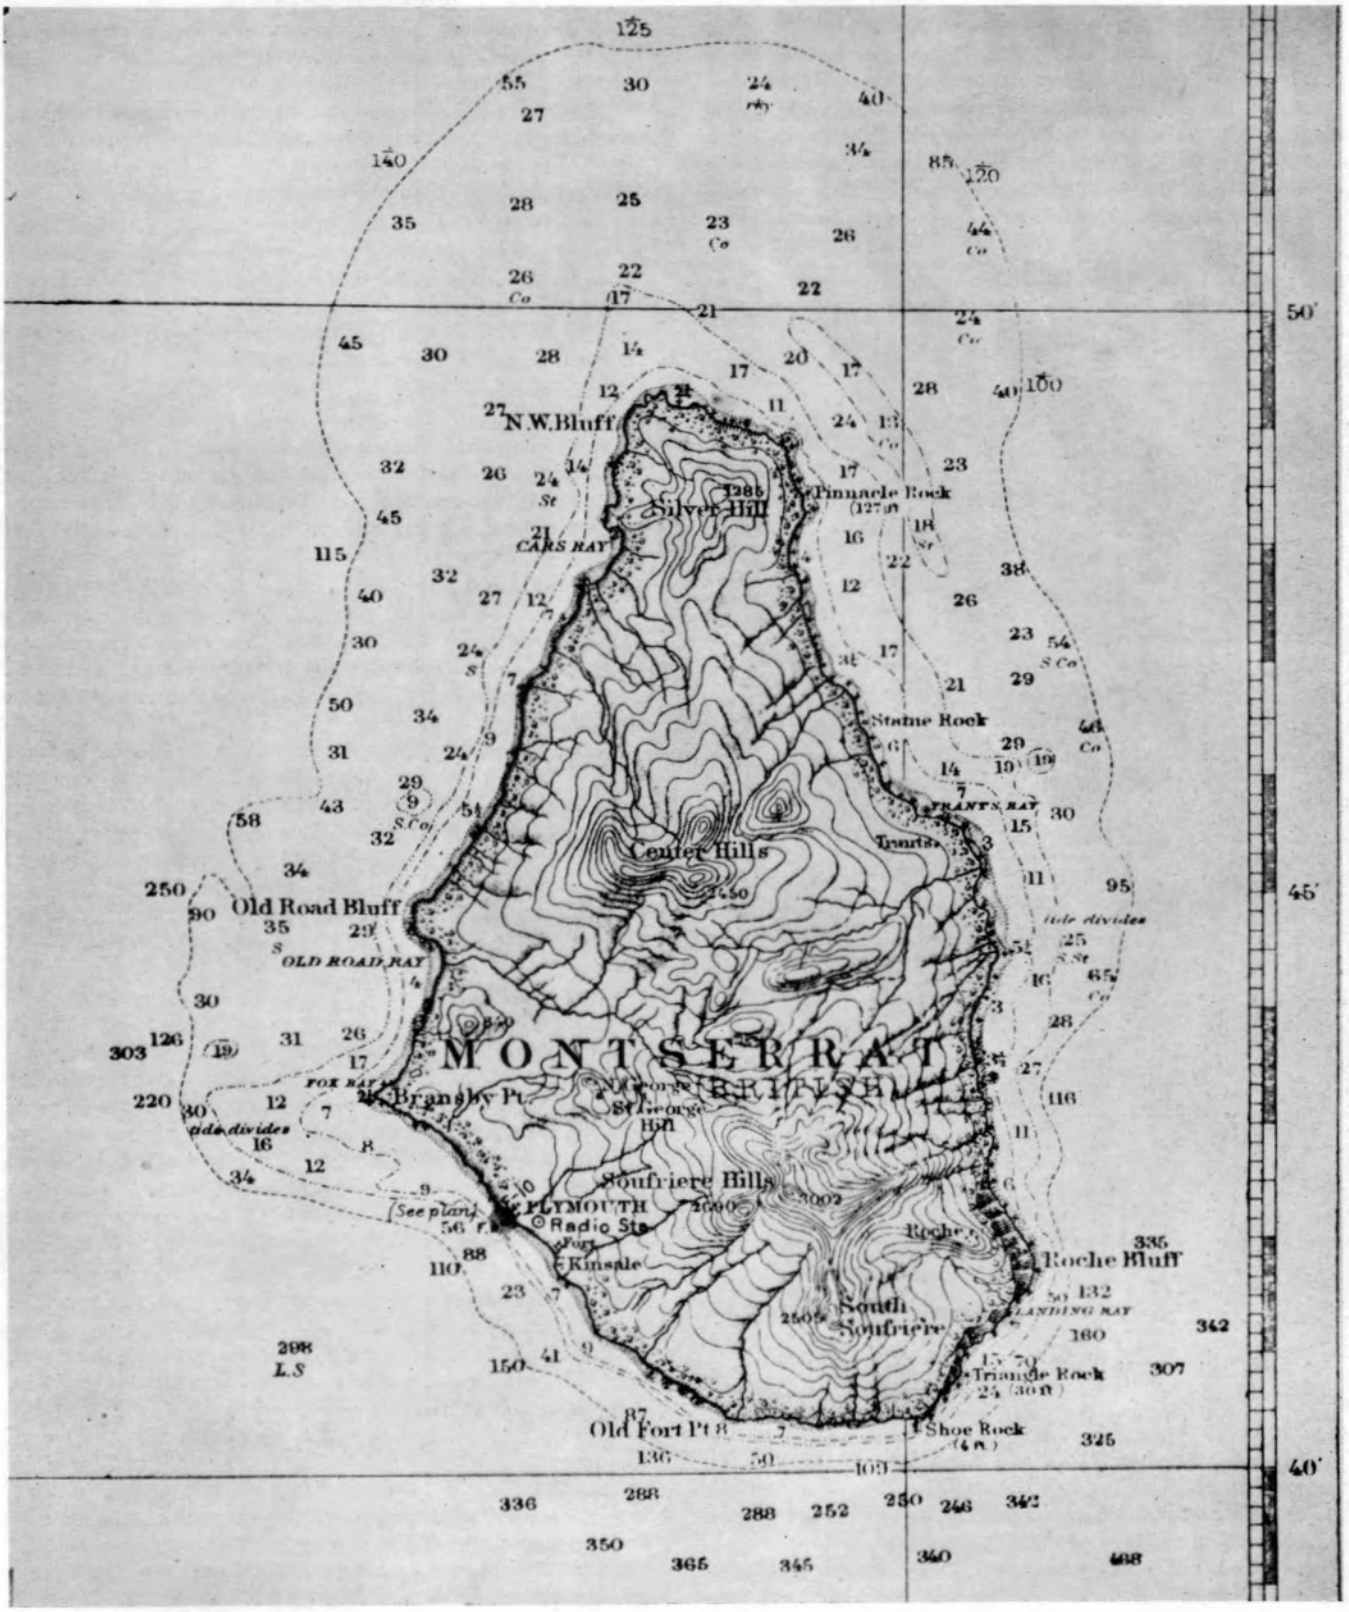

Figure 3. Chart of Montserrat, an island about ten miles long.

on Mont Pele with microphones in the soil. The British consul in Martinique phoned Perret, who was the reported scientist very much alive, and who reported Pele quiet.

May 13-14, 1934 produced sixty shocks, which cracked houses during an exceptional jolt at 2 a.m., the worst in thirty years. All of this was racking and weakening the old masonry.

Perret came by on a steamer en route to New York, visited Gage's Soufriere May 13th, predicted more shocks that day which duly came, and warned of more danger. A terrible shock came at 3 p.m. the 14th, seriously damaging the courthouse, all business was suspended, disorganization and disrupted sanitation were threatened.

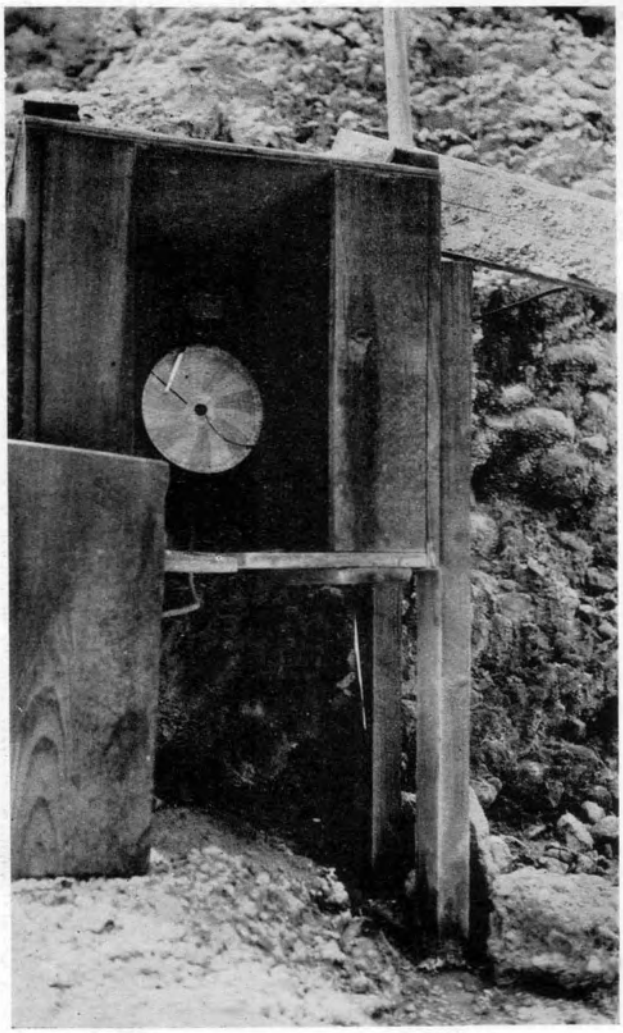

Figure 4. Bristol thermograph at Gage's Soufriere.

A warship was summoned and came May 21-31 to calm the people; earthquakes kept swarming. Following Perret's advice counts were made of the quakes, scientists of the agricultural station made daily visits to Gage's Soufriere and took temperatures, and notes were made on the chemistry of the waters and gases.

In July Mr. Perret was invited to return and install instruments; he had taken a water sample to Washington from the solfatara. No seismograph had yet been supplied.

Mr. Perret wrote Mr. Gomez, the director of agricultural station, suggesting a direction-finding seismoscope which was duly installed: "Suspend a series of weights of one pound each with fine wire as simple pendulums, of lengths varying 6, 12, 24, 48 and 96 inches. By watching these when shock occurs, some will swing, others not, showing period and direction of earth vibration. By setting up sets in different places much may be learned regarding the source of the shocks by coordinating directions."

Perret's hope is for a research organization eventually endowed for the Caribbees; with a base, a motor yacht with apparatus, ready to proceed without delay to any locality where trouble is reported, there to land and investigate conditions.

In Washington he secured support from the Carnegie Institution for investigating the Montserrat crisis, and sent vacuum tubes for collecting gases. He secured a Bristol gas-expansion recording thermograph with weekly charts, the lead-covered bulb to be buried in a gas fissure at Gage's solfatara; also microphone, and maximum thermometers.

He arrived and set up the instruments the end of November. Throughout his work he watched closely the luni-solar combinations, which might influence earth-tide stress in relation to gas tension in subterranean magma. The gas tension is localized in the crust. The earth tide varies seasonally, and varies exceptionally with certain sun and moon positions. The whole crust pumps with the earth tide.

The sudden frothing of volcanic magma in a subterranean fissure is a large force accumulated locally of a different kind, subject to release if the small tidal force relieves pressure exceptionally on certain dates. It is quite possible that deep plutonic earthquakes are so released, and are concerned with changes of state of magma.

Perret's reports to the governor were printed in the Leeward Islands Gazette between December 12, 1934 and May 19, 1936 in a series of letters from Montserrat, on the occasions of his several visits, coming sometimes by steamer, sometimes in haste by airplane and sloop from Martinique through Antigua. For a man of seventy they show extraordinary vigor; he made nine reports; and he built a hut within the crater gorge where he actually tried to sleep, until he injured throat and eyes with the deadly gases.

The Bristol thermograph (Figure 4) was set up in the bottom of the steaming gorge at Gage's. It registered 105° C. and the strong shocks also made of it a seismograph, by disturbing the ink pen. Mercury in saucers, for observation of small tremor, was placed in four localities. Gas tests were made with lead acetate and litmus paper. The hydrogen sulphide was tested thus even at Plymouth. The litmus at Gage's showed water sour with sulphuric acid, and air in the gorge which was alkaline. A gas irritating to eyes was thought to be hydrogen persulphide. Photographs were taken.

Vacuum tube collections were sent to Washington for gas analysis. The water analysis showed heavy charge of hydrogen sulphide, iron, alumina, sulphur, silica and organic matter; acidity 0.1 per cent, chlorine a trace; the gas analysis showed equal amounts of sulphur and chlorine. No fluorine could be detected in the waters.

A very sharp culmination of many earthquakes at 11 a.m. December 12, 1934 did more damage, was experienced by Perret, and differed from the widely felt May shocks in being highly localized, near Gage's, as though from magma close to the surface. This was disquieting with reference to possible eruption. The gas pressure had increased and spread at Gage's. The hydrogen sulphide was diagnosed as coming from dry vents lower than the wet solfatara. No tremors actuated the mercury surfaces between shocks, and the latter were sharp and brief. Absence of volcanic tremor indicated absence of moving magma, and the microphone confirmed this. The local observers were instructed to carry on with the instruments when Perret returned to Martinique.

Perret's second visit was in February-March 1935, and systematic observations had meanwhile been reported by the local men. He occupied his hut (Figure 5) in the crater gorge, observing the thermograph; the mercury bath with bell-glass cover mounted in a niche; a microphone buried in the ground; an air-microphone for the pressure-note of gas emission; a seismic pendulum for detecting direction of movement in earth shocks, with a mirror reflecting the beam from an electric torch at night.

A new hydrogen sulphide vent opened whistling the night of February 20, 1935. The other acrid alkaline gas that affected eye tissue made night stays impracticable. Tight-fitting goggles helped in daytime. Some subterranean sound was heard occasionally. The Bristol thermograph gave a deceptive indication of rising temperature on the record, which proved to be due to corrosion and weakening of the metal spiral. Check with thermometer proved error. "Bread-crust" bombs like Pele's were found in the gorge. Perret expressed intention of return in May, the critical month of 1933 and 1934.

The next visits of the American volcanologist were in April and May, 1935 and a severe, prolonged and deep shock did more damage on May 6, and exhibited much horizontal movement. The area shaken was farther north. The earthquake was preceded by early morning tremors, and very heavy rains came at 3:55 p.m. and were followed by aftershocks all night. The wide-spread effect relieved apprehension of volcanic eruption for Perret; the disturbance was not craterally localized.

Perret called attention to the sum total of the energy released and dissipated in the long series of earthquakes. If this energy had been concentrated in a single shock, like the Tokyo earthquake of 1923, the wreckage and loss of life might have been far worse. The comportment of the population, largely Negro, was good.

The deeper and more diffuse quality of the May 6 shock of 1935 satisfied the investigator that the volcano eruption danger had culminated at the December 1934 shocks, when high gas pressure and temperatures were dominant at the solfataras. Both had diminished in May 1935 when the deep earthquake came, and did tremendous seismic damage. Mr. Perret stated definitely to the authorities that possibility of more strong shocks remained, but that we might "now discard all likelihood of volcanic eruption."

To make such a statement as this required courage. The event bore out its accuracy. In a paragraph of his final report when the Royal Society Committee was about to take his place he says, "It has been inspiring to work in such an atmosphere of discipline and good will, and I shall remember with pleasure **—in spite of such anxiety and responsibility as cannot be imagined by those who do not know**—the days of my investigations here."

The boldface are the reviewer's. Here is a man working devoted and alone. He is working that black men may live and their habitations be preserved, in a hot and humid climate amid poison gas. He is apt to receive for it the nosey snubbing of "superior" men of science who dwell in superior laboratories in the urban atmosphere of a superior climate, and who do not dirty their fingers with the poisonous solfataras of volcanoes.

Withal his inventive ingenuity never relaxed. He finally installed at Howes Estate near the solfatara a "Seismeter" of his own construction made out of three pedometers of the pace-counting watch pattern. This is shown in Figure 6. Two are laid horizontally with their pendulum interiors at right angles to each other, to beat and record on their dials the "paces" of the earth east-west and north-south respectively. The third is laid vertically, as it would be if attached to a man's belt in walking, and records the upright jolts of the earth. All shocks above a certain minimum of intensity will record. By reading the three dials after one of the savage shakings of the earth, the number of units above the intensity minimum, prescribed by the sensitivity of the pedometer, for each direction, describes what has happened at the instrument locality.

Thus the quake of November 10, 1935 gave 1v, 9n, 3e; that of November 11 was much more vertical, 7½v, 6n, 5e; while that of November 12 was intermediate, 4½v, 2n, 1e. In these v is vertical, n is north-south, and e is east-west.

The seismeter has the further quality that its dials may be read after any shock series, but not changed; and it goes on summing up, just as the pedometer does for a pedestrian, the totality of earthquakes for any period of time, regardless of whether there is present an observer to read it. Thus this extraordinary worker in the wilderness finds time to invent and add to the progress of science, even in the midst of quakes and ruins and fumes!

Hawaiian Volcano Observatory Report for July 1937

VOLCANOLOGY

The only events of importance at Kilauea Crater have been two spells of local earthquakes lasting about a day each July 22 and July 30. Each of these produced moderate earthquakes which were felt. Numerous distant earthquakes were recorded.

The following are the weekly Observatory totals for Halemaumau and the seismographs:

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Tremors and Quakes
July 4.....	8.00	2	6.0	22
" 11.....	9.25	0	7.0	37
" 18.....	6.50	0	9.5	18
" 25.....	26.00	0	11.5	84
Aug. 1.....	22.75	0	5.5	45

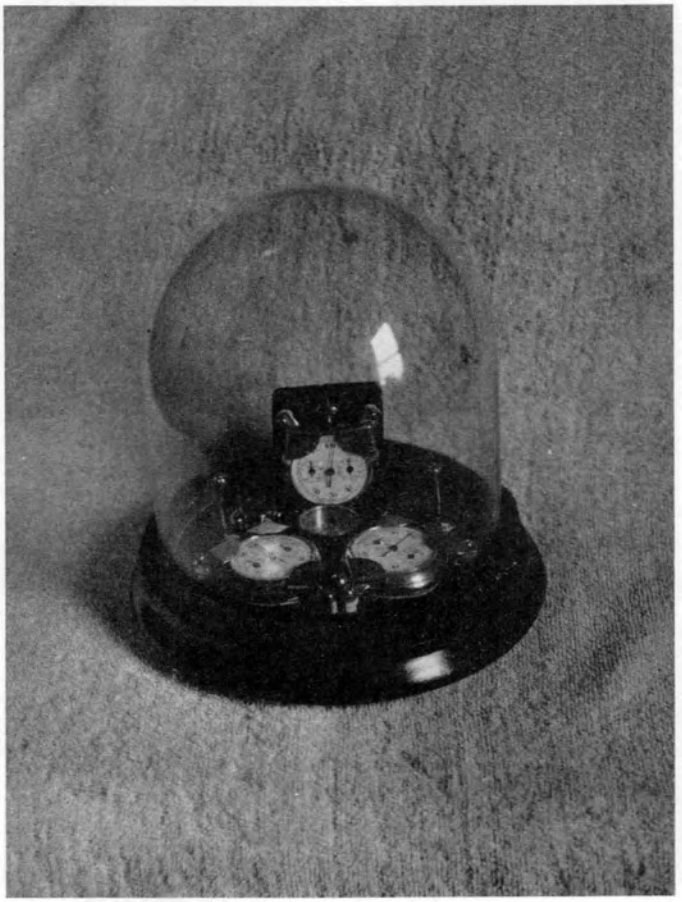

Figure 6. Experimental Seismeter installed at Gage's Oct. 25, 1935, records and integrates ground movement in vertical and horizontal components. (3) Totalizes on 9 dials (3 on each pedometer).

Frank A. Perret.

Sequence of Events by Weeks

The first week produced nothing more conspicuous at Halemaumau pit than two small slides.

The second week showed the pit still quieter.

The third week nothing was noted at Halemaumau but on July 14 Park officers on the upper Mauna Loa trail reported steam from a cone on the Northeast Rift at about elevation 11,000 feet, and bluish fume from cracks a quarter mile farther south.

The fourth week no slides were reported but the earthquakes of July 22 probably made avalanches. It was noticed July 25 that the northeast wall of Halemaumau has developed a buttress resulting from landslips on each side. The talus slopes NE, NW, SW, SSE, and E from the pit center all have buttresses of rock between them. The migration of landslip area from year to year since 1924 has kept the pit fairly symmetrical. The talus cones were made by such landslips and the buttresses are each backed by cracks concentric with the rim, and below the rim, that were formerly fissures in the upper country.

The last week produced excessive rainfall (more than 16 inches July 31-August 1), and a spell of earthquakes July 30.

Slides at Halemaumau

The only recorded slides from the wall of the pit were:

July 1, 1:22 p.m., made dust and noise.

July 2, 9:17 a.m., rocks fell from east wall 200 feet below rim.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim-crack locations resulted during July in aggregate movement as follows:

Week ending forenoon of:

July 2, 30 locations, 9 opened, 5 closed, opening 6.0 mm. At the east Crack No. 52 closed 4.5 mm.

July 9, 30 locations, 7 opened, 4 closed, opening 7 mm.

July 16, 30 locations, 8 opened, 1 closed, opening 9.5 mm.

July 23, 30 locations, 11 opened, 1 closed, opening 11.5 mm.

July 30, 30 locations, 3 opened, 4 closed, opening 5.5 mm. Most of this was at Crack No. 25, east rim.

SEISMOLOGICAL DATA

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the times indicated and whenever possible a determination of depth of focus has been made.

June 30, 5:43 am, very feeble, located 3.5 miles deep under area 1.5 miles west of Kilauea Crater. 19° 25.0′ N; 155° 18.9′ W.

June 30, 8:46 am, very feeble, a deep quake with epicenter near Honokaa. 20° 4.0′ N; 155° 33.0′ W.

July 2, 9:16 am, very feeble, 2.6 miles deep and 2.0 miles west of Kilauea Crater. 19° 24.8′ N; 155° 19.4′ W.

July 3, 6:49 am, slight, 3.0 miles deep and 1.0 mile SW of Ahua Kamokukolau, 19° 22.0′ N; 155° 17.0′ W.

July 10, 9:43 pm, very feeble, thought to be of shallow origin near center of Kilauea Crater.

* For local seismicity definition see Volcano Letter 371.

† Includes teleseisms and distant earthquakes.

July 13, 5:40 pm, very feeble, originated near SE rim of Kilauea Crater.

July 16, 3:20 pm, very feeble, probably originated in rifts 1.5 miles S of Ahua Kamokukolau.

July 16, 6:51 pm, feeble, 3.5 miles deep in vicinity of Kipuka Ki, 2.0 miles NW of Uwekahuna. 19° 27.3′ N; 155° 19.2′ W.

July 18, 10:55 am, very feeble, 1.7 miles deep in W portion of Kilauea Crater near Uwekahuna Bluff. 19° 25.3′ N; 155° 17.0′ W.

July 18, 10:56 am, very feeble, 1.6 miles deep under Kilauea Crater rim near Uwekahuna Bluff. 19° 25.6′ N; 155° 17.1′ W.

July 18, 7:29 pm, very feeble, probably originated in NE rift of Mauna Loa near summit crater.

July 19, 8:36 am, very feeble, 1.7 miles deep in Kilauea Crater near the old Stone Corral. 19° 24.7′ N; 155° 16.3′ W.

July 22, 8:53 am, very feeble, probable origin, Kilauea SW rift near Cone Peak.

July 22, 10:38 am, feeble, probable origin in Chain of Craters near Puhimau.

July 22, 10:41 am, very feeble, 1.5 miles deep under SE rim of Kilauea Crater near Keanakakoi. 19° 24.5′ N; 155° 15.9′ W.

July 22, 10:53 am, very feeble, 2.2 miles deep, 6.0 miles N of Ahua Kamokukolau. 19° 23.3′ N; 155° 16.3′ W.

July 22, 11:14 am, very feeble, probably originated in Kilauea Crater near Halemaumau.

July 22, 11:18 am, very feeble, 1.6 miles deep, 1.8 miles NW of Puu Ohale. 19° 22.3′ N; 155° 17.9′ W.

July 22, 11:40 am, moderate, 1.8 miles deep and 1.7 miles SE of Pit seismograph. 19° 23.5′ N; 155° 15.8′ W. Reported felt in Park Headquarters Area; and at Kilauea Military Camp.

July 22, 11:45 pm, very feeble, 3.0 miles deep SE rim of Kilauea Crater near Keanakakoi. 19° 23.0′ N; 155° 15.6′ W.

July 23, 3:30 pm, very feeble, probably of shallow origin near center of Kilauea Crater.

July 24, 3:20 pm, very feeble, probably originated in Chain of Craters Area near Puhimau.

July 30, 2:40 pm, moderate, probable origin, Mauna Loa NE rift near Puu Ulaula.

July 30, 3:46 pm, feeble 2.8 miles deep in vicinity of old Koa Mill, 1.5 miles N of Kilauea Crater. 19° 27.1′ N; 155° 17.0′ W.

July 30, 3:50 pm, feeble, 2.8 miles deep in Chain of Craters rift near Lua Mau Crater. 19° 23.9′ N; 155° 15.4′ W.

July 30, 8:05 pm, very feeble, 5.5 miles deep in Chain of Craters rift near Kokoolau. 19° 23.1′ N; 155° 14.0′ W.

July 30, 8:17 pm, very feeble, 3.5 miles deep near Kipuka Puaulu, 2.5 miles NW of Kilauea Crater. 19° 27.0′ N; 155° 18.9′ W.

July 30, 8:46 pm, very feeble, 2.4 miles deep near Ainahou Ranch House. 19° 20.8′ N; 155° 14.0′ W.

July 30, 9:14 pm, very feeble, probably originated in Chain of Craters near Pauahi.

July 30, 9:29 pm, feeble, 2.7 miles deep and 0.7 mile E of Hiiaki Crater, Chain of Craters rift. 19° 22.8′ N; 155° 13.5′ W.

July 31, 10:11 pm, slight, 4.7 miles deep under Kilauea Crater rim 0.5 mile NE of Uwekahuna. 19° 25.7′ N; 155° 17.3′ W.

July 31, 10:13 pm, slight, location of focus same as preceding quake.

July 31, 10:27 pm, very feeble, 5.0 miles deep and 1.0 mile NE of Volcano Observatory. 19° 26.5′ N; 155° 15.3′ W.

August 1, 2:56 am, feeble, location of focus same as preceding quake.

August 1, 9:43 am, very feeble, 2.8 miles deep in rift area 0.8 mile N of Puu Ohale. 19° 21.9′ N; 155° 16.8′ W.

A period of continuous tremor lasting 26 minutes began at 9:24 am, July 6.

Microseismic motion of the ground at the Observatory was light July 5, 10 to 13, 17, 19 to 21, and July 26; moderate June 28 to 30, July 4, 7 to 9, 14 to 15, 18, 22 to 23, 27 to 30, and August 1; strong remainder of month.

Teleseisms or Distant Earthquakes registered at Kilauea as follows: July 1, 4h 28m pm, H.S.T., undetermined phase; July 3, 7h 46m 19s pm, H.S.T., undetermined phase; July 11, 7h 13m 55s am, undetermined phase, reported by Central Station of the Jesuit Seismological Association as located 20° 7′ N; 108° 3 W (west coast of Mexico); July 22, preliminary phase, 6h 47m 56s am, originated 3,010 miles from Kilauea and epicenter reported by Central Station of Jesuit Seismological Association as 64° 5′ N; 145° W (Central Alaska); July 25, preliminary phase, 5h 26m 44s pm, H.S.T., distance—3,780 miles and July 25, 10h 18m pm, undetermined phase.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts towards or away from the Pit.

At the Observatory the total accumulated tilt for the year ending August 1 was 9.8″ S and 1.85″ E.

TABLE OF TILT

Week Ending	Observatory	Halemaumau West Station
July 4	0.26″ N 20° W	1.55″ N 60° W
July 11	0.00	2.17″ N 68° W
July 18	1.13″ N 17° E	10.13″ N 82° W
July 25	0.36″ S 47° W	11.02″ N 71° W
Aug. 1	0.51″ S 60° E	6.35″ N 55° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
July 4	3.75″ N 60° W	2.22″ toward
July 11	3.40″ S 60° W	1.62″ from
July 18	10.85″ N 43° W	0.72″ toward
July 25	5.31″ N 86° E	12.89″ from
Aug. 1	10.37″ S 41° W	7.19″ from

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis-Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

THE VOLCANO LETTER

No. 450 monthly Department of the Interior National Park Service August 1937

VOLCANOES IN THE NATIONAL PARKS—

Radio Talk, KHBC, Sept. 28, 1937, Hugh H. Waesche

Because of their spectacular nature and their interference with man's activities, volcanoes have always been of intense interest to the human race. With primitive peoples they have been associated with the supernatural, but when attacked by modern scientific thought they serve as major stepping stones in the solution of many problems concerning the origin and history of the earth on which we live. Most advanced, and going beyond previous thought is the systematic study of volcanoes with protection of life and property in mind.

Many of our National Park areas contain volcanoes as major features. Other National Parks contain volcanic features of secondary importance. Of twenty-seven National Parks listed August first of this year, five have volcanic histories of major interest, and at least nine others contain some evidence of past volcanic history. So, more than half of our National Parks have a geologic story to tell of which some portion is volcanic.

In this series of Parks, volcanic conditions of practically every kind known are demonstrated, from the currently very active lava volcanoes in Hawaii, to ash deposits laid down in Shenandoah and Mammoth Cave National Parks many millions of years ago in that geologic period known as the Ordovician, when man's arrival on earth was in the very distant future and probably all life was still confined to the oceans. This variety of volcanic evidence applies equally to both kinds of activity, and amounts of activity.

Five National Parks illustrate stages of volcanic activity very clearly. Hawaii National Park heads the list as the most active, being the location of Kilauea and Mauna Loa. Lassen Volcano in Northern California illustrates a second stage of activity as well as holding the unique position of being rated the only active volcano within the boundaries of continental United States, excepting Alaska. Mount Rainier in Washington represents the dormant stage, Crater Lake a dormant or extinct volcano with a special history, and Yellowstone, an ancient volcanic region much eroded but with enough residual heat to produce a very special type of geyser activity found at only three localities in the world.

Not one of these volcanoes has been listed definitely as extinct, as that is a term which should not be applied too hastily. No doubt some of these volcanoes are extinct, but definite statement to that effect would certainly be open to question. Vesuvius in Italy was considered extinct until seventy-nine A. D. but that opinion was rudely changed with the destruction of Pompeii.

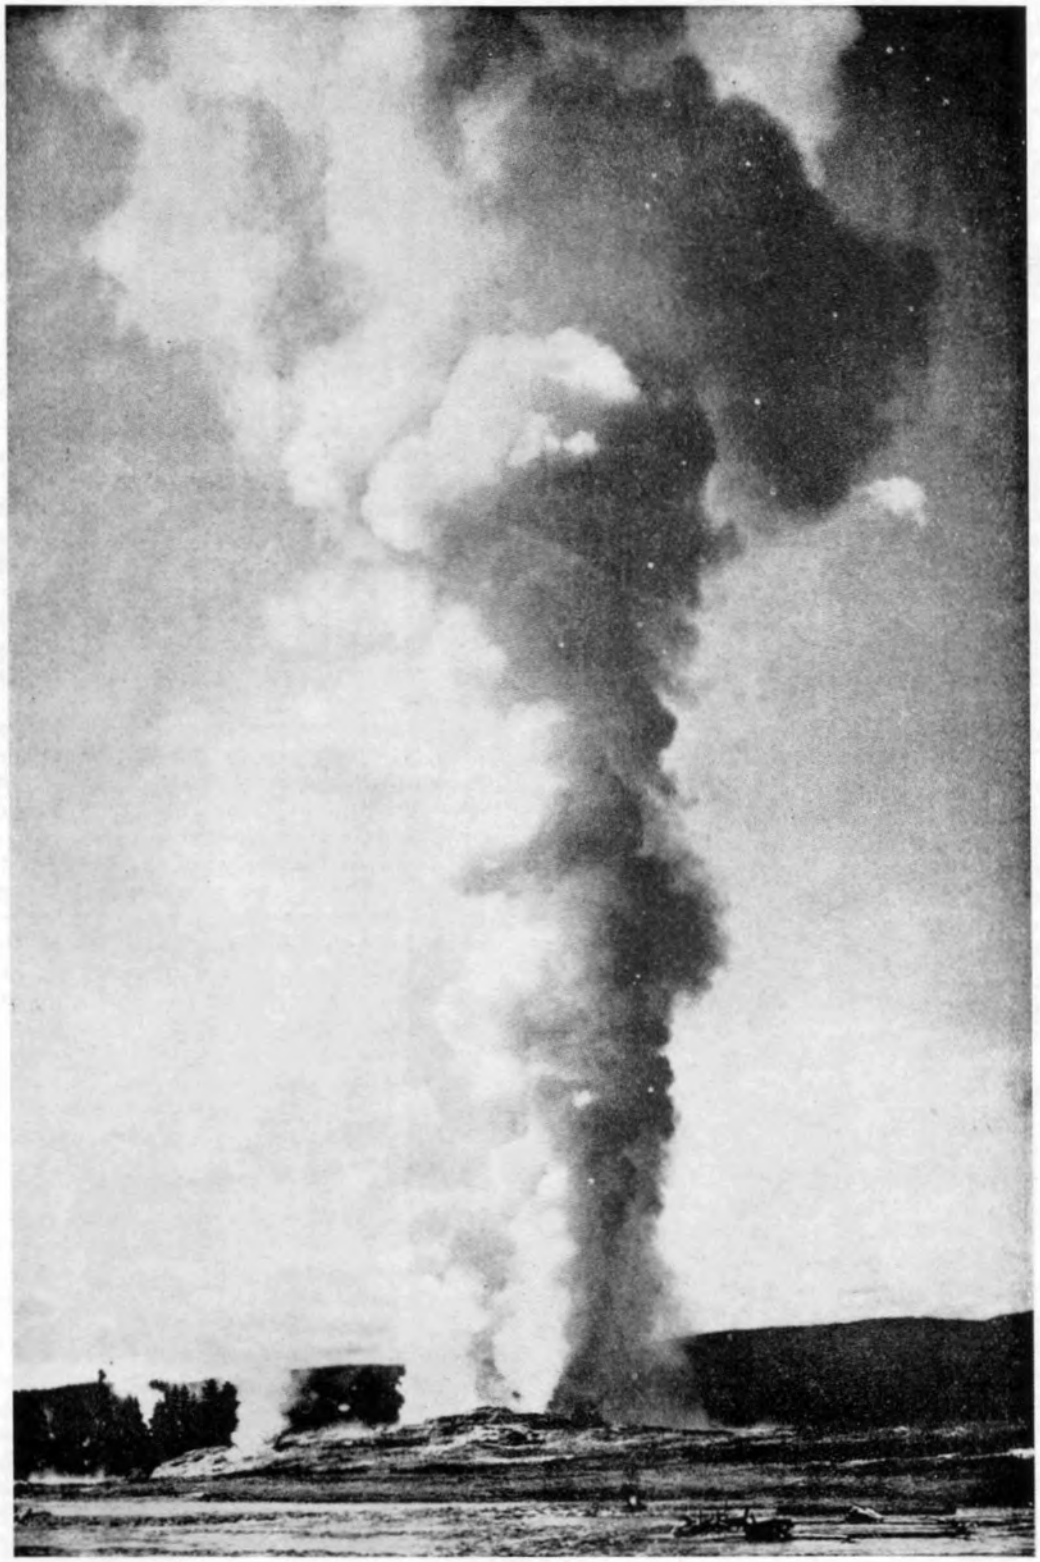
Aside from the volcanoes in the National Parks there are others in National Monuments such as Katmai in Alaska, Sunset Crater, Arizona, Capulin Mountain, New Mexico, and the Lava Beds of California. Various types of volcanic structures are also exhibited in Craters of the Moon in Idaho, Devil's Post Pile in California, Devil's Tower, Wyoming, Grand Canyon National Monument and Death Valley National Monument.

It is not surprising that the first and greatest area to be set aside as a national park was volcanic. Only a volcanic region could produce the superlative and dynamic landscape which holds this honor. Everyone has heard of and knows something of Yellowstone, the "Grand Old Man" of all the parks, both in the United States and elsewhere. It is located in the northwestern corner of Wyoming with a slight overlap into the states of Idaho and Montana. This region was rather inaccessible and practically unknown until the middle of the last century. A few men had visited the region, however, and brought back glowing tales of the wonders to be seen there. As far as these reports were concerned the public was very incredulous and the situation was such that few dared to tell of the things they had seen, as several lecturers were actually stoned in the streets as imposters. The first official and accredited exploration of the Yellowstone region was made by the Washburn-Langford expedition of 1869. Their glowing reports of the wonders of the region led to its establishment as our first National Park in 1872.

The feature of greatest interest in Yellowstone is that unusual form of volcanic activity, the geyser. It is justly celebrated in this respect as there are only two other places in the world where geysers are common, New Zealand and Icelana, and Yellowstone has more geysers than those two combined. There are more than three thousand geysers or hot springs within the Park and every conceivable type or form of either is represented.

A geyser may be thought of as a water volcano. They can occur only in places where the internal heat of the earth is near the surface. Water from the surface plus some added from depth flows into an opening in the form of a more or less tubular vent, or maybe even a crack, and eventually reaches regions of highly heated rocks below. When this happens steam is formed but does not escape because of the heavy column of water above. After a time, however, the steam pressure becomes equal to or slightly greater than that exerted by the water column and as soon as this condition is reached the water is forced out and appears at the surface as a fountain.

The height of the fountain, frequency of play, and force of the water depend on conditions which vary widely with the different geysers. Such conditions are size of orifice at the surface, temperature below the surface, length and size of the tube leading to the hot rocks, ground water level, and probably other conditions which are not known.



There are six principal geyser basins in the Yellowstone, all lying in the west and south-central sections of the Park. Some geysers erupt quite regularly. The most famous of these are Old Faithful, Daisy and Riverside. Old Faithful erupts about once an hour year in and year out and shoots a shaft of water over one hundred and fifty feet in the air for four minutes. The water temperature is about two hundred degrees Fahrenheit. Besides the geysers, the entire region contains many hot springs which are in most cases clear water with a beautifully colored background of orange, yellow, green or blue created by algae which live on the rocks forming the container. Other springs are filled with mud in constant agitation which, in one case, is named the Paint Pot. At Mammoth Hot Springs the water has brought to the surface large amounts of lime in solution which is precipitated on reaching the air. These mineral deposits build high terraces of beautifully encrusted basins over which the water flows.

Practically the entre region incorporated in Yellowstone is volcanic. Not only the surrounding mountains but the great interior plain is made of material once ejected as ash and lava from depths far below the surface. In some places entire forests have been buried by ashes blown from these ancient volcanoes, in another place lava which poured out on the surface cooled so rapidly that volcanic glass was formed, now represented by the famed Obsidian Cliffs. Yellowstone's volcanoes were probably active in that geologic age known as the Tertiary, millions of years ago. Since that time the region has quieted down, and has even been through a period of glaciation. The stage of erosion there, plus the lack of recent activity, marks the area as one in which a great volcanic exhibition had been through its youth, maturity and is now in advanced old age with only enough heat left over to keep the geysers busy.

Several hundred miles west of Yellowstone lies an area of a quarter million square miles which is the greatest field of volcanic activity in the United States and one of the greatest in the world. Large portions of the States of Washington and Oregon, and lesser portions of California, Nevada, Idaho, Montana and Wyoming are within this area. It includes the Cascade Range of Mountains extending from northern California across Oregon into Washington.

Within this range are three of our National Parks, all volcanoes, and they are, in order, south to north, Lassen Peak, Crater Lake and Mt. Rainier. Of this group, only Lassen is considered active. Crater Lake was probably active as recently as eight hundred years ago. Mt. Rainier near Tacoma, Washington, is considered "king" of all the towering volcanoes of this region. It is a huge volcanic cone over 14,000 feet in height and covering more than 100 square miles. A few steaming vents and hot springs are all that remain of activity which was evidently on a very grand scale in its past history. Now this huge mass of lava, cinders and ashes is covered by snow and ice resulting in a glacier system. Mt. Rainier is now an imperect cone, but once it was complete like the famous Fujiyama of Japan. Then it was probably 16,000 feet high. Sometime in its late history an explosion or engulfment occurred which took 2,000 feet off the top and left Mt. Rainier beheaded. Indian legends tell of a great eruption, but no man really knows when this great mountain was last active.

The southern limit of the Cascade Range is marked by Lassen Peak. This volcanic pile is the only aggressive member of the group to which it belongs. It had been quiet for over two hundred years although one or more doubtful eruptions are reported, and "mud" flows have occurred within the last five hundred years as estimated from buried logs.

Yellowstone National Park. Wyoming.

On May 30, 1914, a series of eruptions began from Lassen which lasted through June of 1917. The first eruption was short and mild, opening a new vent in the summit crater. The materials thrown out the first year were not excessively hot. By March of 1915 over one hundred and fifty explosions had occurred, probably aided by water from an unusually heavy winter snowfall. On May 19, 1915, there appeared the first glowing lava which spilled over the western edge of the crater to flow down the slope one thousand feet. That night several destructive mud flows poured into valleys down the slope.

Three days later a mushroom-shaped cloud of smoke and dust arose four miles in the air accompanied by a hot blast of gas which rushed down the northeast slope destroying every living thing for ten miles. So violent was this blast that trees on Raker Peak three miles away were all felled uniformly in the direction of the outburst. The heat turned snow in its path to water. After this convulsion the energy of the Volcano was mostly spent although occasional outbursts of steam and ash continued for two years when it finally subsided.

At the present time Lassen is quiet, although from time to time there are earthquake shocks. There are many hot springs, boiling mud pots and sulfurous deposits in and around Lassen Peak. A seismograph station is maintained at Lassen for recording earthquakes as is done here in Hawaii. Lassen was formerly a part of the study program of the Hawaiian Volcano Observatory. Lassen Peak is 10,453 feet above sea level and is surround by lava fields, and other volcanic cones illustrating many phases of volcanic activity. Lassen's activity will probably be resumed in the future.

Although Grand Canyon National Park is set aside as a great example of stream erosion, it has some evidences of volcanic activity of a minor nature which occurred millions of years ago. However, within sixty miles of Grand Canyon is one of the largest extinct volcanoes in the United States. This is the San Francisco Mountain area of Arizona. Included in this region is Sunset Crater, a 700-foot cinder cone and associated lava fields. The latter locality has been recently active—that is within a thousand years. Some of the lava associated with Sunset Crater is very similar to our Hawaiian aa. Sunset Crater is a National Monument.

The Devil's Tower in Wyoming is an interesting volcanic exhibit. It is a 600-foot pile of vertical jointed lava similar to that to be seen in Makaopuhi Crater here in Hawaii National Park. It tops a 600-foot mound of sedimentary rock and can be seen for a hundred miles in any direction. Some people think it is an intrusive plug, but there are others who think it is a remnant of an old intrusive sheet, and there is a lot of evidence to back this latter theory.

In the country north of Lassen National Park there is an area in California near the Oregon line known as the Lava Beds National Monument. This large region is typical of its name and contains many lava tubes similar to our Thurston Lava Tube. Some of the tubes contain ice the year around and are known as ice caves.

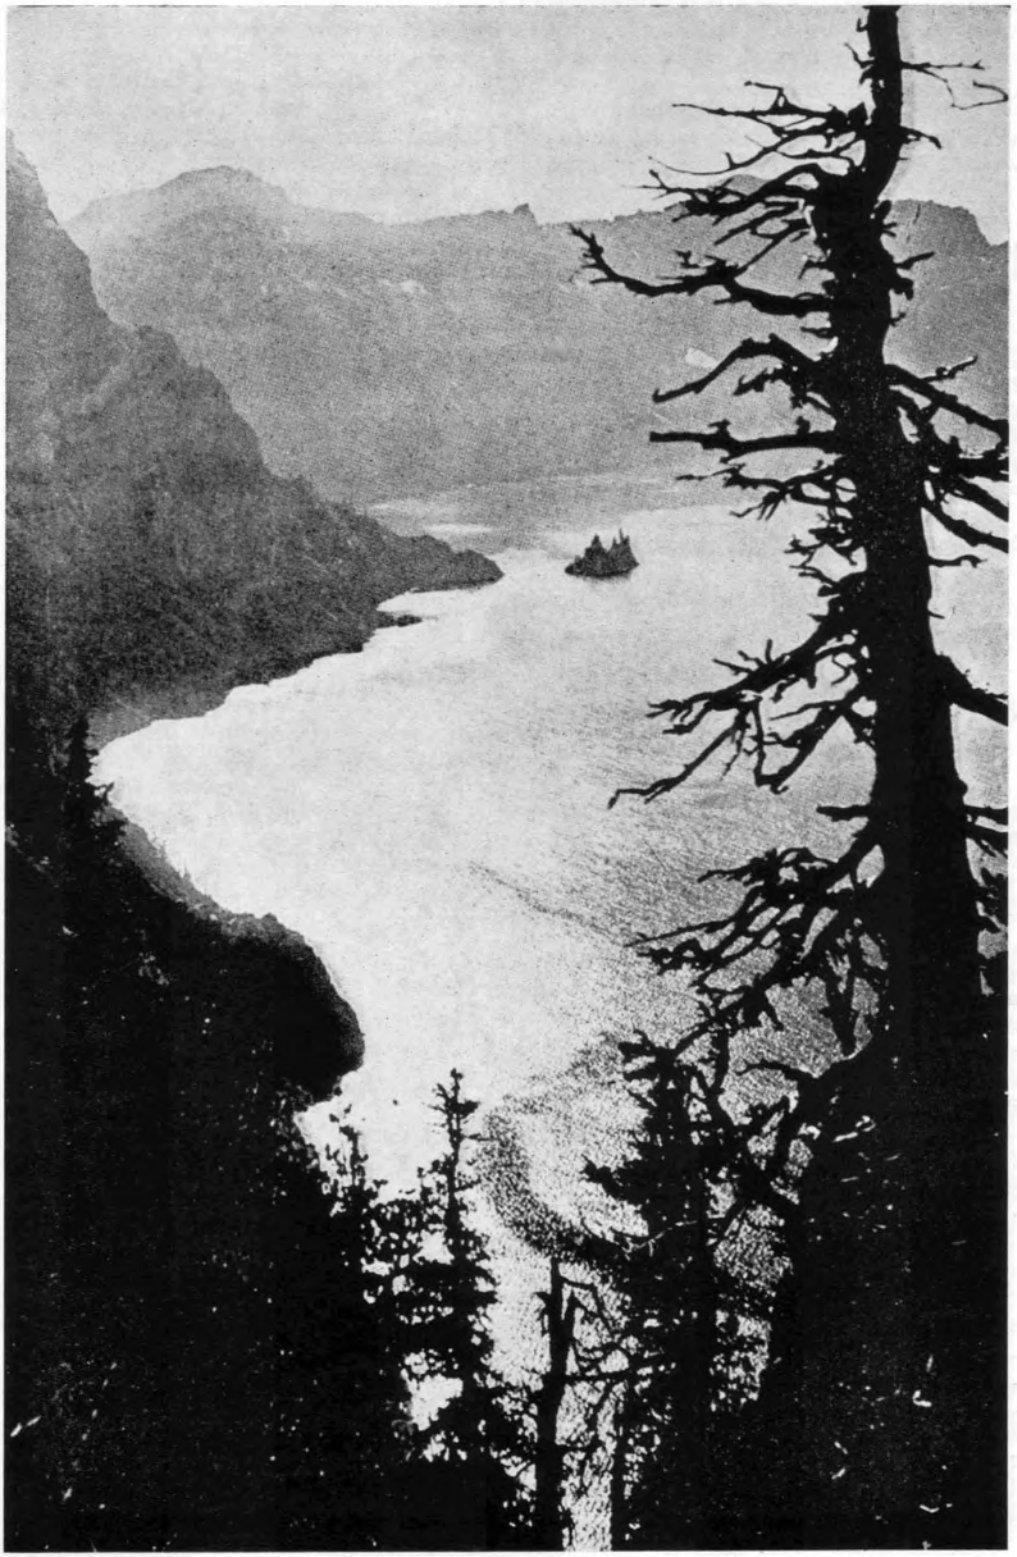
Alaska is one of the most active volcanic regions of the world. A belt of volcanoes extends for 1,500 miles through the Alaskan Peninsula to the west part of the Aleutian Islands. Katmai is one of this series of volcanoes. It is 6,970 feet high, located on treacherous Shelikof Strait, opposite Kodiak Island.

Very little attention was paid to Katmai until June, 1912, when it announced itself to the world with an explosion that was heard in Juneau, 750 miles away. Earthquakes followed this blast and then came a spell of smoke and dust causing sixty hours of darkness in Kodiak, a hundred miles away. Dust fell in Ketchikan, 900 miles away and fume was carried by the wind to Vancouver, fifteen hundred miles away. Hazy atmosphere was noted over the United States the succeeding weeks and even peculiar atmospheric effects were noticed in Europe the following summer.

The scene of this explosion was made a National Monument in 1918. One of the most interesting phases of development at Katmai was the formation of the valley of 10,000 smokes near by. This has been described at length in the National Geographic Society's publications.

This review of volcanic National Parks and Monuments is by no means conclusive. However, it does give an idea of the great variety of volcanic activity to be found within the United States and its territories, with unlimited possibilities for study and research, or entertainment for those who prefer a spicier type of geologic story, connected with their Parks. Volcanoes can be depended upon to put on a good show when they are so minded in spite of their temperamental natures. To people of Hawaii, visits to the other areas should be interesting.

Kilauea Lava Flow of 1823



A major structural feature of Kilauea is the fracture zone extending twenty miles SW of the Crater, in the general direction of Pahala. This rift disappears out into the sea. It is commonly spoken of as the Kilauea SW Rift and is the feature indicated by that term frequently used in the Volcano Letter.

Although most of the Kilauea eruptions have occurred in the summit crater within historic times, some major activity has taken place in the regions associated with the SW Rift. The numerous prominent cinder cones and flows of the Kau desert in this vicinity testify to abundant activity before historic recording began.

The first nineteenth century flow from Kilauea occurred in 1823. It issued from the "Great Crack" twelve miles SW of Kilauea Crater. A minor flow took place in the SW rift zone eight miles from the Crater in 1868. The identity of this flow has often been confused with the more extensive flow of 1823. The confusion, however, has been straightened out with reasonable certainty by Stone, Stearns, and Jaggar, who have covered the question in published articles. The third and last SW Rift flow was that of 1920, resulting in the formation of Maunaiki. All of these flows are correctly shown on the latest maps. In the last 110 years there have been only three known periods of activity in the SW Rift.

The morning of February 26, 1937, a party of National Park officials visited the area of the Keaiwa Flow (local name for 1823 flow). This group included Mr. John D. Coffman, Chief Forester of the National Park Service, and Mr. E. E. Tillett, Field Supervisor of the Emergency Conservation work for the Islands.

The 1823 flow was found to be of considerable interest and unusual in that it seemed to have issued from the Great Crack which probably opened up immediately preceding the eruption and, no doubt, was accompanied by rather strong earthquakes. By Ellis' dates the outflow was about February, 1823, and the most serious earthquake about May. The lava formed a comparatively thin skin over older flows, leaving many small kipukas or islands of the older material and thus indicating a very fluid condition. Lining the Great Crack, there are rounded lava balls similar in appearance to bombs but of a much different origin and in two localities there are indications of phreatic explosions. The lava balls are accretion-spheres formed of hardened liquid lava around fragments in the chasm, swept out by later gushes which embedded them. The absence of cinder or driblet cones would indicate that the lava issued from the earth in a somewhat different fashion from the usual Hawaiian flow which has both at its source. A very striking and prominent feature is the presence of many tree molds. These are of a wide variety as to form. Some are several feet in thickness and

Crater Lake National Park. Oregon.

as much as six feet in height. The forms of the trees responsible are well preserved and the relative position of trunk and branches is often indicated. None of the molds observed was apparently formed by trees with a trunk of more than three or four inches in diameter. The direction of flow is clearly indicated by the flow lines around the molds and a piling up of the lava on their north sides. The flow definitely moved south as it should across the contours, toward the sea.

The history and general description of the flow has been so thoroughly covered by several writers that no further discussion will be given here. Those wishing to know more of an unusual Kilauea Rift flow are referred to the following articles:

Hawaiian Volcano Observatory Report for August 1937

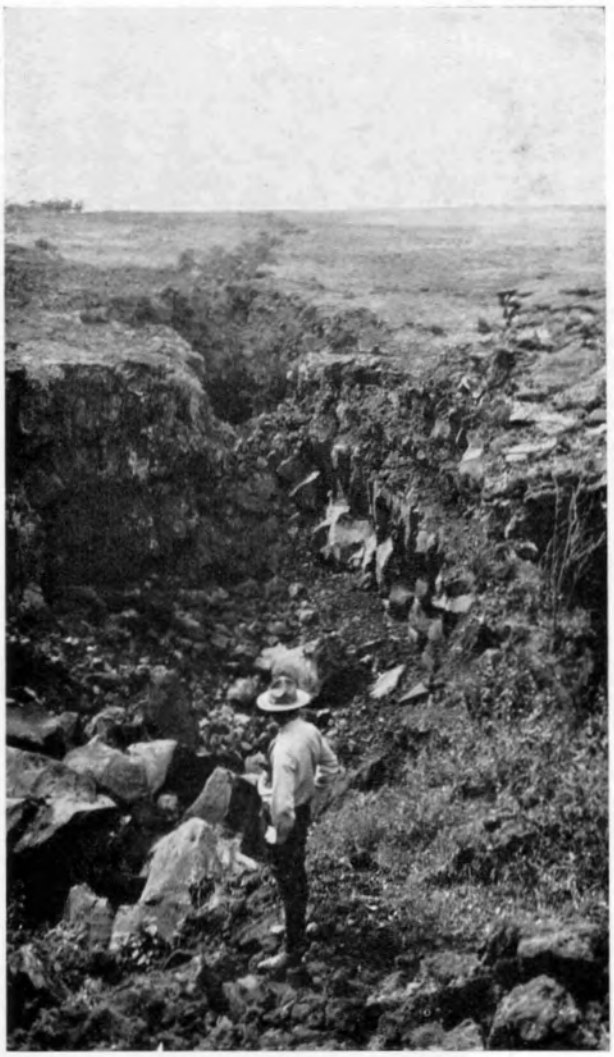
VOLCANOLOGY

The most important event at Kilauea Crater was a fall of the rim rock of Halemaumau pit at the east, at 8:41 am August 22, carrying away the measurement marks of Crack No. 25 and also No. 24; at Crack No. 25 excessive opening had been revealed by measurement for weeks. The crash of the avalanche produced earthquake disturbance marked on the seismographs. The disturbance of the rim occasioned by this avalanche caused many subsequent slides, enlarging the talus, and gradually adjusting the cliff. There was increase of tremors for the last fortnight of the month, but no good method has yet been developed to prove cause and effect in the relation between slides and tremors. It is of interest to note, however, that the succession of cliff adjustments following a big avalanche is not unlike the succession of aftershocks following an earthquake.

The following are the weekly Observatory totals for Halemaumau and the seismographs.

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Tremors and Quakes
August 8.....	9.50	1	25.0	26
" 15.....	10.75	1	40.5	34
" 22.....	11.75	22	95.5	35
" 29.....	17.50	3	15.0	47

There were felt shocks of Kilauea origin August 3, 7, 10, 23, and 27; and two others of Mauna Loa and Hualalai origin August 16 and 18, felt on the west side of the island. Of all the measured shocks 27 indicated Kilauea distances of origin and three were from Mauna Loa or beyond. Distant earthquakes August 10 and August 20 indicated origins about 5,500 miles away, the second reported of destructive intensity on Luzon in the Philippines.



Sequence of Events by Weeks

The first week produced low seismicity and nothing more at Halemaumau pit than the excessive opening of Crack No. 25 at the east, which was one of the steaming extensions of the caved-in cracks of the east notch that had collapsed destroying Crack No. 28 on May 7. This opening of Crack No. 25 had been noticed repeatedly since May.

The second week produced only one slide, but the rate of opening of Crack No. 25 almost doubled.

The third week produced the avalanching crisis with Crack No. 25 opening three times as much as the week before and the observed slides numbering 22. Seismicity, owing to the increased numbers of tremors, rose steadily during the month.

The fourth week produced only three observed slides, the taluses at the base of Halemaumau wall had been enlarged, aggregate crack opening dwindled, but seismicity continued to increase.

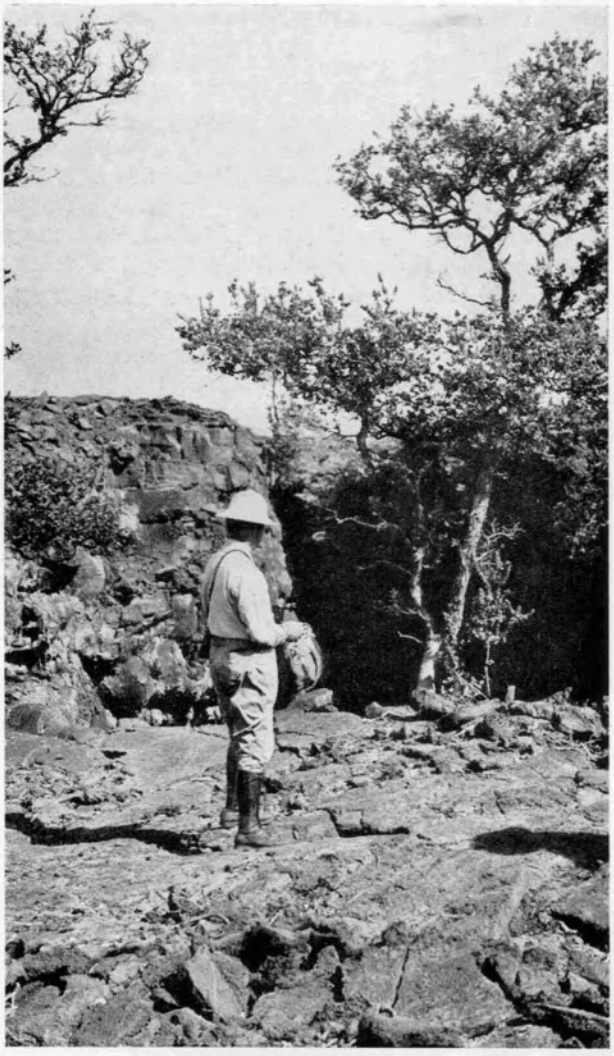
Looking south along the great crack from which issued 1823 flow as viewed at Puna Trail crossing. Waesche.

Slides at Halemaumau

The recorded slides from the wall of the pit were:

August 2, 2:20 a.m., a noise like sliding during excessive rain, possibly a cataract at Uwekahuna.

August 12, 1:00 p.m., dust from west side of pit.



August 17, 2:30 p.m., eastern slide.

August 20, 11:20 a.m., western slide.

August 21, 11:40 a.m., noisy east slide, leaving scar 30 feet down.

August 22, 8:40 a.m., very large slide east making very feeble earthquake on seismograms.

August 22, 9:45 a.m., large dust cloud east.
August 22, 9:57 a.m., dust floated westward.
August 22, 10:28 a.m., eastern slide.
August 22, 10:35 a.m., eastern slide.
August 22, 10:50 a.m., slides continued.
August 22, 11:00 a.m., more slides.
August 22, 11:05 a.m., more of east rim fell.
August 22, 11:19 a.m., slide west-northwest.
August 22, 11:20 a.m., very large eastern slide.
August 22, 11:30 a.m., more slides.
August 22, 11:33 a.m., " "
August 22, 11:45 a.m., " "
August 22, 11:50 a.m., " "
August 22, 11:55 a.m., " "

Looking north along the great crack from same locality. Waesche.

August 22, 12:10 p.m., " "
August 22, 12:19 p.m., " "
August 22, 12:20 p.m., rim rock fell and slides continued.
August 22, 3:00 p.m., rim rock fell in a large slide east; talus below now showed great enlargement.
August 24, 3:45 p.m., eastern slide.
August 25, 12:50 p.m., large dust cloud northwest rim.
August 26, 9:38 a.m., slight northwest slide.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations resulted August in aggregate movement as follows:

Week ending forenoon of:

August 6, 30 locations, 12 opened, 1 closed, opening 25.0 mm. Crack No. 25 east opened 18.0 mm.

August 13, 30 locations, 13 opened, 1 closed, opening 40.5 mm. Crack No. 25 opened 31 mm.

August 20, 30 locations, 7 opened, 6 closed, opening 95.5 mm. Total opening was 99 mm., six cracks exhibiting a closing of 3.5 mm. Crack No. 25 by weeks had exhibited the following:

July 30, 6.0 mm. opened.

August 6, 18.0 mm. opened.

August 13, 31.0 mm. opened.

August 20, 96.0 mm. opened.

August 22, the cracked block collapsed, showing that the rate of opening had made forecast of the rim breakage.

August 27, 27 locations, 17 opened, 00 closed, opening 15.0 mm.

Cracks 24 and 25 had been destroyed August 22 and No. 51 on northeast rim was mutilated by unknown causes.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Distant† Earthquakes	Weekly* Seismicity
Aug. 8.....	18	6	2	0	0	9.50
Aug. 15.....	27	6	1	0	1	10.75
Aug. 22.....	27	6	2	0	1	11.75
Aug. 29.....	36	9	0	2	0	17.50

*For local seismicity definition see Volcano Letter 371.
†Including teleseisms or those shocks over 5,000 km. distant.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the times indicated and whenever possible, a determination of depth of focus has been made.

August 2, 3:45 am, very feeble, 1.3 miles deep E rim of Kilauea Crater near junction of Byron and Waldron Ledges. 19° 25.3′ N; 155° 15.6′ W.

August 3, 1:39 am, very feeble, probably originated in NE portion of Kilauea Crater.

August 3, 8:52 am, feeble, probably originated in Chain of Craters near Hiiaka.

August 6, 10:41 pm, very feeble, 2.4 miles deep, S rim of Kilauea Iki. 19° 24.8′ N; 155° 14.8′ W.

August 7, 7:09 am, feeble, 5.7 miles deep, SE rim of Kilauea Crater. 19° 24.2′ N; 155° 16.2′ W.

August 8, 4:40 pm, very feeble, of Kilauea origin.

August 8, 5:06 pm, very feeble, of Kilauea origin.

August 9, 5:39 pm, very feeble, 0.9 mile deep in rifts 0.4 mile W of Keanakakoi Crater. 19° 24.2′ N; 155° 16.4′ W.

August 9, 8:57 pm, very feeble, 3.6 miles deep in area 1.5 miles W of Kilauea Crater. 19° 25.0′ N; 155° 18.9′ W.

August 10, 5:13 am, very feeble, 0.7 mile deep SE rim of Kilauea Crater near Keanakakoi. 19° 24.4′ N; 155° 16.2′ W.

August 10, 5:00 pm, feeble, 2.3 miles deep, E portion of Kilauea Crater near Kilauea Iki. 19° 25.2′ N; 155° 15.9′ W.

August 11, 4:57 am, very feeble, 5.0 miles deep, 3.8 miles SE of Observatory. 19° 23.7′ N; 155° 13.1′ W.

August 12, 11:56 am, very feeble, of Kilauea origin.

August 12, 2:21 pm, very feeble, thought to have originated in Kilauea Crater immediately NE of Halemaumau.

August 16, 4:39 am, feeble, 18 miles deep, SW slope of Mauna Loa, 13 miles from Summit Crater. 19° 16.0′ N; 155° 38.0′ W.

Tree mold in 1823 Lava Flow. Waesche.

August 18, 5:27 pm, feeble, probably of deep origin under Hualalai. Felt in Kona and dismantled seismograph at Kealakekua.

August 18, 9:31 pm, very feeble, of MaunaLoa origin.

August 19, 3:22 am, very feeble, 1.0 mile deep, N portion of Kilauea Crater near Kilauea Military Camp. 19° 25.8′ N; 155° 16.6′ W.

August 21, 10:49 pm, very feeble, 0.8 mile deep, Kilauea Crater near E rim of Halemaumau, 0.4 mile N of Pit seismograph. 19° 24.7′ N; 155° 16.9′ W.

August 22, 4:21 am, very feeble, 3.8 miles deep, 3.2 miles N of Uwekahuna. 19° 28.2′ N; 155° 17.3′ W.

August 22, 8:41 am, very feeble, caused by slide from E rim of Halemaumau.

August 22, 11:49 pm, very feeble, E portion of Kilauea Crater 0.5 mile deep. 19° 25.0′ N; 155 ° 15.9′ W.

August 23, 12:45 am, very feeble, of shallow depth, Kilauea Crater 0.7 mile SSW of the Observatory. 19° 25.3′ N; 155° 15.9′ W.

August 23, 3:02 am, slight, 0.5 mile deep E portion of Kilauea Crater. Dismantled Pit seismograph. 19° 25.0′ N; 155° 15.9′ W.

August 23, 2:20 pm, very feeble, 1.0 mile deep, W edge of Keanakakoi Crater (SE rim of Kilauea Crater). 19° 24.1′ N; 155° 16.1′ W.

August 23, 7:41 pm, very feeble, 4.3 miles deep, 0.7 mile NW of Uwekahuna. 19° 25.6′ N; 155° 18.0′ W.

August 25, 12:04 am, very feeble, 0.7 mile deep under SE rim of Halemaumau. 19° 24.4′ N; 155° 16.9′ W.

August 27, 12:12 am, slight, 1.5 miles deep SE rim of Kilauea Crater, 0.3 mile NE of Keanakakoi. Reported felt by few near Hawaii National Park Headquarters and at CCC Camp. 19° 24.4′ N; 155° 15.8′ W.

August 27, 12:15 am, very feeble, 0.9 mile deep, Kilauea Crater, 0.3 mile N of Keanakakoi. 19° 24.6′ N; 155° 16.0′ W.

August 29, 7:36 am, very feeble, thought to have originated near Pit seismograph and shallow depth.

The preliminary waves of a teleseism began to register at Kilauea at 2h 38m 1s, pm, H.S.T. August 10. Distance was 5,520 miles. The preliminary waves of another teleseism began registering at 1h 41m 29s, am, H.S.T. August 20. Distance from Kilauea was 5.465 miles and reported location was in the Philippine Islands, where it was of destructive intensity, especially on the Island of Luzon.

Microseismic activity of the ground at the Observatory was light August 5 to 9, 18, 21, 27 to 29, strong August 3, 4, 24, 25 and moderate the remainder of the month.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum of radial tilts toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending August 29 was 10.80″ S and 0.46″ E.

Week Ending	Observatory	Halemaumau West Station
August 8	1.12″ N 53° E	5.78″ S 82° W
August 15	1.17″ S 69° W	5.04″ N 40° W
August 22	0.31″ S 8° E	6.73″ S 73° W
August 29	0.58″ N 45° W	2.62″ S 44° W

Week Ending	Halemaumau Southeast Station	Pit Resultant
August 8	7.29″ N 63° W	0.67″ toward
August 15	0.23″ S 66° W	2.67″ from
August 22	5.18″ N 45° W	1.53″ from
August 29	7.78″ N 17° W	5.35″ toward

THE VOLCANO LETTER

No. 451 monthly Department of the Interior National Park Service September 1937

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

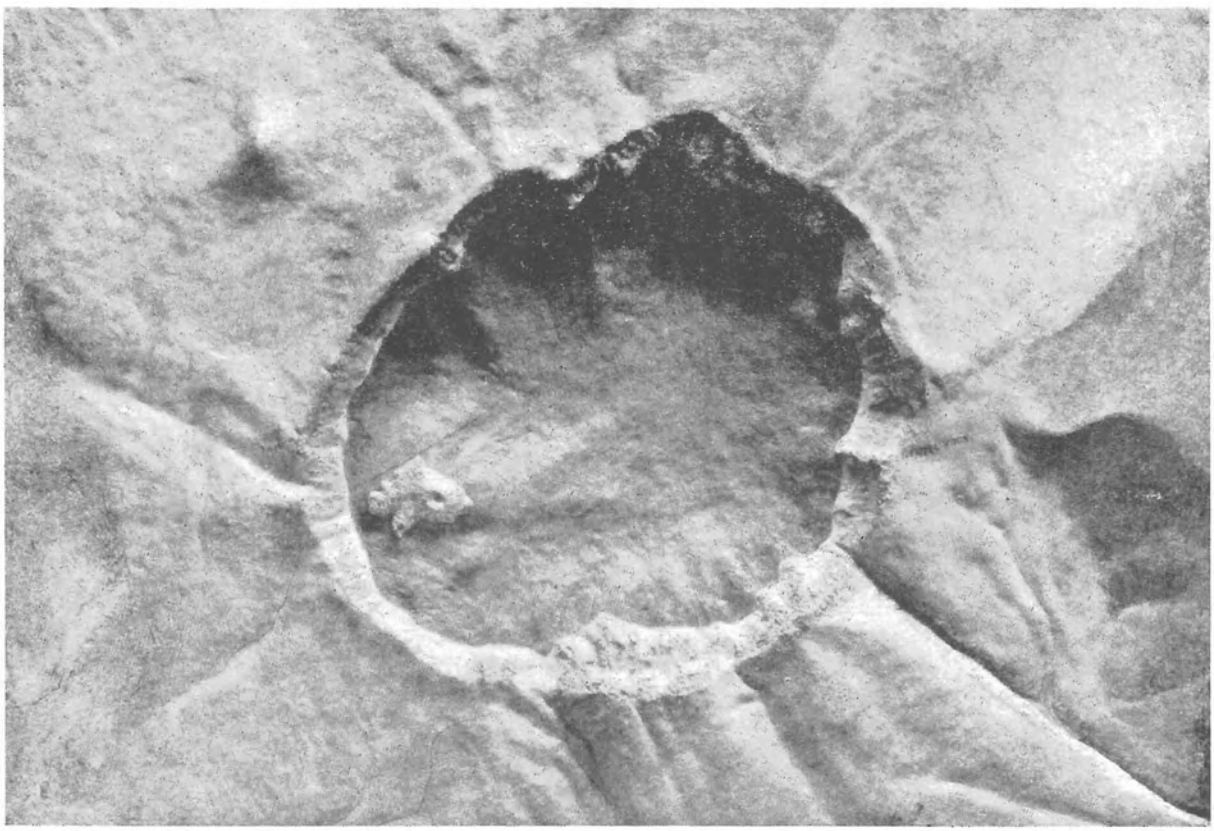

Fig. 1. Model of Crater Lake (after Diller).

CRATER LAKE NATIONAL PARK—

By H. H. Waesche

Certain areas in the United States and its territories have been set aside by the Federal Government as National Parks. Included in these are such well known places as Yellowstone, Grand Canyon and Yosemite Valley. National Parks are of importance because they contain within their boundaries some feature of both exceptional beauty and scientific interest which should be protected for the pleasure and benefit of the notion. Crater Lake National Park is one in this great system of recreational areas. It is probably not so well known as those mentioned but it is a region of unusual beauty and of great geologic interest.

The Park is located in south central Oregon, about seventy-five miles north of the California line. The central feature of the Park is Crater Lake which is a body of pure, sapphire blue water. The water is so blue that the officials often jokingly are accused by visitors of having put bluing in it. The Lake is relatively large, being from four to six miles across and two thousand feet deep. It is surrounded by cliff-like walls rising from five hundred to two thousand feet above the surface of the water. The walls are of many colors with reds, grays, purples, yellows and browns predominating. It is no wonder that such a spot is spoken of as the gem of our National Parks. Its moods are many, with color in unbelievable variations, ever changing with light alterations from sunrise to sunset. As a background and giving additional color there are many trees forming numerous patterns and designs of green. A gasp of admiration is

the first expression offered by most visitors, followed by a moment of silence as though they were trying to believe that such a place could be real. As is true of most scenes of nature that are so striking, Crater Lake cannot be described, so we sholl deal in this discussion with its history and geologic story.

Although pioneers entered what is naw the state of Oregon at o comparatively early date, it was around eighteen fifty before they began to filter into the southern port of the stote. The region was none tao accessible and the sparse population was in constant dread of Indian wars. Gold had been discovered in California and many people were moving westward. Many of these, disappointed in California, migrated to Oregan. It was not long before gold was discovered there too and exploration and prospecting in southern Oregon advanced accordingly. A band of California prospectars came to the mining town of Jacksonville to prepare for a trip into the mountains, keeping their purpose a secret. They were betrayed by one of their members ta a group of Oregon miners who learned that they were searching for a "Lost Cabin Mine," supposed ta be near the head of the Rogue River. The Oregon group immediately started after the California party which tried unsuccessfully to evade them. Both parties eventually ran aut of food and through the effarts of John Wesley Hillman, leader of the Oregon group, the parties combined in order to hunt for game. On June 12, eighteen fifty-three, Hillman went ahead of the hunting group, and rode up a deep canyon, which, judging from its size, he thought would lead to a higher slope. He let the mule pick its own way while he peered through the woads for game. Imagine his astonishment when the mule stopped on the rim of a deep blue lake lying many hundreds of feet below. Here he beheld a scene of unsurpassed beauty. Other members of the party soon joined the leader and they agreed to call the body of water "Deep Blue Lake."

Gold and Indian wars caused men soon to forget Crater Lake sa that in eighteen sixty-two anather group of miners "rediscovered" the lake only to learn afterwards of the Hillman party's previous visit. A third "discavery" was made in eighteen sixty-five by soldiers from Fort Klamath who called it Lake Majesty. The name was changed to Crater Lake in eighteen sixty-nine by some visitors from Jacksonville and it has been known by that name ever since.

In eighteen eighty-five William Gladstone Steel first visited Crater Lake. He had heard of this natural wonder as a school boy and had resolved to visit the locality. He came to Oregon in eighteen seventy-twa but it was nine years later before he could find anyone who had heard of the lake and several more years passed before he found anyone who had seen it. He was so impressed when he finally reached his destination that he immediately started agitation to make the area a National Park. Seventeen years later his efforts were rewarded. Congress established Crater Lake National Park in May, nineteen hundred and two. Judge Steel devoted the rest of his life to the development of the park and was for years Park Commissioner. He died in October of 1934.

The U. S. Geological Survey made a survey of the area in eighteen hundred eighty-six and at the same time sounded the Lake.

Paved roads are now to be found in the Park and it is visited by over one hundred and sixty thousand persons annually.

The story of the origin of Crater Lake is coupled with the geology of the Cascade range of mountains. These mountains are formed an the surface of volcanic rocks which have been poured out through a series of vents along a weak zone of the earth's crust. The vents are represented by a long line of volcanoes extending from Lassen Peak in northern California ta Mt. Baker in Washington. Others of this series are Mt. Shasta in California, Mt. Theilsan, the Three Sisters and Mt. Hood in Oregon, and Mt. Rainier in Washington. All af them are now extinct or dormant, although hot springs and steam vents are found on Mt. Shasta, Mt. Rainier and Mt. Hood. Within historic times only one of the entire group has been conspicuously octive. This one is Mt. Lassen in California which erupted in nineteen fourteen and again in nineteen twenty-three. Previously it had been inactive like the others but early explorers and Indians reported some eruptions. All of these volcanic peaks are comparatively high, ronging from ten thousand to nearly fifteen thousand feet abave sea level. All are snow-capped the year around and abound in glaciers. They are some of the most picturesque and rugged mountains of the United States.

Crater Lake now occupies a yawning pit which marks the site of an old volcanic peak of this group which probably rivaled in grandeur the towering Mt. Rainier or Mt. Shasta. It is supposed ta have been at least fourteen thousand feet high and may have reached the fifteen thausand foot mark. This former mountain has been given the name Mt. Mazama. Crater Lake is naw six thousand feet and the rim is between seven and eight thousand feet above sea level. How do we know a mountain formerly existed here? What has become of that ten thausand foot mass of rock that once extended to the summit? That is the mystery of Crater Lake! Scientists are still trying to solve this great geologic mystery drama. A number af possible solutians have been offered but none seems satisfactorily to fit the facts af the case. Apparently where now all is peaceful and quiet, formerly gigantic forces of nature waged a fierce, spectacular struggle with each other.

The walls of Crater Lake are built up of alternate layers of rock. Some of these are dense and athers are fragmental. This shows that Mt. Mazama was built by a series of explosions alternating with periods when molten lavas poured out of its vent and down its slopes. The explosions blew material high into the air which settled back around the old vent. The accumulation of explosive materials plus the outpourings of molten lava resulted in the building of the cone of Mt. Mazama. There must have been times when Mt. Mazama was quiet over periods of many years. This is shown by the irregular form of the rim and af materials deposited by running water and glaciers. At several points the Lake rim is indented by large U-shaped depressions which have the typical outlines of glacial valleys. These valleys have been cut off, as their cross sections show that they must have extended much farther up mountain slopes since destroyed. At other localities loose gravels and assorted materials show the effect of glacial deposition. In a few cases running water has cut "V" shaped valleys. One of the most interesting valleys of all is one which is filled by a great lava flow. Here one can see evidence of a regular succession of events which helps to prove the existence of Mt. Mazama, of glacial action, stream action and intermittent volcanic activity. First a "U"-shaped valley was formed in the alternate lava flows of Mt. Mazama, by a glacier, which represents a long period of snow accumulation and volcanic inactivity. Then the glacier receded and streams cut a "V"-shaped valley in the old glacial valley. This was followed by explosive activity which filled the floor of the valley with pumice, a light frothy volcanic rock. Soon after the explosion the valley was completely filled by a massive lava flow which even overflowed on the broader mountain slopes. Another explosion covered the lava flow with a layer of pumice similar to that over which it had flowed. At times forests grew on the slopes of Mt. Mazama as they do on Mt. Rainier today. The trees were even similar to those of the present. Charred logs, buried in volcanic ash, give mute evidence of the fate which overtook these trees. All of the rock layers do nat run parallel to the mountain slopes. In a number of places peculiar layers cut across the other more horizontal layers at right angles. These forms are known as dikes. They show that the column of molten material in the old vent was under pressure and that there were weak places in the wall af the cone. The

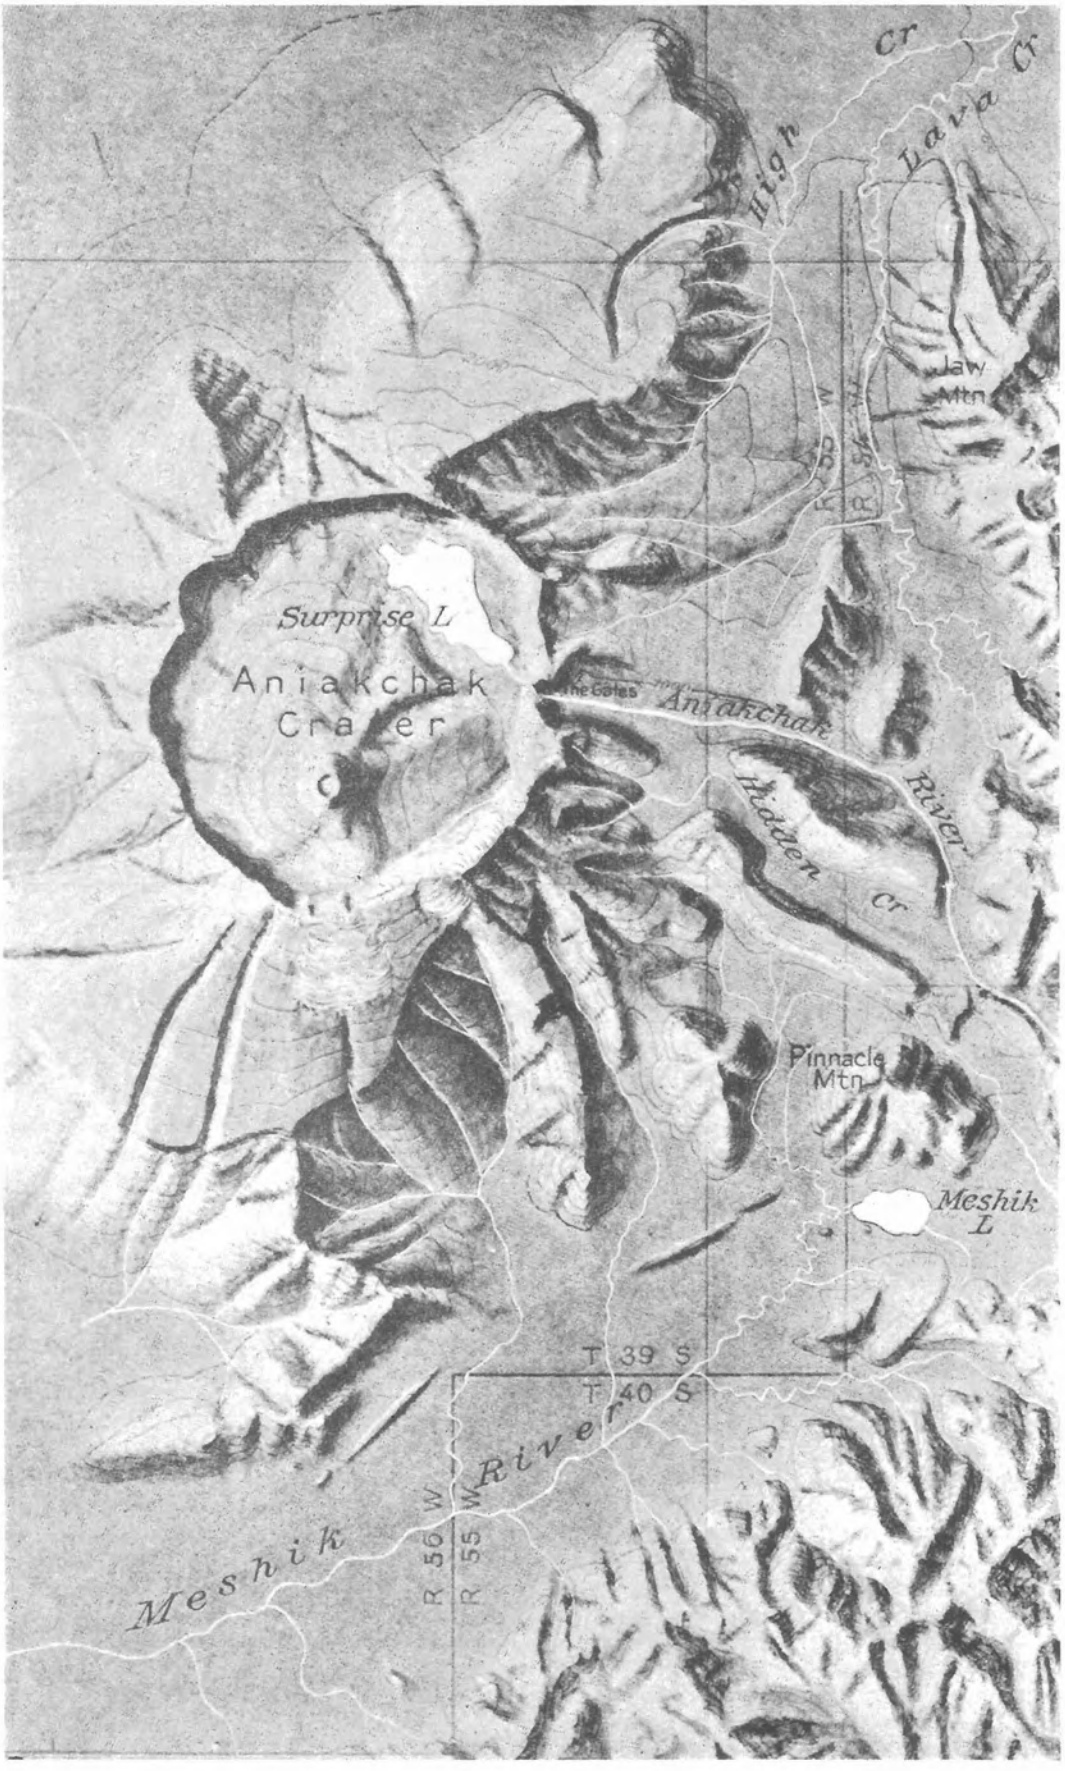

Fig. 2. Relief Map of Aniakchak Crater and Vicinity, Alaska Peninsula (after W. R. Smith).

pressure caused molten rock to flow into these weak zones, producing a number of radiating rib-like rocks which project from the flows because of their greater resistonce to weathering. Such forms, likewise, indicate a former volcano.

The building of Mt. Mazama is no mystery—it is the destruction of the mountain which leads to extensive speculation. There are three explanations which have been offered to account for this great catastrophe. The first and oldest one has been the most popular. According to this theory the lava in Mt. Mazama's vent gradually receded into the earth becouse of the eruptions of a neighboring volcano. This removed the support af the upper part of the cone which caved in ond was engulfed, leaving the large crater which the Lake now occupies. The second supposition was that gigantic explosions blew the mountain top off, and distributed it over the londscape for possibly hundreds of miles in every direction. The third possibility was a process similar to that going on today in Hawaiian volcanoes. There the molten lava rises and falls periodically in a large pit and in so doing causes sections of the rim of the pit to fracture and perhaps to fuse in the lava column.

The lack of lorge frogmentol materials in the vicinity of Crater Lake which should be present if explosion had occurred, caused the earlier thinkers to accept the subsidence theory. More detailed examination of the surrounding areas by later investigators shows that explosive materials several hundred feet in thickness extend for many miles in every direction. Furthermore, some of the lava loyers near the lake turn abruptly upward as though some force had bent them in that position; then, too, there is no known case of a whole volcano subsiding and it seems to be contrary to lows of eorth structure for seventeen cubic miles of rock to go back into the earth where pressures should be high. On the other hand, numerous mountains of the same type as Mt. Mozamo hove been known to destroy themselves by explosian. Examples of the latter are the great explosion of Katmai in Alaska in 1912 and Krakatoa in Java in 1883. The best explanation at present seems to be a modification of the first two ideas. That is, the croter wos probobly produced from old Mt. Mazama by one or more explosions followed by slumping of the walls which sank into the pit, leaving the original upturned edges caused by the explosion in several places. Be that as it may—Mt. Mazama did exist and was destroyed, leaving a crater around four thausand feet in depth and averaging obout five miles in diameter. And we still hove our mystery!

Following the great mountain destruction, volcanic activity started again and built severol small cones inside the crater. Two of these are now submerged below the lake but the third is over seven hundred feet in height and is quite a good sized volcano in its own right os it rises twenty-seven hundred feet above the crater floor. It possibly represents the last gasp of a dying volcano.

Meanwhile woter was beginning to accumulate in the croter. The precipitation at Croter Lake National Park averages about seventy inches per year. At that rate any depression would soon tend to fill up, praviding seepage and evaporatian were nat tao great. This is what has happened. Figures show that evaporation at Crater Lake amounts to about fifty-five inches per year and that leaves fifteen inches to account for seepage thraugh the lower slopes awoy from the Lake. There are no known major streams flowing into the Lake ond none flowing out on the surface. The water is not salty but is quite fresh. Since rain water is practically distilled water ond only slight solution of the rock walls takes place, this condition is easily exploined.

Geologically speaking, Crater Lake is a young feature on the earth's surface. The extensive glaciatian af the slope of Mt. Mozama indicates that it probobly existed during the glociol age so that its destructian must have come about since that time. The last glacial periad was between twenty-five and fifty thousand years ago. The age of the trees on Wizard Island, the largest of the cones in the crater, ranges up to eight hundred years. It is thought that Wizard Island was last active not more than two hundred years before the date of the aldest tree. That means thot it was probably active within the last thousand years. To look at this young volcano ane would think it had been active only yesterday, so fresh are its lavas and so little has it been affected by the erosive forces of the weather. The steepness of the crater walls and the rapid rate of erosion now going an show that the Crater is fairly new as the walls seem to be little changed by erosion.

The region around the Lake is heavily forested with hemlocks, pines ond firs. Where these grow within the rim they both aid and retard erosion. They split the rocks with their growing roots and hald the soil in place on steep slopes by these same roots. Trees play an important part in the geology of this region.

Crater Lake, as is true of all lakes, is at best a temporary earth feature. Erosion of the walls with a consequent filling of the lake, aided by stream valleys cutting back the outer slopes, will eventually cause this mysteriously beautiful lake to be destroyed. However, it will take generations to accomplish this end so that man will enjoy this superb spot for many years to come.

ORIGIN OF CRATER LAKE CUP—

Mr. Waesche's moderate statement of the controversy about the origin of Crater Lake cup should be supplemented by the following reading for anyone interested:

1. Crater Lake National Park. Natinal Pork Service pamphlet, Washington, 1936, page 9, "Destruction of the Mountain."
2. Mount Mazama: explosion versus callapse, by W. D. Smith and C. R. Sworzlow. Bull. Geol. Soc. Amer., Vol. 47, p. 1809. 1936.
3. The Glacial History of an extinct volcano, Crater Lake Nationol Park, W. W. Atwood Jr. Journ. Geol., Vol. XLIII, No. 2, February-Morch, 1935.
4. Gealogical History of Crater Lake, by J. S. Diller, Department of the Interior, 1912 (Gov't Printing Office, Washington, 10 cents).
5. Engulfment ot Krakatoa 1883. Review of Stehn, Volcano Letter No. 234, June 20, 1929.
6. Geology ond Geography of Niuafoou Volcano, mop and sections, Volcano Letter No. 318, January 29, 1931.
7. Volume relations of Explosive Eruption 1924 (Kilauea) Monthly Bulletin Haw'n Volc. Obs'y., Vol. XII, No. 12, December, 1924.
8. Gealogy and Mineral Resources af the Aniakchak District, Alaska, by R. S. Knoppen, Bulletin U. S. G. S. 797-F, 1929.

There is no reason for such an immoderate controversial position favoring only the explosive process as is taken by No. 2 above. Nature works gradually even at active volcanoes. The great steam blast eruptions of the world hove been accompanied by what Mercalli called "sprafandomenti", deepenings by callapse.

Atwood ond Stehn, Nos. 3 and 5, cited for support of explosion by No. 2, both endarsed engulfment. The Notional Park pamphlet No. 1 states a moderate position. Diller was moderate in all his writings, and a judicial observer (No. 4).

Niuafoou (No. 6) is cleorly an **engulfment plus steam-blast** kind of sink crater, the dome was quite like Kilauea, and the crater lake was formed millions of years ago (cited in No. 2 (p. 1828) os formed in 1886; when in fact a mere minor steam-blast accurred).

Kilauea steam-blast eruptions are no different from those of basaltic valconoes anywhere, and the combined engulfment and explasion of 1924 removed valumes one part by explosion and 250 parts by engulfment. (No. 7).

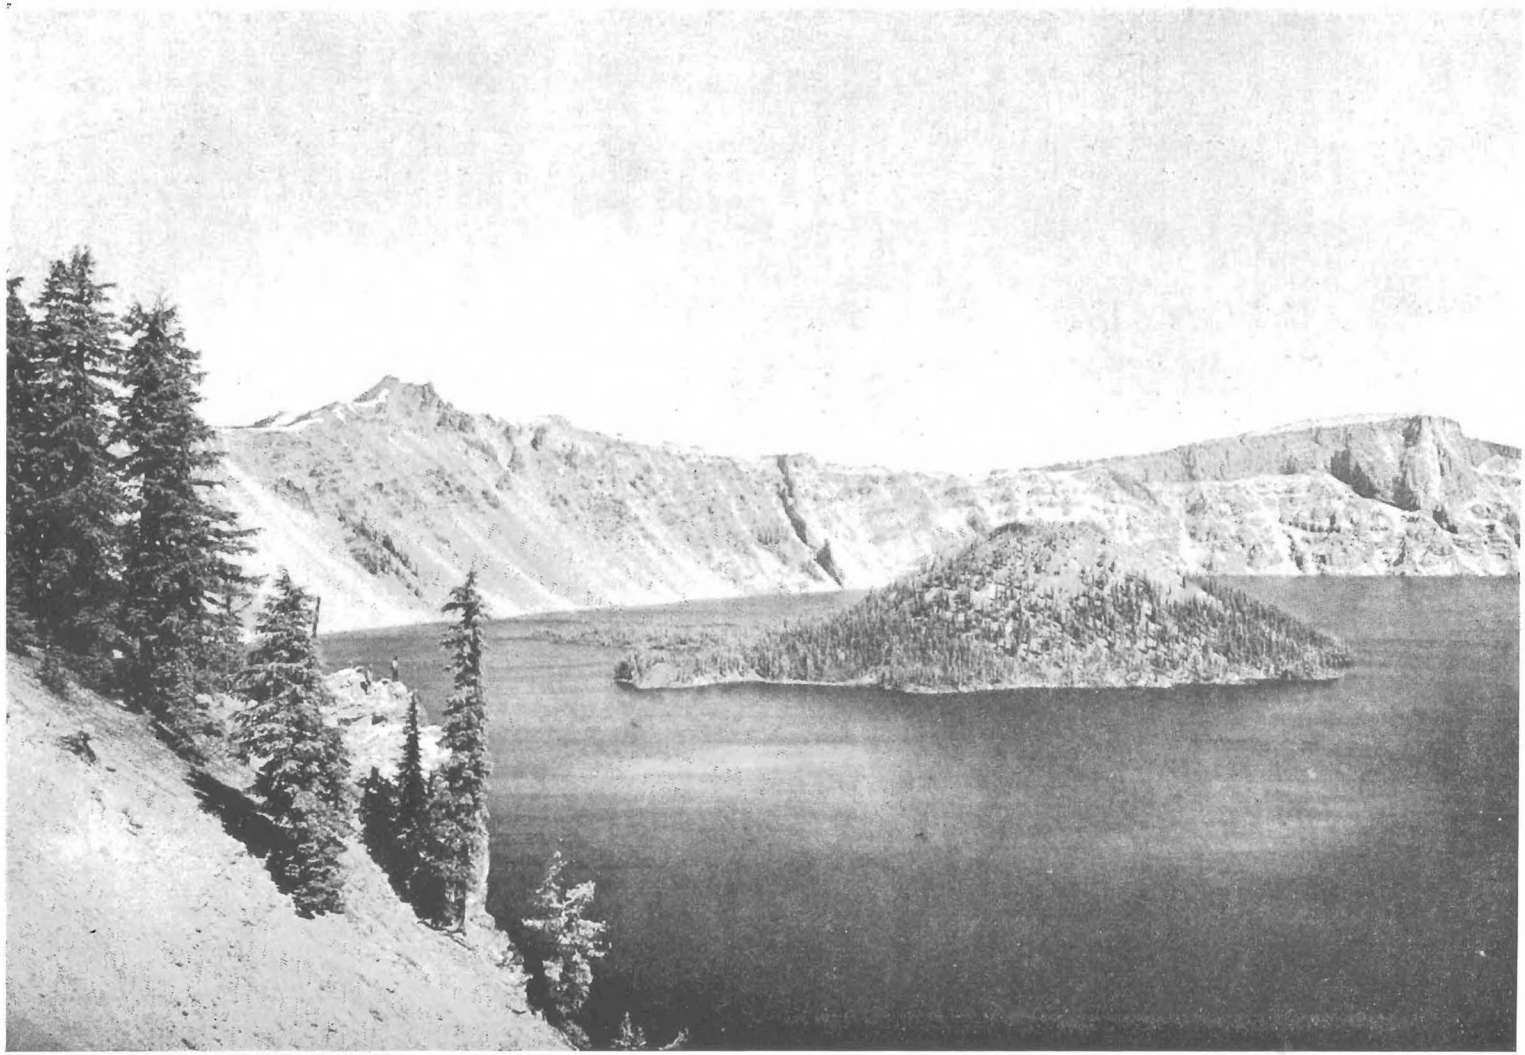

Fig. 3. Western Border of Crater Lake, from Victor Rock to Llao Rock (after Diller).

The basis for reconstruction of mountains over such saucer craters as Crater Lake, Niuafaou, Aniakchak, Batoer in Bali, or Aso in Kyushu, was stated admirably by Diller (No. 4, p. 24): "The glaciation and structure of the rim clearly establish the former existence of Mount Mazama but there may well be doubt as to its **exact form and size".**

Veniaminof Crater west of Aniakchok, (No. 8) but 5000 feet higher, is a triplicate of Aniakchak and Crater Lake, but full of ice spilling over in valley glaciers. It is the same height and size as Crater Lake, 6 miles across, and 8000 feet above sea-level; but it is a mountain, because it rises from sea-level.

Restore glaciation to the Cascade Range and you don't need a mighty peak of five cubic miles to scratch ledges, deposit till, and make U-shape valleys. The great Veniaminoff cup is itself at the **top** of a peak.

Finally, the geologist objection to voids underground is answered by underground intrusive bodies with straight-sided fracture boundaries that would fit together if the igneous matter (lava) were removed. If a void can form to let **up** the lava, it can form to let down the lava into crevices when whole mountain ranges are faulting and rifting.

At the Hawaiian volcanoes when lava lakes are rising and falling, this is happening all the time. The craters are on down-slipping fault rifts.

The tremendous event of the Vesuvian crisis, when a steam-blast eruption happens, is a "sprofondamento", a deepening. The amount of surface lava, dust and rocks is trivial compared to the croterol evacuation.

But the notion that such a volume as the contents of Monte Somma was left by the single evacuation of the Pompeiian eruption, is as fantastic as that Niuafoou crater was completely made in 1886.

The total volume of everything poured out and blown out of Vesuvius from 79 A. D. to the present would scarcely change the profile of the volcano. We know the history (Sapper). And we know that such eruptions as 1631 and 1906 engulfed the peak, which was subsequently restored from within.

A process of caving in and filling up again is normal extrusive volcanism and normal intrusive volcanism. The normal result is a gas loss to the atmosphere, a magma loss into crevices of the crust; and a compensating igneous bulk in the crust, for the substratum loss of igneous volume.

When the magma loss is a few cubic miles from a big cauldron, it means there has been a cycle of inflation; followed by a cycle of deflation, made up of hundreds of events such as submarine lava flows, or interstitial intrusive dikes along rifts tectonically opened.

The Hawaiian vents systematically robbed each other at progressively lower levels from 1855 to 1924. The 1924 vent was under the ocean where there is a slope to levels 18000 feet below sea-level in forty miles horizontally.

There was every opportunity for graben and cross-fault lava drainage in California and Oregon, from Miocene to Pleistocene time, for 20000 feet of depth, from the rim of Crater Lake to the broken shore blocks under the Pacific. And extrusive volcanism decayed from Miocene to the Present.—T.A.J.

Hawaiian Volcano Observatory Report for September 1937

VOLCANOLOGY

The month was notable at Kilauea Volcano for a decline of seismic phenomena and pit movements, except for a group of large distant earthquakes about the equinox, and at the same time a revival of many slides at Halemaumau in a new place, namely at the north.

The following are the weekly Observatory totals for Halemaumau and the seismographs.

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Tremors and Quakes
September 5.....	6.00	3	3.00	20
" 12.....	5.25	9	0.50	18
" 19.....	3.50	7	6.00	9
" 26.....	2.25	27	6.50	9
October 3.....	5.25	7	4.00	18

A shock was felt near Kilauea Crater September 15. Most of the very feeble shocks were of Kilauea origin, and most of the local disturbances were tremors. Distant earthquakes were registered September 3, 15, 19, 20, 23 and 29.

Sequence of Events by Weeks

The first week produced three slides in Halemaumau.

The second week produced nine slides and the smallest total opening of cracks since November 28, 1936.

The third week produced seven slides and declining seismicity.

The fourth week produced crumbling of the Halemaumau wall at the north and northwest taluses, twenty-seven slides being counted, while seismicity continued to decline.

The fifth week produced seven slides, mostly at the northeast wall, and increased numbers of tremors.

Slides at Halemaumau

The recorded slides from the wall of the pit were:

August 30, 9:25 a.m., making fresh scar 300 feet below northwest rim, and recording an Halemaumau seismograph.

August 31, 11:00 a. m., large slide NW, sending up dust.

September 3, 12:30 p.m., eastern slide extending the notch of August 22 southward.

September 6, 9:47 a.m., noise of falling rocks east.

September 6, 9:57 a.m., dust at the east.

September 6, 11:05 a.m., dust at the east.

September 6, 12:10 p.m., dust at the east.

September 6, 12:33 and 12.38 p.m., more dust.

September 7, forenoon, slides had carried away part of the east edge.

September 8, 12:39 p.m., slide from 50 feet below rim east.

September 8, 1:10 p.m., large slide north.

September 8, 2:18 p.m., dust east.

September 15, 2:33 p.m., rim rock fell east.

September 18, 8:53 a.m., slide east without noise.

September 18, 9:00 a.m., dust at the east.

September 18, 9:10 a.m., heavy dust cloud east.

September 18, 1:00 p.m., eastern dust.

September 19, 12:20 p.m., thick dust cloud north.

September 19, 2:55 p.m., noise of falling rocks east side.

September 20, 9:30 a.m., noise of northern slide.

September 20, 9:45 a.m., northern dust cloud.

September 20, 10:30 a.m., northern dust cloud.

September 20, 10:35 a.m., northern dust cloud.

September 20, 11:25 a.m., dust seen from Observatory, north.

September 20, 12:40 p.m., noise of falling rocks north.

September 20, 12:45 p.m., largest slide of this day, noise and dust north.

September 20, 12:55 p.m., 2:40 p.m., 3:25 p.m., northern slides making dust.

September 21, 9:20 a.m., northwest dust clouds.

September 21, 9:25 a.m., northern slide.

September 21, 9:30, 9:52, 10:00, 10:05, 10:13, 10:17, 10:20, 10:24, 10:49, 11:05 a.m., and 12:05 p.m., northwestern slides making dust.

September 25, 10:25 a.m., dust and noise from the west.

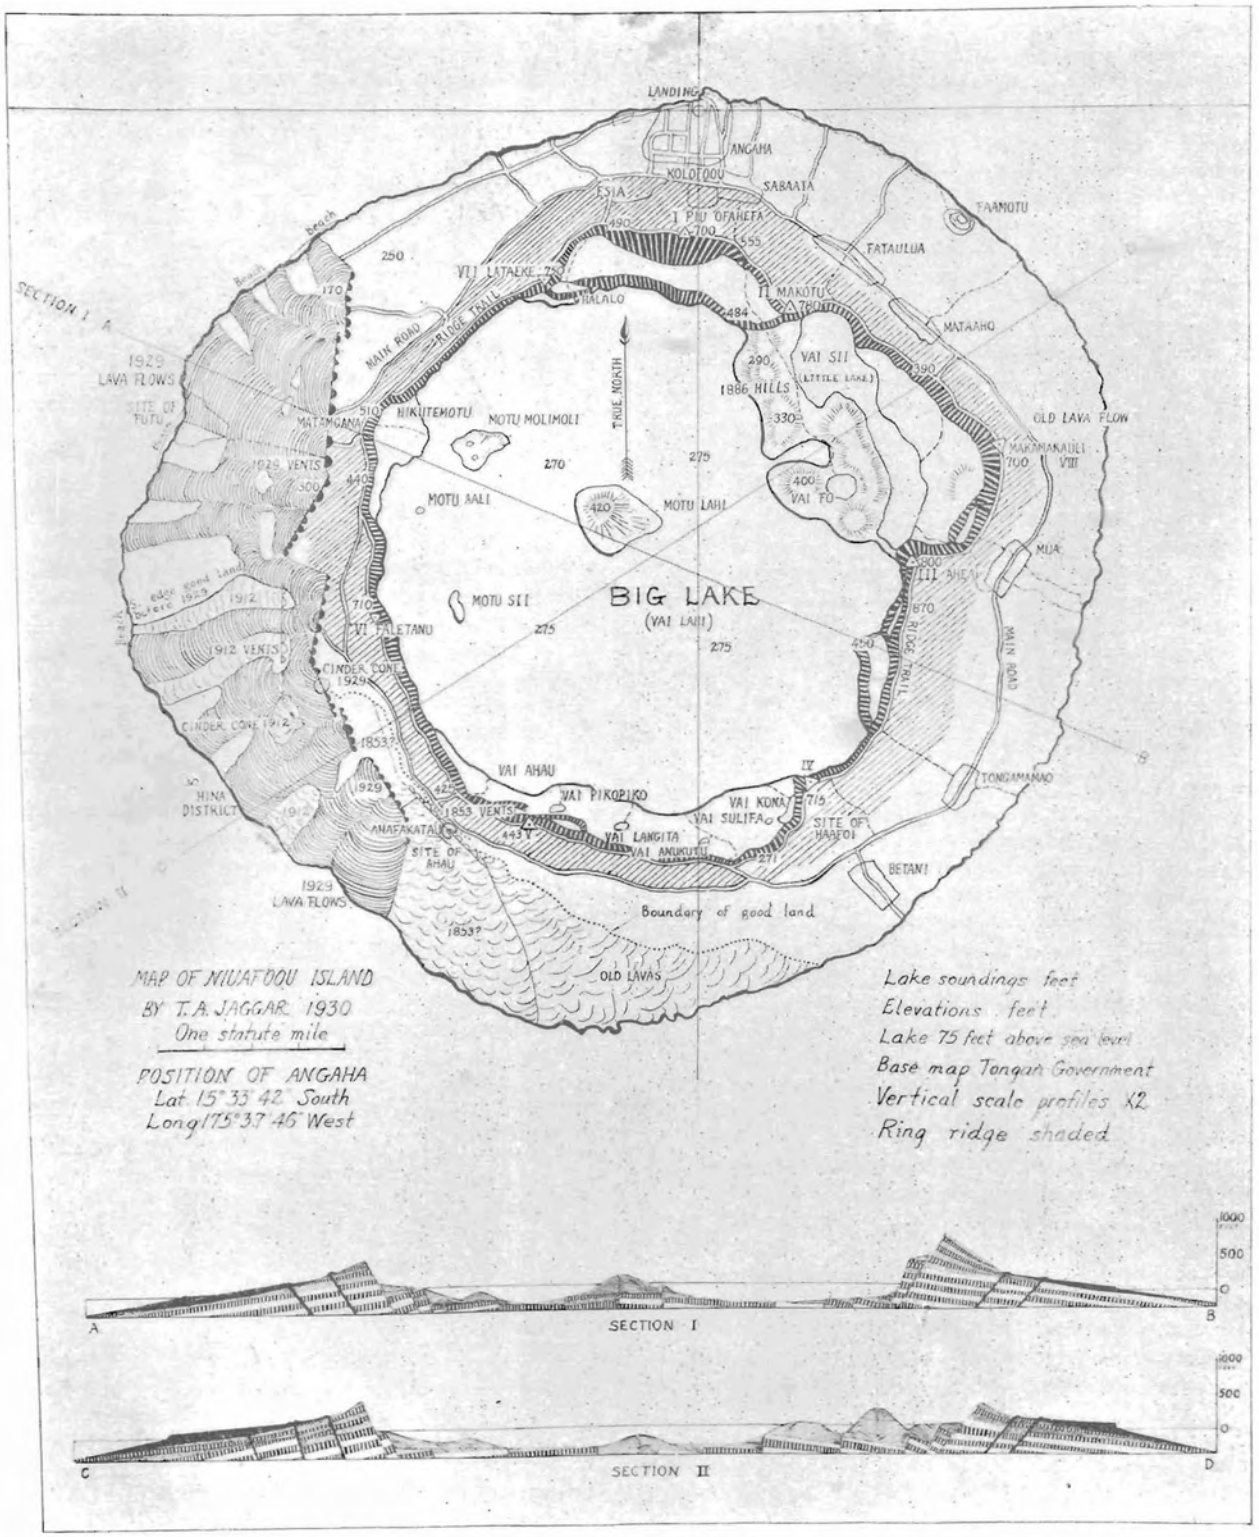

Fig. 4. Map of Niuafoou.

September 26, 10:02 a.m., 1:15 p.m., and 2:15 p.m., slides at the north side.

September 29, 10:25 a.m., slide at northwestern wall.

September 29, 1:10 p.m., sliding under both NE and N walls.

September 29, 1:15 p.m., 1:45 p.m., 1:50 p.m., and 3:25 p.m., slides from northeast wall.

October 1, 2:00 p.m., large slide at east wall.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations resulted during September in aggregate movement as follows:

Week ending forenoon of:

September 3, 27 locations, 4 opened, 1 closed, opening 3.0 mm.

September 10, 27 locations, 3 opened, 4 closed, opening 0.5 mm.

September 17, 27 locations, 8 opened, 1 closed, opening 6.0 mm.

September 24, 27 locations, 6 opened, 0 closed, opening 6.5 mm.

October 1, 27 locations, 7 opened, 1 closed, opening 4.0 mm.

Oct. 3.....	15	3	0	1	5.25

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus has been made.

August 31, 10:51 am, very feeble, 12 miles deep, Hilina Kapukapu Fault, 2.0 miles N of Keauhou Point. 19° 17.5′ N; 155° 14.1′ W.

September 1, 8:34 pm, very feeble, 1.4 miles deep and 0.6 miles NW of Uwekahuna. 19° 25.8′ N; 155° 17.7′ W.

September 1, 8:55 pm, very feeble, location same as preceding.

September 5, 6:44 pm, a tremor at the Observatory, very feeble in Kona. Probably originated under W slope of Hualalai near seacoast and about 10 miles N of Kealakekua.

September 9, very feeble 1.3 miles deep, NE portion of Kilauea Crater, 8:08 am, 0.8 mile SW of the Observatory. 19° 25.5′ N; 155° 16.2′ W.

September 12, 4:30 am, very feeble, 2.6 miles deep, N rim of Kilauea Crater, 0.6 mile W of Kilauea Military Camp. 19° 26.1′ N; 155° 17.1′ W.

September 12, 4:32 am, very feeble, 1.0 mile deep, 0.4 mile SE of Keanakakai, 19° 24.1′ N; 155° 15.7′ W.

September 13, 3:56 am, very feeble, probably originated in area 1.0 mile E of Kilauea Iki.

September 15, 8:04 pm, feeble, 0.8 mile deep, Kilauea Crater 0.5 mile W of Byron Ledge, 19° 24.6′ N; 155° 16.2′ W. Reported felt by many in "CCC" Camp and near Park Headquarters.

September 19, 6:07 am, very feeble, 3.0 miles deep, 1.6 miles N of N rim of Kilauea Crater. 19° 27.6′ N; 155° 16.6′ W.

September 19, a tremor at the Observatory, very feeble on Kona instrument. Probably originated in Mauna Loa SW rift near 1919 source cone.

September 21, 8:59 pm, tremor at H.V.O., very feeble in Hilo, dismantled Kona seismograph, 25.0 miles deep, NE rift of Mauna Loa 4.0 miles W of Puu Ulaula, 19° 31.6′ N; 155° 31.0′ W.

September 27, 7:01 am, very feeble, of Kilauea origin.

October 1, 9:34 am, very feeble, 2.8 miles deep and 0.8 mile SE of the Observatory and 0.5 mile N of Kilauea Iki. 19° 25.6′ N; 155° 15.0′ W.

October 1, 7:05 pm, very feeble, 1.2 miles deep E portion of Kilauea Crater near Byron Ledge, 19° 24.9′ N; 155° 15.7′ W.

Microseismic motion of the ground at the Observatory was light September 2-7, 20, 22, and 28-30; strong September 10, 12, and 25; and was moderate the remainder of the month. All dates inclusive.

Teleseisms registered as follows:

September 3, "P" waves at 8h 25m 17s am, distance from Kilauea 2415 miles.

September 15, "P" waves at 2h 06m 45s am, distance from Kilauea 3485. Reported location Solomon Islands. 9° S; 164° E.

September 15, undetermined portion at 9h 26m am.

September 19, "P" waves, 8h 54m 15s, pm, no determination of distance.

September 20, undetermined portion at 11h 21m 50s pm.

September 23, "P" waves at 2h 45m 47s am, distance from Kilauea 3390 miles. Reported location, Solomon Islands 6° S; 154° E.

September 29, undetermined portion, 1h 16 m 6s am. Reported felt and to have been located in Japan.

Hawaiian Standard Time used for above reports.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau the algebraic sum of radial tilts toward or away from the pit.

At the Observatory the total accumulated tilt for the year ending October 3 was 10.85" S and 0.12" E.

Week Ending	Observatory	Halemaumau West Station
September 5	0.20" S 50° W	7.75" S 83° W
September 12	0.33" N 4° E	1.55" S 59° E
September 19	0.75" N 57° E	4.32" N 74° W
September 26	0.63" N 38° E	1.49" S 60° W
October 3	0.88" S 85° E	2.68" S 87° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
September 5	8.46" N 45° W	0.51" Toward
September 12	1.20" N 60° W	2.32" Toward
September 19	2.11" N 86° W	2.72" From
September 26	4.70" N 2° E	2.39" Toward
October 3	1.75" S 73° W	2.05" From

Crater Angles

Crater angles measured September 5, showed closing of 2.65" across Halemaumau and opening of 0.58" as compared with similar measurements of June 29, 1937.

* For local seismicity definition see Volcano Letter 371.
† Including teleseisms or earthquakes over 5000 km from Kilauea.

THE VOLCANO LETTER

No. 452 monthly Department of the Interior National Park Service October 1937

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

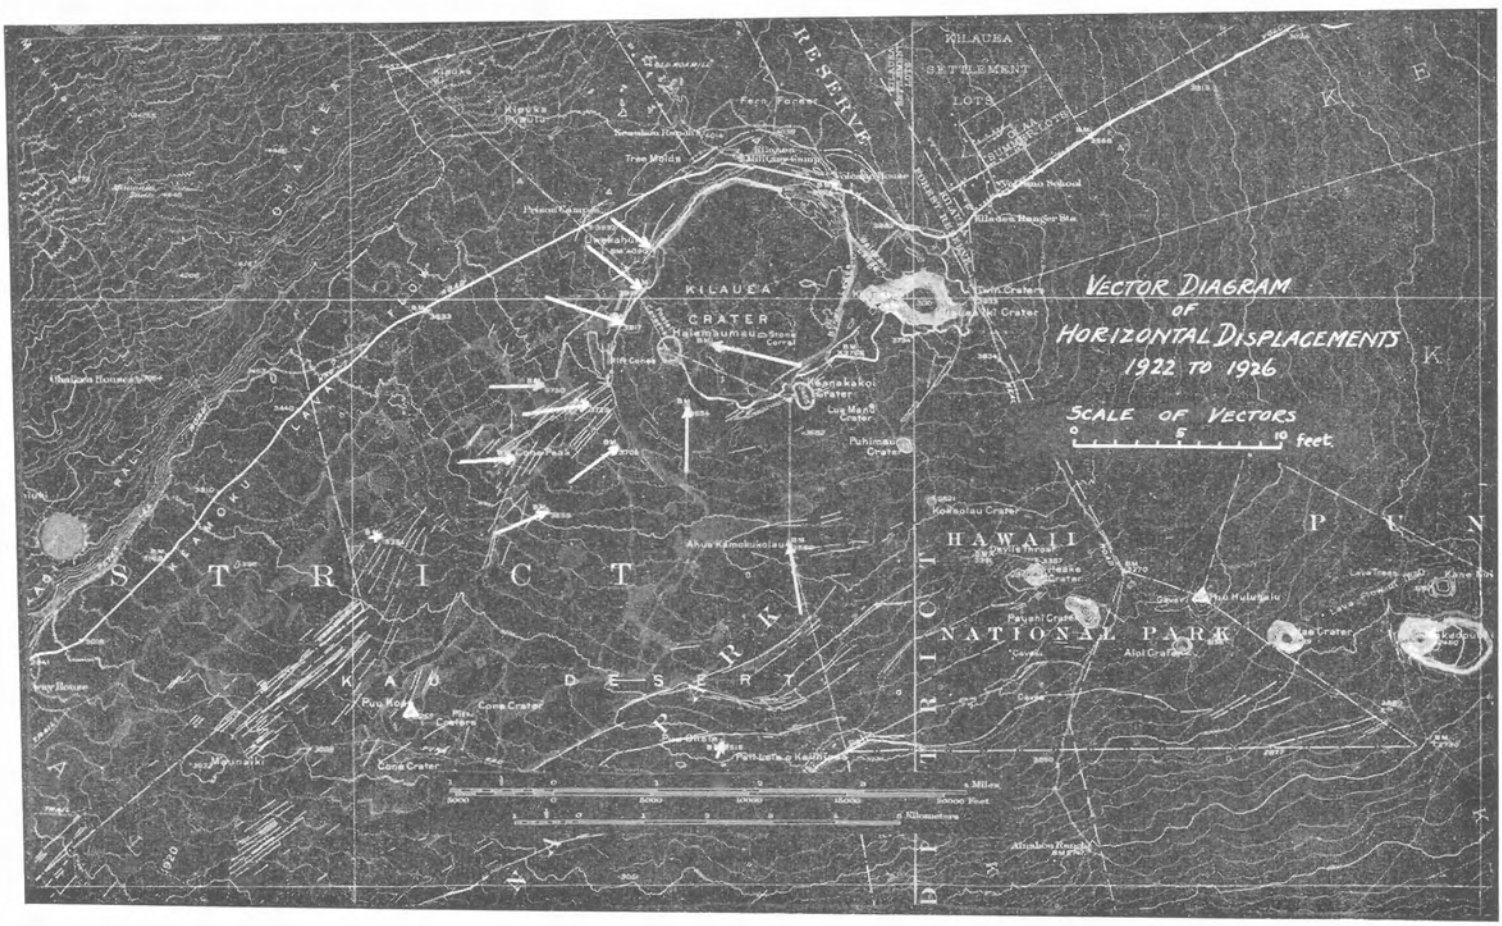

Figure 1. Map of Kilauea Crater; the tip of each white arrow on a monument; proved to move toward the center about 1924; by as many feet as the arrow is long by the scale.

TRIANGULATION AND LEVEL CHANGES AT KILAUEA—
Radio Talk June 22, 1937

By Hugh Waesche, Assistant Geologist, Hawaii National Park

On previous occasions (Volcano Letter February and April, 1937) I discussed earthquakes, crack measurements and tilting of the ground at Kilauea. Most of you probably are somewhat familiar with these phases of our work. Today I shall attempt to tell you about two other studies which have proved most interesting from the scientific standpoint but which are probably not so well known by the general public. (See also May and July 1936, Volcano Letter.)

Movements of the large volumes of lava below the earth's crust should create changes on the earth's surface. These movements in all probability would not be visible to the human eye, although in many cases they actually are. Two, well established, and reliable means of detecting such disturbances are by using instruments which would show by actual measurements, amounts of change of elevation and amount of horizontal dis-

placement in and around volcanic areas. For changes of a vertical nature the precise level and far horizontal displacements on engineer's transit are used, to establish measurements of a refined type just as is done by the U.S. Coast and Geodetic Survey and the U.S. Geological Survey in their land survey and location work. A great amount of triangulation and leveling has been done in volcanic regions in Japan, particularly at Asama, with very definite and positive results. Similar work has been done in California along earthquake-making faults, with a great deal of success.

Measurements of this nature have been a part of the working program at Kilauea since the establishment of the Observatory in 1912. In 1920 at the First Pan-Pacific Scientific Congress in Hawaii, there was published among its recommendations the following: "Great earthquakes and volcanic eruptions are often preceded and followed by elevations, depressions and horizontal displacements in the regions concerned; therefore this Conference **recommends** that precise leveling and triangulation be carried on at definite intervals in selected seismic and volcanic districts in order to ascertain precursory and other changes in underground stress accompanying great seismic and volcanic disturbances."

Horizontal ground displacements may be thought of as expanding or contracting areas of the earth's surface. Their measurement with a transit is called triangulation. At Kilauea there have been four epochs or periods of such surveys. The first was as a part of the original Hawaiian Government Survey of 1871, reaching Kilauea in 1897; the second was by R. M. Wilson of the U.S. Geological Survey in 1922; the third was by J. C. Beam in 1926 and the fourth by Wilson in 1926. Inasmuch as the second and fourth were run by the same engineer under as near identical circumstances as possible, they are considered of greatest value. These two epochs are also of special interest in that respectively they precede and follow the explosive activity of Kilauea in 1924. Kilauea crater and the outer slope of the volcano, as far south as Puu O Hale, were a part of the surveyed area.

In triangulation procedure various points in a given area are selected as the key or control locations. From these stations angles are turned off repeatedly to other stations in the system or net, and from the average angle values, azimuth determinations and intervening distance calculations and relative positions are determined. It of course is not so simple as this may have sounded, as there are many sources of error, such as refraction because of heat and moving air and poor visibility. Corrections are made for all of these.

Careful comparison of results showed quite definitely that the older surveys did not agree with the newer ones, nor did the survey of 1922 agree with that of 1926. Of the sixteen stations used probably the most familiar to you are, the monument in front of the Volcano House, the Little Beggar on Kilauea crater floor, Uwekahuna and the Spit. Another quite familiar location point is on the summit of Puu Hulu Hulu which may be seen on a trip down the Chain of Craters road. In a general sort of way it was found that there was little or no change between certain specifically selected points well outside of Kilauea crater such as the Observatory, Ohale, Koae, and Puu Hulu Hulu. On the other hand, relative to these fixed stations other locations showed considerable movement toward Halemaumau accompanying the collapse after the explosive eruption. A map was plotted using vectors to show this movement. More or less radial movement toward the pit from all directions was thus definitely shown. (Figure 1.)

Triangulation on a minor scale is still carried on from the Observatory. The same "Berger" transit used by Wilson in his earlier surveys is set up on the Observatory bench mark about every ten days, and the angles across Kilauea crater, from its southeast rim to Uwekahuna on the northwest rim, and across Halemaumau in the same direction, are determined. Each angle is measured six times in a forward or clockwise direction and then repeated in a reverse direction in the same manner. The results are then averaged and calculations made, and this in turn plotted for comparison on coardinate paper; so that a continuous relative picture of opening or closing of the crater, and of the pit, is available. Over longer periods changes are readily observed, but for short periods, due to errors which are unavoidable, changes are not so marked. The probable error calculated by Wilson was plus or minus two and one half seconds of arc, which is more than the usual variations which are now encountered from one reading to the next. Recent readings since the Mauna Loa eruption of 1935 seem to indicate, to date, a gradual closing of both crater and pit angles, as though the lava underneath Kilauea may have receded following that eruption. It would be safer, however, to say that no apparent change of appreciable magnitude has occurred within the past two years.

As was the case with the triangulation surveys, the level surveys may be divided into epochs. There were three of them. The first run was made in 1912 by the Birdseye party of the U.S. Geological Survey; the second by R. M. Wilson in 1921 and 1922, and the third in 1926 and 1927, also by R. M. Wilson. The instrument used is shown in Figure 2, sighting on a rod not shown. Just as with the triangulation, the last two of these runs were made before and after the explosive eruption in 1924. There were two classes of level determinations. One class consisted of lines run from tidal bench marks at sea level to the summits of Kilauea and Mauna Loa. The second class was of a local nature run only in the vicinity of Kilauea. The first two were what is known as "third order" leveling and the third run was "first order" leveling. In "first order" leveling invar metal rods are used and the level is shaded; in earlier runs wooden rods were used. Accuracy is of a very high degree in "first order" levels.

Probably the greatest problem encountered in running the levels from Hilo to the Volcano was changes of rod length. The wooden rods of the early surveys were found to vary from their original Bureau of Standards length. This variation was usually an increase in length with increase of moisture absorption. After very careful analyses Wilson applied corrections to take care of this. His conclusions are published in Research Publication number 10 of the University of Hawaii (Ground Surface movements at Kilauea Volcano) and are most interesting. The level results seem to check the triangulation and tilt values and, at the same time, seem to be more tangible in their demonstration of a factor in volcanic change, which had been suspected here and demonstrated elsewhere.

It would be hard for a visitor who has been to Kilauea frequently to realize how great the level changes were after that 1924 eruption. The Volcano House seems quite substantially located on the northeast rim of Kilauea crater, yet between 1921 and 1926, the Volcano House went down nearly four feet (3.56). Uwekahuna too looks firmly planted—a sort of Gibraltar, yet it sank nearly five feet (4.56) in the same period. As far south as Puu Hulu Hulu and Puu Koae the ground sank between three and four feet. In a general way and as would be expected, amounts of depression increased toward Halemaumau, reaching a maximum sinking of thirteen feet near the old spatter cone, "Little Beggar," about two-tenths of a mile east of Halemaumau. In fact, it seems pretty certain from tilt and levelling data, that between 1912 and 1921 the entire slope of Kilauea to sea level rose; and then sank between 1921 and 1927 in gradually increased amounts as the crater of Kilauea

was approached, and with a very rapid rate of change at Halemaumau. Hilo was thought possibly to have risen slightly, and then to have gone down about six-tenths of an inch after 1924.

Local levels in Kilauea crater were run regularly in 1934 and 1935 and until February 1936. This line started at the Spit bench mark, southeast rim of the crater and made a loop around Halemaumau. Occasionally the run was made just to the northwest bench mark on that rim of Halemaumau. This particular line is used in order to obtain relative displacements between the actual crater floor and its rim. Plotted results of this level line have proven very significont. Among other things it hos been discovered that a relative chonge in Kilauea crater of several millimeters within twenty-four hours is not unusual. Following the 1934 eruption of Kilauea the northwest rim of Holemaumau apporently settled about six inches with reference to the southeast crater rim. In August 1935 the lowering ceased, and the value remained unchanged until Mauna Loa erupted in November. Immediately the Kilauea crater floor began to settle again, and by February 1936 it had settled another two inches. Apparently settling has continued and as soon as possible new determinations will be made.

From this brief review it will be seen that surveys of this sort are very important and informative parts of the Hawaiian Volcano Observatory program. This work will be continued and the results noted with interest relative to future eruptions and thus more knowledge of our volcanoes will be accumulated, and activity predictions made more accurate.

Week Ending	Seismicity	Slides	Crack Openings, mm.	Local Tremors and Quakes
October 10.....	7.00	4	7.00 mm.	12
" 17.....	6.25	0	0.00 mm.	12
" 24.....	4.75	4	2.50 mm.	14
" 31.....	6.00	2	4.75 mm.	16

A feeble shock October 18 and a stronger one classed os "slight" October 25 were felt in National Pork and Hilo, and were Kilauea movements. Of nine measured shocks for the month seven were from Kilauea, one from Mauna Loa, and one from Mauna Kea.

Sequence of Events by Weeks

The first week produced four observed slides, the second week was very quiet, the third week with its four slides may have had them started by the earthquake of October 18. The fourth week showed only two slides that were observed, and an increase in number of spasmodic tremors.

Slides at Halemaumau

The recorded slides from the wall of the pit were:

October 4, 9:33 a.m., large slide NE.

October 4, 11:13 a.m., dust NE.

October 4, 11:18 a.m., dust from slide NW.

October 4, 1:39 p.m., another slide NW.

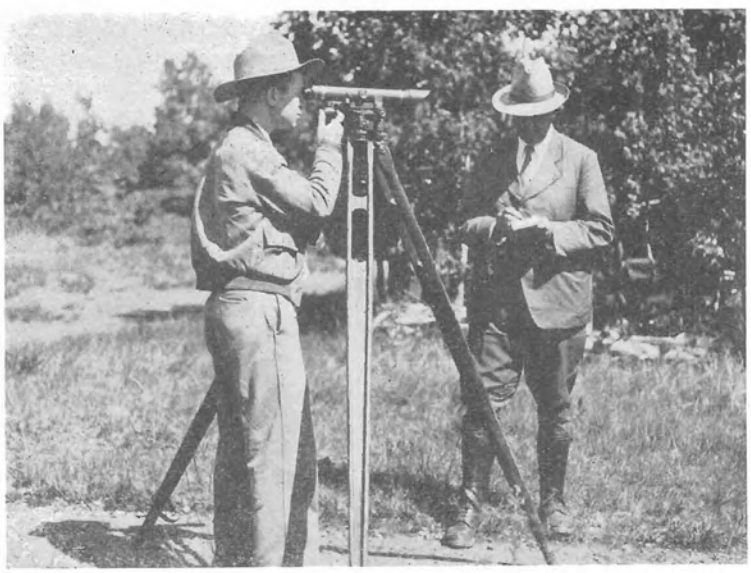

Figure 2. Precise level sighted on a rod marked in decimals of a foot, held upright by a rodman (not shown). Waesche sighting, Jaggar entering notes.

Hawaiian Volcano Observatory Report for October 1937

VOLCANOLOGY

The month at Kilauea Volcano showed little change in local tremors and movements about Halemaumau pit. As in September, there was a revival of slides from the walls toward the end of the month.

The following are the weekly Observatory totals for Halemaumau and the seismographs.

October 18, 11:15 a.m., dust observed over north rim.

October 18, 12:15 p.m., another slide at the same place.

October 19, 9:31 a.m., slide from NW wall heard at Uwekahuna Museum.

October 19, 10:08 a.m., slide at east rim observed from Tourists' Stand.

October 31, 11:20 a.m., dust rising at north wall.

October 31, 2:10 p.m., slide at the west wall.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations resulted during October in aggregate movement as follows:

Week ending forenoon of:

October 8, 28 locations, 11 opened, 3 closed, opening 7.0 mm.

October 15, 28 locations, 2 opened, 3 closed, opening 0.0 mm.

October 22, 28 locations, 6 opened, 2 closed, opening 2.5 mm.

October 29, 28 locations, 10 opened, 2 closed, opening 4.5 mm.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquake	Distant† Earthquakes	Weekly* Seismicity
Oct. 10.....	26	1	0	0	2	7.00
" 17.....	15	5	0	0	0	6.25
" 24.....	11	2	1	0	0	4.75
" 31.....	14	1	0	1	0	6.00

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible a determination of depth of focus has been made.

October 7, 1:49 am, very feeble, 15 miles deep under Mauna Kea. 19° 48.7′ N; 155° 30.4′ W.

October 14, 10:32 am, very feeble, 1.8 miles deep in Kilauea Crater 0.5 mile W of Byron Ledge, 19° 24.6′ N; 155° 16.2′ W.

October 15, 3:24 pm, very feeble, of shallow origin in cracks SW of Keanakakoi. 19° 24.1′ N; 155° 16.2′ W.

October 17, 12:58 am, very feeble, 0.5 mile deep in cracks near SE rim of Kilauea Crater 0.5 mile SE of Pit seismograph. 19° 24.1′ N; 155° 16.6′ W.

October 18, 12:44 am, feeble, 28.0 miles deep, SE slope of Mauna Loa 10 miles west of Kilauea Crater. 19° 26.3′ N; 155° 25.0′ W. Reported felt at Hawaii National Park Headquarters and in Hilo.

October 19, 5:56 am, very feeble, 1.1 mile deep in Kilauea Crater 0.4 mile E of Pit seismagraph. 19° 24.4′ N; 155° 16.7′ W.

October 22, 11:36 pm, very feeble, of shallow origin, SE rim of Kilauea Crater. 19° 24.0′ N; 155° 16.4′ W.

October 25, 5:43 am, slight, 9.0 miles deep in Hilina Fault system 8.0 miles S of the Volcano Observatory. 19° 19.8′ N; 155° 15.0′ W. Felt by many at Hawaii National Park Headquarters and in Hilo.

October 30, 11:44 am, very feeble, 4.1 miles deep and 0.4 mile W of Ahua Kamokukolau. 19° 22.9′ N; 155° 16.4′ W.

Microseismic motion of the ground at the Observatory was moderate October 4 and 5 and strong the remainder of the month.

A portion of a teleseism was recorded at Kilauea beginning at approximately 8h 11m pm, HST., October 4. Reported location was 3200 miles ESE of Hawaii; 22° N; 108° W. An unidentified portion of another teleseism began recording at approximately 7h 00m am, HST, October 6.

Periods of continuous tremor which registered on the Observatory seismograph were: 16 minutes beginning at 10:30 pm, October 6, and 9 minutes beginning at 1:43 pm October 16.

H.H.W.

* For local seismicity definition see Volcano Letter 371.
† Including teleseisms or earthquakes over 5000 km from Kilauea.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau the algebraic sum of radial tilts toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending October 31, was 9.83″ S and 0.38″ W.

Week Ending	Observatory	Halemaumau West Station
October 10	1.25″ N 9° E	1.55″ West
October 17	1.41″ S 35° W	3.37″ N 78° W
October 24	0.58″ S 11° E	1.43″ N 29° E
October 31	1.62″ N 40″ E	4.17″ S 53° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
October 10	3.47″ N 54° W	1.75″ Toward
October 17	3.99″ N 43° W	0.92″ Toward
October 24	3.18″ S 70° E	2.01″ From
October 31	8.29″ N 29° W	4.68″ Toward

H.H.W.

Crater Angles

Measurement of Horizontal Angles across Kilauea Crater from the Observatory October 16, showed slight opening of the Halemaumau value, and closing of the Kilauea Crater value, compared with similar measurements September 15. From Kilauea Crater SE rim to Uwekahuna there was closing 1.16″, September 15 to October 6 and closing 2.68″, October 6 to October 16. Total closing 3.84″. From the SE Pit B. M. to NW Pit B. M. there was opening 1.57″, September 15 to October 6 and closing 1.48″, October 6 to 16. Total opening 0.09″.

Levelling at Kilauea

October 12 and 13, a series of levels was run from the Spit B.M. on the SE rim of Kilauea Crater, to the NW Pit B. M. on the NW rim of Halemaumau. A Stanley level was used, and the results obtained were the first check on this determination since February 10, 1936 when a U. S. Geological Survey model precise level was used. Between September 3, 1936 and January 26, 1937, five sets of levels over the same line were run, using a new U. S. Coast and Geodetic Survey type precise level. These in no case gave satisfactory checks on closure of the circuit. The run made with the Stanley level giving a satisfactory check, October 12, 1937 showed that results obtained with the Geodetic Survey level were of value in spite of inaccuracies, in that they were of qualitative value indicating continuous relative lowering of the floor of Kilauea Crater with reference to the SE rim since October 1934 at the close of the Halemaumau inflow at that time. Level determinations of October 12, 1937 showed that the NE rim of Halemaumau (floor of Kilauea) had relatively lowered 19.7 centimeters since February 10, 1936 (closing stages of Mauna Loa Eruption) and 37.8 centimeters since October 17, 1934, with reference to Spit B. M. SE rim of Kilauea. Between August 13, 1935 and November 26, 1935, relative change of elevation between the same stations was 4.0 millimeters, or essentially no change in the period leading up to the Mauna Loa eruption. The termination of the Mauna Loa eruption marked the beginning of another period of relative lowering of Kilauea Crater floor which has continued up to the present time. The period of unchecked levels run between September 3, 1936 and January 26, 1937 in general confirmed this apparent downward movement. It must be remembered that Spit B. M. on SE rim of the greater crater might have been relatively elevated, hence the word "apparent".

THE VOLCANO LETTER

No. 453 monthly Department of the Interior National Park Service November 1937

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

KILAUEA VOLCANO LABORATORY
OF THE UNIVERSITY OF HAWAII 1937—

By T. A. Jaggar

Research at the Kilauea Volcano Loboratory with workers from the University began on July 13 with the arrival of Dr. Stanley S. Ballord, accomponied by Mr. Paul Gow, chemist of the Hawaiian Sugar Planters' Association. They made preliminary chemical tests for three days, setting in operation oxy-flomo blow-pipe opporotus for melting glass. This ond numerous items of equipment ond supplies for making vocuum tubes, and collecting volcanic gases were put in working condition.

Spectrograms made with the large quortz spectrograph of the H.S.P.A. in Honolulu shaw domination of carbon monaxide. An onalysis carried out at the University by Assistant Professor J. H. Poyne shows carbon dioxide, sulphur dioxide, nitrogen and oxygen, but no corbon monaxide nor hydrogen. The results shaw chemical reactions in progress even at the relatively low temperoture of Sulphur Bonk. The analysis residue is used for spectroscopic work. On August 17 Dr. Bollord and Dr. Eller set up new apparatus, and during the ensuing fortnight Dr. Bollord collected samples af speciolly dried gas with filter tubes for removing excess of corbon ond sulphur.

Dr. Ballard reports as follows:

I left Honolulu baund for Hila via Inter-Island steamer on Friday, August 13, arriving there the following day. We left the Big Island to return to Honolulu on Sunday, August 29. The two weeks spent at the volcano observatory were most worth while from the research point of view. The major accomplishment was the collection of four tubes of solfataric gas from the Sulphur Banks wells. One of these tubes was filled, using a method similar to that used for some of the collections of last year, in order to determine whether any major changes in the constitution af the gas had occurred since then. The other three were collected thraugh an ice pack in order to condense out the large steam content and through two traps containing concentrated patassium hydroxide. The gases were passed thraugh the potassium hydroxide solution in order to absorb the large content of carban dioxide and sulphur dioxide which had been detected spectrographically and chemically in the 1936 collections. Spectrographic examinations had shown that so much carban monoxide, carban diaxide, or arganic matter was present that other constituents could not be detected by this method. The chemical analyses canducted by Dr. J. H. Payne, Assistant Professar of Chemistry, had revealed a large sulphur diaxide content, sa large in fact that the determination of nitrogen, axygen, and combustible gases wos difficult and uncertain.

Figure 1 shows 250 cc. tube connected with 70-foot well drilled at Sulphur Bank, Kilauea. This is set up for sucking the well gas through an ice pack. The inner box is packed with ice and covered. A hand suction pump is used.

Figure 2 shows the gas being drown through two bulbs packed with ice and salt and a Milligan gas tower absorption bulb contoining a 50% solution of caustic potash. A three-way stop-cock below is used to flush the line before collection. The bulbs are for the purpose of obsorbing steam, carbon dioxide ond sulphur dioxide.

Instructor Iwao Miyake did the following important work in checking aver the Observatory shop tools and the seismographs of Halemaumou, Hilo, Uwekahuna and Kana:

1. Mode a list of necessory shop supplies.
2. Turned out flonge and mounted the new chuck for the Observatary shop lathe.
3. Overhouled the Uwekahuna seismograph. The vertical component wos nat working.
4. Overhauled the Pit seismograph and adjusted the clock contacts.
5. Built seismograph constant measuring device.
6. Overhauled the Kana seismograph and took complete data necessary far constant determinotion:
   a. Established known points an seismograph boom for future canstant checking measurements.
   b. Worked out a routine for constant checking measurement and taught same to Mr. Yasunaka.
7. Overhauled Uwekahuna seismograph drive clock.
8. Installed and adjusted new electric contact points an Uwekahuna time marking clock.
9. Overhauled the Hilo seismograph and took complete data necessary for constant determination:
   a. Established known points an seismograph baam for future constant checking.
   b. Rebuilt timing clock and put in new electric contact points far time marking.

Mr. Miyake arrived July 14 and Dr. Eller July 31. Special studies were made of all the seismological instruments an the island of Hawaii, and the constants of the instruments were determined.

Mr. Miyake finished his shap work and seismographic tests August 4. Professor Eller continued wark here until August 18.

Dr. Eller reports as follows an his new tilt-meter:

"As my main interest in the work at the H. V. O. is the study af tilt measurement, most af my time there was spent in that connection. Several trips ta the pit and to the country around Kilauea served to make the general lay of the land

familiar to me. This wos followed by a study of maps of the region, for the purpose of planning possible points for future placing of tiltmeters for an extended program of tilt measurement.

"Also o recording tiltmeter, constructed in Honolulu, wos adjusted and put in proper working order, and installed in the seismograph room at the Hawaiian Volcano Observatory. This is of a design which I hope will be found useful for future work. This meter is still in operation and I am receiving records from it eoch week. So far these records show little change from the original setting, due to slight activity in the Kilauea region during the past few months.

"A considerable study was mode of the tilt records available at the Observatory, and notes taken from them for future study."

Dr. Jaggar was greatly assisted by the physicists in his work of designing and building a set of ten earthquake recorders to

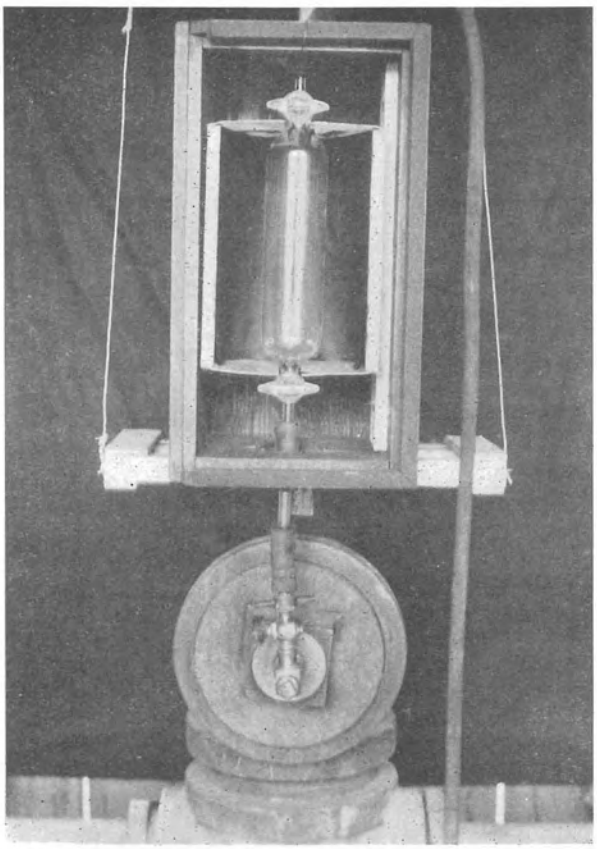

Figure 1. A tube for gas collection over Sulphur Bank well by suction and packing in ice.

be located at the telephone exchanges of the island. Several of these instruments have been tested out, at the Kilouea laboratories with a view to progressive improvement of detail.

The investigations of the summer of 1937 on volcanologic physics, by Professors Jaggar, Eller ond Ballord, Instructor Miyake, and geophysical assistant Sato, aided by the mechanical staff of the Hawaiian Volcano Research Association, namely H. Yasunaka and A. Okuda, have started new work that will be carried out both here and in the University laboratories throughout the coming year. Aided by the Department of Chemistry and by the large spectroscope of the Sugar Planters' Association, a new effort is under way to understand the gas action and rock crystallization that constitute volcanic activity, and eventually makes the soil, air, and water of Hawaii.

The following address was delivered at Radio Station KHBC, Hilo, August 17, 1937, by Professor Eller:

"TILTING OF THE GROUND"

Two yeors ago plans began to develop at the University of Hawaii for cooperation in the work of the Hawaiian Volcano Observatory. So far active participation has been restricted to a few weeks during the summer when members of the teaching stoff were free to work at Kilauea.

The Deportment of Physics of the University has entered into this program from several angles, as there are many problems connected with the work of the Hawaiian Volcano Observotory that are more physical than purely geological. In the main these are: the study of the gases from the volcano, and the volcanic rock, which are being examined spectroscopically to determine their constituents, both as to the elements present and their quantity; and the study of movement of the earth, both temporary and permanent.

Earth movements and displacements af seismic origin are of interest because of their possibilities in forecasting earthquakes ar eruptions. The earth movements at Kilauea are observed primarily for the purpose of studying volcanic activity which might result in eruption. They are in the nature of quakes of varying degrees of magnitude, and tilting af the earth's surface. Observations and measurements of these movements were begun early in the history of the Hawaiian Volcano Observatory.

The earthquakes are recorded by several seismographs, three of which are at Kilauea, one in Kona and one at Hilo. From the records of these instruments it is possible to determine the magnitude, character and location of quakes originating in various parts of the island of Hawaii, say in Halemaumau, or Mauna Loa, both af which are sources of many of the disturbances noted. These quakes result from movement of the underlying lava, and by their nature assist in the forecasting of eruptions.

Tilting of the ground, sometimes sudden, but more often gradual, accompanies the movement of the underlying lava. A tilt is a change in the angular relation between a portion of the earth's surface and the horizontal. Tilting is usually very slight, and is measured in seconds of arc. A tilt of one second, which is fairly large as tilts go, represents the angle through which a line about three and one-half miles long is rotated about one end when the other end is raised one inch. Such ground movements can be measured by precise leveling, but this method is expensive and slow, and not suitable except over a fairly extended area.

It is apparent, then, that an instrument for measuring a localized tilt must be very sensitive to change af angle of its supports. The seismographs, such as are in use for earthquake measurement, are utilized for tilt measurement, and are sufficiently sensitive, but a seismograph installation is much too expensive to use for the large number of tilt stations that are needed.

A type af tiltmeter has been developed at the Hawaiian Volcano Observatory which is very satisfactory for indicating the tilt, both in magnitude and direction, but has the disadvantage that it is not a recording instrument. It must be visited and read to determine the tilt. Two of these instruments are in use on the floor of Kilauea crater, near Halemaumau, and are read at twenty-four hour intervals, but there is no record of any variations that might occur between readings, nor of the time when any particular amount of tilt takes place. Furthermore, these instruments are not of a type to be made self-recording, except photographically, and that has its disadvantages.

There is need for a tilt-measuring device that is sensitive, economical in construction and operation, which will record the tilt hourly, at least, and that need be visited not oftener than once a week, at which time the record can be removed and

replaced by a new, blank record sheet. Many such instruments could be placed around Kilauea crater and the rifts about this region and a very complete record of the tilting of the ground obtained which would be of great value in the study of the lava movements below the ground, as well as in the prediction of future eruptions.

It is in connection with the development of such an instrument that I am spending a few weeks at the Hawaiian Volcano Observatory this summer. I have a model in operation from which daily records are now being obtained. This model appears to have possibilities for development into the type of device required for the more widespread study of tilts which I have mentioned.

At the present time tilting is being measured at Halemaumau, as before stated, and also at some of the seismograph stations, by measurements taken from the seismographs. Such measurements have been carried on continuously at the Obser-

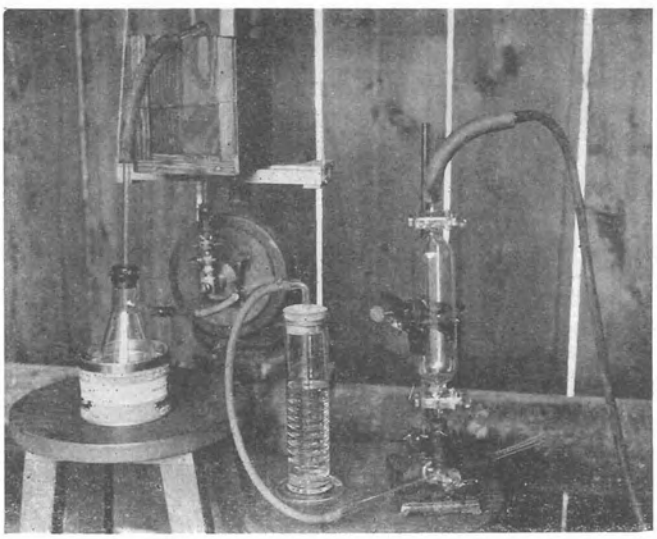

Figure 2. Gas drawn through salt-and-ice mixtures and KOH before reaching collecting tube.

vatory for many years, and have shown that volcano tilts coordinate with lava movement, and that seasonal tilts also occur over large areas. The annual variation of tilt at the main Hawaiian Volcano Observatory station takes place along a line about NNE and SSW. The tilt is greatest to the NNE about the end of December and the greatest SSW value is in May or June, and varies through a range of from twelve to eighteen seconds of arc in the different years. At the same time there is now a slight residual tilt toward the west which is at the rate of less than one second per year.

The tilt stations on the crater floor, near Halemaumau, indicate in general, tilts to or from the pit as being predominant. This shows a swelling and subsidence with the rising and recession of the underlying lava, or one might say, a sort of diaphragm action of the crater floor. These movements at the pit are very localized, and do not show ground movements over a larger area as would stations around the crater rim, or at points on Mauna Loa.

In most cases the tilts as measured at the various stations have been gradual, with small daily change. Likewise a tilt of one day might be in an entirely different direction from that of the day before, but in general, over a period of several days, or in many cases several months, the tendency of the tilt is in one definite direction. Then there may be a reversal of the tilt over an extended period, so that at no point does the tilt continue indefinitely in one direction.

At times, especially of considerable seismic disturbance, a tilt of several seconds may occur between readings of the instruments. This large change probably takes place in a few seconds of time, at the time of the quake. But whether the tilt be large or small, gradual or sudden, it gives definite information of movement of underlying lava, and an extended tilt study should assist greatly in following the course of this movement.

Hawaiian Volcano Observatory Report for November 1937

VOLCANOLOGY

The Hawaiian volcanoes were quiet during the month, and there was little motion in the walls of Halemaumau pit at Kilauea.

The following are the weekly Observatory totals for Halemoumou and the seismographs.

Week Ending	Seismicity	Slides	Crack Openings	Local Tremors and Quakes
November 7.....	6.75	2	3.00 mm.	19
" 14.....	3.75	0	5.05 mm.	11
" 21.....	4.00	2	0.00 mm.	11
" 28.....	9.75	0	0.00 mm.	24

The slight earthquake November 27 damaged the Holemaumau seismograph and was felt in National Park. Of the measurable local seismic disturbances, sixteen were from Kilauea, one from Mauna Loa and one from northwest of Mauna Kea.

Sequence of Events by Weeks

The first week produced two slides from Halemaumau walls, two more were noted during the third week and on November 28 scars of a slide appeared in Puu Huluhulu crater after the sharp jerk of the earthquake of November 27.

Slides at Halemaumau

The recorded slides from the wall of the pit were:

November 1, 11:05 a.m., dust arose at NW wall.

November 2, 9:00 a.m., another slide in the same place.

November 21, 1:45 p.m., two slides north wall.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations resulted during November in aggregate movement as follows:

Week ending forenoon of:

November 5, 28 locations, 6 opened, 4 closed, opening 3.00 mm.

November 12, 28 locations, 12 opened, 3 closed, opening 5.5 mm.

November 19, 28 locations, 6 opened, 4 closed, opening 0.0 mm.

November 26, 28 locations, 6 opened, 5 closed, opening 0.0 mm.

T. A. J.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seis-

* For local seismicity definition see Volcano Letter 371.

† Including teleseisms or earthquakes over 5000 km from Kilauea.

mograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hila and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of the depth af focus has been made.

November 1, 2:49 a.m., very feeble, probably originated in area immediately NE of the Observatory, NE rim of Kilauea Crater.

November 1, 5:50 p.m., very feeble, 38.0 miles deep in vicinity of Waimea Table Land about 18.0 miles NNW of Summit of Mauna Kea. 19° 59.0′ N; 155° 30.8′ W.

November 3, 1:59 p.m., feeble, probably originated in Kilauea Crater near SE portion of Halemaumau.

November 6, 4:18 p.m., very feeble, probably originated in NE portion of Kilauea Crater.

November 8, 8:58 a.m., very feeble, 1.1 miles under Byron Ledge. 19° 25.0′ N; 155° 15.6′ W.

November 8, 10:13 a.m., very feeble, location same as preceding quakes but of slightly deeper focus.

November 8, 10:25 p.m., very feeble, probably orginated in SE rim area of Kilauea Crater near Keanakakoi.

November 11, 12:02 a.m., very feeble, probably originated in Western portion of Kilauea Crater near Uwekahuna.

November 17, 12:24 p.m., very feeble, 3.9 miles deep, 3.4 miles NW of the Observatory. 19° 27.8′ N; 155° 18.0′ W.

November 23, 4:37 p.m., very feeble, probably originated in NE rift of Mauna Loa about 15.0 miles from Hilo.

November 25, 10:10 p.m., very feeble, 2.2 miles deep NE rim Halemaumau, Kilauea Crater. 19° 24.9′ N; 155° 17.0′ W.

November 25, 10:11 p.m., very feeble, 1.4 miles deep NW portion af Kilauea Crater. 19° 25.6′ N; 155° 17.0′ W.

November 25, 10:23 p.m., very feeble, 1.5 miles deep in SE rim cracks, Kilauea Crater immediately NE of Keanakokoi. 19° 24.4′ N; 155° 16.2′ W.

November 25, 10:26 p.m. very feeble, location same as preceding quake.

November 26, 12:44 a.m., very feeble, af shallow origin SE rim cracks Kilauea Crater. 19° 24.2′ N; 155° 16.3′ W.

November 26, 11:50 p.m., very feeble, probably originated in E portion of Kilauea Crater.

November 27, 11:26 a.m., very feeble, 5.0 miles deep, SW rift zone at junction with Kilauea Crater. 19° 24.5′ N; 155° 17.7′ W.

November 27, 6:35 p.m., slight, 1.1 miles deep, 0.3 mile E of E rim Halemaumau and 0.4 mile from Pit seismograph. Reported felt at CCC Camp, SE rim of Kilauea Crater and around the National Park residential area. Pit seismograph was dismantled and the supports of N-S component broken. 19° 24.4′ N; 155° 16.7′ W.

Microseismic motion of the ground at the Observatory was strong throughout the month.

Four (4) minutes of continuous tremor began recording at the Observatory 3:53 a.m., November 21.

An unidentified portion of a teleseism began registering at Kilauea at 9h 03m 28s, p.m., H.S.T., November 9.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau the algebraic sum of radial tilts toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending November 28, was 10.05″ S and 1.55″ E.

Week Ending	Observatory	Halemaumau West Station
November 7	1.38″ N 48° E	2.62″ N 31° W
November 14	0.65″ N 61° W	2.80″ N 80° W
November 21	0.00″ 0	5.16″ N 82° W
November 28	1.00″ N 79° E	4.14″ N 71° W

Week Ending	Southeast Station Halemaumau	Halemaumau Resultant
November 7	1.62″ S 34° W	1.69″ From
November 14	3.43″ N 46° W	0.89″ Toward
November 21	6.42″ N 28° W	2.79″ From
November 28	8.59″ S 16° E	4.37″ From

H. H. W.

Crater Angles

Meosurement of Horizontal Angles across Kilauea Crater from the Observatory November 27, showed slight closing of the Kilauea Crater value and slight opening of the Halemaumau value as compared to similar measurements October 16. From Kilauea Crater SE rim to Uwekahuna there was opening 0.09″, October 16 to November 10, and closing of 0.25″, November 16 to 20. Total closing 0.16″. From the SE Pit B. M. to NW Pit B. M. there was opening 1.40″, October 16 to November 10, and closing of 0.84″, November 10 to November 27. Total opening 0.56″.

H.H.W.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis-Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

WORK OF THE OBSERVATORY 1937—

The Hawaiian Volcano Observatory is administered under the Branch of Research and Education of the National Park Service. In collaboration is the Hawaiian Volcano Research Association, an educational corporotion of the Territory of Hawaii which supplements the work of the Government. The staff in 1937 was:

T. A. Jaggar, Volcanologist
H. H. Waesche, Assistant Geologist in charge of seismology
S. Sato, Librarian
H. Yasunaga, General Assistant
A. Okuda, Mechanic

Associates of the Observatory in Honolulu are:

Willard H. Eller, Associate Professor of Physics
Stanley S. Ballard, Assistant Professor of Physics
Iwao Miyake, Instructor in Physics
L. W. de Vis-Norton, Secretary and Assistant Treosurer, Hawaiian Volcano Research Association
Mrs. B. Y. Ching, Clerk

The Directors of the Hawaiian Volcano Research Association are:

F. C. Athertan, Castle & Cooke, Ltd.
R. A. Cooke, C. Brewer and Co., Ltd.
D. L. Crawford, University of Hawaii
A. L. Dean, Alexander and Baldwin, President

W. F. Dillingham, Oahu Railway & Lond Co.
J. R. Farrington, Honolulu Star-Bulletin
W. F. Frear, Bishop Trust Building
L. T. Peck, Stangenwald Building
W. W. Thayer, Stangenwald Building
L. P. Thurston, Honolulu Advertiser

Volunteer operators of seismographs for the Research Association on the island of Hawaii are:

R. V. Woods, Kealakekua
St. Mary's School, Hilo

The routine of the Observatory, besides the accumulation of data exhibited in the Volcano Letter, which involves attention to five seismographs, two clinographs, weather records, levelling and triangulotion, and measurements at Halemaumau pit, includes also circulation of a weekly press report for Island newspapers, transmittal of a monthly report to the National Pork Service, transmittol weekly ond monthly of weather data to U.S. Weather Bureau and preparation of scientific papers.

Mauna Loa and Proposed Hilo Barriers

As outlined in Volcano Letter of January and March, this subject has been throughout 1937 an important activity of the Observatory, involving os it does a large engineering program for the protection of Hilo, the acquisition of additional land on Mauna Loa, and the establishment of a Mauna Loa seismograph at the terminus of the Park Road.

The Barrier Project for defending Hila from lava flows was announced at a lecture by T. A. Jaggar to Hilo Chamber of Commerce January 19, followed by the proposal of the Hawaiian Volcano Research Association to acquire all lands on Mauna Loa above 7,000 feet that might be needed for patral by the National Park Service. This action was authorized in February by the Board of Directars af the Research Association and an expedition over the ground on Mauna Loa was made in March by Chief Farester Caffman of the Park Service, and Mr. Tillett, Superintendent of Hawaiian Emergency Conservation Wark, along with Superintendent Wingate, the Volconologist and athers. March 23 a resalution by Hila Chamber af Commerce requested the Rivers and Harbors Committee of Congress ta provide for a survey af the barriers for the protectian of Hila harbor. This was incorporated in the Rivers and Harbors Bill in May, and the bill was passed in August. The several awners af the upper lands on Mauna Loa, including the Territarial Government, expressed tentative approval of the enlargement af the Park, as might be later demanded by Act af Congress. In July and August Colonels Thamas and Browne of the U.S. Engineers went over the lands on Mauna Loa, Mauna Kea and at Hilo where the barriers would be constructed. General Markham, Chief of Engineers, inspected the field in November, and the U.S. Engineer in charge af Hawaii, Major P. E. Bermel, held a hearing in Hilo December 17 where the harbor protectian was discussed.

On September 9 a site was selected on the upper side af the present terminus of the Mauna Loa road far a cellar of concrete with double walls to hause a seismograph of Hawaiian type, and this cellar was nearly completed at the end of the year, built by Emergency Conservation labar.

Seismology and Engineering

Mr. Waesche was engaged in January in applying a relay to the radia apparatus receiving time signals, so that these signals were written directly an seismagraph drums. He prepared earthquake maps of Kilauea crater and the island af Hawaii. He assisted in arrangements for a new kiosk at Halemaumau ta exhibit ta travelers histary of eruptions. A levelling instrument gave much trauble during the year, but a substitute instrument was obtained, and it was discavered that the northwest Halemaumau benchmark had lowered relative ta the Sand Spit south af Kilauea about fifteen inches since October 1934. In December a rotary wind-measuring instrument was set up on the Observatory roof, so as to record directly on the chronographs of the seismograph cellar. A similar instrument was obtained for the Rest House on Mauna Loa.

Investigation of simplified seismological instruments for volunteers has occupied the staff. Four new model shock recorders were built during the first half of the year having in view the recording of three components of motion by means of weights suspended by flat springs.

In May a second series of experiments was begun with normal pendulums designed to actuate a mercury contact, ring a bell, and exhibit intensity by length of swing.

The object of this work wos to install annunciators at telephone exchanges which would give a numerical value to intensity of an earthquake. The operators would enter the number on o postal card sent the Observatory. It was finally decided to use a rectangular heavy mass capable of swinging in one direction only, with a very light horizontal high-magnification lever, making contacts with mercury in six cups. These connect with a six-point annunciator, grades one to six being shocks progressively stronger.

The normal activities of the Observatory in seismalogy and engineering will be found described in the articles by Mr. Woesche in Volcano Letters of February, April and October. The instrument that will be placed in the Mauna Loa cellar consists of a pair of pendulums built in our shop, magnifying earth motian one hundred times, and writing an smoked paper wrapped round a drum driven by clockwork. This instrument will be visited once a day by a member of the staff who will change the drum. The location is eleven miles fram the Observatory WNW, an the Mauna Loa slape ten miles below the resthouse. This will give the Observatary a definite check an shacks occurring under the rift belt of Mauna Loa.

The shock recorders and annunciatars are simple instruments in wooden cases designed ta screw an a wall anywhere, announce an unfelt earthquake by ringing a bell, and proclaim its size by the distance to which the pendulum swings. When an electric annunciator dial is used the length af the swing is indicated by a number. The operatar after noting the hour and the number, sets the annunciator back ta zero. Plans far making one af the madels self-recording are nat yet perfected, but tests have been made with ink, smaked paper, and photographic film.

Kilauea Laboratory, University of Hawaii

The wark of the University physicists was outlined in November Volcano Letter. S. Sata, a University assistant, is resident at the Observatory as librarian and has introduced order into the library by classifying, filing and card cataloging the earthquake and eruptian natices clipped fram the press, also the books, pamphlets, notes, and photographic negatives that are parts af the invaluable Kilauea records.

Among things filed are the lang smaked paper seismograms, fixed with shellac varnish and stared by thausands. The wark af classifying finds these congested by overflow fram the metal case originally made for them. All the records are in a room eighteen feet square fram which baoks had ta be ejected with transfer to the University building five hundred yards away. In the attempt at economy of space, there have been packaging and staring surplus publicatians, correspandence, and the less used baoks, in the hat, dry, wooden Observatary attic; transferring seismalagical pamphlets to the Assistant Geologist's wooden office, and lastly filing, selecting reserves, and setting apart sets far binding, of the Observatory Bulletin and of the Volcano Letter, the entire file af the latter being kept in the ald wooden Observatory building. This building alsa houses as fire hazards chemical and phatagraphic work, electric saldering irons, and kerasene smoking apparatus for the daily seismagraph routine

in the basement. Here also are main switchboxes and fuses; and battery equipment for radio time signals.

This situation is a continuous fire menace for the storage of the valuable records and publication files of the twenty-six years of work of the Hawaiian Volcano Research Association. The record material cannot even be studied properly, for there is no room for large tables nor for modern filing cases and everything has to be distributed to five rooms in three different buildings.

There is no solution for this problem of congestion other than the creation of a new large fireproof Hawaiian Volcano Observatory building.

Dr. H. Nagaoka of the Institute of Physical and Chemical Research in Tokyo has discovered at Asama Volcano that a magnetometer needle moves suddenly during underground volcanic disturbance. Theoretically this should be true, for liquid lava on solidifying or liquefying changes its magnetic attroctiveness. At Asama various intermittent disturbances of the magnetic needle are observed several weeks before an explosion

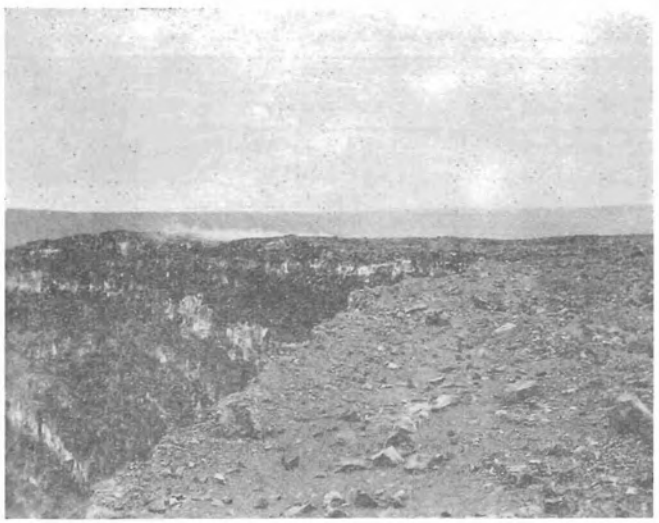

Figure 2. Crack locality No. 25 after caving into pit August 22, 1937. Photographs by Waesche.

of the volcano, and the rumbling is always accompanied by great magnetic changes. A specialized magnetograph was constructed giving the value of the time-rate of variation, serving as an indicator of rapid magnetic disturbances and registering the vertical component. It is relatively insensitive to magnetic storms. Professor Eller is greatly interested in the possibilities which this apparatus has for exhibiting the melting or the congealing of Hawaiian eruptive lava underground. Experiments are in progress for melting the lava and studying its change of magnetic properties.

As candidate for the degree of Master of Science Mr. A. E. Jones presented a thesis at the University of Hawaii on "Empirical Studies of the Seismic Phenomena of Hawaii" and on September 23, came up for examination which he passed satisfactorily. This thesis presents a statistical investigation of many seismograms of the Hawaiian Volcano Observatory.

In these days of Kodachrome photography an appeal may be made to amateur photographers interested in the Hawaiian volcanoes to explore the great rift belts and to photograph them. Either still or motion pictures in color, for purposes of projection and exhibition, should be made of the hundreds of subjects, such as cracks and pits and canes, that lie along the southwest rift of Mauna Loa in Kahuku, the northeast rift near the Rest House, the vicinity of Kulani; and the great extent of the Kilauea rift in the forest to the east of the Chain-of-Craters; and along the many pits and cones of the Kau Desert. There is here a magnificent opportunity for photographic exploration in the wilderness, something that few people seem to care to do.

Hawaiian Volcano Observatory Report for December 1937

VOLCANOLOGY

Until the solstice season of December 20, the month at Halemaumau pit of Kilauea volcano was extraordinarily quiet. After solstice local seismicity became three times as great, and five large distant earthquakes were recorded, in part from the Mexico-Central America region. Sixteen of the local shocks were from Kilauea, one from Mauna Loa and one from Hualalai.

The following are the weekly Observatory totals for Halemaumau and the seismographs:

Week Ending		Seismicity	Slides	Openings Crack	Local Tremors and Quakes
December	5.....	3.75	0	3.5 mm.	10
"	12.....	2.25	0	1.0 mm.	7
"	19.....	2.00	0	6.0 mm.	7
"	26.....	6.50	1	0.0 mm.	20
January	2.....	7.50	0	2.5 mm.	19

Perceptible earthquakes occurred in Hilo December 28, Kona December 30, and at National Park January 1.

Sequence of Events by Weeks

The first week was quiet, with noticeable blue fume showing over Halemaumau during humid Kona weather.

The second week was even quieter, and the seismic index for the third week was astonishingly small just as it was a year ago at this period. This was interrupted by a landslip in Halemaumau the fourth week, and the fifth week showed increased numbers of earthquakes near and far.

Slide at Halemaumau

A recorded slide from the wall of the pit was:

December 21, 4:08 p.m., a considerable slide from the north rim.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations resulted during December in aggregate movement as follows:

Week ending forenoon of:

December 3, 28 locations, 11 opened, 6 closed, opening 3.5 mm.

December 10, 28 locations, 8 opened, 6 closed, opening 1.0 mm.

December 17, 28 locations, 10 opened, 2 closed, opening 6.0 mm.

December 24, 28 locations, 6 opened, 4 closed, opening 0.0 mm.

December 31, 28 locations, 8 opened, 3 closed, opening 2.5 mm.

T.A.J.

Jan.	2.....	10	8	1	2	7.50

* Including teleseisms of earthquakes over 5000 km. from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Valcano Observatory on the Island of Hawoii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances begon at the time indicated and whenever possible, a determinatian of the depth of focus has been mode.

December 1, 9:15 am, very feeble, probably originated in Kilauea S W rift, 19 miles from the Observatory and 4.0 miles N of Palina Point.

December 2, 8:00 pm, very feeble, 3.1 miles deep, W rim of Kilauea Crater 0.6 mile SW of Uwekahuna, 19° 25.2' N; 155° 17.9' W.

December 3, 6:58 am, very feeble, 1.4 miles deep and 0.8 mile W of Puhimau Crater. 19° 23.6' N; 155° 15.8' W.

December 7, 12:47 pm, very feeble, 11.0 miles deep, 7.0 miles W of Volcano House. 19° 26.9' N; 155° 21.8' W.

December 12, 5:30 pm, very feeble, 21.0 miles deep under Hualalai. 19° 41.5' N; 155° 50.7' W. Felt in Kohala and at Paauilo.

December 25, 2:18 pm, very feeble, 2.5 miles deep and 0.4 mile SW Kokoolau Crater. 19° 23.1' N; 155° 15.2' W.

December 25, 5:26 pm, very feeble, 6.0 miles deep Kilauea SW rift 7.5 miles from Halemaumau. 19° 20.2' N; 155° 22.2' W.

December 26, 1:58 am, very feeble, probably originated in SW portion Kilauea Crater in vicinity af Halemaumau.

December 26, 6:42 am, very feeble, location of epicenter same as preceding but probably of slightly greater depth.

December 27, 2:19 pm, very feeble, 06. mile deep under W portion of Kilauea Iki, 0.2 mile E of Kilauea Crater rim. 19° 25.1' N; 155° 15.4' W.

December 28, 11:27 am, very feeble, 1.5 miles deep in Kilauea Crater immediately W of Kilauea Iki. 19° 25.3' N; 155° 15.8' W.

December 28, 7:15 pm, very feeble, 11.0 miles deep and 4.0 miles off coast S af Hilina Pali. 19° 12.6' N; 155° 14.2' W. Reported felt in Hilo.

December 29, 6:18 pm, very feeble, probably originated in Kilauea SW Rift.

December 31, 4:34 pm, very feeble, probably originated near center of Kilauea Crater.

January 1, 2:39 am, very feeble, 17.0 miles deep in Hilina Fault 3.5 miles S of Kamakaia Hills. 19° 16.0' N; 155° 20.3' W.

January 1, 9:16 am, feeble, 4.8 miles deep near Heake Crater, 19° 22.6' N; 155° 14.1' W.

January 1, 10:44 pm, very feeble, 13.0 miles deep under SW slope af Mauna Loa 5.0 miles NE of Kauna Point. 19° 05.6' N; 155° 49.5' W.

January 2, 6:01 pm, very feeble, probably originated in area approximately 12.0 miles NE of the Observatory.

Microseismic motian of the ground at the Observatory was moderate, December 16 to 21 and on December 24; the remainder of the month, the motion was strong.

Teleseisms registered as follows:

December 21, "P" waves at 5h 19m 20s pm, distance from Kilauea was about 3,200 miles and epicenter was apparently off W Coost of Mexico. 17° N; 106° W, by preliminory determination U. S. Coast and Geodetic Survey.

December 21, 9h 08m pm, no information obtained on location.

December 23, 2h 57m 25s pm, "P" waves, distance from Kilauea was appraximately 3,700 miles. Epicential location 16° N; 98° W, by preliminary determination, U. S. Coast and Geodetic Survey.

January 1, 1h 07m 41s pm, "P" waves. No determination of distance.

January 2, 12h 06m 50s pm, "P" waves, probable distance from Kilouea, 3,600 miles.

Hawaiian standard time used for all preceding reports.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau the algebraic sum of radial tilts toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending January 2, was 9.7" S and 0.47" E.

Week Ending	Observatory	Halemaumau West Station
December 5	0.46" S 41° W	2.92" S 81° W
December 12	1.01" S 50° W	2.98" N 33° W
December 19	0.97" N 65° E	2.38" S 66° W
December 26	0.82" S 26° E	4.23" N 58° W
January 2	0.25" N 27° W	0.00 Unchanged

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
December 5	9.17" S 67" W	0.56" From
December 12	10.40" S 73° W	1.91"Toward
December 19	10.08" N 12° E	4.24" Toward
December 26	1.62" S	4.72" From
January 2	6.29" N 15°W	5.83" Toward

Crater Angles

Measurement of horizontal angles acrass Kilauea Crater from the Observatory, December 22, indicated opening of both the Halemaumau and Kilauea Crater values compared with similar measurements made November 27. At that time the Halemaumau value from the SE Pit B.M. to the NW Pit B.M. increosed 2.51" and the Kilauea Crater value from the SE rim to Uwekahuna increased 0.44".

Leveling at Kilauea

On December 9, a series of levels similar to that of October 12 was run in Kilauea Crater fram the Spit B. M., SE rim of Kilauea Crater to NW Pit B. M. an the NW rim of Halemaumau. Results af this run indicated relatively no change or not more than 4 millimeter lowering of the NW Pit B. M. relative to Spit B. M. The Lietz, Coast and Geadetic Survey type precise level was used far the December levelling. It checked favorably with the Stanley "Wye" level used far the October determinatian.

THE VOLCANO LETTER

No. 455 monthly Department of the Interior National Park Service January 1938

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

743

View of the Sulphur Bank, Kilauea. Notice the cliff in the background which is doubtless the wall of a Kilauea crater much older than the present one. Most of the gas collections were made at the wells which are beneath the temporary laboratory building in the left foreground.—National Park Service Photo.

THE VOLCANIC GAS PROBLEM

By Stanley S. Ballard

Research Associate in Geophysics, Hawaii National Park, and Assistant Professor of Physics in the University of Hawaii.

More and more attention is being focused upon the problem of the analysis of volcanic gases. Overlooked almost entirely until recent years, the evolution of gas is now considered to be one of the major phenomena accompanying a volcanic eruption. In fact some volcanologists feel that a satisfactory solution of the volcanic gas problem will shed much light on the fundamental problems of volcanology. In particular, it is thought that here may be found the source of some of the enormous quantity of heat that is given off at the time of eruption. The volcanic gases appear to have their origin underground in the fluid magma. As the magma rises during an eruption the hydrostatic pressure upon it is greatly decreased and at the earth's surface is so small that the gases here come out of solution and are given off into the atmosphere, usually in flames. Fortunately they can be analysed by chemists and physicists, the results of analysis being of course turned over to the volcanologist or the geochemist for interpretation.

There are at least four distinct approaches to the volcanic gas problem. First there is the possibility of photographing the spectra of the burning gases at the time of eruption. This would involve setting up a light portable spectrograph in the field near the fluid lava and focusing upon the slit of this instrument by suitable lenses the light from the flames of the burning gases emanating from cracks in the advancing lava flow. The photographs thus obtained would not be pictures of the flames themselves, but would be spectra of the substances burning in the flames. A trained spectroscopist could readily interpret these spectrograms to tell what elements or molecules in the burning gas gave rise to each of the spectrum lines. In the past vol-

canic flames have sometimes been examined through small hand spectroscopes, but the writer doubts whether results obtained in this woy are particularly significant. Even a person experienced in spectroscopy can easily mistoke the colored line of one element for some neighboring line of another element and thereby make an incorrect visual anolysis. For this reason it is felt that the photographic method, giving a permanent record which can be compared later with standord spectrograms of the various suspected elements, is much preferable. It is hoped that a small field spectrogroph can be obtained for use in this connection at the next eruption of Kilaueo or Mauna Loa.

The second approach to the problem is through the collection of gases emanoting from the fluid lova at the time of eruption, and their subsequent onalysis in the laboratory by chemicol and spectroscopic means. It is important to collect the gases **before** they burn, if possible, and to make the collections so as to exclude air from the surrounding atmosphere as completely as possible. Collections of volcanic gases were made at Kilauea in 1912 by Drs. Day and Shepherd of the Geophysical Laboratory of the Carnegie Institution of Washington, ond further collections were made in 1917, 1918 and 1919 by Dr. Shepherd and Dr. Joggor at Kilouea ond at Mauna Loa. These samples were onalysed in the Washington laboratory by Dr. Shepherd, the results being reported in papers appearing in the monthly bulletins of the Hawaiian Volcano Observatory and in national geological journals. No opportunity to collect volcanic gases has presented itself since the writer has been in the Territory, but a new type af collecting tube which it is hoped is somewhat of an improvement upon the vacuum tubes used previously has been devised. This new type of tube is described below.

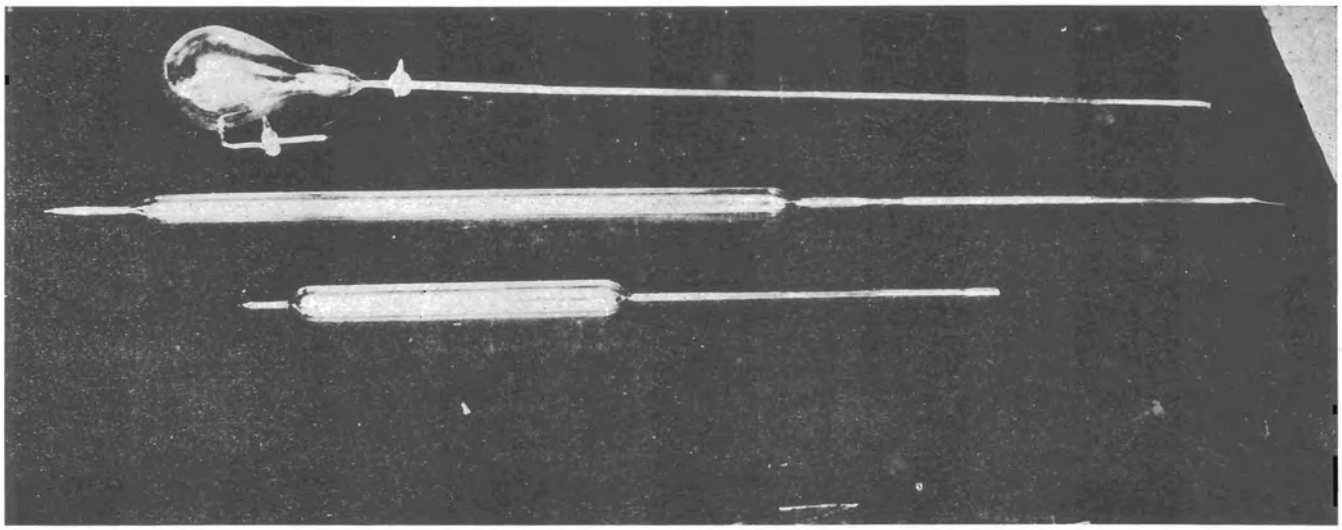
The third approach consists of extracting dissolved gases fram samples of cold lava after the eruption is over, and then anolysing these gases. The extraction is performed by heating a ground portion of the rock in a vacuum furnace. When the rock comes up to the softening temperature large volumes of occluded gos, mony times the volume of the rock in some cases, are driven off. The chief difficulty here appears to be in developing analytical methods for handling accurately the rather small somples of gas obtained. Suitable methods have been warked aut by Dr. Shepherd and some analyses of gases driven off in the vacuum furnace from lava samples are given in his 1925 poper in the Journal af Geology. An attractive feature of this approach to the volcanic gas problem is that collections need not be made at the time af eruption when field conditions are seldom ideal, but may be made some weeks later after the excitement is over. In fact one should be able to go oround the island of Hawaii, stop at the various doted lova flows and obtain suitable samples of rock, take them back to the laboratory, drive off their occluded goses, analyse these gas somples, and have a time-history of the composition of Howoiian volcanic gas.

The lost approach to the volcanic gas problem is by far the least direct of the four. It involves the collection and analysis of the sulphuraus fumes emanating from vents in the immediate neighborhood of the croter. Of course there is often a general steam crack activity in a volcanic region, but the emonotions here seem to consist largely af steam. This is doubtless ground water that has seeped down into the warmer regions af the ground, been vaporized and returned to the atmosphere as steam. There are often, however, small areas at which free sulphur is brought up from the depths and deposited at the surface, building up the so-colled sulphur banks. The emanations in these cases consist of steam, sulphur vapor and oddi-tional gases. The important question here is as ta haw intimotely volcanic these solfataras can be considered to be. Da same af the gases rise directly from the bed of molten magma that is thought to underlie the volcanic region? If so, the analysis of the reodily accessible and continuously fuming solfataric goses should afford an index to the activities of the magma below. In the case of Kilauea, sulphurous fuming regions can be seen around the bottom edge of Holemaumau pit, around the edge of Kilauea crater beneath the present CCC camp, and at the edge of a still older, prehistoric Kiloueo crater. This lost area is located near the Hawaiian Volcano Observotory and the Kilouea Volcano House and is the Sulphur Bank that is visited by practically oll tourists to the Pork, being but 100 yards off the main highway. At this location collections of solfataric gases were made some 16 years ago by Dr. E. T. Allen of the Geophysicol Laboratory. His results as published in the Bulletin of the Hawaiian Volcano Observatory for August 1922 are os follows:

Steam	96.2%
Fixed Gases	3.7
Sulphur Dioxide	.096
Sulphur Vapor	.004
Hydrogen Chloride	Trace

These are volume percentages far a temperature of 95.5° C ond a pressure of 646 mm.

There are discussed below the collections and onolyses of Kilauea Sulphur Bonk gases which have been carried out by the writer during the last two years. The chief purpose of this investigotion was to study the less obvious solfataric gases, that is, those other than steam ond sulphur vopor. The actuol collec-tians were made at various times during an interval of over a year, and it wos hoped thot some variation in the constitutian af the gases might be found. No significant variation hos appeared, but the writer feels that collections and anolyses should continue to be made at perhaps monthly intervals, the program lasting long enough to include o period of activity of Halemaumau. If voriations in constitution are faund to occur during the period of activity, the results will surely justify the work involved. In fact there is the possibility ond hope thot such variations might exist and might be correlated with volcanic octivity sufficiently to enable predictions of eruptians to be made through gos anlaysis as well os through a study of seismic records. Whether such prediction will ever be possible or whether this is only a fond dream, only time can tell.



Collection of Volcanic Gases

The collection of the goses billowing forth from fluid lava at the time of eruption is ordinorily effected by the use of vacuum-type collecting tubes. A typical tube consists of a large bulb of several hundred cubic centimeters copocity to which is joined a long, narrow glass tube which moy be severol feet in length. The whole assembly is originally evacuated to o high degree. Then when the end of the long glass tube is thrust into the volconic flame and the tip of the tube is broken off or melted through, gas will rush into the evacuated volume. If it can be successfully tropped there, the collection is complete. A desirable feature is thot outside air may be eliminated fram the collection as completely as possible.

Vacuum-type tubes of the sort used in the collections of Drs. Day, Shepherd ond Jaggor ore pictured on page 7 of Volcano Letter Number 437 for July 1936. The largest tube in this figure is the smallest tube shawn in Figure 1. Above this tube is the largest vacuum-type tube used by them. Note the long drawn-out tip which could easily be broken off by striking the end of the tube against the lava when the time ta make the collection arrived. Note olso the narrowed portion of the slender tube near the lorge bulb which is designed for reody sealing off with a gasoline torch after the callectian is completed. The tip of the lower tube has in its end a plug of glass af law melting point which should soften quickly in the intense heat of the volcanic flame, allowing the gas to rush in. The chief difficulties encountered with these tubes were in causing the tip ta

break or melt at the appropriate time, and in sealing the tube quickly before contaminating air entered.

The top tube in Figure 1 is the first vacuum-type collecting tube designed by the writer in collaboration with Mr. Paul Gow, Assistant Chemist at the Experiment Station of the Hawaiian Sugar Planters' Association. Features of this tube are a type of tip which is certain in its action, and a method of sealing the collected sample quickly so that no outside air can enter to contaminate it. The breakable tip is simply a crook-necked tip which is scored with a file to insure breaking at the bend, the breaking being effected by a quick jerk on a wire attached at one end to the crook and at the other to the collector's right hand, the tube being held in his left hand. After the gas has

744

Figure 1. Old and new vacuum-type volcanic gas collecting tubes. Capacities are approximately as follows: Upper (new style) tube, 800 cc.; center tube, 450 cc.; lower tube, 350 cc.—National Park Service Photo.

rushed into the evacuated volume it is trapped there simply by turning through ninety degrees (i.e. from open to closed position) the large vacuum-ground stopcock between the three-foot long slender glass tube and the large bulb. In Figure 2 is pictured the original tube along with two later "stream-lined" models. These differ from the original tube in two important respects. First, the side arm with small stopcock which was attached to the large reservoir bulb has been eliminated. This attachment was used in evacuating the bulb. Evacuation is now effected through a small side tube which is sealed off with an oxy-gas flame when the tube is evacuated to as high a degree as possible. The second improvement is in the greater mechanical strength obtained by making the weld between the large bulb and the stopcock very short and hence very sturdy. These latest tubes are made to order by a New York glass-blowing firm. The long slender tube is added locally in order to save freight charges. Then the breakable tip is drawn out and the tube is evacuated. The price complete per tube is under five dollars. The tubes may also be clamped to a sturdy pole, the stopcock being rotated by a "remote-control" device not shown in the figure. This recourse would be necessary in cases where the collector could not approach to within three or four feet of suitable gas sources.

No opportunity to test these tubes under actual field eruption-time conditions has presented itself as yet. The original tube pictured in the figures was tested at the Sulphur Bank in the summer of 1936, however, and appeared to work most satisfactorily. The difficulties which might be encountered with the tubes would be the result of the fragile nature of any piece of glass apparatus or of the failure of the vacuum-ground stopcock to hold a vacuum in the tubes while they are in storage awaiting eruptions. In general these stopcocks have been found to be quite satisfactory, two tubes now at the Hawaiian Volcano Observatory having held a vacuum perfectly for six or eight months to date. It should be remarked that at the Observatory there is now a complete outfit for evacuating these tubes and for doing any glass blowing and repairing that might be necessary.

Collection and Analysis of Solfataric Gases

The analyses about to be reported upon should be thought of still as preliminary studies which supplement the first analyses made by Dr. Allen in 1922. The purposes were to establish the identity of the 3.7 per cent of "fixed gases" reported by Allen, to see if there were any gases being given off which were unusual in nature, and to establish what definitely volcanic gases were emanating from the solfataras. Interest was centered particularly upon the combustible gases hydrogen and carbon monoxide which are known to burn in volcanic flames; sulphur vapor, another known volcanic gas, is very evidently a constituent of the solfataric gases. The analyses therefore do not concern themselves with either the amount of the sulphur vapor or the steam that was being given off at the vents.

The first collections were made in August and September of 1936. A temporary shack suitable to house collecting equipment was erected by the Park Service over the wells that had been sunk at the Sulphur Bank area some fifteen years ago. The best collections were made from the manifold connecting these three wells, the side wells being 15 feet deep and the center well some 70 feet deep. The figure on page 2 of Volcano Letter Number 453 for November 1937 illustrates the "vertical wet" method of collection from the wells. In this case the sulphurous fumes are drawn by a hand-vacuum pump through a collecting tube until it is thoroughly flushed with the gas, whereupon the collection is effected simply by shutting off the collecting tube stopcocks, thereby trapping some of the gas inside. By surrounding the tube with an ice pack much of the steam is made to condense and run back into the walls, thus giving a sample which is considerably enriched in the fixed gases. This type of collecting has proved the most satisfactory and dependable of the several methods tried, and a sample has been collected using this method each time the region has been visited by the writer. There were also made field collections at sulphurous fuming spots in the vicinity of the Sulphur Bank. As a "control" we collected a sample using the field collection technic at the steaming bluffs a mile or two from the Sulphur Bank along the

government road, in a region where no sulphur fumes could be detected. It is interesting to note that even in this non-sulphurous area sulphur dioxide to the extent of 1.3 per cent of the dry gas (i.e. air and carbon dioxide) was detected.

Upon returning to Honolulu one of the samples was tested spectrographically using the excellent spectroscopic facilities of the Experiment Station of the Hawaiian Sugar Planters' Association. The only lines or bands detected on the spectrum plates were those of carbon monoxide and hydrogen. The hydrogen lines were undoubtedly due to water vapor (steam) present in the sample, whose molecules are broken down by the high voltages applied to the spectrum tube to hydrogen and oxygen atoms, the hydrogen lines showing clearly. The predominance of carbon monoxide bands cannot be taken as a guarantee of the presence of carbon monoxide in the sample, as indeed later chemical analysis showed. It is well known to spectroscopists that carbon dioxide gas as well as almost any organic material will break down under the extreme electrical conditions existing in a spectrum tube into carbon monoxide, which has a very strong and easily excited spectrum. These spectroscopic analyses therefore served only to show that it would be necessary to subject the samples to chemical analysis. It was at this point in the investigation that the writer called upon Assistant Professor John H. Payne of the University of Hawaii Department of Chemistry for assistance. And the Ballard-Payne collaboration has continued harmoniously since that time.

Chemical analyses were made by Dr. Payne in his university laboratory using the standard Burrell gas analysis equipment and methods. His results showed that sulphur dioxide was the chief constituent (other than steam, of course) of the solfataric gases collected. Other constituents were carbon dioxide and air, the latter being principally nitrogen and oxygen. In none of the dozen-odd samples analysed was any significant trace of combustible gases such as carbon monoxide, hydrogen, hydrocarbons, etc., found. The occurrence of definite amounts of these gases would have established beyond question of doubt the intimately volcanic origin of the Sulphur Bank gases. The amount of air present in the samples varied greatly from sample to sample, depending upon the method of collection as well as the place of collection. A sample analysis of a vertical wet collection is as follows:

Sulphur Dioxide	58.6%
Carbon Dioxide	4.6%
Oxygen	7.0%
Residue	29.8%
Combustibles	None

These are volume percentages at room temperature and pressure in Honolulu; that is, approximately 20° C and 760 mm. All analyses were conducted with saturated water vapor present, so that the percentages are those of the **dry** gases. The residue was tested spectroscopically and found to be nitrogen, as expected. The ratio of nitrogen to oxygen is seen to be approximately 4:1, the normal atmospheric ratio. The air in the samples is hence thought to be of atmospheric origin, having leaked into the porous ground and come up again with the solfataric gases. The analysis of the 1936 gases showed that so much sulphur dioxide was present, as high as 90 per cent in some cases, that any relatively rare constituents might indeed escape detection. Therefore, we decided to make the 1937 collections in such a fashion as to eliminate this large SO_2 content.

745

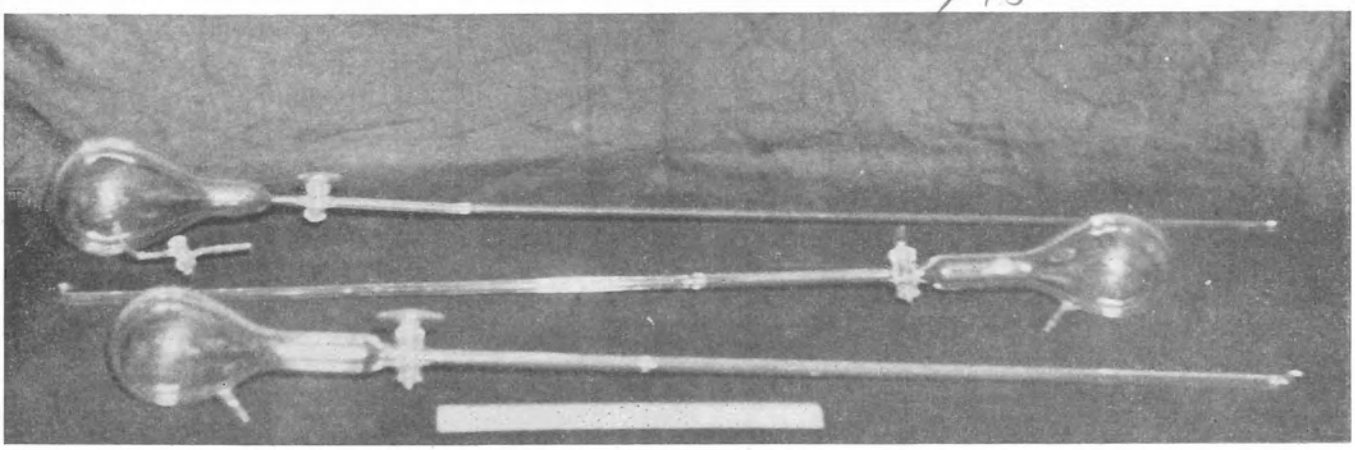


Figure 2. Improved vacuum-type volcanic gas collecting tubes. The upper tube has a capacity of 800 cc. (see Fig. 1). The two lower tubes are of the newer, sturdier construction and have capacities of 500 cc. each. Note the foot ruler which gives the scale of the figure.—University of Hawaii Photo.

Several samples of gas were collected in September 1937. As illustrated in the picture printed on page 3 of Volcano Letter Number 453 for November 1937, the gas was drawn first through a condenser which was packed with ice and salt and hence removed a large portion of the steam, then through two absorption tubes which contained a 50 per cent caustic potash solution. The function of the potassium hydroxide was to absorb the major percentage of the sulphur dioxide and carbon dioxide, allowing the minor constituents of the gas, if any, to be concentrated in the sample. Analysis of these collections showed that the absorption of the sulphur and carbon dioxides was not complete. However, the last traces of these gases were removed in the laboratory and the residue was treated with hot lime and magnesium in order to absorb the nitrogen content known to be present. The gas remaining after this operation was examined spectroscopically as shown in Figure 3 and found to consist chiefly of argon, which is known to be present to the extent of about 1 per cent in the atmosphere. No traces of the other rare gases, helium, neon, krypton and xenon, could be detected. In Figure 3 is shown the complete analytical equipment which consists of the chemical train of seven pipettes which hold the solutions to absorb the various gases, the gases being forced through the solutions by the mercury-filled leveling tube held in Dr. Payne's right hand. The gas is then forced into the long horizontal tube in the center of the picture, where upon heating the calcium-magnesium mixture its nitrogen content is absorbed. Then the gas is forced over to the right into the spectrum tube, whereupon its spectrum can be observed and measured using the wavelength spectrometer shown.

It was decided that collections should be made in which there was definitely no sulphur dioxide present, and in Decem-

ber 1937 Dr. Payne and the writer made a flying trip to Hawaii for this purpase. This time the gas was pumped through **four** absorptian tubes cantaining caustic potash, and this time no sulphur diaxide got through! Analysis of these samples showed nothing present but air.

In conclusion, one can state the results of these preliminary analyses as follows: The Kilauea solfataric gases tested cansisted of steam, sulphur vapor, sulphur diaxide, carbon dioxide, and air (that is, nitrogen, oxygen and argon). No new combustible gases and no rare gases other than argan were detected. It is hoped, however, that when larger samples can be collected, larger residues af argan can be obtained which can be studied monthly and cantinued long enaugh to include a period of volcanic activity it could readily be established whether this ratia in solfataric gases affords an index of valcanicity. It shauld alsa be af interest ta make a **complete** analysis comparable ta Dr. Allen's, particularly to see whether there has really been a marked increase in the amount of sulphur dioxide present in relatian to the steam content, as suggested above.

This pragram is being supported jointly by the University af Hawaii, the Hawaiian Valcana Research Association, and the Hawaii Natianal Park. Acknowledgment is made of the kind cooperatian on the part af the Experiment Station of the Hawaiian Sugar Planters' Association in making available the glass-

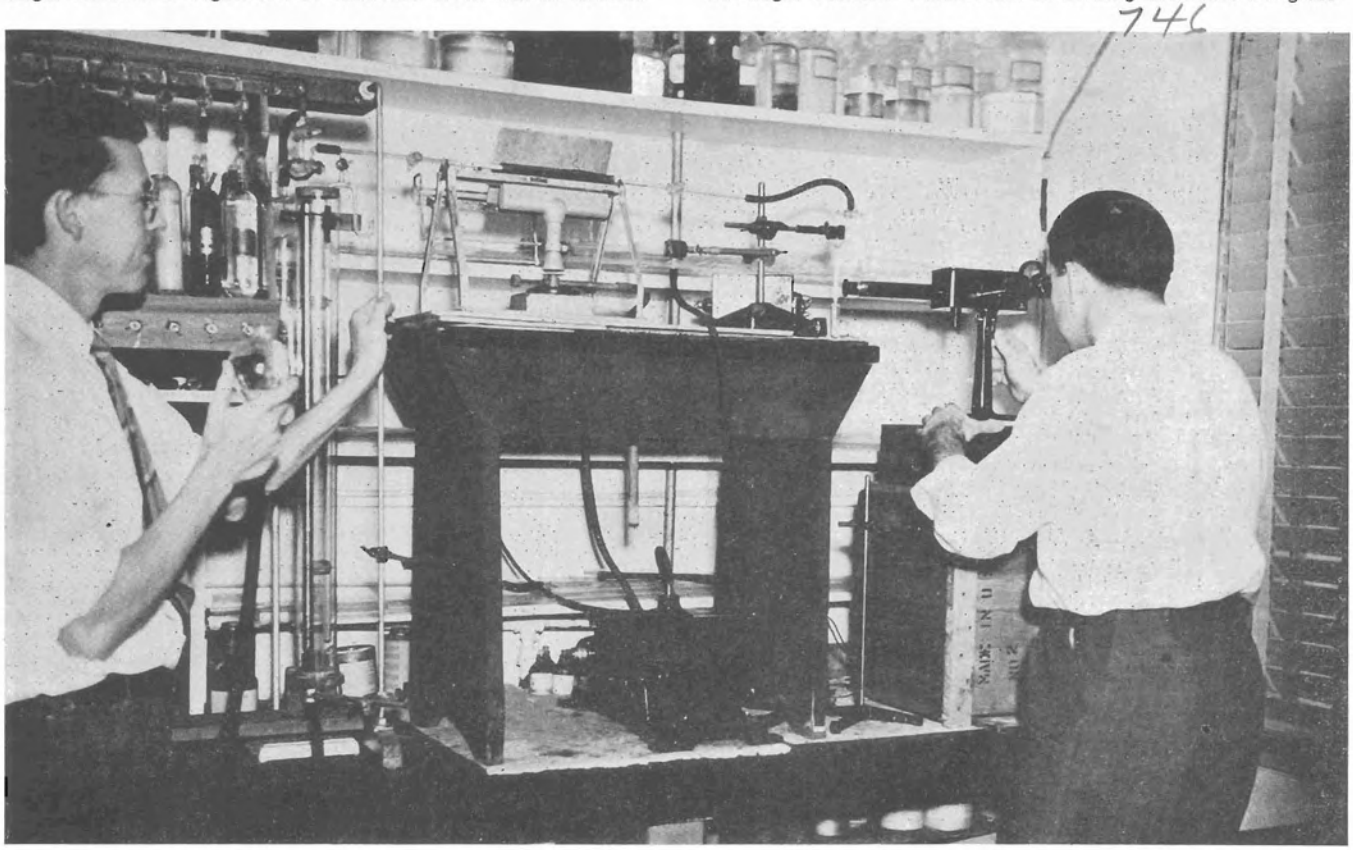

Figure 3. Apparatus set up in the University of Hawaii chemistry labaratory for the chemical and spectroscopic analysis of solfataric gases. Dr. Payne is farcing gas into the nitrogen absarption tube (center af the picture) and Dr. Ballard is measuring the spectrum of the residual gas with a wavelength spectrameter.—University af Hawaii Phata.

by mare searching **spectrographic** methods which may possibly reveal traces of helium and athër rare gases which could nat be detected by the visuol spectrascopic methods here employed. Referring again ta Dr. Allen's analyses, we would judge that his 3.7 per cent of fixed gases was air and carbon dioxide. If the sulphur dioxide content af the gases has not changed since 1922, then Allen's collections must have been very badly cantaminated with air. It is interesting to note that A. Brun of Geneva made partial analyses of these gases in 1910 and detected **no** sulphur dioxide. Twelve years later Allen detected a very definite amount of sulphur dioxide, and fifteen years still later sulphur dioxide was faund to be by far the predaminating gas, save water vapor. We are preparing for publication elsewhere a paper which will describe more fully the technical details of this program of analysis.

As regards future plans for solfataric gas anolysis, we hope to establish a fixed technic af sampling—probably the vertical wet collection method, and continue to test the sulphur dioxide vs. carbon dioxide ratio, which ratio has been in the range 10:1 to 15:1 for comparable collections. If collections could be made

blowing skill af Mr. Gow and the facilities af the spectroscopic laboratary. Obviously the successful completion af the solfataric gas analyses was made possible only through the active cooperation af Dr. Payne and of his student assistant, Mr. Luther Foster, to whom thanks are due.

Hawaiian Volcano Observatory Report for January 1938

VOLCANOLOGY

The volcanoes of Hawaii have remained quiet. The seismicity which had increased about the solstice, again trebled in value the first three weeks of January. The most notable event of the month was a very strong earthquake January 22 that centered on Maui, doing much damage there. It was very strong on Malokai, Lanai and Kahoolawe, and alarming at Honolulu and in Kohala. It was generally felt in the Hawaiian Islands.

Apparently the middle belt of this earthquake extended from central Maui westward towards Kahoolawe. The serious character of the shock raised questions of earthquake-proof canstructian in Honalulu. It is of interest that the strong 1868

earthquakes offected the eost-west foults of south end of Hawaii islond; the 1929 disostrous shocks of north Kona extended to Mauna Kea and affected a nartheast-southwest belt there; the 1938 cotaclysm affects an eost-west belt through Moui; and this series suggests a migration of fault movements on the transverse fractures across the west-northwest line of the Hawaiian Islands. The next important transverse fracture is the one crossing the north side of Molokai, which extended westward would poss Honolulu close to Diamand Head. If this fracture should move, it might be disastrous for Honolulu.

Of the meosured earthquakes 22 were from Kilauea, 5 were from Mauno Loo, and 8 were beyond Mouna Loa. Feeble shacks somewhat felt occurred January 3, 14 and 17. A slight shock wos felt in Hilo Jonuary 9. After the big Moui shock there wos marked decline in seismicity. The first week of the month had been notable for some earthquakes indicating distances of origin corresponding to north Kono and Kohala.

The following are the weekly Observatory totals for Halemaumau and the seismographs.

Week Ending	Seismicity	Slides	Crack Opening	Local Tremors and Quakes
January 9.....	16.75	2	6.5 mm.	40
" 16.....	16.00	1	0.5 mm.	49
" 23.....	17.50	2	3.0 mm.	21
" 30.....	6.75	0	11.3 mm.	21

Slides at Halemaumau

The recorded slides from the wall af the pit were:

January 5, 1:25 p.m., narth rim of pit.

January 9, 3:46 p.m., dust arose during moderate earthquake.

Januory 14, 9:25 a.m., slide from north wall, noise of falling stones heard at a distance and cloud of dust.

January 21, 9:45 a.m., north rim.

January 22, 10:03 p.m., noise of slides heard accompanying earthquake.

A fresh scar from a slide on the wall was found at Alealea pit af the Chain-af-Craters.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locatians resulted during Jonuary in aggregate movement as follows:

Week ending forenoon af:

January 7, 28 locatians, 11 opened, 3 closed, opening 6.5 mm.

January 14, 28 locations, 5 opened, 4 closed, opening 0.5 mm.

January 21, 28 locations, 10 opened, 4 closed, opening 3.0 mm.

Jonuary 30 (nine days), 28 lacations, 13 opened, 2 closed, opening 11.3 mm.

T. A. J.

* For local seismicity definition see Volcano Letter 371.
† Including teleseisms or earthquakes over 5000 km from Kilauea.

Epicenters af the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcana Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the twa subsidiary stations at Uwekahuna and the SE rim af Halemaumau respectively. The more distant shocks were located with the aid of seismogroms from Hilo and Kealakekuo. The disturbonces began at the time indicated and whenever possible, a determination af depth of focus has been made.

Januory 3, 11:36 om, very feeble, 40 miles deep under Hualalai. 20° 42.8′ N; 155° 48.0′ W.

January 3, 12:33 pm, feeble, located 47 miles deep under Mauna Loa NE rift zone. 19° 30.7′ N; 155° 25.7′ W.

Jonuary 3, 6:02 pm, very feeble, 40 miles deep under summit crater area of Mauna Loa. 19° 26.2′ N; 155° 35.8′ W.

January 3, 8:51 pm, very feeble, 1.0 mile deep, 0.5 mile SE af Pit seismagraph. 19° 24.0′ N; 155° 16.7′ W.

January 5, 2:31 am, slight, 5.0 miles deep in Hilina Kopukano Fault system, 3.0 miles N of Apuo Point. 19° 18.1′ N; 155° 11.6′ W.

Januory 9, 2:49 am, very feeble, of Kilauea origin.

Jonuary 9, 3:47 pm, moderate, 3.8 miles deep near SW rim of Kiloueo Iki. 19° 24.8′ N; 155° 15.2′ W. Dismantled Pit and Observatory seismographs. Reparted felt by many at CCC Camp, SE rim of Kilauea Crater ond by severol oround the National Park Headquarters areo.

January 9, 4:40 pm, very feeble, 3.4 miles deep and 3.5 miles NW of H.V.O. 19° 27.9′ N; 155° 18.0′ W.

Jonuary 10, 4:55 pm, very feeble, 1.8 miles deep and 2.8 miles SE af the Volcano Observatary. 19° 24.5′ N; 155° 13.5′ W.

Januory 10, 6:04 pm, very feeble, 1.3 miles deep NW rim of Kilauea Crater, 0.8 miles N NE of Uwekahuna. 19° 26.0′ N; 155° 17.2′ W.

Jonuory 10, 6:11 pm, very feeble, 4.2 miles deep in vicinity of Kipuka Puaulu. 19° 27.0′ N; 155° 18.3′ W.

January 10, 10:24 pm, very feeble, 0.8 mile deep in Byran Ledge Area, E rim of Kilauea Crater. 19° 24.6′ N; 155° 15.3′ W.

January 11, 11:37 pm, very feeble, 1.8 miles deep in Kilauea Crater, 1.0 mile SW of the Observatory. 19° 24.6′ N; 155° 16.7′ W.

January 12, 12:21 am, very feeble, 1.6 miles deep under Byron Ledge, E rim af Kilauea Crater. 19° 24.8′ N; 155° 15.6′ W.

January 13, 2:36 pm, very feeble, af shallow arigin, SE rim of Kilauea Crater. 19° 23.9′ N; 155° 16.2′ W.

January 13, 3:39 pm, very feeble, of shallow origin in orea immediately SE of Keanakakoi. 19° 24.0′ N; 155° 15.6′ W.

January 13, 3:29 pm, very feeble, of shallow origin, SE rim of Kilaueo Crater. 19° 24.4′ N; 155° 15.6′ W.

January 13, 5:45 pm, very feeble, 0.4 mile E of Pit seismograph, 0.7 mile deep. 19° 24.3′ N; 155° 16.6′ W. Dismantled Pit seismograph.

Januory 14, 6:19 am, very feeble, 1.5 miles deep near SW rim of Kilauea Iki. 19° 24.8′ N; 155° 15.2′ W.

January 14, 5:40 pm, feeble, 8.0 miles deep, along seacoast 3.5 miles S of Hilina Pali. 19° 15.0′ N; 155° 17.0′ W. Reported felt in city af Hilo.

January 15, 5:33 pm, very feeble, probably ariginated in Mauna Loa NE rift 4.0 miles NE of Puu Ulaula.

January 17, 11:39 am, feeble, 0.8 mile deep E portian af Crater, 1.0 mile E af Halemaumau. 19° 24.6′ N; 155° 15.9′ W. Reported felt on NE rim of Kilauea Crater.

January 17, 4:27 pm, very feeble, 1.0 mile deep, in Kilauea Crater near W end of Kilauea Iki. 19° 24.9′ N; 155° 15.5′ W.

January 22, 4:36 am, very feeble, located in Mauna Loa NE rift in vicinity of Puu Ulaula. 19° 32.0′ N; 155° 26.6′ W.

January 22, 10:03 pm, maderate to strang near shock, probably centered about 60 miles below the ocean surface near a point 25 miles N of Pauwala Point, Maui. 21° 12′ N; 156°

06′ W. This shock was felt throughout the Hawaiian Islands and recorded on seismographs throughout the world. It was felt most strongly on the Island of Maui and by nearly everyone. Damage to property was estimated to have been about $150,000, and included disruption of water tanks and dams, interruption of telephone service, cracked walls and roads, slides along roads and upsetting of objects in buildings. The road to Hana, Maui, was closed by slides from steep adjoining slopes. Greatest damage was in vicinity of Wailuku and Kahului. On Oahu the intensity of the shack was considerably less thon on Maui but is thought to have been greater than on Hawaii. In Honolulu mony people were alarmed and theatre patrons rushed hurriedly out of the buildings. Light flashes visible for 20 miles were reported from Hilo; radio transmission interference was reported on the shorter wove lengths. In the Volcano district, Hawaii, long swinging motions were described causing loose objects to move and tall slender objects such as floor lomps to swoy. Pheasants squawked, dogs barked and most sleepers were awakened. Buildings creaked ond doors swung on their hinges. A report from Hilo indicated that ceiling lights swung in an E NE-W SW direction. All seismographs in operation in the Hawaiian Islands were dismantled with the exceptian of the strong motion instrument at the Hawoiian Volcono Observatory. This instrument made a complete record. Felt portion of quake was thought to have lasted, one and one-half to two minutes.

January 26, 9:01 pm, very feeble, located 1.1 miles deep, in Kilauea Crater, 1.0 mile NE of Pit seismograph. 19° 24.9′ N; 155° 16.2′ W.

January 27, 5:22 om, very feeble, 2.0 miles deep, 1.3 miles SW af the Observatory in Kilauea Croter. 19° 25.2′ N; 155° 16.4′ W.

January 28, 2:23 am, very feeble, 2.5 miles deep and 0.7 mile N of Uwekahuno NW rim of Kilouea Croter. 19° 26.0′ N; 155° 17.5′ W.

January 29, 6:02 am, very feeble, probably of shallow origin neor center of Kilauea Crater.

Microseismic motion of the ground at the Observatory was strong throughout the month.

27 minutes of continuous tremor began to register at the Observatory at 3:35 am, January 19.

An unidentified portion of a teleseism began recording at Kilauea at 12h 58m 25s, H.S.T., January 24.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Holemaumau the algebraic sum of radial tilt toward or away from the Pit.

At the Observatory the totol accumulated tilt for the year ending January 30, was 6.3″ S and 0.48″ W.

Week Ending	Observatory	Halemaumou West Station
January 9	0.75″ N 53° W	5.07″ N 48° W
Januory 16	0.86″ S 5° E	6.26″ S 65° W
January 23	0.51″ S 4° W	8.70″ S 44° W
January 30	1.58″ S 30° W	4.38″ N 19° E

Week Ending	Holemaumau Southeast Station	Halemaumau Resultant
January 9	2.59″ N 87° W	1.84″ From
January 16	6.41″ N 80° W	1.28″ From
January 23	3.73″ N 57° W	3.29″ From
January 30	16.20″ S 18° W	7.45″ From

Crater Angles

Measurement of horizontal angles across Kilouea Crater from the Observatory, January 11, indicated closing of the Halemaumou value and slight opening of the Kilauea Crater value compared with similar measurements made December 22. The Halemaumau measurement from the SE Pit B. M. to NW Pit B. M. showed a decrease of 1.51″ and the Kilauea Crater value from the SE rim to Uwekahuna showed an increase of 0.67″.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcono, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations ot various ploces on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations far which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

THE VOLCANO LETTER

No. 456 monthly Department of the Interior National Park Service February 1938

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

PUBLICATIONS RELATING TO HAWAIIAN VOLCANOES
T. A. Jaggar

As supplement to an address delivered by the writer at the Annual Meeting March 31, 1932, of the Hawaiian Volcano Research Association in Honolulu, there was published in Volcano Letter No. 384, May 5, 1932, a list of publications.

Since 1932 numerous articles, popular and scientific, have accumulated as the output of workers at the Hawaiian Volcano Observatory. Many of these are on hand as reprints, one of which will be sent while they last to anyone interested who addresses The Hawaiian Volcano Observatory, Hawaii National Park.

Publications of the Observatory

The suspension of the Volcano Letter. Jaggar, Volcano Letter No. 385, May 12, 1932.

Eruption in Lake Rotorua, New Zealand. Jaggar, Volcano Letter 386, May 19, 1932.

Ash Eruptions in the Andes. Jaggar, Volcano Letter 386, May 19, 1932.

Eruption of Merapi in Java. Joggar, Volcano Letter 387, May 26, 1932.

A Note on Kamtchatkan Volcanoes. Jones, Volcano Letter 390, August 1932.

Results of One Year's Crack Measurements. Wingate, Volcano Letter 393, November 1932.

Lassen Report No. 32. Finch, Volcano Letter 395, January 1933.

Earthquake-Tidal Wave March 2, 1933. Jaggar, Volcano Letter 397, March 1933.

Puna Triangulation. Wingate, Volcano Letter 400, June 1933.

Lassen Report No. 33. Finch Volcano Letter 401, July, 1933.

What May be Learned From Tilt. Wingate, Volcano Letter 432, February 1936.

How to Make a Simple Seismograph. Finch, Volcano Letter 433, March 1936.

A Trip Up the 1935 Mauna Loa Flow. Waesche, Volcano Letter 433, March 1936.

Lassen Volcano, California. Farmer, Volcano Letter 433, March 1936.

Earthquakes in the U. S. de Vis-Norton, Volcano Letter 434, April 1936.

Volcanic Area of Bufumbira, Uganda. Palmer, Volcano Letter 434, April 1936.

The Influence of Volcanic Research in Hawaii. Joggar, Volcano Letter 434, April 1936.

University of Hawaii Summer Session. Jaggar, Volcano Letter 434, April 1936.

Hawaiian Volcano Observatory Report for February 1938

VOLCANOLOGY

Much study was given the question of the meaning of the strong earthquake that affected Honolulu January 22. Parallels exist in the history of the Observatory, and several earthquakes in the past quarter century centered under Maui.

Measurements about Halemaumau pit showed increase of motion throughaut February. Alternation between motions on the Hualalai-Mauna Loa rifts and much higher frequency on the Kilauea fractures continued. This alternation may imply lowering of lava under Hualalai-Mauna Loa after the 1929 and 1935 crises, and return of lova under Kilauea especially along the eastern rift belt, for an eruption that is near ot hand.

The following are the weekly Observatary totals for Halemaumau pit of Kilauea Crater and the seismographs:

Week Ending	Seismicity	Slides	Crack Opening	Local Tremors and Quakes
February 6.....	11.75	0	2.5 mm.	37
" 13.....	10.00	1	6.0 mm.	36
" 20.....	23.25	5	10.0 mm.	55
" 27.....	12.50	9	9.5 mm.	38

Notable shocks were a moderate one on northeast rift of Mauna Loa February 17, and one the next day at Kilauea. There were two feeble Kilauea shocks February 20 and 21. A slight shock of Mauna Loa origin dismantled the Kona seismograph February 25. These illustrate the alternation referred to. Of all measured shocks, twenty-three were from Kilauea, two from Mauna Loa, two from Hualalai, and one from Mauna Kea.

Sequence of Events by Weeks

The first week produced nothing of importance except two distant earthquakes. The second week Kilauea remained quiet. The third week showed notable increase of tremors, number and strength of earthquakes, and some slides, with decrease of tilt at the Kilauea rim and increase at Halemaumau. Seismicity was cut in half the fourth week, though slides continued: tilt at Halemaumau changed from inward to outward by 18 seconds, and at the Observatory tripled in amount westerly. The opening of cracks at Halemaumau rim increased during the month.

Slides at Halemaumau

The recorded slides from the wall of Halemaumau were:
February 8, 9:30 a.m., fresh scars and dribbling rocks SE.
February 8, 4:22 p.m., slide north wall.
February 9, 9:11 a.m., slides at north cliff.
February 14, 9:42 a.m., dribbling rocks north.
February 20, 11:35 a.m., dust from slide N.
February 20, 12:07 p.m., slide NE.
February 21, 11:10 a.m., slide NE.
February 21, 11:30 a.m., dust rising NE.
February 21, 12:05 p.m., dust rising NE.
February 25, 9:53 a.m., slide north.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations around Halemaumau resulted during February in aggregate movement as follows:

Week ending forenoon of:

February 4 (5 days only), 28 locations, 7 opened, 2 closed, opening 2.5 mm.

February 11, 28 locations, 9 opened, 1 closed, opening 6.0 mm.

February 18, 28 locations, 11 opened, none closed, opening 10.0 mm.

February 25, 28 locations, 14 opened, 1 closed, opening 9.5 mm.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Moderate Earthquakes	Distant† Earthquakes	Weekly* Seismicity
February 6..	27	10	0	0	2	11.75
" 13..	32	4	0	0	0	10.0
" 20..	39	13	1	2	0	23.25
" 27..	28	9	1	0	0	12.50

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus has been made.

January 31, 3:57 pm, very feeble, located approximately 5.0 miles ENE summit of Hualalai at a depth of 29.0 miles. 19° 43.3′ N; 155° 47.5′ W.

February 1, 8:43 am, very feeble, probably located in Kilauea SW rift zone.

February 1, 5:44 pm, very feeble, probably originated in Chain of Craters to SE of Kilauea Crater.

February 3, 12:23 am, very feeble, 0.6 mile deep in Kilauea Crater 0.6 mile NE of Halemaumau. 19° 24.7′ N; 155° 16.4′ W.

February 3, 7:09 am, very feeble, probably originated in N portion of Kilauea Crater.

Februory 6, 8:05 pm, very feeble, 25.0 miles deep, 7.0 miles NW of Humuula. 19° 45.5′ N; 155° 32.8′ W.

February 6, 10:14 pm, very feeble, 11.0 miles deep, 2.0 miles SE of Kilauea Crater. 19° 23.5′ N; 155° 15.5′ W.

February 7, 11:10 pm, very feeble, 1.1 miles deep near center of Kilauea Crater. 19° 25.1′ N; 155° 16.6′ W.

February 8, 2:07 am, very feeble, 35.0 miles deep and 3.5 miles NW of summit of Hualalai. 19° 44.2′ N; 155° 53.3′ W.

February 8, 8:20 pm, very feeble, 1.2 miles deep, SE rim of Kilauea Crater, 1.2 miles E of Halemaumau. 19° 24.5′ N; 155° 15.9′ W. Report felt at CCC Camp (ald).

February 9, 1:07 pm, very feeble, 1.5 miles deep SE portion Kilauea Crater. 19° 24.2′ N; 155° 16.2′ W.

February 14, 10:15 pm, very feeble, 3.3 miles deep 0.3 mile N of Puhimau Crater. 19° 24.1′ N; 155° 15.0′ W.

February 15, 10:13 am, very feeble, probably originated in Kilauea Crater near NE rim.

February 16, 3:54 pm, very feeble, 2.0 mile deep in SW portion of Kilauea Crater near SW edge of Halemaumau. 19° 24.6′ N; 155° 17.3′ W.

February 17, 2:18 am, moderate, 8.0 miles deep in NE rift zone, Mauna Loa near Puu Ulaula. 19° 33.0′ N; 155° 27.0′ W. Dismantled seismographs at Observatory and Pit, reported felt strongly in Kona and in Hawaii National Park. Felt slightly by many in Hilo.

February 17, 2:38 am, very feeble, 7.0 miles deep, Mauna Loa NE rift. 19° 32.0′ N; 155° 26.6′ W.

February 17, 4:05 am, very feeble, 1.3 miles deep in Kilauea Crater, near N rim of Halemaumau. 19° 24.9′ N; 155° 17.1′ W.

February 17, 8:41 am, very feeble, 2.0 miles deep near Keauhou Ranch House, 1.3 miles N by E of Uwekahuna. 19° 26.5′ N; 155° 17.1′ W.

February 18, 11:22 am, very feeble, of shallow origin in area between Keanakakoi and Lua Manu Crater. 19° 24.2′ N; 155° 15.7′ W.

February 18, 1:18 pm, very feeble, 2.0 miles deep near center Kilauea Crater. 19° 25.1′ N; 155° 16.4′ W.

February 18, 10:53 pm, moderate, 0.5 mile deep in E portion of Kilauea Crater. 19° 24.9′ N; 155° 15.9′ W. Felt only locally in Hawaii National Park near Kilauea Crater.

February 19, 3:15 am, very feeble, probably originated in NE portion of Kilauea Crater.

February 20, 1:37 am, feeble, 3.5 miles deep under SE portion of Kilauea Crater. 19° 24.4′ N; 155° 16.1′ W.

February 21, 3:45 am, feeble, 2.0 miles deep SE portion of Kilauea Crater. 19° 24.1′ N; 155° 16.0′ W.

† Including teleseisms or earthquakes over 5000 km from Kilauea.
* For local seismicity definition see Volcano Letter 371.

February 23, 1:23 pm, very feeble, probably originated NE portion of Kilauea Crater.

February 24, 2:19 pm, very feeble, probably originated near center of Kilauea Crater.

February 25, 6:00 am, very feeble, "P" lost in hour mark on Observatory record. No definite locotion but apparently of Hualalai origin. Reported felt in Kona.

February 26, 9:16 am, very feeble, of Kilauea origin.

Februory 26, 4:35 pm, very feeble, of Kilauea origin.

At 8h 46m 07s am, HST February 1, the "P" waves of a teleseism began to record at the Observatory. Distance from Kilauea 5,150 miles. Reported location was west of Aru Island in Banda Sea region of the Malay Archipelago, 4.0° S; 132.50 E. Another teleseism began to register ot 4h 5m 27s pm HST, February 4. Distance undetermined.

Microseismic motion of the ground ot the Observotory was moderate February 2, 3, 12, 13, 14, and February 21; strong the remainder of the month.

Tilting of the ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, and at Halemaumau the algebraic sum of radial tilt toward or away from the Pit.

At the Observatory the total occumulated tilt for the year ending February 27, was 3.76" S and 3.91" W.

Week Ending	Observatory	Halemaumau West Station
February 6	2.06" S 54° W	1.82" N 2° W
February 13	1.83" S 44° W	4.38" N 10° E
February 20	0.85" S 49° W	5.00" S 65° W
February 27	2.68" S 53° W	14.75" N 61° W

Week Ending	Holemaumau Southeast Station	Halemoumau Resultant
February 6	5.90" N 54° W	4.02" Toward
February 13	3.95" S 70° W	2.17" Toword
February 20	6.42" N 51° W	8.19" Toward
February 27	2.14" N 72° W	10.28" From

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory February 21, indicated no change in the Halemaumau value and slight closing of the Crater value compared with similar meosurements of January 11. The Halemaumau meosurement from the SE Pit B. M. to NW Pit B. M., showed opening of 1.42", January 11 to February 3 but closed 1.42" between February 3 and February 21 for a total no change. The Crater measurement from the SE rim to Uwekahuna showed o closing of 0.17" January 11 to February 3 and closing of 0.67" Februory 3 to February 21. Total closing 0.84".

H.H.W.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawoii, is leosed and operated by the United States Gavernment, Department of the Interior, National Park Service. The Association mointains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, r search fellows, instrumental plonts, explorations and special investigations for which there is no gavernmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, ond other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge ta members of the Association and to a restricted exchonge list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis Norton, whose address is 320 Jomes Campbell Building, Honolulu, T. H. Contributions of orticles, photographs, publications and clippings about volcano and eorthquake events, instruments and investigations are always welcome, and if suitable, will be published with due ocknowledgment.

THE MAUI EARTHQUAKE OF JANUARY 22, 1938

On the evening of January 22, 1938 at about 10:03 a moderate to strong earthquake registered on all the seismographs operated by the Hawaiian Volcano Observatory. The Hilo and Kona seismographs apparently dismantled at the arrival of the first impulse of the secondary waves. The instrument at the SE rim of Halemaumau as well as that at Uwekahuna NW rim of Kilauea Crater were dismantled shortly after the preliminary waves had started to register. At the Observatory the Bosch-Omori seismograph was dismantled within a few seconds after the beginning of the preliminary wave registration as was the vertical mation instrument. The only instrument to receive a complete record of the quake was the low magnificatian instrument at the Valcano Observatory, NE rim of Kilauea Crater. The latter was specifically designed and built in the Observatory shops to register local shocks of strong intensities. It magnifies ground movement about eleven times.

The earthquake was classified as a near shock which includes those from 100 to 750 miles distant. It was felt throughout the Hawaiian archipelago and registered on seismographs as far away as Fordham University in New York City. In this respect it differed from the usual quakes so common in the Territory, and particularly on the Island of Hawaii, which sel-

dom are felt more than a few miles from their point of origin and practically never register off the island on which they occur. Inasmuch os there are ot leost three volconoes on the Island of Hawaii which ore considered octive, earthquakes there of varying intensities and of olmost daily occurrence, are expected and do occur. On the other islonds, eorthquokes though comparotively rare, are not uncommon.

The January 22 earthquoke was an exception: it definitely was not located on the Island of Howaii. It was felt about equally on Oahu and Hawaii. The Island of Kauai was apparently least disturbed, although it was reported as being the strongest ever felt there by older residents. All indications, both instrumental and by reports, were that the center of the disturbance was in the vicinity of the Island of Moui. The exact center was difficult to locate because of the disruption of seismographs and somewhat misleading observations received from persons near the epicenter. The final location, as determined by the Observatary, by the Coast and Geodetic Survey and by the Jesuit Seismalogical Assaciatian is in very clase agreement. Toking on average af these determinations, the epicenter would be located in the ocean about eighteen miles north of Pauwala Point on the Island of Maui.

First reoctions of some af the Oahu residents were interesting. Felt quakes in Hanalulu are comparatively rore ond the people of that city ore inclined to overlaok the fact that they most certainly live in a region where earthquakes are assured, ond thot strong ones moy occur ot ony time. Consequently when this shack was felt no one suspected that such o thing os an earthquake could possibly be centered nearer Hanolulu than to Kiloueo Volcono on the Island of Hawaii. Consequently, the rodio stations and telephone communicotions between the Islands were busy with calls from Honolulu trying to find aut whether the "Big Island" had been completely blown off the mop or hod sunk into the seo. Their first thought wos thot if the shack was that strong in Honolulu, it must be terrific on Hawaii. The Observatary was swamped with calls from all directions. It is suspected that there was o tinge of disoppointment from those elsewhere who discovered that on this island the earthquake not only had been of relatively moderate intensity but thot most of the people seemed octually to hove enjoyed it.

REPORTS FROM THE SEVERAL ISLANDS

Kauai:

Reported as severest quoke in memory of older residents. Felt as two separote shocks resulting in some minor damoge to some household articles.

Oahu:

Because of the early hour at which it occurred most of the people apparently felt the earthquake. A great deal of excitement resulted. Hotels ond theaters were filled with people; at the Alexander Young Hotel elevators stuck, dancers on the roof were forced to scurry down the stairs, orchestras continued to play while entertainers went on with their performances. There was a rush from all the downtown theaters. The Waikiki Theater was completely emptied in a few minutes. The excitement of persons downtown was shared by those in private homes who rushed from their houses ta see what had occurred. Residents of Manoa Valley reported three separate shocks, at 10:03, five minutes later, and a third shock at 10:23. A check by the County palice division showed that no bridges nor roads had been damaged, no highways blocked, though apparently 40 racks rolled on the Kamehameha highway at Kipapa Gulch. The largest was about twa feet in diameter. One automobile was damaged when it struck a rock in the road, but there were no injuries. At the Oahu Prison a four pound strip of ceiling fell in one cell. Preparations were made for the removal of prisoners if the tremor continued. However, no damage apparently was done to either telephone or power lines. Damoge on Oahu seemingly wos limited to breokage of crockery ond glassware. Hanging objects swung from the ceilings and some small articles were knocked from shelves.

Molokai:

The quoke here opened cracks between two and three inches in width ond twenty five to one hundred feet in length on the east Molokoi road at Mapulehu. From Ohia to Mapulehu stone walls collapsed, otherwise damage was confined ta crockery and other household possessions.

Lanai:

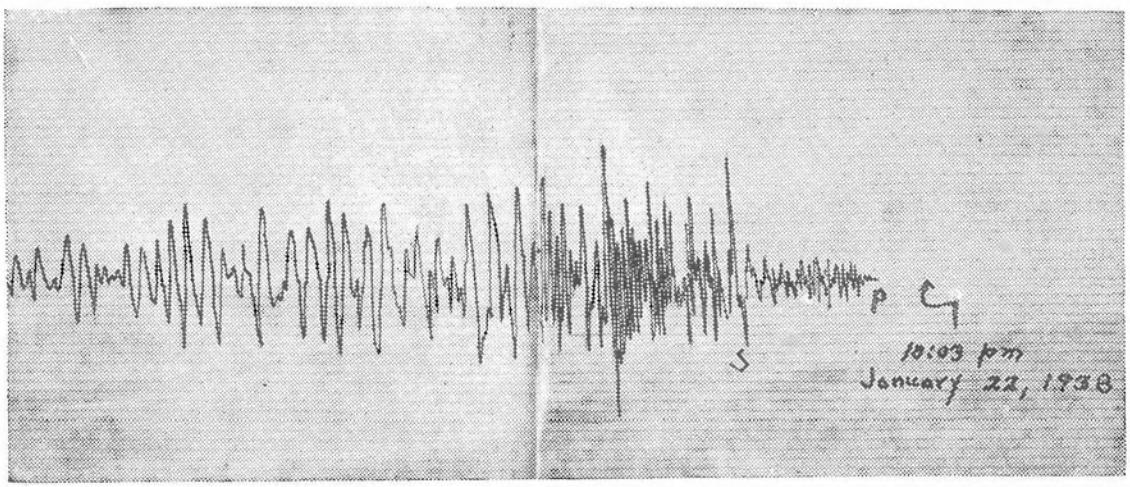
A radiogram received ot the Observotory from the monager of the Pineapple Company an Lanai, stated that "the quake did no damage ta the reservoir or water development project. There was a twa inch crack in the breakwater twenty feet leeward of the light, accampanied by slight settling. The pipe lines of the Maunalei Gulch abave and below the pumphouse were broken in several places by falling rocks. There was na damage ta pipes running over palis ta the reservoir. Slight damoge accurred to plumbing in houses. In stores some supplies were thrown on the floar. A crack 10 feet wide and 15 feet deep was reparted in the Maunalei region."

Maui:

The north caost of East Moui was prabably the hardest hit of any portion of the Territory. There the earthquoke took no toll of life, and resulted in few injuries, but inflicted considerable property damage throughout Maui's most isolated communities. Two large oil tonks owned by the Standord Oil Company were lost. Both tanks, containing diesel oil and kerosene respectively, were shattered. Thirty thousand gallons af the ail flowed into the neorby sea from the domoged tanks. The little town of Hana, Maui, was completely blacked by road slides between Poliku and Hana. The worst landslide was at Waikane. The Kaupo-Kieahu troil wos blocked by bod landslides. The Keanae stone crusher was completely covered by a londslide. The powerhouse of the Koeleku Sugar Company was thrown out of commission. Immediotely following the quake Hano was without lights for fifteen minutes. Ronches in southern Moui suffered heavy domoge as water tanks and stone walls were razed by the quake. Mr. H. A. Baldwin of the Maui Agricultural Company, Ltd. reports as follows:

"Your letter of the 4th inst. to hand some time ago and I apologize for not replying sooner; however, I have not yet been able to learn definitely just whot hoppened on Kahoolawe during the earthquake. I hope to get this information within o few doys and will write you again. I know there was considerable of a shoke up os a watertonk on the northern coast of the Island, which was set on a comparatively salid foundation, was turned over. I think part of the foundatian was built of loose rocks.

"You say you wish to know if Pauwela or Kahoolawe gat the severest shock. I think the idea that Pauwela experienced more of a shock thon other portions of Maui is erroneous. Certainly the greatest damage in the way of slides an gulch sides and road cuts was east of Pauwela. The country from Koilua on to Nahiku received what was apparently a very much heavier shock than at any time during my life, which goes back 67 years. The road has nat yet been fully opened up and there were numerous slides blocking up our ditches for considerable distances up the gulches."



Concrete buildings in Lahaina were cracked. A landslide broke the intake pipe near the Lahaina River and flumes were used Sunday ta carry water from the stream to the old intake. Storage tanks between Wailuku and Kahului were damaged. Kahului was without water for a brief period. At Wailuku the Hollister drugstore, the Kress store, and the Courthouse showed

some damage to the interiors of the three buildings. Walls of the Kahului Theater were cracked by the quake, while the fire station tower was moved one-half inch. According to Mr. Edgecomb of the US Lighthouse Service mercury wos thrown from the floats of the revolving mechanism of some of the big lighthouses on Maui. District Ranger Peck of the Hawaii National Park stationed at Haleakala on Maui reported as follows:

"The earthquake that occurred on the evening of the 22nd jarred many tons of rocks into the road, several of them very large, and a number of small cracks appeared in the pavement. Fortunately the road was not completely blocked and by noon today we had it cleared enough to make it safely passable.

"I think we can clear the road in a reasonable length of time with the one man I have for help, pravided mother earth does not soon decide to go into another dance.

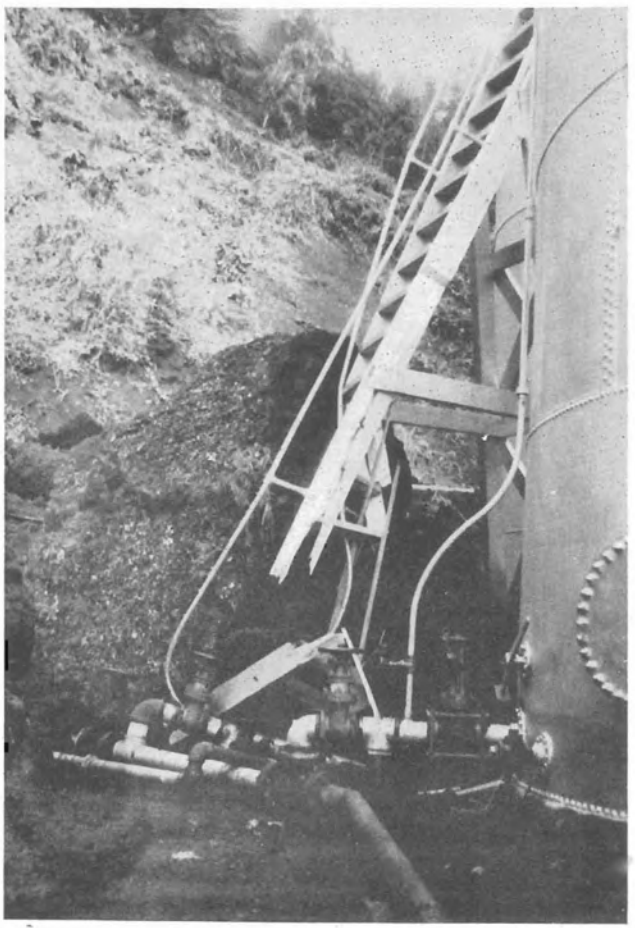
"I have not yet had time to inspect the Halemauu trail, which I fear may be in bad shape. I will inspect it very soon and report.

This seismograph record shows plainly the vibrations set up by the earthquake of January 22nd, 1938. Reading from right to left—note the normal line at the right, the intensification of the record and then the still disturbed line which shows that tremors were running through the earth long after they could be felt by human beings.

"No apparent damage was done to any of the buildings. Numerous cracks appeared in the road below the park area, some of them one and one half inches wide."

Communication with the town of Hana was completely severed, for several days. The only cammunication was by way of observation from an airplane which was chartered in Honolulu.

Hawaii:



Compared with the residents of the other islands, those on the Island af Hawaii were quite calm. The shock was felt by mast people but was na greater in intensity in most parts of the island than shocks which commonly occur here. At first Mauna Loa ar Kilauea were thought to be responsible for this earthquake. Examination of the records at the Observatary, however, changed that opinion and by the next morning the evidence indicated a near shock 100 miles or more from Kilauea. Throughout this island the earthquake motion was apparently of a slow, swaying type. Cancensus of opinion expressed by residents throughout the Big Island was that the quake, while one of the longest ever experienced, was not as severe as some of the big shocks af 1929, which climaxed the series of earthquakes, apparently centered under the Hualalai district. Certainly the intensity af this quake was not as great as that recorded June 28, 1935, when stone walls in Hilo were cracked, nar was this quake as great in intensity on the records of the Volcano Observatory as that of 11:58 p.m. the night of September 30, 1935. Reports indicate that the shock was strongly felt in the Kohala district and gradually became less intense toward the southern tip of the Island of Hawaii. In Kohala, dishes were broken in many homes throughout the district. Pictures were knocked from walls, chandeliers crashed to the floor and furniture was generally disarranged. Small landslides occurred along the Kohala Mountain road. The shock was likewise strongly felt alang the Hamakua Coast district. At the home of George Becker in Honomu many dishes were broken when china cabinets swayed and their contents crashed to the floar. At the home of John M. Ramsay, Manager of the Honomu Plantation, a large crack appeared in the ceiling going straight through the house from front to back. Despite the severity of the shock, there was no panic in any section of the island. In Hilo, people were awakened and ran from their homes but the excitement soon subsided. It appears to have been most strongly felt in the Pueo district, which usually reports earthquakes as stronger than in other sections of town. In that area some homes reported that stoves and iceboxes were moved as much as two ar three inches from their original positions.

Location of the Epicenter by Seismograms

Only one complete record of the earthquoke was available for study. That recard was the one from the low magnification instrument located ot the Hawaiian Volcano Observatory, NE rim of Kilauea Crater. Partial records were available from the US Coast and Geodetic Survey seismograph located at the University of Hawaii in Honolulu, and instruments aperated by the Volcano Observatory in Hilo, Kealakekua, Uwekahuna Bluff (Kilauea Crater), SE rim of Halemaumau, the Bosch-Omori at the Observatory and a vertical component instrument also at the Observatory. All of these were dismantled at either the beginning of the preliminary phases or a few seconds afterward. The Hilo and Kona instruments apparently dismantled with the first impulse of the secondary phase.

The location was made from azimuths determined by the first impulses of the preliminary waves on the several seismograms and from Hawaiian travel times compiled by Mr. A. E. Jones, formerly of this organization. Also available was the preliminary arrival time at the Honolulu station, which is in charge of Commander J. H. Peters, who is making an intensive study of all phases of the earthquake. Assembly af all the

information available resulted in a comparatively reliable location although considerable checking and rechecking of the data was necessary to attain this end. First reports from the Volcano Observatory placed the disturbed area 154 miles N, 55° W of Kilauea. The distance was determined by the S-P interval of 22.8 seconds from the low magnification record and the ozimuth indicated by the Bosch-Omori instrument to the same lacation. From these data the epicenter was tentatively placed at a point in the sea 20 miles S of Palaaa Paint, Lanai. Comdr. Peters in Honolulu, using the first impulse time value at the University of Hawaii in conjunction with that at the Observatary, made his preliminary lacatian at a point off the South Point af Maui, Cape Hanamanioa. The preliminary waves began to register at Kilauea at 10h 03m 20s p.m. HST; at the University of Hawaii at 1h 03m 15s p.m. HST. Using these twa time values the lacatian was definitely on a line running raughly

Baulder which hit S. O. Ca. tanks at Hana in slide fram north slape of Kauiki hill.

NE-SW through the western partian of Kahaolawe and Pauwela Paint, Maui. On the basis af direction determined from the Bosch-Omori instrument the quake was thaught to be about sixty ar seventy miles deep and in the vicinity of the channel between Maui and Kahaolawe.

When seismograms from Kana, Hilo and other statians around Kilauea were examined directions did not agree with those af the Basch-Omori. Macraseismic reports likewise did not agree completely with the preliminary location. Directions from all the statians except the Observatary converged an a general locality to the north of Pauwala Paint north of Maui. The directions were:

Volcano Observatory	N 55° W
Pit Seismograph	N 24° W
Uwekahuna	N 23° W
Hilo	N 28° W
Kealakekua	N 3° W

Meanwhile, it appeared that the Hilo and Kealakekua instruments had nat dismantled until the beginning of the secondary phase. On this assumptian the graphical methad of Isikawa was applied ta the three stations, Hila, Kealakekua and Volcana Observatory, using the Jones travel times far the S-P values determined. Mare careful study placed the Basch-Omari S-P value at 22.3 seconds. The resulting location agreed roughly with directians indicated abave, amitting the Observatary. A depth of 65 miles was indicated. This was the final lacatian as determined fram the Observatory (See Volcano Letter 455, January 1938). The epicenter thus determined was a paint 25 miles N af Pauwala Point, Maui, 21° 12′ N; 156° 06′ W. By ather methods Commander Peters had arrived at appraximately the same location. The final computations from completely assembled data of local as well as distant statians places the epicenter at the above value. Time of origin was 10h 03m 08s p.m. HST.

Rassi-Farel Intensity values for a few localities an the Island of Hawaii were

Kilauea	IV
Kealakekua	IV-V
Puu Waawaa	VI
Haakena	IV

Kohala—probably same as Puu Waawaa

Same of the local residents thought this was probably the heaviest earthquake in 20 years. Dr. Jaggar has gone over the records since 1912 and has compiled the following list of near shocks showing that their accurrence has been relatively frequent.

Quakes—Hawaiian Volcano Observatory—150 to 500 Km

1912—Oct. 13, record imperfect
Dec. 5, 279 miles
1913—July 31, 136 miles
1914—Mar. 30, 93 miles
Aug. 8, 140 miles

1916—June 6, 93 miles
June 7, 125 miles
July 23, 140 miles
1918—June 14 ..? Felt Maui?
Nov. 2 ? Felt Maui
1919—Jan. 29, 177 miles, felt in Honolulu.
Sept. 14 ? Maui?
Sept. 18 ? Felt Maui?
1920—Mar. 30, 33 miles, felt Maui?
May 15, 60 miles, felt Maui? and Honolulu.
1923—Dec. 25 ? Felt Lanai, Maui, Honolulu and Molokai.
1926—Mar. 19, 124 miles, felt Maui and Honolulu. Mauna Loa eruption came April 10.
1927—Mar. 20, 110 miles from HVO. 4:52 a.m. Seismogram illustrated Fig. 14. Bulletin March, 1927. Felt in all Hawaiian Islands.
Aug. 3, felt in Honolulu? 9:42 a.m., moderate.

Hawaiian Volcano Observatory Report for March 1938

VOLCANOLOGY

The month at Kilauea Volcano showed decline in seismicity and apening of cracks, but some increase of slides during the last two weeks. The following are the weekly Observatary totals for Halemaumau and the seismographs.

Week Ending	Seismicity	Slides	Crack Openings	Local Tremors and Quakes
March 6	27.50	0	6.5 mm.	62
" 13	11.50	1	15.0 mm.	40
" 20	4.75	0	7.0 mm.	11
" 27	11.50	10	7.0 mm.	39
April 3	5.50	4	3.0 mm.	20

Crack in Wailua pali road above Keanae flats.

The writer has examined the records of the ones of March 1926 and 1927. They are in many respects similar to that of January 22, 1938. Their distances of 124 and 110 miles respectively would be correct for East Maui with Haleakala in mind.

It is very definitely a mistake to think that eorthquakes are unlikely in other parts of Hawaii. The imposing list shown here is proof that they can and may occur at frequent intervals. Their intensity is unpredictable and consequently it would be well to take that into consideration in discussing constructional developments in the Hawaiian Islands.

Twenty-seven of the measured shocks were of Kilauea origin, four were of Mauna Loa, and four were from beyond Mauna Loa. A moderate felt shack of Kilauea origin occurred February 28, slight felt shocks occurred March 2 and 7, the first under Kilauea Crater, and the second a deep source under Kilauea.

Distant earthquakes were registered March 22 and 25, this occurrence just after equinox being usual.

Sequence of Events by Weeks

The first week produced nothing of importance except that

the tilt at Halemaumau continued to be away from the pit. This tendency lasted until March 20, and with it the Observatory cellar began to show northeasterly tilts. The second week there were some sliding and increased opening of cracks. The third week was quiet. The fourth week showed notable increase of slides, and just after the equinox the tilt at the Halemaumau cellars turned inward. The fifth week was quiet.

Slides at Halemaumau

The recorded slides from the wall of the pit were:
March 8, 4:34 p.m., small slide NE wall.
March 22, 10:19 a.m., slide heord from W cellar.
March 22, 10:30 a.m., slide from N wall.
March 25, 10:23 a.m., small slide N wall, from near bottom.
March 25, 10:55 a.m., dust cloud from W wall.
March 25, 11:03 a.m., dribble of rock, N wall.
March 25, 11:06 a.m., dust above W wall.
March 25, 11:11 a.m., dust over W wall.
March 25, 11:20 a.m., dribbling of rock N and W wall.
March 25, 3:15 and 4:15 p.m., dust above N wall.
March 26, 10:20 p.m., noise of slide in pit.
March 29, 1:25 p.m., noise below W rim.
March 29, 2:20 p.m., noise from N wall.
March 30, 9:25 a.m., noise of slide NE and NW walls.
March 30, 5:43 p.m., dust cloud over NE rim.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations resulted during March in aggregate movement as follows:

Week ending forenoon of:

March 4, 28 locations, 10 opened, 2 closed, opening 6.5 mm.

March 11, 28 locations, 15 opened, 0 closed, opening 15.0 mm.

March 18, 28 locations, 10 opened, 1 closed, opening 7.0 mm.

March 25, 28 locations, 11 opened, 0 closed, opening 7.0 mm.

April 1, 28 locations, 6 opened, 1 closed, opening 3.0 mm.

April 3	18	2	0	0	0	0	5.50

* Including teleseisms or earthquakes of over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus has been made.

February 28, 5:44 pm, very feeble, 2.1 miles deep in Kilauea Crater 0.6 mile E of Halemaumau. 19° 24.6′ N; 155° 16.2′ W.

February 28, 9:40 pm, moderate, dismantled both components of Observatory seismograph and felt at Hawaii National Park Headquarters area; 2.8 miles deep in Kilauea Crater near N rim of Halemaumau. 19° 24.8′ N; 155° 17.1′ W.

March 1, 7:58 am, very feeble, 2.4 miles deep in Kilauea Crater 0.4 mile NE of Halemaumau. 19° 25.0′ N; 155° 16.7′ W.

March 1, 1:20 pm, very feeble 1.0 mile deep near center of Kilauea Crater. 19° 24.9′ N; 155° 16.5′ W.

March 1, 1:48 pm, feeble, 1.6 mile deep under Byron Ledge, E rim of Kilauea Crater. 19° 24.8′ N; 155° 15.7′ W.

March 1, 2:40 pm, very feeble, 1.0 mile deep in NE portion of Kilauea Crater. 19° 25.4′ N; 155° 15.8′ W.

March 1, 6:24 pm, very feeble, 1.3 mile deep SE rim area of Kilauea Crater. 19° 24.4′ N; 155° 15.4′ W.

March 1, 7:29 pm, feeble, 2.1 miles deep in Kilauea Crater 0.6 mile E of Halemaumau.

March 1, 9:52 pm, very feeble; of Kilauea Crater origin.

March 1, 10:50 pm, very feeble, of Kilauea Crater origin.

March 2, 3:16 am, slight, 2.7 miles deep, Chain of Craters rift near Kokoolau Crater. 19° 21.9′ N; 155° 15.1′ W.

March 2, 4:22 am, very feeble, 1.3 mile deep SE rim area of Kilauea Crater. 19° 24.4′ N; 155° 15.4′ W.

March 3, 3:47 am, of shallow origin probably near center of Kilauea Crater.

March 3, 5:13 am, feeble, probably originated near SE rim of Kilauea Crater in vicinity of Keanakakai.

March 3, 6:00 am, very feeble, probably originated in NE portion of Kilauea Crater.

March 4, 5:53 am, probably of Kilauea origin.

March 7, 12:04 am, very feeble, 30.0 miles deep in saddle between Mauna Loa and Mauna Kea. 19° 43.0′ N; 155° 27.0′ W.

March 7, 5:56 am, moderate, 28.0 miles deep, Mauna Loa NE rift about 8.0 miles SW of Hilo. 19° 42.0′ N; 155° 32.0′ W. Reported felt by many in Hilo, Kona and Hawaii National Park.

March 8, 4:05 am, feeble, probably of Kilauea origin.

March 8, 4:06 a.m., very feeble, of shallow origin in Kilauea Crater.

March 10, 4:15 am, very feeble, probably originated in NE portion of Kilauea Crater.

March 10, 6:42 am, feeble, probably originated near Halemaumau in Kilauea Crater.

March 15, 1:30 am, very feeble, originated in NE portion of Kilauea Crater.

March 15, 11:12 am, very feeble, 1.5 miles deep, Kilauea Crater 0.8 mile E of Halemaumau. 19° 24.7′ N; 155° 16.3′ W.

March 20, 11:00 am, very feeble, 20.0 miles deep under Mauna Loa summit Crater. 19° 27.0′ N; 155° 37.0′ W.

March 21, 10:02 am, very feeble, probably originated near Halemaumau in Kilauea Crater.

March 25, 6:14 pm, very feeble, probably originated in Mauna Loa SW rift.

March 26, 9:12 pm, very feeble, of Hualalai origin. Windows reported to have rattled in building in Hookena.

March 31, 9:05 am, very feeble, probably originated in Mauna Loa NE rift.

April 3, 2:56 pm, very feeble, 4.0 miles deep, 1.7 miles NW of Kilauea Crater in vicinity of Kipuka Puaulu. 19° 26.1′ N; 155° 18.7′ W.

Teleseisms were:

Morch 7, 7h 30m 06s pm HST, beginning of unidentified portion.

March 22, 5h 5m 34s am, HST, beginning af secondary wave recording. Location by reports from U. S. Coast and Geadetic Survey, 53° N; 131°8 W, in vicinity af Queen Charlotte Island, Southern Alaska.

March 25, 5h 36m 35s am, HST, beginning af unidentified portion.

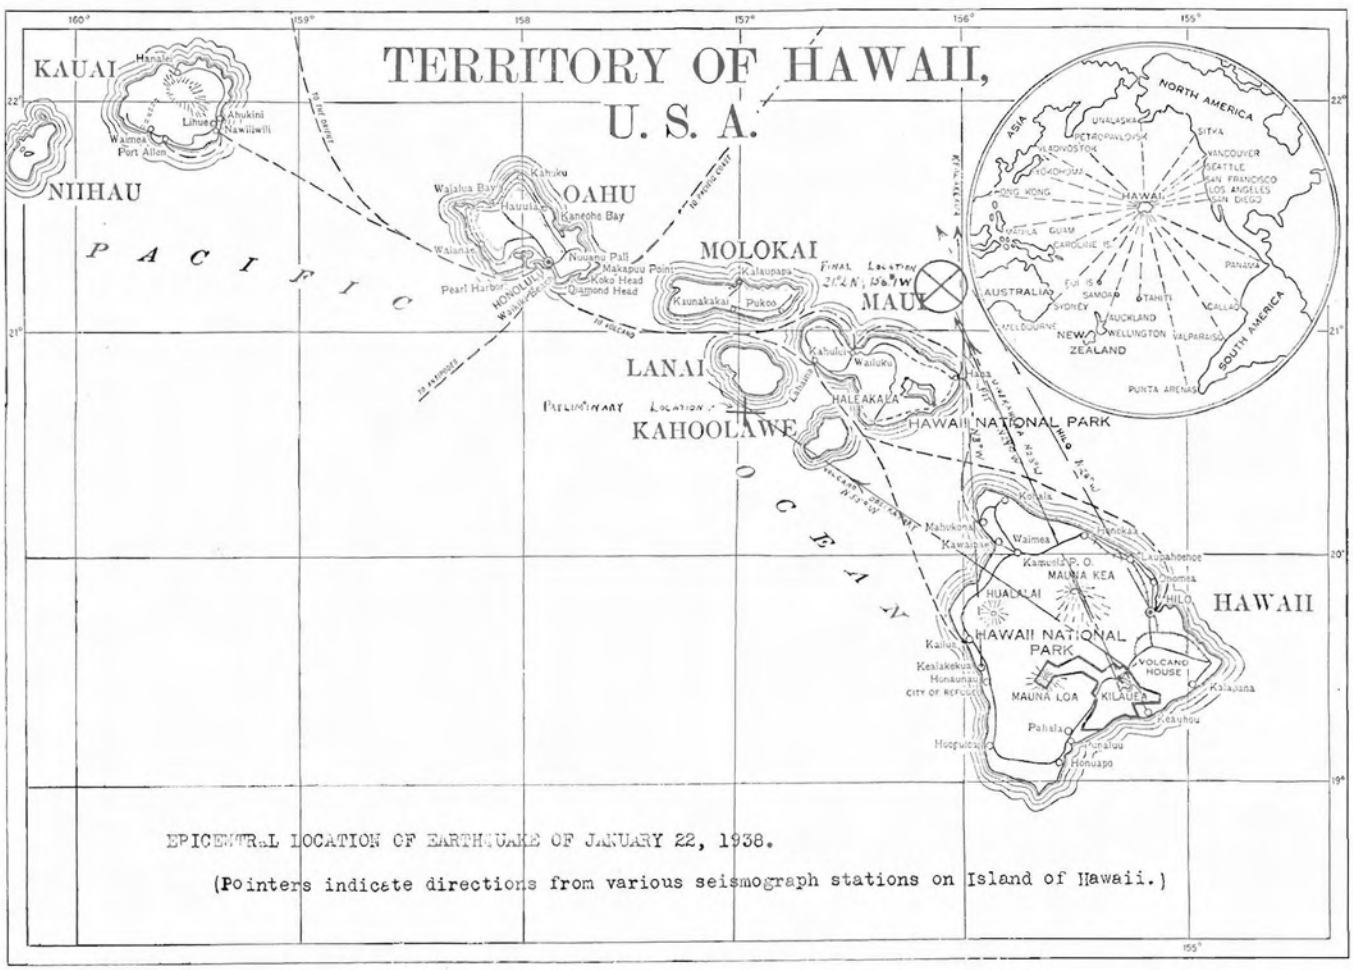
Microseismic motion of the ground at the Observatory was:

Light, March 20, 22 and 23.

Moderate, March 4, 5, 6, 7, 12, 13, 14, 15, 16, 21, 31. April 1 and 2.

Strong, the remainder of the month.

Tilting of the ground:



The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum of radial tilt toward or away from the Pit:

At the Observatory the total accumulated tilt for the year ending April 3, was 3.64"S and 4.42"W.

Week Ending	Observotory	Halemaumau West Station
March 6	1.81" S 27° W	9.54" N 85° W
March 13	1.40" N 66° E	5.90" S 74° W
March 20	0.66° S 75° W	5.90" N 80° W
March 27	1.52" S 55° W	3.07" N 12° W
April 3	0.20" N 40° E	4.17" N 80° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
March 6	2.59" S 79° W	8.94" from
March 13	6.48" N 29° W	0.51" toward
March 20	2.33" S 22° W	6.79" from
March 27	5.18" N 24° W	4.72" taward
April 3	7.52" N 13° W	2.78" toward

H.H.W.

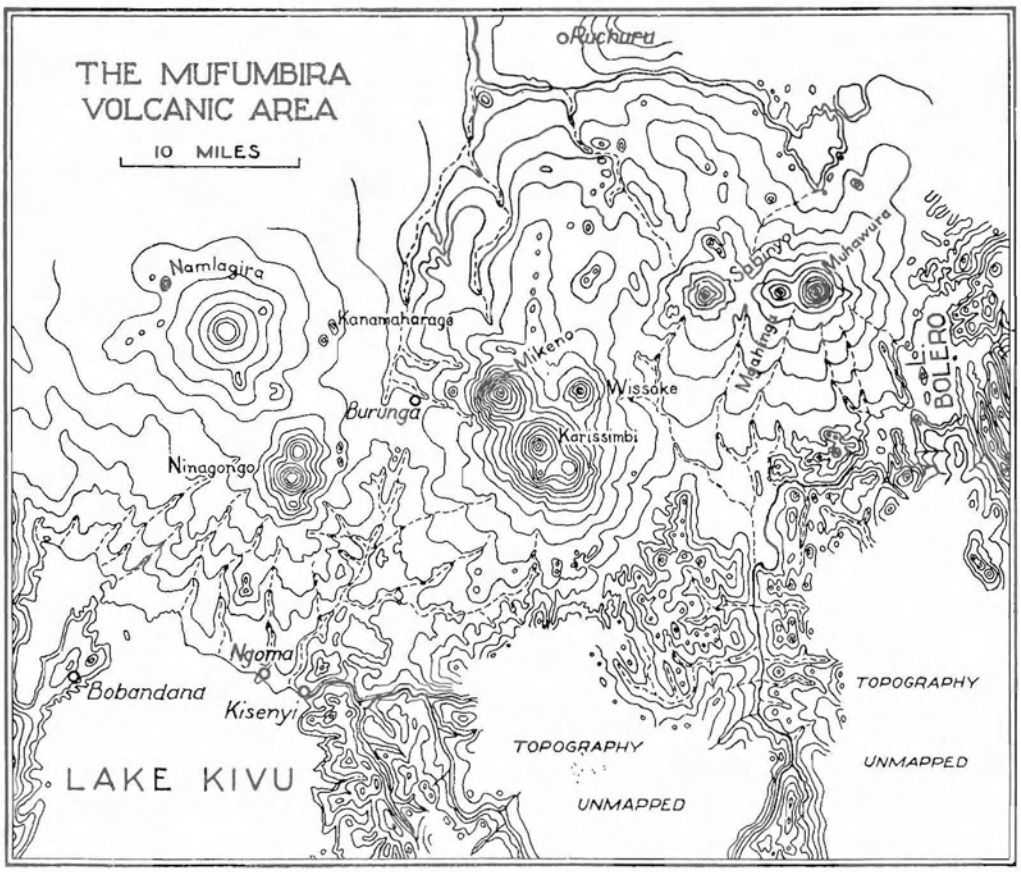
EPICENTRAL LOCATION OF EARTHQUAKE OF JANUARY 22, 1938.

(Pointers indicate directions from various seismograph stations on Island of Hawaii.)

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.



The Secretary of the Association is Mr. L. W. de Vis Narton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

THE VOLCANO LETTER

No. 458 monthly Department of the Interior National Park Service April 1938

Map of Virunga or Mufumbiro Volcanoes (after Bowen).

EXCURSION TO NYAMLAGIRA VOLCANO, VIRUNGA OR MUFUMBIRO RANGE, PARC NATIONAL ALBERT

By P. PHILIPPSON
(Translated by Jaggar)
(Bulletin de Club Alpine Belge Sept.-Dec. 1934, p. 137)

In order to reach Lake Kivu in coming from the north by the mail route of Rutshuru the automobile road crosses the Virunga volcanic belt, passing between imposing profiles of the extinct volcanoes Mikeno (4,437 meters) and Karisimbi (4,506 meters) on the East; and the active volcanoes Nyamlagira (3,058 meters) and Niragongo (3,470 meters). The most active unit and doubtless the most recent of the whole group is Nyamlagira, situated about 15 kilometers from the route that we leave, when an hour's march south from the Mission of Tongres-Ste-Marie, in order to enter upon a pilgrimage across a plain of lava of more or less ancient origin. The most recent fields of lava were crossed first showing a vegetation of ferns and shrubs growing in the crevices of the rock, whereas on the flank of the mountain proper the very old age of the lava flows shows decomposition with the formation of soil and development of forest.

Nyamlagira is a dome, shaped like a turtle back, and is thereby distinguished from the other volcanoes of the chain, some of which are pointed (Karisimbi) or truncated cones (Niragongo) and others have peaks of jagged rock (Mikeno and Sebinyo). There are fresh tracks of herds of elephants; pigeons flap their wings on all sides, brilliantly colored butterflies flit about the undergrowth or are abundant on the orchids that are both terrestrial and aerial. One of the most remarkable kinds is an orchid possessing a white flower with a scarlet heart seen in large numbers during June and July on tree trunks covered with moss; another species is much smaller with fleshy flowers that are blood red.

Along the trail there are frequent leopard tracks, and occasionally the mark of lions. At places where the lava is covered with earth and moss, the footprints of the wild animals show with remarkable distinctness.

The track had been recently cleared and we travelled without difficulty, but this appears to be not invariable; the guide told us that shortly the trail would be blocked again by trees overthrown by elephants, or by windfalls that result from storms of extraordinary violence. Some months before our visit, four native porters had been frozen to death by a storm of hail that took them by surprise on the flank of the mountain.

After a march of about two hours and a half we passed a pond in the bottom of old craters. It is the watering place of elephants, for everywhere one sees their tracks. The water, which is the product of rain, is foul. This is the only water found between here and Kannusi, which is about four hours' march beyond this place.

On emerging from the crater we reach immediately the camp called Mushumangabo that commands a superb view of the whole country. Off to the east the magnificent cones of Mikeno and Karisimbi stand out in sharp relief; to the south is Niragonga and to the west Nyamlagira. Toward the south and southwest, between the two last named volcanoes, numerous subsidiary volcanoes produce an impression of much volcanic outpouring.

We continue our march toward the camp Mumurima, on the north side of the volcano close to 2,400 meters of altitude. The trail traverses a lava plain apparently older than the first part crossed before arriving at Mushumangabo. The jungle becomes denser and in places we passed through lovely old forests where the lava with bare surfaces is not so often seen.

A few hundred meters before arriving at the camp, we crossed the bed of a lava torrent and after a short climb found ourselves in a clearing where there are huts for the porters. Here we pitched our tent and soon the night enveloped us. In the big trees around the camp a goodly number of wood pigeons roosted and out of the bush came the calls of the wood partridge, more properly called francolins. We could also distinguish the whistle of the rock rabbit (hyrax) and from the valley came the bleat of a "harness" antelope calling to its mate. The landscape by moonlight was splendid; the ocean of jungle on the Rutshuru plain extended away to infinity, framed both east and west by a border of mountains.

Early the next morning we set out for the mountain top. Vegetation gradually disappeared. First through a cold lava channel, in the midst of equatorial plants and giant shrubs, then over a desert region, we arrived at the rim of the crater. It was truly fantastic. In a depression 2.3 km. in diameter bluish water vapor and greenish sulphur fume surrounded a rocky islet: truly a vision of the magic castle of the fairy stories. From the bottom of this enormous pit 150 meters deep the dull rumble of molten lava gave the impression of fiery power, and of the role of heat as creator and destroyer within our globe.

We set up our two tents close to the edge of the crater, on a solidified platform, where the wind incessantly brought to us sulphur smells. The night is cold and the porters have disappeared. They are entombed in a long subterranean gallery. By moonshine we reach the margin of the inner crater by way of plains covered with sulphur in ebullition. The spectacle is Dante-esque: here are glowing lavas in fusion bursting through the midst of black surfaces, and active eruption cones growling and emitting jets of flame and whirls of vapor.

Early in the morning we extracted our blacks from under the lava plain (the underground gallery where they lived had only a small opening) and we climbed down into the inferno for a depth of 100 meters. Surrounded by steam and sulphur we found the walking troublesome on this lava, that may break in underfoot at any moment. We approached within a few meters one of the active cones where fused lava was boiling; strong gushes of sulphur gas prevented any long stay.

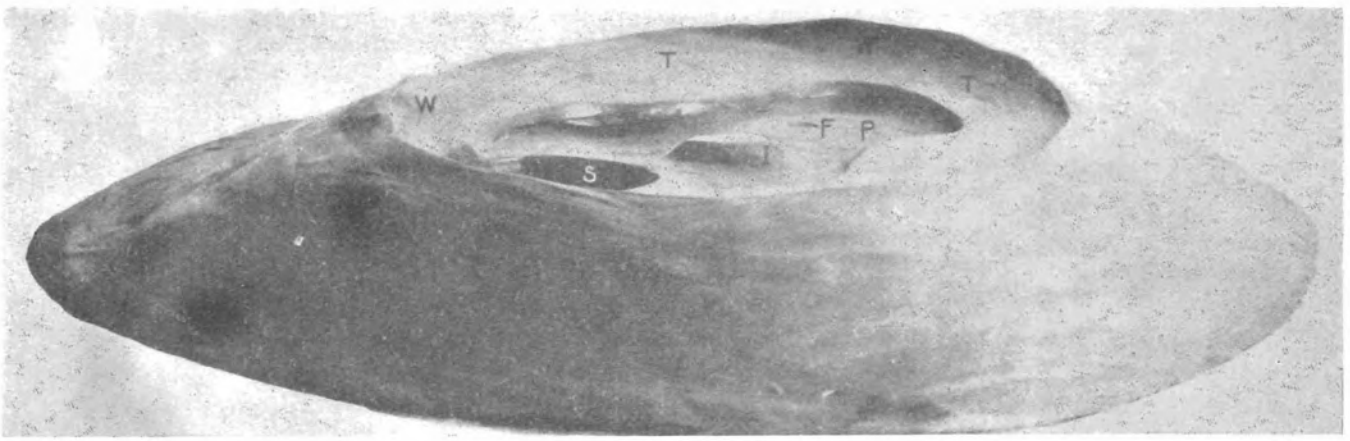
The edges of the vents, yellow with crystals of sulphur, made contrast with the red of the boiling lava; on the interior crust of these little craters from two to twenty meters in diameter, and ten in number, there are clinging long tresses of hair (filamentous lava) which are agitated by the currents of hot air. After visiting several of these cones, and dodging the lava spatter and the dense clouds of sulphur vapor that they disgorged, we finally reached the base of the central island by walking across hot lava surfaces. The island is of massive rock 80 meters high.

After studying the map, I undertook the first ascent of the craggy height and in 20 minutes reached the summit. The only difficulty was a climb through a chimney for a height of four meters. The summit is covered with volcanic gravel surrounding a shallow funnel. The panoramic view was extensive.

Toward the north on the middle platform, could be seen the active region with its cracks, chimneys and cones spouting lava, lava which poured incessantly through subterranean tunnels into the big pit in the southwestern part of the crater. The bottom of this pit forms a lower platform. The level of the bottom of this large pit, 750 meters across, was in January 1932 at elevation 2,767 meters, in January 1933, 2,810 meters, and in June 1933, 2,828 meters. This regular elevation gives a measure of the amount of lava that has poured into this lower pit from the active area amounting to about twenty million cubic meters per year. At this rate the lower pit will be filled with lava about September 1934, and the level of the middle platform will be built up in from 3 to 4 years to elevation 2,904 meters, corresponding to the height of the active sources; unless a flank eruption of Nyamlagira drains the crater and again lowers the level of the bottommost flow.

The last eruption of Nyamlagira in 1912 was by way of the new subsidiary volcano Rumoka, situated 20 kilometers south-southwest from the main dome. Another eruption in about the same direction came from the Singiro vent erroneously called Nahimbi, 6.5 kilometers from Rumoka and about 15 kilometers from Nyamlagira. Between these two outbreaks there was another in 1905 from the volcano Kanamaharagi, 11 kilometers east of Nyamlagira, and about 13.5 kilometers N.N.E. from Niragongo.

From 1901 to 1912 there were four eruptions. From 1912 to 1933 external outbreaks have not occurred, but the level of the crateral lava within Nyamlagira has always risen. It is possible to calculate almost exactly the time when the lava level will reach the elevation (2,952 meters) of the upper platform, which is also the level of the overflow of this great volcano; but usually a breach occurs elsewhere.



The study of the two active volcanoes of Albert National Park is part of the programme of the Belgian Scientific Institution. Such study will be of great interest to the geologists.

Hawaiian Volcano Observatory Report for April 1938

VOLCANOLOGY

Slides at Halemaumau pit were erratic with the greatest cancentration in numbers during the first and third weeks. The slides undoubtedly were responsible far many of the tremors reported during those periods. Seismic activity showed a slight increase toward the latter half of the manth. Occurrence af earthquakes indicating distance of origin Mauna Laa as well as Kilauea shows that movement is taking place at both volcanaes. At Kilauea tilt and angle measurements would suggest that lawering of the crater floor is continuing. A summary of data for the Kilauea station for April 1938 follaws:

Week Ending	Seismicity	Slides	Crack Openings	Local Tremors and Quakes
April 10	13.50	21	9.0 mm.	50
" 17	8.50	1	6.0 mm.	28
" 24	11.75	23	—0.5 mm.	35
May 1	12.25	11	4.5 mm.	43

Photograph of madel of summit af Nyamlagira as viewed from southwest. (W, main outer crater-wall; T, inner terrace; P, lava pit; F, fountain-basin; I, island; S, sink-hole.)

Faur of the quakes were af proper distance far Mauna Loa northeast rift, five may have originated deep under Mauna Loa elsewhere, a shock April 15 was felt strongly at Kapapala and a feeble earthquake April 12 was located twenty miles fram Kilauea. The sixteen earthquakes remaining originated under or near Kilauea crater.

Frequency of Events by Weeks

The first week produced slides at Uwekahuna, very slight tilt at the Observatory, more pronounced tilt at Halemaumau. The second week had less sliding and crack opening, and increased tilt at the Observatory. The third week showed increase of earthquakes and slides, unusual closing of the Halemaumau rim cracks and notable change of direction of tilting at the Observatory and at Halemaumau west. The fourth week produced additional slides and less tilting.

Slides at Halemaumau

The recorded slides from the wall of Halemaumau were:

April 4, 9:25 a.m., W wall.
April 4, 11:25 a.m., NW wall.
April 4, 11:44 a.m., NW wall.
April 4, 12:27 p.m., NW wall.
April 4, 1:27 p.m., NW wall.
April 4, 1:30 p.m., N wall.
April 4, 5:00 p.m., large dust cloud from NNE rim.
April 7, 7:45 a.m., W wall.
April 7, 8:05 a.m., W wall.
April 7, 8:10 a.m., NW wall.
April 7, 8:15 a.m., W wall.
April 7, 8:24 a.m., W wall.
April 7, 8:40 a.m., W wall.
April 7, 10:16 a.m., W wall.
April 7, 10:25 a.m., W wall.
April 7, 11:00 a.m., W wall.
April 7, 11:40 a.m., W wall.
April 17, 12:17 p.m., small slide NW wall, naise heard at Uwekahuna.
April 21, 12:45 p.m., dust over W rim.
April 23, 9:15 a.m., dust clouds NW.
April 23, 11:10 a.m., dust clouds NW.
April 23, 11:12 a.m., dust clouds NW.
April 23, 11:15 a.m., dust clouds NW.
April 24, 9:00 a.m., dust from W rim.
April 24, 9:10 a.m., dust from W rim.
April 24, 9:18 a.m., dust from W rim.
April 24, 9:31 a.m., dust from W rim.
April 24, 10:05 a.m., dust from W rim.
April 24, 10:12 a.m., dust from W rim.
April 24, 10:16 a.m., dust from W rim.
April 24, 10:31 a.m. dust from W rim.
April 24, 11:02 a.m., dust from W rim.
April 24, 11:08 a.m., dust from W rim.
April 24, 11:23 a.m., dust from W rim.
April 24, 12:09 p.m., dust from W rim.
April 24, 12:15 p.m., dust from W rim.
April 24, 12:23 p.m., dust from W rim.
April 24, 12:25 p.m., slides from N rim.
April 24, 2:00 p.m., slides from N rim.
April 24, 3:06 p.m., slides from N rim.
April 24, 3:12 p.m., slides from N rim.
April 25, 11:02 a.m., slide from N or NW walls.
April 25, 11:05 a.m., slide from N or NW walls.
April 25, 12:25 p.m., slide from N or NW walls.
April 25, 1:16 p.m., slide from N or NW walls.
April 25, 1:25 p.m., slide from N or NW walls.
April 25, 2:28 p.m., slide from N or NW walls.
April 28, 1:45 p.m., slide from W rim.
April 29, 10:50 a.m., moderate slide from N rim near hot crack.
April 29, 2:30 p.m., slide from W rim.
May 1, 12:25 p.m., slide from N rim.

Measurement of Halemaumau Rim Cracks

Weekly measurements of rim crack locations around Halemaumau resulted during April in aggregate movement as follows:

Week ending forenoon of:

April 9, 28 locations, 13 opened, 1 closed, opening 9.0 mm.
April 15, 28 locations, 11 opened, 3 closed, opening 6.0 mm.
April 22, 28 locations, 7 opened, 5 closed, closing 0.5 mm.
April 29, 28 locations, 8 opened, 1 closed, opening 4.5 mm.

T.A.J.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Distant* Earthquakes	Weekly† Seismicity
April 10	46	4	0	0	13.50
April 17	24	3	1	0	8.50
April 24	25	8	1	1	11.75
May 1	37	6	0	0	12.25

* Including teleseisms or earthquakes of over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

April 7, 8:28 pm, very feeble, 2.2 miles deep, Kilauea Crater, near NE rim of Halemaumou. 19° 24.9′ N; 155° 17.0′ W.

April 9, 3:00 am, very feeble, probably originated in area about 1.0 mile NE of Kilauea NE crater rim.

April 10, 7:04 pm, very feeble, of shallow origin near Byron Ledge. 19° 24.6′ N; 155° 15.4′ W.

April 10, 7:05 pm, very feeble, of shallow origin near W portion of Kilauea Iki. 19° 24.9′ N; 155° 15.3′ W.

April 12, 8:48 am, a feeble earthquake registered. It was probably of Mauna Loa origin although there was no record of it either at Hilo or Kealakekua. Distance from the Observatory was 20.0 miles.

April 15, 2:36 pm, very feeble, no location but reported felt at Kapapala Ranch. Distance from the Observatory 18.0 miles.

April 16, 12:57 am, very feeble, 22.0 miles deep in vicinity of Kapapala Ranch. 19° 18.5′ N; 155° 29.5′ W.

April 19, 2:12 am, very feeble, 1.9 miles deep in NW portion of Kilauea Crater. 19° 25.4′ N; 155° 16.8′ W.

April 19, 2:56 am, very feeble, 2.6 miles deep, in vicinity of Lua Manu Crater. 19° 24.0′ N; 155° 15.5′ W.

April 19, 8:48 am, very feeble, probably originated under NW rim of Kilauea Croter.

April 19, 8:46 pm, very feeble, of Kilauea Crater origin.

April 22, 1:04 am, very feeble, of shallow origin, SE rim area of Kilauea Crater. 19° 24.1′ N; 155° 16.2′ W.

April 23, 5:51 am, feeble, of Kilauea origin.

April 23, 8:21 pm, very feeble, located at junction of SW rift with Kilauea Crater. Reported felt at CCC camp, SE rim of Kilaueo Croter and at the Kilauea Military Camp, N rim of Kilauea Crater.

April 23, 8:22 pm, very feeble, location probably same as preceding shock.

April 24, 4:54 am, very feeble, probably located in Kilauea SW rift about 20.0 miles SW of the Observatory.

April 27, 3:42 pm, very feeble, probably originated in NE portion of Kilauea Crater.

A period of continuous tremor, lasting 20 minutes, began recording at 12:59 pm, April 5.

An unidentified portion of a distant earthquake began to register at 6h 02m 24s pm, H.S.T., April 21.

Microseismic motion of the ground at the Observatory was light April 14, 15, 16, and 21; moderate April 4, 5, 10, 11, 12, 13, 22, 23, 24, 25, 26, 30; strong the remainder of the month.

Tilting of the ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum of radial tilt toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending May 1, was 1.62" S and 1.30" W.

Week Ending	Observatory	Halemaumau West Station
April 10	0.37" S 45° E	4.32" N 76° W
April 17	1.22" S 69° W	2.83" N 80° E
April 24	1.29" N 45° E	8.05" S 84° W
May 1	0.68" N 30° W	2.29" S 66° E

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
April 10	1.59" S 49° W	1.35" from
April 17	4.96" N 64° W	1.55" toward
April 24	5.96" N 44° W	0.61" toward
May 1	3.08" N 62° W	1.11" toward

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory April 20, indicated closing of the Halemaumau value and slight opening of the crater value compared with similar measurements of February 21. The Halmoumau measurement from SE Pit BM to NW Pit BM showed closing of 2.58" and the crater measurement from the SE Crater rim to Uwekahuna showed an opening of 0.90".

THE VOLCANO LETTER

No. 459 monthly Department of the Interior National Park Service May 1938

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

ERUPTION OF NYAMLAGIRA VOLCANO 1938

(A letter from Dr. Jean Verhoogen)

Nyamlagira Volcano north of Lake Kivu in the Belgian National Park of the Congo District is a volcano of first magnitude containing lava pits in its crater similar to those of the Hawaiian volcanoes. It is characterized by dominant outflows of lava, and is distinguished as an intensely active lava producer in the midst of the interior of the great continent of Africa. It ranks with Mauna Loa and Etna, and yet is as remote from the ocean as they are near it. Its height is 3,058 meters, its position 1° 35′ S latitude, 29° 11′ E longitude. It had a voluminous eruption of lava estimated three cubic kilometers in 1894, an ash eruption from a side crater to the southwest in 1899, a lava flow in 1902 from a southern parasitic crater and it formed new mixed cones in 1904 and 1905. Other eruptions were in 1907 and 1912, the latter a flank lava flow that put out very liquid streams that reached Lake Kivu. Other activity in 1920 and 1926 shows how continuous is the release of pressure at this volcano and in 1904 there was an eruption from the bottom of the northwest corner of Lake Kivu with boiling of great surfaces of the lake accompanied by rumbling. There were possibly sixty-six eruptions in all between 1801 and 1914. (Sapper.)

From April 27 to May 26, 1935, Mr. Jean Verhoogen worked at the Hawaiian Volcano Observatory as a student sent from Belgium to prepare himself for volcanological work in the Belgian Congo. He acted as a temporary assistant at the Kilauea laboratory in order to learn the routine, and afterwards worked in graduate geological studies on California volcanoes. He published "Mount St. Helens" (Bull. Dept. Geol. Sci. Univ. Cal. 24-9-263, 1937), and took courses at both California universities; afterwards he became a teacher at Brussels.

Under date of June 12, 1938, Dr. Verhoogen writes to the Volcanologist at Hawaii National Park that he is at work on Nyamlagira volcano. When word came that a major eruption had begun the National Park Institute sent Verhoogen by airplane to Africa arriving February 1938. Dr. Verhoogen writes:

"What happened is this: you remember from Bowen's description that in September-October 1929 (N. L. Bowen, Trans. Amer. Geophys. Union 1929-30, pp. 301-307, 10 figures) the crater of this volcano consisted of a sink-hole SW, a middle platform, and an upper one, all enclosed within the walls of a caldera. The lava was issuing from tunnels in the edge of the middle platform, down the cliff margin of the sink and filling the latter.

"In 1934 the sink-hole got filled up. The lava began to pile up on the middle platform until it reached the level of the upper platform in December 1937. A few flows spread out through a gap in the caldera wall into the local 'Kau Desert' (by analogy with Kilauea, Hawaii.)

"On January 28, 1938, four fissures opened simultaneously on the SE and SW sides of the volcano, and a deluge of exceedingly fluid lava poured out. Gigantic sinking took place in the crater, and the middle platform and the sink hole appeared again. The flows from the fissures stopped quite soon.

"A new volcano was born lower down half an hour after the stoppage of the flows, on the SW side, and about a mile from Nyamlagira crater. It has been active up to June 1938 and the history is following, from up-hill down the slope.

"(a) An ever increasing number of spatter cones, all on two main lines, spitting vesicular lava in the early days of their existence, and only flames later.

"(b) A lava lake, 100 meters long, 60 meters wide, in which the lava entered from the south and disappeared all around the northern banks.

"(c) The source of a lava flow which flows down the mountain at 12 miles an hour in the open part of the channel. Total discharge has been one hundred million cubic meters from this stream (June 1938). This flow is almost entirely buried in a self-made tunnel. The construction of this tunnel was most interesting to watch.

"The intermediate lava lake on the mountain flank over the rift has had a most surprising behavior. The level sank steadily, until one day it divided up into two smaller lakes. In the southern pool, lava was fed from below the southern bank (the feeder was visible), but in the northern pool lava entered from the north. The level of the northern pool continued to lower, and as the pool got smaller and smaller, the lava which kept on entering from the same vent had to run down a bank quite a distance to the pool. Then this stream of lava solidified.

"Now there is still a circulation in the pool, lava entering apparently from below the banks. Activity on these pools consists of rising gases, folding crust, engulfment of the crust, and wild fountains which last a few minutes, so that there results a rapid sinking of the level. The level starts rising again, a crust is formed, folds appear, engulfment begins, a fountain sprouts up, and the level sinks. At the present time the whole cycle takes about 10 minutes in the southern pool, and is very irregular in the northern pool. It suggests more a geyser action than anything else.

"I have with me an optical pyrometer which works wonders, as it allows measurement in inaccessible spots. A number of measurements has shown that the lava is just as hot in the stream half a mile below its source as it is in the hottest fountain.

"I have taken still pictures, movie films and color films. The attempt to collect gases with vacuum tubes was only partially successful, as the tubes broke in transport, and the fusible tips failed to fuse. I think I have one air-free sample.

"I am expecting a spectograph. The spatter cones keep on day and night heaving huge yellow flames, almost sufficient to read by: I have not seen blue flames."

This is a perfect description of the Halemaumau activities of 1917-19, the masking and heat-holding effects of lava tunnels, the rift eruption of Kau Desert 1919-20, and the concealing of vent cracks as soon as lava covers them and forms concentric banks.

A translation showing what preceded the 1928 eruption was printed in the April Volcano Letter.

T. A. JAGGAR.

Hawaiian Volcano Observatory Report for May 1938

VOLCANOLOGY

The measurements at Halemaumau pit showed nothing exceptional until the forenoon of May 28. On that day, beginning about 6:00 a.m., almost continuous quaking developed with several moderate shocks that were generally felt. On that same day it was discovered that one large crack and numerous small ones were developing in an East-West direction, athwart the Chain-of-Craters road between Pauahi and Aloi pits, east rift of Kilauea Volcano.

The nature of the development appeared to be block faulting with downthrow to the south and there is possibly some graben faulting. This motion along the eastern rift belt of Kilauea mountain implies extension westward of the active cracks of 1924 at Kapoho, 1922 at Makaopuhi and 1923 in the upland west of Makaopuhi. A hot spot on the cracks which is killing the verdure indicates the presence of active lava below.

Diminishing seismic activity continued to the end of the month and a seismoscope was placed near the Chain-of-Craters road. Halemaumau showed no sign of breaking out.

Location of the earthquakes indicates that their epicenters were partly some five to six miles from the Observatory and a few of them were as close as two miles distant. These distances correspond to the southeast rim of Kilauea, and to Pauahi pit or slightly beyond.

The following are the local weekly data for the month at the Observatory and Halemaumau:

Week Ending	Seismicity	Slides	Crack Openings	Local Tremors and Quakes
May 8	10.50	3	2.5 mm.	36
May 15	11.75	5	5.5 mm.	40
May 22	8.75	0	3.0 mm.	27
May 29	247.75	8	4.0 mm.	726

Shocks capable of being felt occurred on May 5, of Kilauea origin, and also of May 28 to 30 as indicated above. Shocks of Mauna Loa origin occurred May 17, felt at Kapapala and Pahala. The last three weeks of the month were notable for strong distant earthquakes six in number located near Mexico, Papua, Borneo, Japan, the Philippines, and Oregon. This world-wide sympathy in time, with a similar seismic activity of down-breaking fault blocks of Kilauea, occurring a month before the summer solstice season of 1938, is worthy of close attention.

It should be noted that the accumulated tilt for the year always tending southward at the Observatory, and the tendency of levelling surveys to show the south bench marks of the Kilauea rim low with reference to the Halemaumau rim, and much evidence of crater angles closing, all tend to agree with downsinking of fault blocks. It should be noted that whenever the levelling (see October and December Volcano letters 1937) reports relative elevation of Spit bench mark (a southern rim bench of Kilauea crater) and the northwest Pit bench mark at Halemaumau, the statement that the crater floor has lowered may mean that the southern rim bench has been raised. And the statement that the Halemaumau rim is higher, may mean that the Spit bench mark is relatively lower. The northwest station on the Halemaumau rim is on the Mauna Loa side of the rift belt; Spit bench mark is on the side of Hilina Pali fault blocks. If one of the fault blocks adjoins Kilauea crater, its movement downwards might produce a relative tilt to the northwest between Spit bench mark and the western rim of Halemaumau. There has been a notable amount of northwest tilting lately in the Halemaumau southeast station. The spell of downfaulting with road cracks and earthquakes at the Chain-of-Craters rift belt is confirmatory of a trend noticed for years past, suggesting southwesterly tilt at the Observatory, and general lowering of the southern side of Kilauea crater and its floor.

Sequence of Events by Weeks

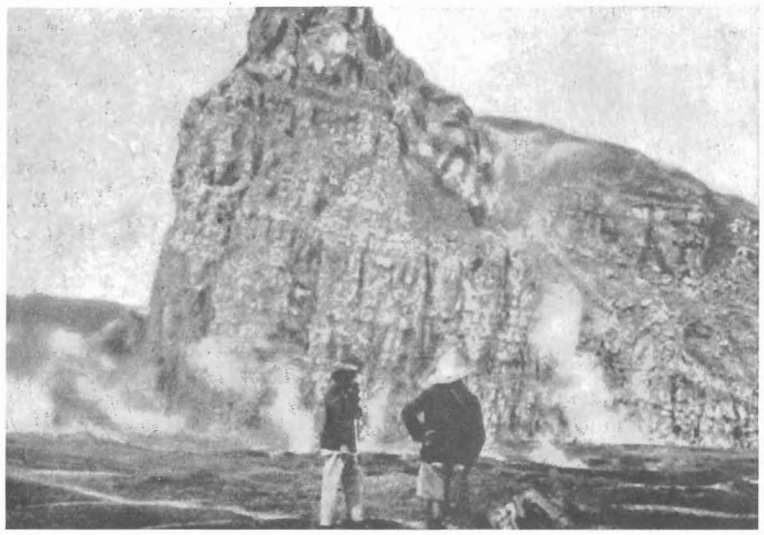
The first week produced westerly tilt at all stations and otherwise nothing exceptional. Second week showed increase of slides, quakes and opening of cracks and the Halemaumau tilt increased to the northwest. The third week was quiet, but the Observatory tilt increased to the southwest. The fourth week was the time of excessive earthquakes and numerous slides. Crack openings were moderate, Observatory tilt was away from the crater, Halemaumau west station tilted east, and Halemaumau southeast station tilted north; the resultant for these two was exceptional tilt toward the pit.

Slides at Halemaumau

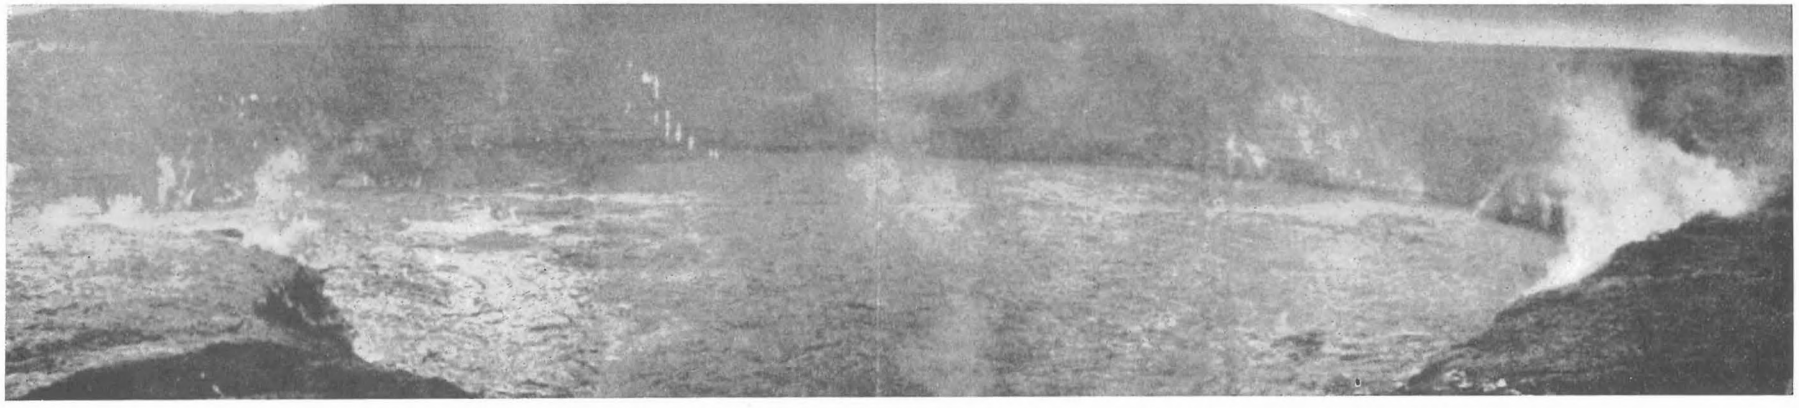
The recorded slides from the wall of the Pit were:

May 2, 3:00 p.m., slide from W rim sent up dust cloud.
May 7, 9:35 a.m., dust rose at N wall.
May 8, 3:43 p.m., slide from N rim.
May 9, 10:25 a.m., N rim.
May 11, 5:40 p.m., large dust cloud N rim.
May 12, 9:52 a.m., rocks dribbled continuously from N wall.
May 12, 11:30 a.m., dust from N wall.
May 15, 12:30 p.m., N rim.
May 25, 9:45 a.m., N rim.
May 25, 9:55 a.m., N rim.
May 27, 10:36 a.m., N rim.
May 27, 10:46 a.m., W wall.
May 27, 1:15 p.m., N rim.
May 28, 1:33 p.m., N rim.
May 28, 1:40 p.m., N rim.
May 29, 4:55 p.m., N wall.

Measurement of Halemaumau Rim Cracks



Weekly measurement of rim crack locations around Halemaumau pit resulted during May in aggregate movement as follows:



Week ending forenoon of:
May 6, 28 locations, 6 opened, 2 closed, opening 2.5 mm.
May 13, 28 locations, 9 opened, 1 closed, opening 5.5 mm.
May 20, 28 locations, 7 opened, 2 closed, opening 3.0 mm.
May 27, 28 locations, 5 opened, 0 closed, opening 4.0 mm.

Chain-of-Craters Crisis

The continuous tremor that began at 6:05 a.m. May 28 and continued until 1:00 p.m. the same day marked an outbreak of seismic motion that included numerous felt earthquakes. This unusually heavy swarm of tremors and earthquakes at the Hawaiian Volcano Observatory was accompanied by visible evidence of breaking and shearing of the ground along the Chain-of-Craters road near Pauahi crater. It was remarkable that this entire seismic spasm continuing into June was localized and shallow, and even the moderate felt earthquakes of Kilauea were not felt at all in Hilo and Pahala. While some of the shocks had epicenters near Devil's Throat, slides at that overhanging pit were not reported until June. The appearance of the tremor on the seismograph record was similar to that which appears during lava movement. Recent discovery of a new hot area in the forest near Kokoolau crater makes the

Pahoehoe lava on middle platform, central crag, and southern sinkhole of Nyamlagira Crater in 1933. (Philippson).

Puna rift belt a possible location for rising lava that has been recovering its pressure since 1924. Kokoolau is a mile toward Kilauea from Devil's Throat, and the new vapors have killed the vegetation within the last year or two. The combination of events probably represents both crustal adjustments and underground lava rising.

On the evening of May 28 a large crack across the Chain-of-Craters road was reported. At least eleven sets of new cracks had developed across the road between Pauahi and Aloi pits with general direction East-West. Seventeen individual cracks were counted on the evening of May 29.

The largest break in the asphalt paving of the road near Pauahi crater had caused the pavement to cave in in a chasm widest toward the west and narrowing half-way across the road to a three-inch crack extending on in the country rock beyond. There is evidence in the bushes away from the road of an old chasm in the rock. The cracks cross the road obliquely in plan. The widest part of the big hole in the road was five to six feet across. A hump in the paving near the Devil's Throat was higher than before as tangential compression had there been at work. This hump has been growing since the road was built some years ago, and its increase, as well as the development of the Kokoolau hot area indicates that the movements of the present crisis are accelerations of a process long continued.

The evidence for shallow depth of these earthquakes, and the correspondence of the distance of epicenters with the crack area of the Chain-of-Craters, and the location of some of the shocks much closer to Kilauea, as well as the strength of the vertical record, make it certain that we have good correspondence here between deformation of the land and epicentral distance. If an outbreak of Halemaumau follows, the expectancy will agree with the outcome. T.A.J.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Moderate Earthquakes	Distant† Earthquakes	Weekly* Seismicity
May 8	32	3	1	0	0	0	10.50
May 15	33	7	0	0	0	2	11.75
May 22	21	5	1	0	0	3	8.75
May 29	593	107	9	14	3	1	247.75

* Including teleseisms or earthquakes over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

May 5, 11:38 am, very feeble, 18 miles deep under area 15 miles east of Summit Crater of Mauna Loa and seven miles NW of Kilauea Crater. Reported felt at Kapapala Ranch. 19° 27.0' N; 155° 21.5' W.

May 5, 3:17 pm, feeble, 1.5 miles deep in SE rim area of Kilauea Crater. 19° 24.5' N; 155° 15.6' W.

May 6, 8:15 am, very feeble, 1.3 miles deep and 0.4 mile SE of Keanakakoi. 19° 23.9' N; 155° 14.4' W.

May 6, 8:18 am, very feeble, 1.7 miles deep in Kilauea Crater 1.5 miles SW of the observatory. 19° 24.7' N; 155° 16.3' W.

May 9, 2:30 am, very feeble, 0.9 miles deep near Puhimau Crater. 19° 23.6' N; 155° 14.9' W.

May 10, 3:50 pm, very feeble, 22.0 miles deep and 10.0 miles N of summit of Mauna Kea. 19° 57.5' N; 155° 27.0' W.

May 10, 10:05 pm, very feeble, 1.8 miles deep in Kilauea Crater 1.0 mile SW of the observatory. 19° 25.2' N; 155° 16.1' W. Reported felt at CCC camp NE rim of Kilauea Crater.

May 14, 3:47 am, very feeble, probably originated in Kilauea SW rift about 13.0 miles SW of the Crater.

May 15, 9:16 am, very feeble, probably of Kilauea Crater origin.

May 15, 12:44 pm, very feeble, 0.6 mile deep in SE rim area of Kilauea Crater near Keanakakoi. 19° 24.3' N; 155° 16.1' W.

May 16, 3:35 am, feeble, 11.0 miles deep in Hilina-Kapukapu Fault system. 4.0 miles south of Makaopuhi Crater. Reported felt rather strongly in Pahala and at Kapapala.

May 16, 4:36 am, very feeble, of Kilauea Crater origin.

May 17, 2:13 am, very feeble, 27.0 miles deep under Mauna Loa summit Crater. Reported felt at Kapapala Ranch and at Pahala. 19° 27.5' N; 155° 33.5' W.

May 20, 8:18 pm, very feeble, probably originated near Kokoolau Crater.

May 23, 11:33 am, very feeble, 3.2 miles under Kilauea Crater. 19° 25.1' N; 155° 16.4' W.

May 23, 11:46 am, feeble, of shallow origin near SE rim of Kilauea Crater in vicinity of Keonakakoi. 19" 24.3' N; 155° 15.9' W.

May 23, 11:50 am, very feeble, of Kilauea Crater origin.

May 23, 1:25 pm, very feeble, 1.8 miles deep in Kilauea Crater 1.0 mile SW of the observatory. 19° 25.2' N; 155° 16.1' W.

May 24, 3:15 am, very feeble, probably originated in Chain-of-Craters rift near Devil's Throat.

May 28-29: beginning at 6:05 am, May 28, a period of continuous tremor lasting 414 minutes began to record at the Volcano Observatory and ended at about 1:00 pm the same day. Within that period of 7 hours there occurred 3 moderate, 12 slight, 7 feeble and 66 very feeble earthquakes for a total of 88 disturbances excluding the tremor. The greatest concentration of these was between 6:00 and 9:00 am, during which period the tremor reached its greatest intensity and there were 3 moderate, 7 slight, 4 feeble and 52 very feeble shocks. Seismic activity continued abnormally high the remainder of the week. For the entire day, May 28, there were 3 moderate, 12 slight, 7 feeble, 85 very feeble earthquakes and 499 minutes of tremor. There was considerable decrease in activity on May 29 although seismic activity was high. On that day there occurred 2 slight, 1 feeble, 16 very feeble earthquakes and 84 tremors.

Moderate earthquakes:

May 28, 6:32 am, distance from observatory 4.0 miles.
May 28, 6:52 am, distance from observatory 4.0 miles.
May 28, 6:57 am, distance from observatory 5.0 miles.

Slight earthquakes:

May 28, 6:22 am, distance from observatory 4.3 miles.
May 28, 6:33 am, distance from observatory ? miles.
May 28, 6:34 am, distance from observatory 5.0 miles.
May 28, 6:47 am, distance from observatory ? miles.
May 28, 7:26 am, distance from observatory 2.4 miles.
May 28, 8:13 am, distance from observatory 3.8 miles.
May 28, 8:21 am, distance from observatory 5.0 miles.
May 28, 9:32 am, distance from observatory 4.6 miles.
May 28, 9:38 am, distance from observatory 3.5 miles.
May 28, 10:21 am, distance from observatory 2.7 miles.
May 28, 11:07 am, distance from observatory 3.8 miles.

May 28, 11:46 am, distance from observatory, 3.2 miles.
May 29, 9:48 am, distance from observatory 4.0 miles.
May 29, 6:32 pm, distance from observatory ? miles.
Feeble earthquakes:

May 28, 6:07, 6:19, 6:32, 6:52, 8:05, 11:42 am, 12:46 pm; May 29, 10:01 pm with distances averaging about same values as slight and moderate shocks.

The 101 very feeble earthquakes were of similar origin with the exception of one that registered May 28, 7:32 pm, which apparently originated under summit crater of Mauna Loa and May 29, 12:55 pm which indicated a distance of 18.3 miles.

Residents of the Hawaii National Park and at Kilauea Military Camp were generally owakened by the first maderate shock of 6:32 am, May 28. Houses creaked, doors and windows rattled, dogs barked, pheasants squawked and hanging objects swoyed. A few articles on shelves were overturned. The Bosch-Omori and vertical seismographs at the observatory and the Hawaiian type seismograph at the SE rim of Halemaumau were dismantled. Slight earthquakes and the tremar perceptably shaok the ground until after the moderate shocks of 6:52 and 6:58 respectively. Although these disturbonces were registered on the Hilo and Kono seismographs, the recordings were of a minor nature and the shocks were felt only a few miles from Kilauea crater.

The evening of May 28, new cracks in the Chain-of-Craters rood SE of Kilaueo crater were discavered. Eleven groups of them crossed the road between Pauahi ond Aloi croters. Near Pauahi crater and where the most northerly of the cracks crossed the road, a section of the road caved in. The cracks ran roughly in an E-W direction.

General locations of this series of eorthquokes fell within an area extending from Kilauea Crater to Alealea Crater along the Chain-of-Craters rift. Develapment of the road cracks was undoubtedly associated with these eorth disturbonces and the relationship was very close.

The maderate earthquakes of May 28 indicated greater successive distonces from the observotory. The location af that of 6:32 am was 1.9 miles deep in the Choin-of-Craters orea near Kakoolau Crater. 19° 23.3' N; 155° 14.6' W. The maderate shock of 6:52 am, probably originated near Devil's Throat and the one of 6:58 am, neor Pauohi Croter. The earlier quakes seemed to be closer to Kilauea Crater thon the later ones as though same sub-surface disturbance was from the Kiloueo Croter, southeostward.

A hump in the road neor Devil's Throot was noticeobly increased in relative height.

Depths of the earthquakes of this series ranged from shallow ones near the surfoce to two and one half miles.

A portion of the preliminary woves of a teleseism begon to register at Kilauea at 4h 37m 38s am, May 11; from news reports, it was located off W coast of Mexico 16° 8 N; 100° 7 W. The preliminary waves of a second teleseism began recording at 5h 19m 24s am, location in vicinity of East Papua, adjoining New Britain, 4,350 miles from Kilauea; 5° S; 147° E. At 6h 51m 05s am, May 19, the preliminary waves of a teleseism began to register, distance 5,750 miles, located 0.5° N, 119° E, near Borneo. May 22, 8h 58m 32s pm, the preliminary waves of an earthquake strongly felt in Japan began registering at the observatory. It was 3,815 miles from this station. At 10h 04m 01.0s pm, the same day the preliminary waves of a quake felt in Manila reached Kilauea; it was 5,500 miles distant. A portion of a teleseism whose reported location was in Oregon, U.S.A., began registering at Kilauea 12h 57m 51s pm, May 27. All time is Hawaiian standord.

Microseismic motion of the ground at the Observatory was moderate May 3, 13, 14, 18, 19, 20, 22, 23, 24, 27, 28 and strong the remainder of the month. H.H.W.

Tilting of the ground

The following tables show tilt by weeks as recorded by the observatory seismogroph and at Halemaumau, the olgebraic sum of radial tilt toward or away from the pit.

At the observatory the totol accumulated tilt for the year ending May 29 was 3.5" S and 5.7" West.

Week Ending	Observatory	Halemaumau West Station
Moy 8	0.90" S 72° W	3.19" S 43° W
May 15	0.52" S 73° W	4.38" W
May 22	1.10" S 62° W	2.44" S 67° W
May 29	0.74" N 43° E	4.98" N 73° E

Week Ending	Halemaumau Southeost Stotion	Halemaumau Resultant
May 8	6.22" S 85° W	0.98" toword
May 15	7.11" N 59° W	2.16" toward
May 22	6.25" N 30° W	4.38" toward
May 29	6.09" N 3° W	9.01" toward

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the observotory Moy 18, indicated slight opening af the Halemaumau value and closing of the crater volue compared with similar measurements of April 20. The Halemaumau measurements from the SE Pit BM to NW Pit BM showed opening af 0.08" ond the croter meosurement fram the SE Croter Rim to Uwekahuna showed closing of 1.74". H.H.W.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at variaus places on the Islond of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provisian.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis-Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcame, and if suitable, will be published with due acknowledgment.

THE VOLCANO LETTER

No. 460 monthly Department of the Interior National Park Service June 1938

T. A. Jaggar Volcanologist

PLANNED PROGRAM FOR THE HAWAIIAN VOLCANO RESEARCH ASSOCIATION

By T. A. JAGGAR

The following statement on the subject of financing technical publication of the records of the Hawaiian Volcano Observatory was presented April 1, 1938, to a group of business leaders of Hawaiian industry in Honolulu at the call of the Board of Directors of the Hawaiian Volcano Research Association. The meeting was held in the Board of Directors' room of the Hawaiian Sugar Planters' Association.

The Hawaiian Volcano Observatory under the Whitney fund of Massachusetts Institute of Technology was proposed in 1909 with a view to continuous record of Kilauea and Mauna Loa volcanoes. It aimed at an engineering science of volcanic phenomena of all kinds, in order to increase safety of life and property.

The Research Association was founded to safeguard the precious records for Hawaiian use. The financing was by $5 members and voluntary contribution of donors from year to year. It was supplemented by government.

In 1933 the government cut its appropriation. This was the fourth severe crisis that had to be met. As before the Research Association and the University saved the Volcano Observatory. This was followed by an extraordinary scientific success in 1935, namely, the printed prediction of all details of a disastrous eruption of Mauna Loa. A blasting enterprise with army aid led to the eruption stopping. This had been a plan fostered by the late honored L. A. Thurston many years ago.

In 1937 another public service was inaugurated by the association, extending the national park to the whole of Mauna Loa, and surveying for barriers to defend Hilo harbor against lava flow with United States engineers as designers.

The reason for disheartening financial crises depended on the essential instability of annual congressional appropriation 5,000 miles away. The cure is to create a sponsor for technical volcanology which is permanently Hawaiian, to assist the Government.

What is technical volcanology? It is like clinical surgery. Our population is the patient. Volcanic fever or shaking is the disease. Selecting an earthquake-resistant or lava-resistant human intelligence, will make Hawaiians different from peaples of other volcanic lands. Our publications have taught foreign scientists. A Matson ship rescued the people being overwhelmed by a volcano in Papua. The British government sent to us when volcano and earthquakes were wrecking Montserrat. When Napier was demolished, New Zealand sent to Hawaii for instruments.

Volcanology has started making a volcano science publishing the results of observation. It assists soil and water geology, safety by patrols at eruptions, prediction based on history, preparedness based on organization. Hilo and Honolulu are organized.

Hawaiian volcanology has sent forth trained men: Wood at Pasadena, Finch in California and Alaska, Stearns, Powers and Wentworth in Hawaii, Perret in Martinique, Wingate, superintendent of Hawaii National Park, Wilson in Washington, Jones in oil geophysics.

Among its by products are the park itself, Uwekahuna museum and the Kilauea military camp, volcanology in California and Alaska, the Mauna Loa and Haleakala roads. In education your association has collaborated with the University of Hawaii since the college was founded. The University now helps the Association immeasurably. The Government has assisted Hawaiian volcanology liberally since 1919, under respectively weather bureau, geological survey and national parks.

Throughout all the 26 years, however, the anchor to windward that has never dragged has been the Hawaiian Volcano Research Association. Publishing an outline of observations in monthly bulletins has informed scholars what we are doing. Critical eruptions with thousands of earthquakes, and other measurements, have left voluminous records that are still not worked up. Your present director is growing old. He knows these records, notes taken by 15 former workers. They need publication as scientific memoirs during the next 10 years.

Important discovery emerges from codifying and platting the figures of old series of measurements. In 1929 we recorded times, sizes and places of 6,000 earthquakes in three weeks, North Kona was being shaken to bits. We had no time then to do more than place instruments, cheer up the ranchers, keep the recording going, and cover as much ground as possible. It is for such a crisis that we want a simple shock-recorder at every telephone exchange. I wish we had had them in Maui and Oahu on January 22, this year, 1938.

The record of 1929 contains eruptions of Kilauea in February and July, a simultaneous eruption at Tin Can island in Tonga, and the Kona earthquakes as a sign the lava of Mauna Loa was shifting northwest to a new place. The completed story is greatly needed by the British and Tongan scientists studying Samoa and New Zealand. To publish the facts of 1929 is one of many tasks lying in filing cabinets: Notes, maps, curves, photographs and seismograms.

The next eruption of Mauna Loa in December, 1933, was farther north than 1926 and wholly in the summit crater. The northern 1929 earthquake spasm informed us Pahala and Waiohinu at the south were less in danger, the Hilo direction

in greater donger. The lovo outlets hod migrated olong the crock up the south slope to the summit ever since 1868. We studied the intervals, arrived at a probable two yeors after 1933 for an outbreak still farther north threatening Hilo, and published the focts. The flow come exactly two yeors ofter 1933 with outlet five miles forther north, it threatened Hilo, and the bombing deflected it.

This episode, of our Association's 26 yeors, is only one of many critical studies made, which are of use to this territory.

Let us look at large earthquokes: A frocture that broke open Hualolai volcano in 1800; o quake that ripped open o huge crack at Pohalo in 1823; a jalt and lova flow in Puno in 1840 a terrific one with two lovo flows including Mauna Loa in 1868. It suggests migration in the direction of Kahala and Maui.

Next a bad earthquake in Hilo in 1887; the 1929 series of shocks at Puuwaowaa; the Januory, 1938, a crash at Maui affecting Honolulu. What about the great fracture still farther northwest ocross the north side of Molokai? Projected westward it hits Diomond Head on the map, and Diamond Head is Hanolulu city.

In oll, we find o series of big eorthquake sposms, extending through a century, from the Kilauea-Mauno Loa axis to the Haleokola-Kahoolowe axis. Will the Molokai-Diomond Head axis move? It is worth study.

We hove many unstudied records. We need to learn everything possible about cycles and intervals, and obout building codes and fire safety. Mr. Stearns is perfectly sound in recolling the Haleakola eruption of the Kaupa gap obout 1750. It is merely asking, ore our records, that cost us $260,000, warth preserving in permanent form before they are mere scrap poper?

The superintendent of schools, ofter the recent eorthquake in Honolulu, wrote me osking whot to do in cose of severe earthquakes for reconstruction or discipline, in second class school buildings. I told him of California, New Zealand and Japan experiences, and referred him to the authorities.

The nationol guord officer asked me to criticize a written out problem of discipline and organization for Hilo. The terrific destruction of hospitols, roods, cliffs, drug stores, banks, water supply ond docks in Napier, New Zealond, was the model. I sketched and put in print the plan of orgonizotion.

The Chamber of Commerce, during the fright of 1935 when lovo was pouring down Woiluku volley obove Hilo, asked what Hilo should do in case of o quicker flow from o nearer vent straight toword the harbor. We consulted engineers, studied the contour maps, examined precedents and costs, and the borrier plan was the answer. Incidentolly, it turned out that such o flow is very probable.

The Association has no sufficient money in the next 10 years to print the records the society has filed. The immediate need is to publish technicol results under our own imprint before the present director is incapacitated.

The notional park does not publish technical volcanology. It is not economy to spend $260,000 through a quarter century for precious records, and leave them to fire and cockroaches.

The volconologist is no more a prophet of evil thon on army officer. They both have expensive jobs over lorge areas making war against evils.

The one has popular government money, the other is unknown. Hawaii has taken the leod to moke seismic strategy known.

A famous scientist was asked by a lady, "What use is it?" He replied, "What use is a baby?" In the 19th century we had leaf hoppers, now we have parasites; then smallpox and plagues, now vaccination and quarantine; then floods and storms, now control and resistant construction; then slums ond overgrown roads, now welfare and cantoneering. It took a century to persuade people to use common sense sciences.

Volconology is a common sense science. There was earthquoke, lavo and tidal wove destruction, now there is earthquake proof construction, oir bombing and seismic foretelling of woves. Then there was city congestion ond panic, now city planning and educotion. Then there was resistless lava filling, now constructed borriers as plonned. Then there was disaster ond deoth, now preporedness organiaztion.

The Government offers us the plan of o $125,000 reinforced concrete building for the new volcano observatory at Kilouea, with large lobarotories, library, exhibit rooms, auditorium, map room and safe storage.

A group of generous local danors has given o sum of money for beginning the publication of monagraphs.

Summarizing this question of publishing valuable scientific orchives of the Territory of Hawaii, there is needed:

1. Fifteen thousand dollars a year for the next 10 years.
2. To get the $125,000 government laboratory proposed.
3. To complete publications in technical form.
4. To appaint a scientific board to aversee publication.
5. To shift current work and routine publication gradually to Hawaii Nationol Park, with the consent of the park service.
6. To allow the volcanologist to edit finished reports as his chief remaining work.
7. To present this program to the Secretary of the Interior, from the Hawaiian Volcano Research Association, as representing the contributors who have accumulated these records.

Hawaiian Volcano Observatory Report for June 1938

VOLCANOLOGY

The crisis of downfaulting of benches south of Chain-of-Craters that began ot the end of May continued into the first week of June, but died away completely to o quiet spell at the end of the third week, or just at the time of solstice. New cracks were discovered on the trails extending north and south from Choin-of-Craters rood and obout June 5 caving in of the Devil's Throat was discavered and rock falls into that pit continued for a week. It was evident that the breakage crossing the line of the Chain-of-Craters on cracks trending ENE about Pouahi Crater were now being supplemented by the breakage northeostward along the mapped cracks that lie to the southwest of the Devil's Throat. The month of June developed no sign of Halemaumau activity.

The following ore the locol weekly data for the month ot the Observatory at Halemaumau:

Week Ending	Seismicity	Slides	Crack Openings	Local Tremors and Quakes
June 5	65.00	3	3.5 mm.	195
" 12	24.50	12	2.0 mm.	80
" 19	8.00	1	3.0 mm.	24
" 25	15.00	0	0.5 mm. closed	48

Sequence of Events by Weeks

The first week produced notable reduction in the volue of seismicity, the second week further reduction and increase of slides, the third week notable diminution of both, and the fourth week the ordinary increased frequency of local tremors and the registration of one distant earthquake, that would be expected after solstice.

Slides at Halemaumau

The recorded slides from the wall of the Pit were:
May 31, 10:00 a.m., 12:20 p.m., 12:29 p.m., dust cloud NE.
June 6, 11:20 a.m., 5:30 p.m., N rim.

June 8, 9:20 a.m., N rim.
June 9, 8:45 a.m., 8:50 a.m., 3:15 p.m., N rim.
June 10, 9:55 a.m., 10:45 a.m., 10:58 a.m., N rim.
June 12, 12:35 p.m., 1:25 p.m., 1:40 p.m., N rim.
June 17, 5:20 p.m., N rim.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim cracks located around Halemaumau pit resulted during June in aggregate movement as follows:

Week ending forenoon of:
June 3, 28 locations, 7 opened, 6 closed, opening 3.5 mm.
June 10, 28 locations, 8 opened, 5 closed, opening 2.0 mm.
June 17, 28 locations, 5 opened, 2 closed, opening 3.0 mm.
June 24, 28 locations, 2 opened, 3 closed, closing .05 mm.

Chain-of-Craters Crisis

During the week ending June 5 new cracks were discovered on the road to Ainahou Ranch leading south from Pauohi Crater; these were extensions of the cracks which had fractured the Chain-of-Craters road. Eight distinct groups of cracks were counted on the Ainahou road and one on the road leading toword Puu Huluhulu about two hundred yords from the main road leading east. All the older cracks showed some evidence of opening and in some coses down-faulting to the south was pronounced.

On June 6 cracking of the ground around Devil's Throat was discovered and there was evidence of slides from the rim of this pit within the post twenty-four hours. Most of the slides had occurred at the east and south rim, at 2:30 p.m. June 6 rocks were heard falling in Devil's Throat, and cracks were noticed in the masonry wall on its southwest side. Some new cracks were seen on the opposite side and it was evident that the circle of the pit was under stress on all sides. Rock falls continued in this pit during the remainder of the week, and the area was closed to visitors. T.A.J.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Distant*	Weekly† Seismicity
June 5.....	158	31	3	2	1	1	65.00
June 12.....	68	9	3	0	0	2	24.50
June 19.....	18	5	1	0	0	1	8.00
June 26.....	40	6	2	0	0	2	15.00
July 3.....	43	10	1	1	0	0	18.75

* Including teleseisms of earthquakes over 5000 km. from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus has been made.

May 30, 1:43 am, slight, 1.3 miles deep in SE portion of Kilauea Crater, 0.6 mile E of Pit Seismograph. 19° 24.4′ N; 155° 16.5′ W.

May 30, 11:52 am, very feeble, of shallow origin in rifts 1.2 miles SW of Pauahi Crater. 19° 21.6′ N; 155° 14.5′ W.

May 30, 8:54 pm, very feeble, probably originated in Kilauea SW rift about 15 miles from the crater.

May 31, 1:13 am, very feeble, probably of shallow origin, vicinity of Hiiaka crater.

May 31, 1:19 am, very feeble, of shallow origin in rifts 0.5 mile SW of Pauahi crater. 19° 22.0′ N; 155° 14.0′ W.

May 31, 4:53 am, very feeble, 1.3 miles deep under SE rim of Kilauea crater. 19° 24.5′ N; 155° 15.8′ W.

May 31, 5:58 am, feeble, originated at junction of Lele o Kalihipaa and Kalanaokuaiki Palis, 1.7 miles SW of Pauahi crater. 19° 21.4′ N; 155° 14.8′ W.

May 31, 2:16 pm, very feeble, of shallow origin, vicinity of Hilina Pali. 19° 18.8′ N; 155° 16.3′ W.

June 1, 10:27 am, feeble, 3.0 miles deep in area immediately S of Kilauea Iki. 19° 24.8′ N; 155° 15.2′ W.

June 1, 10:38 am, moderate, 7.0 miles deep in Hilina Pali area about 3.0 miles N of Apua Point. 19° 18.2′ N; 155° 11.5′ W. Dismantled seismographs at observatory and SE rim of Halemaumau.

June 1, 8:03 pm, very feeble, probably originated in vicinity of Pauahi crater.

June 2, 3:25 am, very feeble, 1.0 mile deep in Kilauea crater, SE rim cracks 0.4 mile W of Keanokakoi. 19° 24.2′ N; 155° 16.4′ W.

June 2, 4:42 am, very feeble, 12.0 miles deep, Mauna Loa NE rift 4.5 miles NE of Puu Ulaulo. 19° 34.5′ N; 155° 24.5′ W.

June 2, 8:24 am, very feeble, 4.3 miles deep, N rim area of Kilauea crater. 19° 26.1′ N; 155° 16.7′ W.

June 2, 3:33 pm, slight, 15.0 miles deep, Kilauea SW rift near Kooe, 3.5 miles SW of Kilauea crater. 19° 21.7′ N; 155° 19.5′ W.

June 2, 8:55 pm, very feeble, of shallow origin under Byron Ledge, E rim of Kilauea crater. 19° 24.6′ N; 155° 15.7′ W.

June 2, 10:10 pm, very feeble, 1.8 miles deep under NE portion of Kilauea crater. 19° 25.2′ N; 155° 16.2′ W.

June 4, 2:48 am, very feeble, 0.7 mile deep, SE rim of Kilauea crater. 19° 24.3′ N; 155° 15.9′ W.

June 4, 7:57 pm, very feeble, probably originated in Kilauea crater, near N rim of Halemaumau.

June 4, 9:46 pm, very feeble, 0.8 mile deep, NE portion of Kilauea crater, 0.9 mile S by E of Volcano observatory. 19° 25.2′ N; 155° 14.8′ W.

June 5, 1:18 am, very feeble, of shallow origin, near center of Kilauea crater.

June 5, 1:47 am, feeble, 1.0 mile deep near center of Kilauea crater, 0.6 mile NE of Pit seismograph. 19° 24.7′ N; 155° 16.7′ W. Reported felt by mony in Hawaii National Park.

June 6, 1:14 am, feeble, probably originated in cracks about 1.0 mile W of Hiiaka crater. Reported felt by many in Hawaii National Park.

June 6, 7:46 am, very feeble, probably originated in Chain-of-Craters area, vicinity of Hiiaka and Devil's Throat.

June 6, 11:53 am, very feeble, probably originated in rifts, 1.0 mile W of Pauahi crater.

June 7, 11:59 pm, very feeble, 1.7 miles deep under Byron Ledge, E rim of Kilauea crater. 19° 24.9′ N; 155° 15.6′ W.

June 8, 12:07 am, very feeble, 1.8 miles deep in E portion of Kilauea crater. 19° 24.8′ N; 155° 15.9′ W.

June 8, 5:39 am, feeble, of shallow origin in fault blocks along NE rim of Kilauea crater. 19° 25.7′ N; 155° 15.8′ W. Felt by several around National Park Headquarters area.

June 8, 8:32 pm, very feeble, thought to have originated in NE portion of Kilauea crater.

June 9, 7:17 am, very feeble, of shallow origin, SE rim area of Kilauea crater. 19° 24.3′ N; 155° 15.8′ W. Reported felt by few in the National Park.

June 10, 12:27 am, very feeble, 1.1 miles deep in E central

portion of Kilauea crater. 19° 24.8′ N; 155° 16.2′ W.

June 10, 12:51 am, feeble, 1.4 miles deep, E portion of Kilauea crater near Byron Ledge. 19° 25.0′ N; 155° 15.8′ W. Reported felt at new CCC Camp and by residents along NE rim of Kilauea crater.

June 12, 3:39 pm, very feeble, of shallow origin in Kilauea crater about 1.2 miles NE of Pit seismograph. 19° 25.0′ N; 155° 16.7′ W.

June 14, 12:13 am, 1.5 miles deep in NE portion of Kilauea crater. 19° 25.4′ N; 155° 15.9′ W.

June 17, 5:18 am, very feeble, 0.5 mile deep, E portion of Kilauea crater. 19° 24.8′ N; 155° 15.8′ W.

June 17, 7:34 pm, very feeble, probably of shallow origin in NE portion of Kilauea crater.

June 18, 6:26 am, feeble, 1.1 miles deep, in N portion of Kilauea crater. 19° 25.5′ N; 155° 15.4′ W.

June 19, 12:55 pm, very feeble, 1.3 miles deep near center of Kilauea crater (NE rim area of Halemaumau) 19° 25.0′ N; 155° 16.8′ W.

June 19, 6:59 pm, very feeble, probably originated in NE portion of Kilauea crater.

June 20, 10:01 am, very feeble, 1.0 mile deep in N portion of Kilauea crater about 1.0 mile NE of Uwekahuna. 19° 25.9′ N; 155° 16.6′ W.

June 20, 5:22 pm, very feeble, 2.2 miles deep, Chain-of-Craters, near Pauahi crater. 19° 22.4′ N; 155° 13.7′ W.

June 23, 5:46 am, feeble, 1.2 miles deep E portion of Kilauea crater. 19° 24.8′ N; 155° 16.0′ W. Reported felt at new CCC camp and at the observatory.

June 23, 5:53 am, very feeble, of shallow origin near center of Kilauea crater, 1.0 mile NE of Pit seismograph. 19° 24.9′ N; 155° 16.4′ W.

June 26, 1:45 am, feeble, 1.8 miles deep in E portion of Kilauea crater. 19° 24.8′ N; 155° 16.0′ W.

June 27, 1:58 pm, very feeble, 0.8 mile deep, E rim area of Kilauea crater. 19° 24.8′ N; 155° 15.9′ W.

June 27, 3:23 pm, very feeble, of Kilauea crater origin.

June 28, 12:30 pm, very feeble, probably of shallow origin in Kilauea crater near E rim of Halemaumau.

June 30, 11:42 pm, very feeble, 19.0 miles deep under Mauna Loa, 3.0 miles NE by N of Summit crater. 19° 32.2′ N; 155° 33.8′ W.

July 2, 1:29 pm, very feeble, 21.0 miles deep, Mauna Loa NE rift, 9.0 miles NE of Puu Ulaula. 19° 35.5′ N; 155° 20.2′ W. Reported felt strongly at Kapapala Ranch.

July 2, 2:20 pm, slight, 8.0 miles deep in Chain-of-Craters rift 6.0 miles SE of the Valcano observatory. 19° 23.0′ N; 155° 11.5′ W. Reported felt at Kapapala and in National Park area.

July 2, 3:16 pm, feeble, 10.0 miles deep, in Kilauea SW rift 6.0 miles SW of the crater. 19° 22.0′ N; 155° 22.2′ W.

Distant Earthquakes

May 30, "P" waves at 4h 09m 03s am, located 3660 miles from Kilauea. 20° 4′ S; 169° 4′ E in the Solomon Island area.

June 8, "S" waves at 9h 7m 25s am, origin in the Malluca Sea, Dutch East Indies, 5550 miles from Kilauea. 3° 1′ S; 125° 7′ E.

June 9, "P" waves, 11 h 35 m 22s pm, originated off NE coast of Formosa, 5000 miles from Kilauea. 25° 2′ N; 124° 6′ E.

June 15, "P" waves, 3h 56m 22s pm, off the SW tip of Kyushu Japan along E border of China Sea. 29° 2′ N; 127° 7′ E. Distance 4750 miles.

June 20, unidentified portion began to register at 3h 50m 04s am.

June 23, "P" waves at 2h 34m 43s am, located in the vicinity of New Hebrides, 3615 miles from this station. 19° 1′ S; 168° 9′ E.

Hawaiian standard time used in above reports.

Microseismic motion of the ground at the observatory light June 10, 12, 14 to 25 and June 30 to July 3; moderate May 30, June 2 to 6, June 9, 11, 13 and 26 to 29, dates inclusive. It was strong May 31, June 1, 7 and 8. H.H.W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the observatory seismograph and at Halemaumau, the algebraic sum of radial tilt toward or away from the Pit.

At the observatory the total accumulated tilt for the year ending July 3 was 3.76" S and 6.42" W.

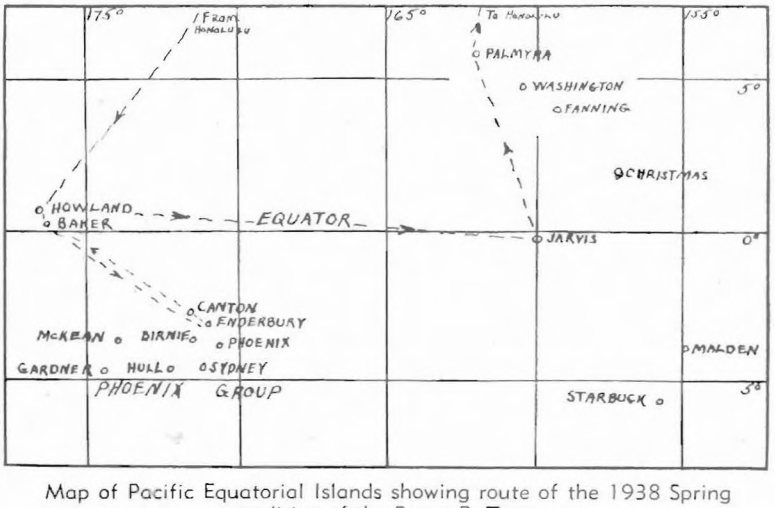
Week Ending	Observatory	Halemaumau West Station
June 5	0.75" S 42° W	6.20" S 16° W
June 12	0.16" S 46° E	8.02" N 68° W
June 19	0.67" N 27° E	4.44" W
June 26	0.54" N 12° W	4.32" S 78° W
July 3	0.62" N 10° W	2.18" S 81° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
June 5	7.91" S 27° E	9.56" from
June 12	1.65" N 69° W	5.85" from
June 19	6.54" N 35° W	1.85" toward
June 26	10.11" N 85° W	2.33" toward
July 3	4.28" N 55° W	1.80" toward

Crater Angles

Measurement of horizontal angles across Kilauea crater from the observatory June 17, indicated closing of both the Halemaumau value and the total crater value. The Halemaumau measurement from the SE Pit BM to NW Pit BM showed closing of 0.84" and the crater measurement from the SE crater Rim to Uwekahuna showed closing of 1.66".

H.H.W.



THE VOLCANO LETTER

No. 461 monthly Department of the Interior National Park Service July 1938

Hawaii National Park
Edward G. Wingate Superintendent

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

Map of Pacific Equatorial Islands showing route of the 1938 Spring expedition of the Roger B. Taney.

AN EQUATORIAL CRUISE

By Hugh H. Waesche, Assistant Geologist

For some years the Department of the Interior of the United States government has sponsored and maintained colonists on the tiny Pacific Equatorial Islands, Howland, Baker and Jarvis. Reference to the accompanying map will show their location to other islands. These pin-points of coral sand are not suitable for sustaining human life as they are practically of desert climate. This has necessitated regular trips to the Islands to deliver supplies to, and replacements in, the colonizing personnel. The colonists who are young Hawaiian men are transferred from island to island and are not allowed to remain away from their homes in Hawaii for more than nine consecutive months at a time. Transportation to and from the islands is part of the regular duties of the U. S. Coast Guard. The Cutter, "Roger B. Taney," makes about three trips per year to these Islands, usually late autumn, early spring and mid-summer.

Mr. E. G. Wingate, superintendent of Hawaii National Park, conceived the idea of some member of the Observatory staff making one of these trips to make general observations, the main issue being the practicability of establishing seismograph stations as an aid in seismological studies of the mid-Pacific areas. Selected for this reconnaissance were Messrs. S. H. Lamb, Park Naturalist, and Hugh H. Waesche, Assistant Geologist of the Hawaiian Volcano Observatory. Mr. Lamb was to make natural history studies of fauna and flora, and Mr. Waesche was to set up instruments for seismometric studies.

There was no opportunity to construct a conventional seismograph. The alternative was to take shock recorders of the mercury cup, annunciator type, developed during the past year by Dr. T. A. Jaggar for use on the Island of Hawaii. These instruments are of little value for recording distant earthquakes but have been of value in studies of local shocks. They are relatively sensitive and will readily indicate the very feeble earthquakes which are not generally felt here in Hawaii. These shock recorders register only maximum intensity for any particular shock giving no indication of phase. They are designed for use by people who have no technical training whatever. Registration of any earthquake is accomplished by annunciators which show a number from one to six, depending on the intensity of the earthquake. Once an earthquake has recorded, the value remains until reset to zero manually, by the observer. If a number of such seismoscopes were well distributed over an area, they should show relative increases of intensity toward the epicenter from all directions with diminishing values in the opposite directions. As no seismologists or otherwise scientifically trained men were among the colonists of the Equatorial Islands the shock recorders were apparently the most desirable; also they were easily portable and could be set up in any given locality with only a screw driver and a pair of pliers in a few minutes. No record paper was necessary, with the other complications which go with recording devices either on smoked paper or by photographic means. All that was necessary was a solid base and daily observation. These were assured.

Two of the shock recorders were available so were crated and prepared for shipment to Honolulu. No definite locality was predetermined for their placement. They were to be placed on the most desirable islands with regard to location and per-

sonnel. Tentatively chosen were Howland and Jarvis if landing were easy; they are widely separated giving a desirable variation of location. On arrival in Honolulu the instruments were put aboard the Cutter and preparations made for the expedition.

The "Taney" sailed from Honolulu at 5:00 p.m. Sunday, February 16, 1938. After four rather uneventful days the party arrived off Howland Island. At 7:00 a.m., March 4, a change in the colony personnel was made but no supplies were taken ashore. That afternoon a landing was made through heavy surf at nearby Baker. Originally Howland Island had been considered as the probable location of one of the shock recorders. However, the day before arrival there, Mr. Black announced that a colony was to be established on Canton Island in the Phoenix Group and suggested that one of the shock recorders be placed on it as the greatest number of more technically skilled colonists were to be there, and that both a shelter and concrete base for the instrument would be found, left by the eclipse expedition the preceding year.

Landing supplies at Enderbury.

Howland Island is located about forty miles north of the Equator and about one hundred miles west of the 175th meridian. Baker Island is about thirty-five miles S. by E. of Howland and the two might well be considered together. They are similar in appearance, geology, and climate. Both are of coral, shells, and lithothamnia and might well have been atolls or parts of atolls formerly although there is no water in their interiors at present. In the vast Pacific Ocean, both are mere specks of land. Howland Island is elongated in shape in a more or less N-S direction with a length of about three and one half miles and a maximum width of about 1.1 miles. Maximum elevation about mean sea level is about ten feet. Baker Island is smaller than Howland, not so elongated, and has a maximum elevation of about fifteen feet. They are saucer-shaped with high ridges of coral sand and debris along the shore line and the low points near, or only slightly above sea level toward their interiors. No evidence of rocks other than of coral or marine organic life were noticed on this trip nor have been reported by any previous visitors. Along the beach are coral sands of varying texture and rather massive reef rock and coral conglomerate near the water's edge. Inland, the sand was of fine texture with accumulations of bird guano in all low or basin areas. As in some other Pacific Islands this guano had been previously worked for commercial use.

The climate of the two islands is quite uniform. This is true of the temperature in particular which probably does not vary greatly from a minimum of about 78° to a maximum of 94° F. daily. Precipitation is light, mostly falling at night or in the early morning before daybreak. Sun pouring on the brilliant white coral sand is reflected as heat. The rising hot air causes rain-producing clouds approaching the islands either to break up or dissipate. Many observers report that clouds moving from the east with the prevailing winds will separate on reaching the edge of the island and pass to the north and south. As would be expected, vegetation is scant. Christophersen reports Boerhaavia and Portulaca as abundant in open spaces. A few clumps of Cordia were reported also on Howland. Attempts are being made to develop a growth of coconut palms brought with soil from Palmyra, but the results so for have not been promising.

Gas-operated lighthouses have been constructed by the colonists on both Howland and Baker. They are automatic and will operate for six months or more without attention. They are about twenty-five feet in height. The lighthouse at Howland has a diorite or similar dark igneous block above the doorway inscribed "Amelia Earhart, 1937" and is a memorial to that flyer who was lost while enroute to tiny Howland Island from New Zealand.

After brief stops at Baker and Howland Islands the "Taney" headed in a southeasterly direction, crossing the Equator about 6:30 p.m. Friday, March 4. On Saturday morning ceremonies were held on deck for benefit of those who had never crossed the "Line" before. King Neptune and Court saw to it that all "pollywogs" became "shellbacks."

Enderbury Island was sighted early the morning of Sunday the 6th. Like Howland and Baker, bright coral sand which reflected the sun's rays with great intensity was the first thing to impress the visitor. It was in strong contrast to the surrounding blue sea. Work of unloading supplies for the new colony to be established was started immediately. Food and water, the latter in old oil drums, were taken ashore. The food was taken through the surf in ship's boats. The water was floated ashore in the drums. This was accomplished by removing one gallon of water from each drug, lashing four to six of them together and then towing them from ship to island. The fresh water in the drums also added to their buoyancy.

Except for thousands of booby (gannet) and frigate (man-o'-war) birds, Enderbury was uninhabited. There were also in evidence the red-tailed tropic bird and several varieties of terns including the very beautiful "love-bird". The latter are snow-white and hover in pairs over the heads of intruders. They seem as though carved from exceptionally white porcelain. The "Taney" remained throughout the day, but sailed for Canton after sundown, leaving a camp, complete supplies and four Hawaiian colonists behind.

Enderbury Island is similar to Howland. It is a coral island about three miles long and one mile wide. It, too, is saucer-shaped with a decided depression toward its center. The low areas are partially filled with soft muddy materials which are principally bird guano. Around one of the muddy areas were several small coconut palms. At the southeastern end of the island were many large angular blocks of rock. From the ship these seemed dark and even looked as though they might be igneous rocks. Close observation showed them to be coral conglomerates evidently tossed upon the beach by wave action.

Enderbury is located about three degrees below the Equator and about one hundred and seventy-one degrees west. Canton Island, the most northerly of the Phoenix group, is about forty-three miles to the northwest.

A party from the "Taney" landed on Canton about 9:00 a.m. Monday, March 7. The American colonists began immediately to put up a temporary camp and to land supplies. As had been anticipated by Mr. Black, an old building with a concrete floor had been left by the Eclipse Expedition of 1937 (see National Geographic Magazine, June 1938). That afternoon a shock recorder was brought ashore and placed in oper-

ation. It was oriented to record earth waves only in a N-S direction. At the Hawaiian Volcano Observatory these shock recorders vibrate with slight motion of the pen continuously. This is probably caused by the microseismic motion of the ground. Vibration of the same nature was observed at Canton. In Hawaii wave motion of the sea on the NE shore of the Island is a suspected cause. This view might be even more readily acceptable on Canton where the motion of the sea acts only on a very narrow strip of land.

Canton is a typical coral atoll. A strip of coral sand and coral conglomerate, 150 feet to a third of a mile in width, almost completely enclosing a shallow coral-bottomed lagoon about nine miles long and three miles wide. The distance along the atoll around the lagoon is reputed to be about twenty-seven miles. To the southwest of the lagoon is a channel connecting it with the open sea. The channel is deep enough for small boats and if deepened could be utilized by larger craft. At

View at Canton Island. Shock recorder located in long low building at right.

various times of the day strong currents move in the channel so that it is used only at times when these are not dangerous. The channel may be as much as a quarter of a mile wide. It is well filled with large sharks which seem to prefer that locality to any other.

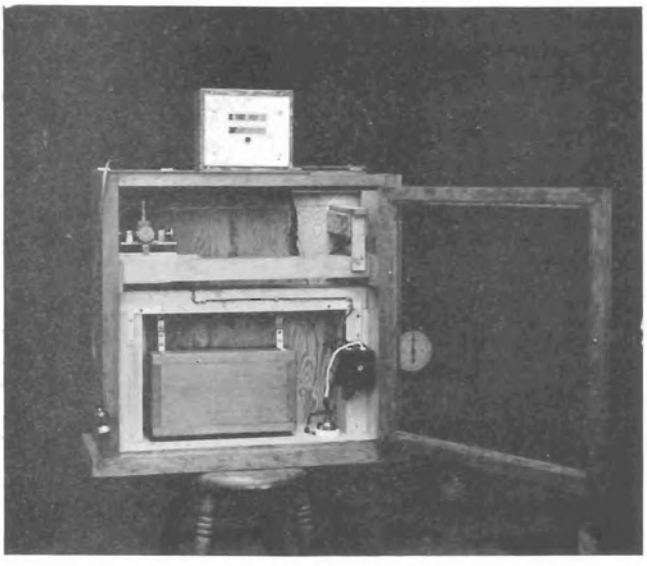
The atoll has two beaches, one to the open sea and one to the lagoon. Exploration of the area around the western lip of the channel revealed only coral sand, fragments and conglomerate. What appeared to be a peculiar rounded earthen mound about a mile and a half from camp turned out to be only a kou tree about twenty feet high which afforded a nesting place for a multitude of birds. The beach to the open sea along the southeast portion is broken by the presence of large quantities of angular slabs of coral conglomerate similar to the ones observed on Enderbury. On the lagoon side the beach is smooth, made up of coral sand and small shell fragments. Tide and waves in the lagoon have had a sorting effect, as various shells and sizes of sand show definite zones of stratification. Low areas lie inland between the beaches, and they as on the other islands contain deposits of guano. Also, one part of Canton rises some twenty feet above sea level.

The climate is mild, has steady easterly winds and a temperature maximum in the daytime of between 85° and 90° F. Rainfall is scant, but enough for several groves of coconut palms to have obtained a good start.

Monday night, March 7, 1938, the "Taney" returned to Enderbury. It remained there until noon Tuesday, completing final arrangements for the party left behind, and then returned to Canton, arriving there at 4:00 p.m. On Tuesday the shock recorder was again checked and it was moved to a more desirable location in the same building, and oriented for E-W movement instead of N-S as previously set up. Final instructions were given to an army sergeant who was to observe the instrument periodically. No registration occurred the two days the writer was at Canton. Apparently none has occurred since. It is not like a volcanic region where local shocks would be expected. A seismograph for recording of distant earthquakes located on Canton should produce some interesting results.

Wednesday evening, March 9, the "Taney" sailed for Howland and Baker Islands, arriving at the former at 8:30 a.m. Friday. By 1:00 p.m. landing of supplies and replacement of colonists had been completed and the ship left for Baker, which was reached at 4:30 p.m. Supplies were landed there and then at 8:20 p.m. the "Taney" again sailed for Howland to transfer a colonist to that island from Baker. Early Saturday morning, March 12, the "Taney" headed east for Jarvis Island nearly one thousand miles away. It was reached early the morning of March 15.

Jarvis is another isolated, saucer-shaped coral island. It is small, having a land area of 1.7 miles. It is about one mile wide and two miles long. The location is 160° W. longitude, 00° 23' S latitude. Jarvis is probably higher above sea level than any of the other islands visited. The beach slopes steeply up from the sea to a rim twenty feet or more above. This rim encircles the entire island. Toward the interior there is a gentle slope which produces the saucer effect. The lowest portion of the depression is in places slightly below sea level, and over most of the area is probably between this low and an elevation of ten feet. As was true of the other islands, the interior depressions are collecting spots for bird guano. The beach is made up of coral sand, and shell fragments of other marine organisms. Along most of the north and east shores there is a bench along the lower portion of the seaward slope. The bench is made up of stratified calcareous conglomerates which have been formed by cementation and consolidation of beach deposits. They are made up of corals and corallines and remains of other marine organisms. Above the conglomerate along the northeast shore are flat, roughly circular coral rocks tossed up by the waves and lying at low angles. Wentworth calls these "coral shingles." They were undoubtedly formed by wave action which was responsible both for their shape and location.



The second shock recorder was taken ashore at Jarvis and set up for operation. The only concrete base available was the floor of the lighthouse. This was considered desirable at first, but Mr. Edgecombe thought that it would be dangerous to place an electrical recording device which produced open sparks so near the gas supply. As an alternate the recorder was set up temporarily in the living quarters of the colonists. This proved very unsatisfactory as the moving of the people around the house caused a great deal of disturbance to the instrument. It was finally decided that the instrument be left in the house as set up but with the current shut off until the colonists stationed at Jarvis could build a concrete base and small shelter nearby. This has been done with the shock recorder oriented to record motion in a N-S direction, at right angles to the one left on Canton.

Explorations of the west and northwest beaches of Jarvis were made and the interesting remains of the barkentine "Amaranth" wrecked in 1913 were examined. It was apparently loaded with coal as pebbles of the black material are well distributed along the adjoining beach. These pebbles are well rounded and water worn.

The "Taney" left Jarvis the same day and sailed for its last stop of the trip, Palmyra Island, where it arrived in the early morning of Thursday, March 17. The day was very stormy with heavy rainfall. The small tree-covered islets composing Pal-

myra were visible only rarely during the day. Crew members fishing off the stern caught several black-finned sharks and a few red snappers. The sky cleared after sundown. Many "booby" birds and terns hovered about the ship throughout the day and several "boobies" flew aboard after dark attracted by the lights.

It had been agreed that there would be a landing party the next day regardless of weather conditions. Conditions were much more favorable on the morning of March 18, so that two of the ship's boats were sent as near the island as feasible. Two small boats with outboard motors were also towed in and with the party were landed on Home Island. From Home Island the party went across the large western lagoon to Cooper Island on the north side. After exploration there the boats returned across the lagoon to the south side, landing in the vicinity of

Type of shock recorder left on Canton and Jarvis Islands.

Paradise Islet. Lunch was eaten on the south side of that island. Soon after noon rain squalls began and occurred at intervals the remainder of the afternoon. A number of pictures were obtained in the morning but weather conditions prevented photographic work later in the day. Most of the afternoon was utilized in making underwater observations of marine life in the channels around Home and Paradise Islets and on the coral shelf to the west of the group.

Palmyra Island, otherwise known as Samarang or Palmoore, is located in the north Pacific Ocean 960 miles S. by W. of the city of Honolulu, Hawaii. Latitude 5° 53' North, longitude 162° 05' W. The island is a regular atoll, well covered with vegetation wherein it differs from other equatorial islands such as Jarvis and Howland. Altogether, Palmyra consists of a group of some fifty-two islets all of which are projections above the ocean surface from one underlying mass of coral growth and debris occupying a space of five and two-thirds miles in an east-west direction and one and one-half miles in the north-south direction. Including the entire extension of reef under water the length is nearly eight miles, east-west. The atoll encloses three large lagoons and one small one. All the larger lagoons have depths of at least twenty fathoms and the large western lagoon has a depth of 28 fathoms. In one of the lagoons are several small islets which are exposed at low tide. The greatest elevation is located on Eastern Islet and is about six feet above sea level. The U. S. Hydrographic Chart gives a maximum elevation of the trees as 91 feet above sea level and these may be observed from a ship 15-20 miles at sea. The largest islet is 46 acres in area and the smallest is reputed to be 0.47 acres.

An extensive coral flat extends to the westward of the islet for about three miles from the shore line where the depth is 6-7 fathoms at high tide. More or less cylindrical coral heads rise from the shelf nearly to the water's surface and are often five feet or more in diameter. Their number increases toward the island proper where the water becomes very shallow and a person can readily walk on the coral bottom. Boat landings can only be made in this vicinity at high tide, and it is the only portion of the island group where one may go ashore safely. At low tide no boats can pass over the coral shelf nearer than one mile from the shore.

Heavy surf of white-foamed breakers continuously roars against the reef from the open sea, to the north, east and south. They are never more than a few hundred feet from shore. This condition is to be expected as Palmyra is in the trade wind area of prevailing northeast and southeast winds the year around. This also accounts for the western side or lee side being the only safe landing point.

On the lagoon side the islets are bordered by strips of white coral sand which may extend inward in the form of spits. At high tide this sand is covered by about ten inches of water; at low tide it is often exposed and dry with never over an inch or two of water. The islets are separated by narrow channels through which flows considerable current at high tide. At low tide the channels are often blocked or the current obstructed by sand bars on the lagoon side. They deepen seaward. It is possible to walk between most of the islands as the water in the channels is seldom more than waist deep. The bottom is sandy toward the lagoon and becomes more rugged with new coral growth toward the sea. This is a natural gradation typical of atolls in general.

The weather at Palmyra is probably rather uniform. No visits to the island have apparently been of length sufficient to make accurate observations. The dense vegetative cover of the island indicates ample rainfall. Determinations for short periods indicate a rainfall of at least one hundred inches per year and probably as much as one hundred and fifty inches per year. All visitors report rain at Palmyra and heavy rainfall occurred the two days of this visit. Daily and yearly temperature range is probably not great. Rock reports a high of 90° during the day and a low of 78° during the night. Tropic islands completely surrounded by ocean and far from other land masses are likely to have a mild and equitable climate.

Palmyra is near no existing commercial ocean traffic lane. It is reached only by privately owned vessels capable of making long ocean voyages or by government vessels of the Coast Guard or Navy. Some people of the Hawaiian Islands visit the island annually in privately owned ships.

The map of Palmyra shows that the group is open at the western end and closed with a point at the eastern end. Prevailing winds and ocean currents from a general easterly direction are probably responsible for this condition as this fits in with the general rule. According to such a rule the coral growth should be most favored on the current side and along the northern and southern tip extremities of the western end of the island where the seaward current carrying the greatest quantities of coral food is likely to flow by and eddy backward, greatly retarded in speed. Corals and calcareous algae are sensitive marine organisms demanding close adjustment of temperature, depth, aeration, condition of water and amount of sandy material present. As a result coral growth would be accelerated on the windward, and less on the more protected, portions of the island. This is borne out by the facts illustrated by the reef extension to the westward and the diminishing of coral growth inward from the sea in the inter-island channels. Coral growth is greatly retarded in the lagoons and over the

entire area surrounded by the islets, where sand and debris brought in from the sea is deposited, destroying the living coral.

During the approach of high tide and for considerable time afterward there is much scouring action in the channels which keeps their seaward end very clean. The slowing of the current in passing through the channels causes deposition of the sand to build fans and shoals into the lagoon. Presumably this process continued over a long period would cause the filling up and elimination of the lagoon, which would go through a brackish marsh stage before attaining that end. After the lagoon had been filled by debris in this manner it seems likely that eventually wave action building up the resulting shore line would produce the elongated saucer type of coral island so common in the South Pacific. Probably because of the open west end on the lee side offering less resistance to the flow of water, the current return to the ocean at low tide seemed to be

Typical colonists on Jarvis Island.

less through channels than at high tide inflow. This also would tend to increase the chance of eventual elimination of the channels by building up from the sea. The heavy surf on the seaward side of the island prevents accumulation of sand or small debris in spits or bars. The outer beaches are of sand and some of coarse gravel and Tridacna shells.

Some coral grows in the inner lagoons contributing to the building processes but is much less vigorous than that on the outer portions of the island, as debris accumulation in the interior is more plentiful and food less available. The inner beaches are formed of fine coral and shell-fragment sand which at some localities become a fine mud quite soft, and often ankle deep. Heavy rains wash great quantities of bird guano into these mud flats. Beach water-lines fluctuate widely between high and low tide over these areas because of their very low angle of deposition. No evidence points to former sea levels above the present ocean level. The inner portions of the various islets are made up of coarse detrital materials with a few composed of calcareous sandstones and conglomerates. The islands to the east are apparently the youngest, and no doubt other islands may develop even farther eastward superseding the existing line of growth.

In order to make proper tide connections the return to the ship was made at 4:00 p.m. Stormy weather was again in evidence on the morning of March 19th. One squall about 8:00 a.m. with a wind velocity of over 60 miles per hour tore away a large portion of the "Taney's" awning. It was thought that weather conditions would not improve so the ship weighed anchor and set a course for Honolulu. The ship arrived at that port at 6:00 p.m., March 21, ending a most interesting cruise of 23 days.

Hawaiian Volcano Observatory Report for July 1938

VOLCANOLOGY

With the exception of the last two weeks of July rock slides from the north and east rim walls of Halemaumau were numerous during the month. The excessive sliding of the first fortnight along with several earthquakes indicating origins of about Halemaumau distance (2 miles) and the occurrence of higher seismicity after the sliding stopped, justifies the inquiry whether the recent fault movements southeast are extending themselves to the Kilauea block. Fuming from the southeast solfatara on the floor has continued. Seismic activity has been ordinary with most of the disturbances indicating Kilauea origins. Three felt earthquakes July 2 were of Mauna Loa origin. The Kona seismograph recorded only five small disturbances, indicating that there is only minor activity taking place under Mauna Loa and Hualalai. Kilauea seems to be currently the most active volcanic center on Hawaii. Two rather feebly recorded distant earthquakes were registered during the week ending July 24.

Observations from time to time of the cracks in the vicinity of Pauahi crater have been made and slight earth movements there are continuing, with a tendency shown both on the ground and by seismic distances for the fault movements to extend themselves northwestward. The hump in the road near Devil's Throat has increased in height. The large crack near Pauahi pit increased in width with increased downthrow to the southeast. The large crack near Aloi pit has widened. Systematic measuring of these cracks is provided for.

Temperature measurements at the hot area near Kokoolau pit have been made with highest readings about 85° C. The area does not appear to have increased its dimensions.

The Chief Ranger reported the discovery Friday, July 15, on an inspection trip to patrol the telephone line, along the trail up Mauna Loa northeast of the summit, that new cracks about four inches wide broke the surface of the trail at three places. The first one encountered was about 1.5 miles above Puu Ulaula resthouse at elevation 10,800 feet approximately; the other two were in the vicinity of 12,000 feet elevation, or about opposite and to the east of the main cone source of the 1935 flow. This is important as suggesting a breakage on the rift belt of Mauna Loa farther east than the fracture of 1935. It is worthy of note that earthquakes near Puu Ulaula shook Mauna Loa after the middle of January 1938, when the startling earthquake of Maui and Honolulu occurred: and that ten days before the earthquake crisis at Chain-of-Craters began, a deep earthquake occurred under Mauna Loa summit crater. These two Mauna Loa seismic events may be correlated with the new cracks.

The following are the local weekly data for the month of July at the Observatory and Halemaumau.

Week Ending	Seismicity	Slides	Crack Openings	Local Tremors and Quakes
July 3	18.75	30	7.0 mm.	55
" 10	10.25	15	0.5 mm.	17
" 17	18.25	28	0.0 mm.	50
" 24	23.25	3	3.5 mm.	67
" 31	20.00	3	0.5 mm. closed	60

One slight and two very feeble earthquakes were felt at Kapapala Ranch July 2. One very feeble earthquake July 13 was felt in Kilauea National Park.

Sequence of Events by Weeks

The first week was notable for many Halemaumau slides and Mauna Loa earthquakes. Slides continued the second week but tremors were less frequent. During the third week slips of rock from the wall of Halemaumau were numerous around the northern and eastern rims and seismic activity increased both at Kilauea and Mauna Loa. For the fourth week numbers of slides decreased to a low figure but earthquakes and tremors increased in number. The fifth week showed Halemaumau very quiet with reference to both slides and crack movements but seismicity remained high; many shocks were of Kilauea origin, a few showed Mauna Loa distance and one seismogram indicated Hualalai.

Slides at Halemaumau

The recorded slides from the wall of the Pit were:

July 1, 8:58 a.m. to 12:58 p.m., 13 slides N and NE.

July 2, 9:32 a.m. to 2:47 p.m., 14 slides N and NE.

July 3, 10:08 a.m., 1:03 p.m., 1:40 p.m., slides from northern walls.

July 4, 1:05 p.m., small slide from new crack high up N wall; rocks dribbled down SW and N walls for a half hour.

July 5, 12:57 p.m., slide N rim.

July 6, 9:33 a.m., 3:29 p.m., 3:37 p.m., 3:41 p.m., N rim.

July 7, 10:49 a.m., 11:19 a.m., N rim.

July 9, 9:45 a.m., 10:00 a.m., 10:45 a.m., 1:07 p.m., 1:30 p.m., 2:50 p.m., northern walls.

July 11, 9:00 a.m., 9:28 a.m., 9:35 a.m., 10:10 a.m., 10:11 a.m., 11:03 a.m., 11:11 a.m., slides from N, NE or E walls.

July 11, 6:47 p.m., dust clouds N rim, indicated large slide.

July 13, 8:50 a.m. to 12:05 p.m., 18 slides from N, NE and E walls.

July 15, 10:00 a.m., N rim.

July 17, 10:40 a.m., 1:13 p.m., northern wall slide.

July 18, 3:43 p.m., NE rim.

July 20, 9:45 a.m., N rim.

July 28, 9:10 a.m., NE rim.

July 28, 9:50 a.m., 10:05 a.m., N rim.

Measurement of Halemaumau Rim Cracks

Weekly measurement of rim crack locations around Halemaumau pit resulted during July in aggregate movement as follows:

Week ending forenoon of:

July 1, 28 locations, 11 opened, 1 closed, opening 7.0 mm.
July 8, 28 locations, 2 opened, 3 closed, opening 0.5 mm.
July 15, 28 locations, 5 opened, 5 closed, opening 0.0 mm.
July 22, 28 locations, 4 opened, 1 closed, opening 3.5 mm.
July 29, 28 locations, 3 opened, 4 closed, closing 0.5 mm.

SEISMOLOGICAL DATA

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Distant* Earthquakes	Weekly† Seismicity
July 10	35	3	0	0	10.25
July 17	33	14	3	0	18.25
July 24	45	20	2	2	23.25
July 31	42	17	1	0	20.50

* Including teleseisms or earthquakes of over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

Frigate birds, found on all islands except Palmyra.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus has been made.

July 4, 2:13 pm, very feeble, probably originated near Pauahi crater.

July 7, 1:56 pm, very feeble, 0.4 mile deep in E portion of Kilauea crater. 19° 24.7′ N; 155° 16.0′ W.

July 12, 9:58 am, very feeble, of shallow origin, Kilauea SE crater rim. 19° 24.2′ N; 155° 16.3′W.

July 13, 10:45 am, feeble, 0.9 mile deep, Kilauea crater, 1.2 miles E of Halemaumau. 19° 24.6′ N; 155° 15.7′ W.

July 15, 4:12 am, feeble, location same as preceding.

July 15, 4:58 am, very feeble, 0.6 mile deep in Kilauea crater rim area near Kilauea Iki. 19° 25.1′ N; 155° 15.4′ W.

July 15, 5:34 am, very feeble, probably originated in Chain of Craters rift near Lua Manu.

July 15, 5:56 am, feeble, 1.6 miles deep in NW portion of Kilauea crater. 19° 25.7′ N; 155° 16.7′ W.

July 15, 11:04 pm, very feeble, probably originated in Chain of Craters rift near Lua Manu.

July 16, 6:52 am, very feeble, 1.4 miles deep, E rim of Kilauea crater, 19° 24.9′ N; 155° 15.7′ W.

July 17, 8:49 pm, very feeble, of shallow origin, NW rim area of Kilauea crater, 1.1 miles SW of the Observatory. 19° 25.2′ N; 155° 16.2′ W.

July 17, 10:51 pm, very feeble, 0.7 mile deep in Kilauea crater, 1.1 miles SW of the Observatory. 19° 25.2′ N; 155° 16.2′ W.

July 18, 4:37 am, very feeble, 1.0 mile deep, Waldron Ledge, NE rim of Kilauea crater. 19° 25.4′ N; 155° 15.5′ W.

July 19, 12:36 am, feeble, of shallow origin (0.3 mile), Kilauea crater, 0.4 mile E by N of pit seismograph. 19° 24.4′ N; 155° 16.3′ W.

July 19, 3:58 am, very feeble, of shallow origin 0.5 mile SE of pit seismograph. 19° 24.1′ N; 155° 16.6′ W.

July 21, 2:36 pm, very feeble, 0.6 mile deep SE rim, Kilauea crater, 1.6 miles E of pit seismograph. 19° 24.2′ N; 155° 15.5′ W.

July 22, 4:29 am, very feeble, 1.7 miles deep, Kilauea crater, 1.2 miles NE of pit seismograph. 19° 25.1′ N; 155° 16.4′ W.

July 22, 4:42 am, very feeble, 0.7 mile deep near Puhimau crater. 19° 24.0′ N; 155° 15.3′ W.

July 22, 5:02 am, very feeble, 0.8 mile deep, NE rim Kilauea crater (Byron Ledge), near Kilauea Iki. 19° 25.2′ N; 155° 15.6′ W.

July 22, 5:49 pm, very feeble, of shallow origin E rim of Kilauea crater. 19° 24.6′ N; 155° 15.7′ W. Felt in National Park residential area.

July 22, 7:32 pm, very feeble, 1.0 mile deep under N portion of Halemaumau. 19° 24.8′ N; 155° 17.2′ W.

July 23, 9:38 am, very feeble, probably originated in vicinity of Kilauea Iki.

July 23, 4:06 pm, very feeble, of Kilauea crater origin.

July 23, 10:09 pm, very feeble, probably originated in N central portion of Kilauea crater.

July 24, 12:54 am, very feeble, probably of Kilauea crater origin.

July 24, 5:20 am, very feeble, probably originated in Chain of Craters near Puhimau.

July 24, 7:51 pm, feeble, of shallow origin (0.6 mile) in SE rim area of Kilauea crater. 19° 24.5′ N; 155° 16.1′ W.

July 25, 7:16 am, very feeble, of Kilauea crater origin.

July 25, 9:31 am, very feeble, 1.5 miles deep, NW rim of Kilauea crater 0.5 mile NE of Uwekahuna. 19° 25.7′ N; 155° 17.1′ W.

July 28, 7:50 am, very feeble, probably originated in Mauna Loa NE rift in vicinity of Puu Ulaula.

July 30, 11:36 am, very feeble, 1.4 miles deep in NE portion of Kilauea crater, 1.4 miles NE of pit seismograph. 19° 25.2′ N; 155° 16.1′ W.

July 30, 9:43 pm, very feeble, 1.7 miles deep, 1.6 miles SE of pit seismograph in vicinity of Puhimau. 19° 23.6′ N; 155° 15.8′ W.

July 30, 9:50 pm, feeble, 0.7 mile deep Kilauea crater, 1.0 mile NE of pit seismograph. 19° 24.9′ N; 155° 16.3′ W.

July 31, 2:54 am, very feeble, 1.5 miles deep, E portion of Kilauea crater. 19° 24.8′ N; 155° 15.9′ W.

July 31, 8:27 am, very feeble, of Kilauea crater origin.

July 31, 8:45 am, very feeble, 2.0 miles deep N central portion of Kilauea crater. 19° 15.1′ N; 155° 16.4′ W.

At 11:49 am, July 9, 22 minutes of continuous tremor began to register.

Distant Earthquakes:

July 21, unidentified portion began recording at the Observatory at 9h 37m 24s pm, H.S.T.

July 24, unidentified portion, 3h 00m 30s am, H. S. T.

Microseismic motion of the ground at the Observatory was light July 4-8, 13, 14, 19-25; moderate July 9, 11, 12, 15-18, 26-31 and strong July 10.

Tilting of the Ground:

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum toward or away from the pit.

At the Observatory the total accumulated tilt for the year ending July 31 was 1.85″ S and 6.30″ W.

Week Ending	Observatory	Halemaumau West Station
July 10	0.61″ N 26° E	5.00″ N 75° W
July 17	0.56″ N 35° W	4.71″ S 75° W
July 24	0.87″ N 14° W	4.47″ S 85° W
July 31	0.85″ N 50° E	4.83″ S 65° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
July 10	4.73″ S 55° E	9.14″ from
July 17	12.70″ N 22° W	7.38″ toward
July 24	5.60″ N 37° W	1.03″ toward
July 31	3.24″ S 47° E	7.71 from

Crater Angles:

Measurement of horizontal angles across Kilauea crater from the Observatory July 21 indicated closing of both the Halemaumau value and the total crater value. The Halemaumau measurement from the SE pit BM to NW pit BM showed closing of 0.83″ and the crater measurement from the SE crater rim to Uwekahuna showed closing of 0.84″.

H.H.W.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

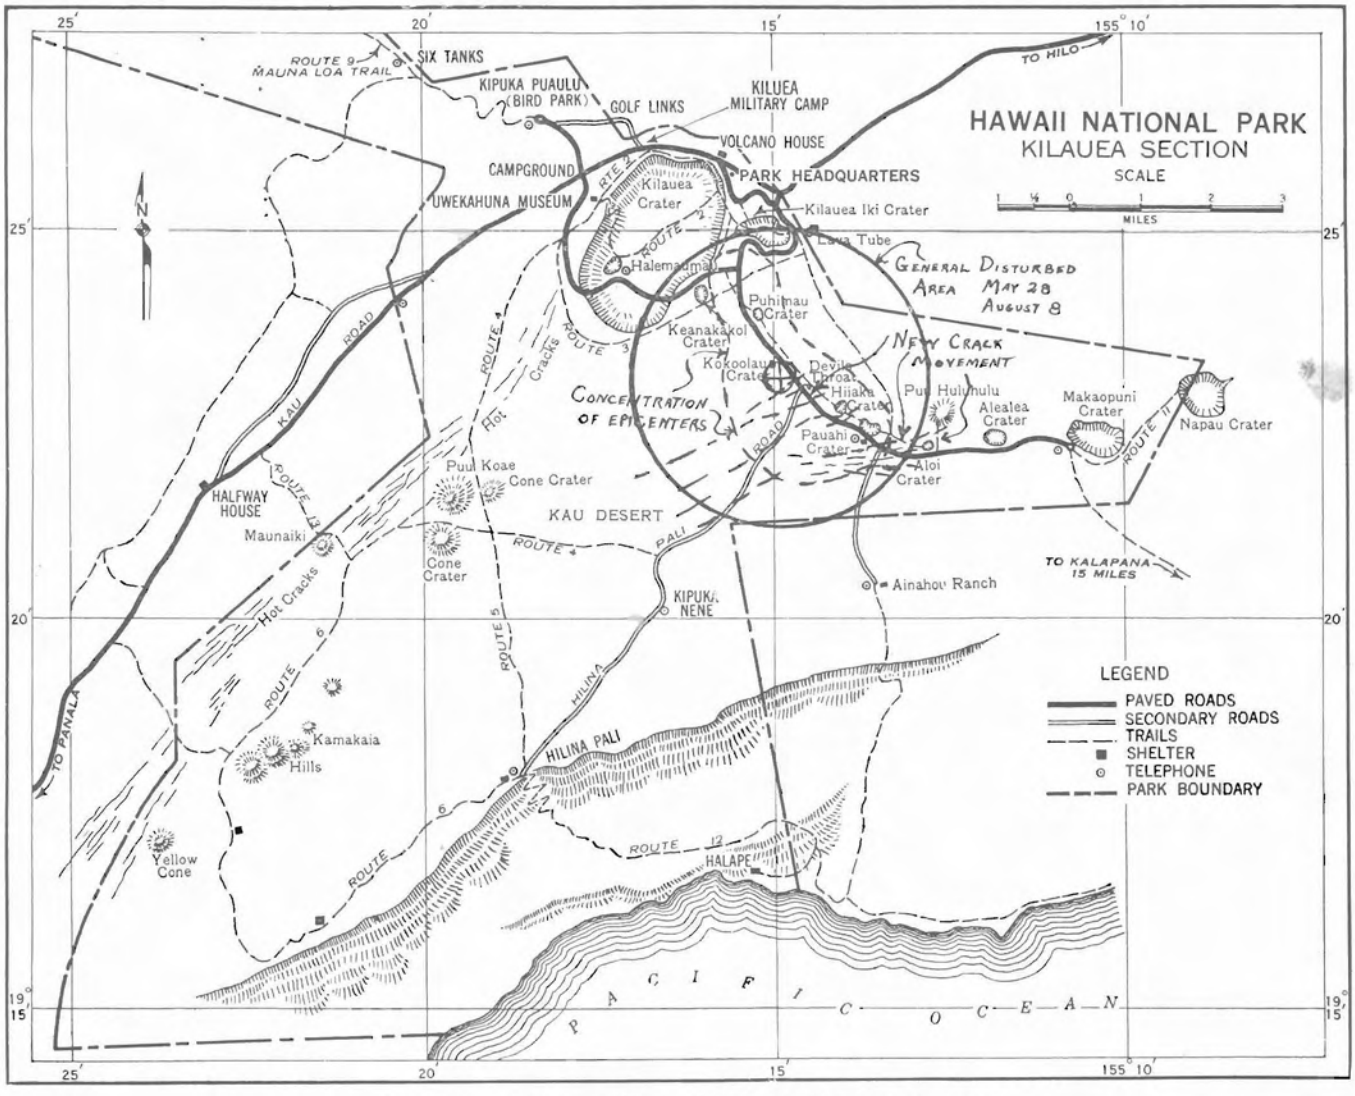
The Hawaiian Volcano Research Association was founded in 1911 for the prosecution of volcano research, more particularly in the Hawaiian Islands and around the Pacific Ocean. Its laboratory at Kilauea Volcano, Hawaii, is leased and operated by the United States Government, Department of the Interior, National Park Service. The Association maintains seismograph stations at various places on the Island of Hawaii and supplements the work of the Government with buildings, research fellows, instrumental plants, explorations and special investigations for which there is no governmental provision.

The Volcano Letter, a monthly, eight-page, illustrated publication dealing with volcanic and seismic interests in Hawaii, the Pacific area, and other sections of the world, is issued by authority of the Department of the Interior, and is supplied free of charge to members of the Association and to a restricted exchange list. It is non-technical in nature and promotes popular interest in its particular field of science.

The Secretary of the Association is Mr. L. W. de Vis-Norton, whose address is 320 James Campbell Building, Honolulu, T. H. Contributions of articles, photographs, publications and clippings about volcano and earthquake events, instruments and investigations are always welcome, and if suitable, will be published with due acknowledgment.

THE VOLCANO LETTER

No. 462 Department of the Interior National Park Service August-December, 1938



Edward G. Wingate Superintendent
Hawaii National Park

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

NOTICE CONCERNING PUBLICATIONS

This number of the Volcano Letter completes the 1938 series, and is published by the University of Hawaii. Hereafter the Letter will be published as a quarterly and will be sent out from the publication office of the University of Hawaii. Members of the Hawaii Volcano Research Association will receive it without cost.

The Third Special Report of the Hawaiian Volcano Observatory has been published by the Hawaiian Volcano Research Association: Ash Formations of the Island of Hawaii, Chester K. Wentworth, 1938, pp. 183; and is ready for distribution upon application to the Secretary, 320 Jas. Campbell Bldg., Honolulu, T. H. $3.00 per copy, postage free.

Map of disturbed area, Chain-of-Craters. Hot vapor killing vegetation is between Kokoolau and Keanakakoi.

Hawaiian Volcano Observatory Report for August-December 1938

VOLCANOLOGY

AUGUST 1938

During this month there was another disturbance of the fault blocks making new crack movement along Chain-of-Craters road similar to the one of May 28, 1938. There were felt earthquakes the forenoon of August 8, the road hump near Devil's Throat increased in elevation, eight new cracks were found between Devil's Throat and Hiiaka pit, and a large number of local shocks were registered instrumentally during the second week of the month. They were not felt in Hilo, but eleven shocks August 8-10 were from Mauna Loa. There were slides in Devil's Throat and Pauahi pit.

Opening of cracks in the road near Devil's Throat amounted to 2.5 and 4.00 mm. between August 10 and 12. The third week two Devil's Throat cracks opened 7.5 mm., and of three cracks between Pauahi and Aloi pits two opened 8.5 mm. The fourth week, of seven cracks marked along the Chain-of-Craters road, one at Devil's Throat opened 1.0 mm., another a half mile east of Pauahi opened 16.0 mm., and one near Aloi closed 14.5 mm. A heavy slide from the west rim of Pauahi crater occurred August 26. Kilauea quakes had decreased in number after August 14 and all but two of the measured shocks showed Mauna Loa distances.

The following are the local data for August:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
August 7	0	0.0 mm.	26
" 14	5	7.0 mm.	454
" 21	0	1.0 mm.	24
" 28	0	5.0 mm.	11

SEPTEMBER, 1938

Slides September 3 at the north wall of Kilauea crater made a new talus there. The week ending September 5 showed some recurrence of movement along Chain-of-Craters rift with settlement of the rim of Pauahi pit, and a new crack at Devil's Throat. On September 26 the large road crack near Pauahi crater caved in farther under the impact of a car.

Inspection of northeast rift of Mauna Loa September 15 showed recent disturbance of the new cracks at 11,000 feet elevation, and the 1935 cone was fuming and depositing sulphur.

The following are the local data for September:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
September 4		1.5 mm.	11
" 11	5	2.5 mm.	11
" 18	2	0.5 mm. closing	9
" 25	1	7.5 mm.	11
October 2	0	5.5 mm. closing	12

OCTOBER 1938

The first week of the month produced no earthquakes and few tremors although there was increase of slides at Halemaumau. During the second week there were no slides and only two small earthquakes. The third week was seismically the quietest of the year to date. The last week produced an earthquake at 6:12 p.m. October 27 on the southwest rift of Mauna Loa that cracked a concrete floor in the village of Naalehu.

The following are the local data for October:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
October 9	24	2.5 mm.	12
" 16	0	5.5 mm.	13
" 23	1	0.5 mm.	6
" 30	0	2.5 mm.	12

NOVEMBER 1938

The month was notable in the Pacific area in producing eleven distant earthquakes, and the local field here was extraordinary in developing large numbers of small slides from the Halemaumau wall, and also some avalanches from the northern corner of Kilauea crater. It is remarkable that the measured local earthquakes of the fortnight ending November 27 were dominantly from sources in the island not within Kilauea Volcano, although there were great numbers of Halemaumau slides.

The following are the local data for November:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
November 6	3 (Kilauea)	0.0 mm.	33
" 13	1 (Halemaumau)	4.5 mm.	10
" 20	23 "	4.0 mm.	24
" 27	93 "	3.5 mm.	30

DECEMBER 1938

The first week showed slides in some of the pits of Chain-of-Craters, and also on the Puna cliffs towards the sea. There was one day of slides in Halemaumau. During the third week some motion occurred along the Chain-of-Craters.

Inspection of Mauna Loa northeast rift December 9-10 showed the upper cone of 1935 steaming and smelling of sulphur dioxide and hydrogen sulphide; parts of the bright yellow sulphur coatings had the orange tinge of either iron or selenium.

The following are the local data for December:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
December 4	7	4.5 mm.	38
" 11	0	1.0 mm.	8
" 18	3	3.5 mm.	17
" 25	0	2.0 mm.	14

SEISMOLOGY AND GROUND MEASUREMENTS

Earthquakes

AUGUST 1938

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Moderate Earthquakes	Distant† Earthquakes	Weekly* Seismicity
Aug. 7	17	9	0	0	0	0	8.75
Aug. 14	1,014	184	56	36	3	0	482.50
Aug. 21	17	6	1	0	0	0	8.25
Aug. 28	10	1	0	0	0	0	3.00

† Including teleseisms or earthquakes of over 5000 km from Kilauea.

* For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

August 2, 8:51 am, very feeble, probably originated near center of Kilauea Crater.

August 2, 9:17 am, very feeble, probably originated in NE portion of Kilauea Crater.

August 3, 9:53 am, very feeble, probably originated near center of Kilauea Crater.

August 4, 9:50 pm, very feeble, same as preceding.

August 5, 8:59 pm, very feeble, 0.9 mile deep under Byron Ledge. 19° 25.5′ N; 155° 15.5′ W.

August 6, 2:59 am, very feeble, 12.0 miles deep under Mauna Kea about 5.0 miles S of Summit. 19° 45.5′ N; 155° 27.0′ W.

During the week, August 7-14 inclusive, 454 local seismic disturbances were recorded on the seismographs of the Hawaiian Volcano Observatory. Between midnight August 7 and 2:10 am August 8, there were three tremors and one very feeble earthquake. At 2:14 am, 840 minutes of continuous tremor began to register, ending at 4:38 pm August 8. During the remainder of the day there were 74 tremors, 184 very feeble, 56 feeble, 36 slight and 3 moderate earthquakes.

The moderate earthquakes were:

5:12 am, 1.3 miles deep, 0.4 miles SW of Hiiaka Crater.

9:44 am, thought to have originated in the vicinity of Devil's Throat.

11:41 am, probably originated in cracks about 0.6 mile W of Kokoolau Crater.

It may be noted that the three were successively closer to Kilauea Crater, indicating distances from the Observatory of 4.7, 3.5 and 3.2 miles respectively.

These and associated shocks were felt by most residents of Hawaii National Park. Those asleep were awakened by the early disturbances. The swarm of earthquakes began after the continuous tremor. The shocks were not felt at any great distance from Kilauea Crater.

For the week there are the following data:

Date	Disturbances	Minutes of Tremor*	Very Feeble Earthquakes	Feeble Earthquakes	Slight Earthquakes	Moderate Earthquakes
Aug. 8	323	917	166	45	31	3
Aug. 9	83	60	11	8	4	....
Aug. 10	22	16	4	1	1	....
Aug. 11	10	8	2	....	....	....
Aug. 12	6	6	....	....	....	....
Aug. 13	8	5	1	2	....	....
Aug. 14	2	2	....	....	....	....
Totals	454	1,014	184	56	36	3

* —840 continuous and 77 spasmodic.

Focal distances of the shocks were between 0.5 and 6.0 miles from the Observatory. The circle on the accompanying map shows the general area of disturbance. The majority of the shocks were located by determinations derived from a study of seismograms from the Observatory, Pit and Uwekahuna seismographs. The epicenters thus determined fell within the irregular area inside the circle on the map. The center of the circle (+) was apparently the center of greatest disturbance and was determined by averaging all the S-P values from the three stations mentioned above. The earthquakes were most strongly felt within the areas indicated. The fact that they were not felt at any great distance (probably not over 7.0 miles) from their source indicates they were local to the Kilauea Crater area, particularly in the Chain-of-Craters to the SE and were of shallow origin. By graphic methods of determination depth of focus was in no case more than two miles. Most were less than 1.0 mile and in many cases appeared to have been less than 0.5 mile. A substantial number indicated depths of 1.5 to 1.8 miles.

Accompanying the earthquakes there was apparently considerable movement of probably preexisting cracks between Kokoolau and Hiiaka Craters. The cracks which had shown movement during May disturbances apparently changed slightly. The latter were located between Pauahi and Aloi Craters. Concentric cracks around Devil's Throat increased and more rockfalls from the rim occurred. Slides also occurred in Pauahi. The hump in the Chain-of-Craters road near Devil's Throat increased in height and the road surface was considerably fractured. Other cracks opened 10 feet north. Three sets of cracks in the road developed to the S of Devil's Throat, i.e., between Devil's Throat and Hiiaka and on the S rim of Hiiaka. Many shocks originated in Kilauea Crater.

One slight shock felt at Kapapala Ranch at 9:45 am, August 8, was apparently located 15.0 miles deep in the Hilina Fault system 7.5 miles SW of the Observatory. 19° 19.0′ N; 155° 15.0′ W.

Another (very feeble) from same general locality registered at 5:53 pm. A third (very feeble) located in Hilina Fault System near the junction with the SW rift 8.0 miles deep occurred at 1:24 am, August 10. 19° 16.0′ N; 155° 19.5′ W.

Other August earthquakes were:

August 15, 6:46 am, very feeble, originated 8.0 miles deep in Kilauea SW rift, 13.0 miles from Halemaumau. 19° 14.5′ N; 155° 24.0′ W.

August 15, 6:14 pm, very feeble, 2.0 miles deep, SE portion of Kilauea Crater. 19° 24.7′ N; 155° 26.1′ W.

August 16, 7:43 pm, feeble, 25.0 miles deep under Mauna Loa, about 20.0 miles W of Kilauea Crater. 19° 25.0′ N; 155° 34.0′ W. Strongly felt in Pahala and at Kapapala Ranch.

August 20, 3:12 pm, very feeble, 2.0 miles deep, Kalanaokoai Pali, 2.0 miles WSW of Pauahi Crater.

August 20, 5:06 pm, very feeble, 14.0 miles deep, Mauna Loa NE rift about 3.0 miles E of Puu Ulaula. 19° 32.5′ N; 155° 26.0′ W.

August 22, 1:19 am, very feeble, 15.0 miles deep, Mauna Loa SW rift, 14.0 miles SW of summit. 19° 18.5′ N; 155° 43.5′ W.

Microseismic motion of the ground at the Observatory was light August 1-8; moderate August 9-13, 18, 24-28 and strong August 14-17, 19-23 inclusive.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the observatory seismograph and at Halemaumau, the algebraic sum toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending August 28 was 1.49″ S and 6.6″ W.

Week Ending	Observatory	Halemaumau West Station
August 7	0.40″ N 15° W	3.19″ N 75° W
August 14	1.20″ N 42° E	8.08″ N 60° W
August 21	0.32″ S 59° W	4.17″ N 69° W
August 28	0.12″ N 68° E	1.61″ S 50° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
August 7	8.42″ N 54° W	5.15″ toward
August 14	10.69″ N 39° W	4.13″ toward
August 21	7.06″ N 72° W	4.01″ from
August 28	2.79″ N 72° W	1.09″ toward

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory August 10 and 22, indicated slight opening of the Halemaumau value and closing of the total Crater value compared with similar measurements July 21. Between July 21 and August 10, the Halemaumau measurement from SE Pit BM to NW Pit BM showed closing of 0.26″ and between August 10 and 22, opening of 0.59″. Total opening 0.33″. Between July 21 and August 10 the Crater measurement from SE rim station to Uwekahuna showed opening of 0.67″ and between August 10 and 22, closing of 1.01″. Total closing 0.34″.

Week Ending	Minutes of Tremor	Very Feeble Earthquakes	Feeble Earthquakes	Distant* Earthquakes	Weekly† Seismicity
September 4	7	3	1	1	4.25
September 11	10	1	0	0	3.00
September 18	6	3	0	0	3.00
September 25	8	3	0	0	3.50
October 2	9	3	0	0	3.75

* Including teleseisms or earthquakes of over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

New hump in road near Devil's Throat, May and August 1938.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

August 29, 2:30 pm, very feeble, 10.0 miles deep. Mauna Loa NE rift 4.0 miles NE of center of summit crater. 19° 30.5′ N; 155° 32.2′ W.

September 2, 2:53 am, feeble, 13.0 miles deep, Kilauea SW rift, 8.0 miles SW of Halemaumau. 19° 20.0′ N; 155° 23.0′ W. Reported felt at Kapalapala and Pahala.

September 2, 4:09 am, very feeble, 17.0 miles deep, Mauna Loa NE rift, 7.0 miles NE of summit crater. 19° 31.5′ N; 155° 29.0′ W. Reported felt at Kapalapala Ranch.

September 3, 7:13 am, very feeble, probably originated about 4.6 miles S of Pit seismograph station in Kalanaokuaiki.

September 9, 6:58 am, very feeble, probably located in Kilauea SW rift near Pahala.

September 14, 5:38 pm, very feeble, 1.6 miles deep in vicinity of Puu Huluhulu, Chain-of-Craters rift. 19° 22.7′ N; 155° 12.6′ W.

September 16, 2:42 pm, very feeble, 1.8 miles deep in Kalanaokuaiki fault, 1.8 miles E of Puu Ohale. 19° 21.2′ N; 155° 15.2′ W.

September 21, 6:17 pm, very feeble, probably originated in Kilauea SW rift about 11.0 miles SW of Halemaumau.

September 24, 1:49 pm, very feeble, 11.0 miles deep, 3.0 miles N of Halfway House between Kilauea and Mauna Loa. 19° 21.4′ N; 155° 25.2′ W.

October 1, 9:04 pm, very feeble, 2.8 miles deep, near center of Kilauea Crater. 19° 25.1′ N; 155° 16.4′ W.

Distant Earthquakes

"P" waves began recording at Kilauea at 1h 30m 33s am, H.S.T., August 30. Distance from the Observatory estimated at 4,400 miles.

Microseismic motion of the ground at the Observatory was light September 3, moderate August 29, 31, September 1, 2, 4, 5, 10-15 and strong August 30, September 6-9, 16-30 and October 1 and 2.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending October 2, was 0.73" S and 5.36" W.

Week Ending	Observatory	Halemaumau West Station
September 4	0.72" N 65° E	2.38" N 41° W
September 11	0.70" N 24° E	3.73" N 45° W
September 18	0.84" N 39° E	6.05" N 80° W
September 25	0.70" N 24° E	2.00" N 20° W
October 2	0.75" S 4° W	1.85" S 61° W

Week ending	Halemaumau Southeast Station	Halemaumau Resultant
September 4	4.57" S 16° E	5.41" from
September 11	10.40" N 39° W	7.99" toward
September 18	5.64" N 4° E	1.43" from
September 25	14.42" N 31° W	13.49" toward
October 2	8.88" N 63° W	6.30" toward

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory, September 7 and 22, indicated closing of the Halemaumau value and closing of the total Crater value compared with similar measurements August 22. Between August 22 and September 7, the Halemaumau measurement from SE Pit BM to NW Pit BM showed closing of 2.66" and between September 7 and September 22, closing of 0.58". Total closing 3.24". Between August 22 and September 7 the Crater measurement from SE rim station to Uwekehuna showed closing of 0.66" and between September 7 and 22 closing of 0.67". Total closing 1.33".

Levelling at Kilauea

Since December 9, 1937 three sets of levels have been run in Kilauea Crater from the S pit BM, SE rim area of Kilauea Crater and the NW pit BM on the NW rim of Halemaumau. The first run, February 8, 1938 showed a relative lowering of NW pit BM with reference to S pit BM of 6.7 centimeters within the preceding two-month period. Similar measurements July 24, indicated a raising of the NW pit BM of 4.6 centimeters since February 8 and from July 24 to September 15, a raising of 0.5 centimeter. As in the February run, the last two are with reference to the S pit BM. It is possible that the movement indicated February 8, may have been a raising of S pit with reference to NW pit and in the last two cases S pit may have lowered. The latter movement seems quite plausible in view of recent visible earth movements along Chain-of-Craters road where cracks indicate apparent downward movements to the south. These measurements give only relative changes between two stations with no reference in either case to changes relative to sea-level.

October 30.....	7	3	2	0	7.25

* Including teleseisms or earthquakes of over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

October 10, 11:52 am, very feeble, 4.7 miles deep, NW rim area of Kilauea Crater about 0.5 mile N of Uwekahuna, 19° 25.7′ N; 155° 17.4′ W.

October 13, 5:09 am, very feeble, 33.0 miles deep, Hualalai-Puu Waawaa area. 19° 47.0′ N; 155° 52.7′ W.

October 19, 7:25 am, very feeble, 15.0 miles deep in Chain-of-Craters area 4.0 miles SE of the Observatory, 19° 23.4′ N; 155° 13.6′ W.

October 25, 12:18 pm, slight, 16.0 miles deep, near Glenwood, 18.5 miles SSW of Hilo. 19° 27.8′ N; 155° 09.5′ W. Reported felt by many in Hilo and by a few in Hawaii National Park.

October 26, 9:38 am, very feeble, 2.6 miles deep in Chain-of-Craters, vicinity of Aloi and Puu Huluhulu. 19° 22.1′ N; 155° 12.6′ W.

October 27, 6:11 pm, slight, 15.0 miles deep under Hualalai. 19° 42.0′ N; 155° 50.2′ W. Reported felt by many in Kona and at Naalehu.

October 29, 7:07 am, very feeble, of Mauna Loa origin.

October 30, 2:46 am, very feeble, probably originated south of Kilauea Crater in cracks near Puu Ohale.

Distant Earthquakes

"P" waves began recording at Kilauea at 4h 01m 58s pm, H.S.T., October 19. Probably originated about 5500 miles from the Observatory.

Unidentified portion began registering at 1h 10m 56s am, H.S.T., October 20.

Microseismic motion of the ground at the Observatory was light October 13, 14, 15; moderate October 12, 16, 17, and strong the remainder of the month.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending October 30, was 0.52" N and 4.74" W.

Week Ending	Observatory	Halemaumau West Station
October 9	1.22" N 40° E	5.00" S 43° W
October 16	0.12" W	2.68" N 18° W
October 23	0.15" S	4.53" S 83° W
October 30	1.24" N 19° E	5.96" N 73° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
October 9	4.96" N 63° W	0.64" toward

November 27.....	24	6	0	1	9.00

* Including teleseisms or earthquakes of over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

October 31, 1:05 pm, very feeble, 20.0 miles deep, Hualalai, 5.0 miles SE of summit. 19° 39.2′ N; 155° 47.7′ W. Reported felt at Puu Waawaa ranch house.

November 2, 12:14 am, very feeble, probable origin, E portion of Kilauea Crater.

November 3, 12:53 pm, very feeble, probable origin, Hilina Fault system about 4.0 miles SE of Makaopuhi.

November 4, 7:40 am, very feeble, 2.8 miles deep in N portion of Kilauea Crater. 19° 25.6′ N; 155° 16.6′ W.

November 5, 10:37 am, very feeble, 1.7 miles deep, 0.5 mile NE of Hiiaka Crater. 19° 23.0′ N; 155° 13.6′ W.

November 5, 10:27 pm, feeble, 2.0 miles deep, 0.4 mile W of Kokoolau. 19° 23.2′ N; 155° 15.2′ W.

November 7, 6:15 am, feeble, 25.0 miles deep, 4.0 miles W of summit of Hualalai. 19° 42.8′ N; 155° 56.0′ W. Reported felt in Kona district.

November 9, 12:01 am, very feeble, probably originated in NE rim area of Kilauea Crater.

November 12, 9:37 pm, very feeble, probably originated in NE rim area of Kilauea Crater.

November 14, 12:17 am, very feeble, probably originated under Halemaumau, Kilauea Crater.

November 18, 2:29 am, very feeble, 28.0 miles deep, 10

miles W by S of summit of Mauna Kea, 14 miles E by N of Puu Waawaa. 19° 47.8′ N; 155° 38.0′ W.

November 18, 3:48 am, very feeble, 3.8 miles deep, 0.8 mile S of Pauahi Crater. 19° 21.7′ N; 155° 13.4′ W.

November 20, 5:31 pm, feeble, 13.0 miles deep in Hilina-Kapukapu fault system, 4.0 miles S by W of Makaopuhi. 19° 19.0′ N; 155° 12.0′ W. Reported felt by several persons in Hawaii National Park Headquarters area.

November 20, 6:08 pm, very feeble, probably originated in Hilina fault system about 3.0 miles SE of Kamakaia Hills.

November 21, 11:13 pm, very feeble, probably originated near Kokoolau, Chain-of-Craters.

November 22, 10:48 am, very feeble, of Mauna Loa origin, NE rift.

November 27, 9:21 am, very feeble, of Kilauea Crater origin, vicinity of Holemaumau.

Four minutes of continuous tremor registered November 10, beginning at 10:33 am. The tremor was superimposed on a portion of a teleseism. At Halemaumau it was equivalent in size to a feeble shock so probably originated in Kilauea Crater near Halemaumau.

Three minutes of tremor registered November 16 beginning at 4:09 pm.

Teleseisms

November 4, 10h 23m 20s pm, "P" waves, distance from Kilauea 3775 miles.

November 5, 12h 30m 05s am, "P" waves, distance 4025 miles. Located in Northern Japan where some damage resulted. Alsa reported felt in Tokyo.

November 5, 10h, 33m 41s pm, "P" waves, distance 3880 miles.

November 6, 11h 18m 37s am, "P" waves, distance 3550 miles.

November 8, 11h 13m 18s pm, unidentified portion.

November 10, 9h 55m 42s am, "P" waves, distance 2485 miles. Apparent location was near Shumagin Islands off S coast of Alaska. U.S.C. & G.S. location of origin was 55° N; 159° S. Seismographic registration of this shock was unusually strong throughout the world. Maximum waves dismantled Bosch-Omori seismograph ot the Hawaiian Volcano Observatory at 10:07 am. Small tidal wave was observed in Hawaiian Islands between 3:00 and 3:30 pm. Reported felt over large portion of Alaska but no damage reported.

November 10, 2h 34m 49s pm, "P" waves, distance 3370 miles.

November 13, 12h 49m 42s pm, unidentified portion.

November 14, 1h 46m 09s am, unidentified portion.

November 16, 5h 31m 37s pm, "P" waves, distance 2420 miles. According to news dispatches, originated Aleutian Islands, Alaska, at approximately same locality as earthquake of November 10.

November 21, 2h 54m 02s pm, "P" waves, distance 3725 miles.

Time used above is Hawaiian Standard, 10h 30m behind G.C.T.

Microseismic motion of the ground at the observatory was moderate December 17, 18, 19 and 26 and was strong the remainder of the month.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending November 27 was 1.1″ S and 4.43″ M.

Week Ending	Observatory	Halemaumau West Station
November 6	0.92″ S 20° E	2.68″ S 75° W
November 13	1.13″ N 80° E	4.17″ N 40° W
November 20	0.40″ S 47° W	6.05″ S 77° W
November 27	0.93″ N 35° E	3.33″ S 55° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
November 6	3.30″ S 80° W	1.08″ from
November 13	3.24″ N 5° W	0.97″ from
November 20	2.91″ N 71° W	3.68″ from
November 27	3.89″ N 55° W	0.73″ toward

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory, November 23, indicated closing of the Halemaumau value and opening of the Crater value compared with similar measurements made October 25. During that period the angle between SE pit BM and NW pit BM closed 1.58″ and the angle between SE rim Station and Uwekahuna opened 1.48″. H.H.W.

DECEMBER 1938

Earthquakes

Week Ending	Minutes of Tremor	Very Feeble	Feeble	Distant*	Weekly† Seismicity
December 4.....	23	11	4	1	15.25
December 11.....	6	2	0	0	2.50
December 18.....	20	6	0	0	8.00
December 25.....	21	2	0	0	6.25
January 1.....	9	5	0	0	4.75

* Including teleseisms or earthquakes of over 5000 km from Kilauea.

† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

November 28, 2.03 pm, very feeble, 1.8 miles deep, 1.0 mile west of Puhimau and 0.6 mile south of Keanakakoi in Chain-of-Craters, 19° 23.7′ N; 155° 15.9′ west.

November 29, 5:43 am, feeble, 4.0 miles deep in SW portion of Kilauea Crater immediately W of Halemaumau. 19° 24.7′ N; 155° 17.6′ W. Reported felt in Hawaii Nationol Park.

November 29, 9:59 am, very feeble, probably originated in Chain-of-Craters area near Kokoolau.

November 29, 10:18 am, very feeble, of Kilauea Crater origin.

November 29, 10:19 am, feeble, of Kilauea origin. Reported felt in national park residential area.

November 30, 4:17 am, very feeble, probably originated in Kilauea SW rift about 2.0 miles from Halemaumou.

November 30, 2:05 p.m., very feeble, of shallow origin in Chain-of-Craters near Puhimau and Kokoolau. 19° 23.4′ N; 155° 15.2′ W.

November 30, 3:08 pm, feeble, 3.2 miles deep, Chain-of-Craters, 1.0 mile N of Hiiaka. 19° 23.5′ N; 155° 14.1′ W. Reported felt in national park residential area.

November 30, 3:13 pm, very feeble, 1.2 miles deep, 0.8 mile E of Keanakakoi, 19° 24.2′ N; 155° 15.2′ W.

November 30, 8:57 pm, feeble, 4.0 miles deep, 1.4 miles W of Pauahi Crater. 19° 22.3′ N; 155° 14.8′ W. Reported felt in Hawaii National Park residential area and at CCC camp.

December 1, 4:32 pm, very feeble, location approximately same as preceding shock.

December 2, 6:53 pm, very feeble, 8.0 miles deep, Mauna Loa NE rift 3.5 miles SW of Puu Ulaula. 19° 30.7′ N; 155° 31.0′ W.

December 2, 9:27 pm, very feeble, same general locality as preceding shock. 19° 31.5′ N; 155° 31.0′ W.

December 4, 4:32 am, very feeble, originated in Mauna Loa NE rift near Puu Kulua.

December 4, 7:34 am, very feeble, 2.2 miles deep in Chain-of-Craters near Hiiaka and Pauahi craters. 19° 22.7′ N; 155° 13.3′ W.

December 8, 11:09 pm, very feeble, of comparatively shallow origin, Mauna Loa NE rift, vicinity of Pohaka Hanalei. 19° 30.0′ N; 155° 33.6′ W.

December 10, 7:59 pm, very feeble, 12.0 miles deep under N slope of Mauna Loa about 5.0 miles N of Puu Ulaula. 19° 36.5′ N; 155° 26.8′ W.

December 13, 7:26 am, very feeble, E slope of Mauna Loa, 5.0 miles E of summit crater. 19° 28.3′ N; 155° 31.0′ W.

December 13, 10:11 am, very feeble, 8.0 miles deep under coast line S of Hilina Pali and 4.0 miles W of Keahou Point. 19° 16.5′ N; 155° 18.0′ W. Reported felt in Hilo.

December 14, 12:13 am, very feeble, in Hilina Fault system, 4.5 miles SE of Makaopuhi.

December 16, 1:18 pm, very feeble, of shallow origin near Devil's Throat. 19° 22.9′ N; 155° 14.5′ W.

December 16, 1:27 pm, very feeble, possibly 35.0 miles deep, under E slope of Mauna Loa. 19° 26.5′ N; 155° 32.0′ W.

December 17, 1:31 pm, very feeble, originated in Kilauea Crater, probably under Halemaumau.

December 19, 5:24 pm, very feeble, probably originated in Kilauea SW rift near Junction with Hilina Fault system.

December 20, 12:51 pm, very feeble, originated in Kilauea Crater near E rim of Halemaumau.

December 23, 7:18 am, a tremor which registered as feeble on Mauna Loa seismograph and originated in Mauna Loa NE rift.

December 26, 6:23 pm, very feeble, probably originated in area 3.2 miles E of Kilauea Iki.

December 27, 6:33 am, originated in Kilauea crater under Halemaumau.

December 28, 3:12 am, very feeble, 1.2 miles deep, Chain-of-Craters, 0.9 mile east of Keanakakoi. 19° 24.7′ N; 155° 15.2′ W.

Continuous tremor:

10 minutes, beginning at 3:45 pm, December 15.

10 minutes, beginning at 7:22 pm, December 19.

Teleseisms

Unidentified portion began to register at the Observatory 4h 17m 28s pm, HST, November 29. Located in Japan, E coast of Honshu. 37° 5′ N; 141° 3′ W.

Microseismic motion of the ground at the Observatory was moderate December 9 and 10 and strong the remainder of the period between November 28 and January 1 inclusive. Stormy weather prevailed at sea contemporaneously.

Tilting of the Ground

The following tables show tilt by weeks, as recorded by the Observatory seismograph and at Halamaumau, the algebraic sum toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending January 1, 1939, was 0.86″ S and 6.82″ W.

Week Ending	Observatory	Halemaumau West Station
December 4	1.12″ S 68° W	7.36″ N 71° W
December 11	0.80″ E	6.00″ S 76° W
December 18	1.10″ N 12° W	0.42″ N
December 25	2.17″ S 30° W	3.22″ S 57° W
January 1	0.80″ N 66° W	3.43″ S 60° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
December 4	2.08″ N 34° W	4.76″ from
December 11	7.08″ N 12° W	0.92″ toward
December 18	3.97″ N 41° E	0.81″ toward
December 25	8.10″ S 49° W	3.32″ from
January 1	10.05″ N 49° E	2.32″ from

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory, December 29, indicated opening of both the Halamaumau and the crater values compared with similar measurements of November 23. Between November 23 and December 13 the Halemaumau measurement from SE pit BM to NW pit BM showed opening of 0.35″ and between December 13 and 29, opening of 0.57″. Total opening of 0.92″. Between November 23 and December 13, the crater measurement from SE rim station to Uwekahuna showed closing of 1.07″ and between December 13 and 29, opening of 1.51″. Total opening 0.44″. H.H.W.

THE VOLCANO LETTER

No. 463 Department of the Interior National Park Service January-March, 1939

Edward G. Wingate Superintendent
Hawaii National Park

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, is leased and operated by the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigations.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

Hawaiian Volcano Observatory Report for January-March 1939

VOLCANOLOGY

January 1939

Until the last week, the month of January was locally quiet at the Hawaiian volcanoes. A feeble earthquake was sharply felt January 15, and there was a notable increase of spasmodic tremors during the last fortnight of the month. These originated under Mauna Loa and Hualalai. Distant destructive earthquakes of large size from Chile and the Solomon Islands were registered January 24 and January 29.

A moderate slide December 30, 1938 from about 300 feet below the north rim of Halemaumau occurred 10:07 a.m. On January 14 rock slides from the east and northwest walls occurred about 1:40 p.m. Slides became more numerous from the western walls of Halemaumau on January 25, ten being counted between 9:55 a.m. and 11:53 a.m.

On the morning of January 17 with nearly calm air much fume hung over Halemaumau originating mostly at the southeast solfatara at the edge of the floor.

Opening of the measured cracks around Halemaumau rim increased somewhat during the month along with the seismicity and the slides. For the week ending January 1, cracks across Chain-of-Craters road near Devil's Throat closed 2.0 mm. The next change noted there was opening of these cracks 1.5 mm. as measured January 20, and again by a like amount January 27. (See map Volcano Letter 462.)

The following are the local data for January:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
January 1	1	0.5 mm.	14
" 8	0	1.5 mm.	32
" 15	1	3.0 mm.	16
" 22	0	3.0 mm.	60
" 29	10	3.0 mm.	45

February 1939

The general conditions in Halemaumau pit as observed February 22 showed a small hole on the southeastern floor of the pit to be steaming near a long white stained crack. Fume above this eastern wall crack had lately been conspicuous. Stain was evident on the 1932 cone southwest, and along the canoe sill at the base of the northeast wall. Margin of the floor was sulphurous in several places. Slides had made a new scar on the south wall February 6 and February 16, and that wall kept scaling off during the last half of the month. The break made a wide white scrape up the entire height of the wall, on the east side of the upright southwestern rift cavern.

Kilauea was quiet the first week of February in contrast to volcanic disturbances in Central America and South America and a reported eruption of Asama in Japan February 3. The second week produced heavy rainfall February 9-10 resulting in clouds of vapor over Halemaumau.

A noisy rock slide fell from the southeast wall of Halemaumau 11:55 a.m. February 6. Rock slides increased during the third week and were noted February 16 at northeast rim 9:25 a.m.; February 17 north wall 7:55 a.m. and west wall 8:53 a.m.; February 18 northeast and north rims 11:00 a.m.; February 19 west wall 10:01 a.m. and northeast rim 10:08 a.m. This was the period when fresh scars and dust streaks were produced on the southeast wall. Two rock slides at the north wall occurred February 21, 9:18 a.m. and 12:10 p.m.

Measurements February 11 showed the new road cracks in the vicinity of Devil's Throat to have opened 2.0 mm., one near Hiiaka pit closed 0.5 mm., and the cracks beyond Pauahi pit were stationary. On February 17 the cracks near Devil's Throat had closed 1.0 mm.; one near Hiiaka closed 0.5 mm.; and one beyond Pauahi closed 0.5 mm. The excessive opening of Halemaumau rim cracks during the week ending February

26 was accompanied by openings of cracks near Devil's Throat 0.5 mm.; Hiiaka 0.5 mm.; and a large crack at Pauahi 1.0 mm.

The following are the local data for February:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
February 5	0	0.0 mm.	17
" 12	1	1.0 mm.	32
" 19	6	5.0 mm.	27
" 26	2	8.5 mm.	15

March 1939

The most distinctive event of March 1939 was excessive rainfall at the beginning of the month. This produced clouds of vapor from the floor of Halemaumau. Precipitation exceeded 19 inches in Hilo in one day, March 2, at Kilauea Crater the rain gauge registered 11.02 inches, and for the week ending March 5, 17.54 inches. The flood was disastrous in Hilo, and the level of water in Olaa Mill well rose three feet above the flood level of 1938 so as to require removal of machinery.

Sharp tilting of the Observatory ground westward March 2 may have been caused by the loading of floor of Kilauea Crater with rain. This was followed by remarkable increase of rim crack openings at Halemaumau for the week ending March 12. Fifteen of twenty-eight crack locations showed opening, one closed, resulting in aggregate opening 17.5 mm. The greater part of this value was contributed by cracks east and southeast. Increased rate of opening of the rim cracks about spring equinox has been noted each year since 1933, generally with accompaniment of rock slides. The strong opening of cracks continued for the remainder of the month.

Observations at Makaopuhi pit March 21, in the Chain-of-Craters, showed that sulphur deposition and fuming are in progress at a hot spot halfway up the crater wall, and a small rock slide was observed at the north rim. On March 29 vapor was observed rising from the talus on the east side of Alealea Crater probably stimulated by deeper penetration of the recent rain.

The cracks near Devil's Throat had opened 2.0 mm. March 3 and 1.5 mm. March 10. The cracks near Hiiaka pit and Pauahi pit had opened 0.5 mm. March 10. Inspection March 21 indicated that new cracks across the road are developing near Devil's Throat, a small portion of the southwest rim of this pit has recently fallen, cracks to the northwest have increased and humps in the road pavement are growing higher near Pauahi and near the Ainahou road. Temperature measurement at the hot area in ohia forest near Kokoolau Crater showed no change and there is no encroachment of solfataric action on the surrounding forest.

Rock slides in Halemaumau were observed at northeast wall March 3, 10:15 a.m. and 10:28 a.m. Two small slides from the north wall occurred at 10:20 and 10:30 a.m. March 6. Slides increased March 27 and were observed 11:51 a.m., northwest wall; March 30, 7:36 a.m., northeast wall and 11:07 a.m. northwest wall; March 31, 8:58 a.m. northeast wall; April 1, northeast rim 11:50 a.m. and 1:30 p.m.

The following are the local data for March:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
March 5	2	4.5 mm.	13
" 12	2	17.5 mm.	17
" 19	0	13.5 mm.	32
" 26	0	10.0 mm	24
April 2	6	13.5 mm.	28

* Including teleseisms or earthquakes over 5000 km. from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus has been made.

January 2, 8:45 am, very feeble, 8.0 miles deep off seacoast 5.0 miles south of Ahua Point. 19° 11.0′ N; 155° 12.7′ W.

January 4, 8:40 am, very feeble, 2.5 miles deep, Kanaokuaiki Pali about 1.5 miles east of Puu Ohale. 19° 21.2′ N; 155° 15.4′ W.

January 7, 5:15 am, very feeble, 7.0 miles deep NE rift of Mauna Loa. 19° 31.5′ N; 155° 33.0′ W.

January 10, 9:41 pm, very feeble, 2.6 miles deep near Hiiaka and Pauahi Craters. 19° 21.3′ N; 155° 13.9′ W.

January 13, 12:01 am, very feeble, 18.0 miles deep in vicinity of Puu Kulua, Mauna Loa NE rift. 19° 34.0′ N; 155° 26.3′ W.

January 14, 10:46 am, very feeble, 1.2 miles deep, 0.7 mile SW of Ahua Kamokukolau. 19° 22.7′ N; 155° 16.7′ W.

January 15, 3:30 pm, feeble, of shallow origin in Kilauea Crater near Halemaumau. 19° 24.5′ N; 155° 16.3′ W. Reported felt by many persons in Hawaii National Park residential area and by a few in Hilo.

January 16, 1:10 am, very feeble, about 13.0 miles deep in Mauna Loa NE rift, in the vicinity of Puu Ulaula. 19° 33.0′ N; 155° 27.0′ W.

January 17, 4:35 pm, very feeble, about 6.0 miles deep under area about 3.0 miles SE of Puu Ulaula, Mauna Loa NE rift. 19° 31.7′ N; 155° 25.8′ W.

January 17, 8:19 pm, very feeble, 13.0 miles deep in Kilauea SW rift about 9.0 miles from Halemaumau. 19° 20.6′ N; 155° 24.5′ W.

January 19, 2:58 pm, slight, 16.0 miles deep under Hualalai. 19° 41.6′ N; 155° 52.0′ W. Reported strongly felt by many persons in Kona and Kohala districts and slightly by some in Hilo and Kau districts.

January 25, 11:42 am, very feeble, probably originated in Chain-of-Craters SE of Kilauea Crater.

February 2, 9:56 pm, very feeble, originated in Mauna Loa NE rift near Summit Crater. 19° 30.0′ N; 155° 32.0′ W.

February 5, 1:57 pm, very feeble, probably originated about 5.0 miles W by N of Pahala. (3.0 miles NW of Kula mountain.)

February 9, 7:45 am, very feeble, 0.9 mile deep at Chain-of-Craters near Pauahi and Hiiaka Craters.

February 10, 9:56 am, very feeble, 3.3 miles deep in same general area as preceding quake. 19° 21.3′ N; 155° 13.9′ W.

February 10, 3:46 pm, very feeble, 10.0 miles deep in Mauna Loa NE rift near Puu Ulaula. 19° 33.0′ N; 155° 27.0′ W.

February 13, 7:17 pm, very feeble, probably originated in area between Devil's Throat and Ahua Kamokukolau.

February 16, 9:26 am, very feeble, probably originated under NE edge of Kilauea Crater floor.

February 17, 6:05 am, very feeble, 25.0 miles deep, 8.0 miles E of Kulani cone. 19° 34.3′ N; 155° 13.3′ W. Reported felt in Hilo.

February 17, 6:36 pm, feeble, 4.0 miles deep under N rim of Kilauea Iki. 19° 25.8′ N; 155° 14.7′ W.

February 18, 4:36 pm, very feeble, probably located in Chain-of-Craters near Kokoolau.

February 21, 2:26 pm, very feeble, 2.7 miles deep in area N of Kilauea Iki. 19° 25.8′ N; 155° 14.5′ W.

February 23, 12:52 pm, very feeble, 5.0 miles deep in Hilina fault system 3.0 miles S of Makaopuhi. 19° 19.2′ N; 155° 11.0′ W.

February 26, 7:53 am, very feeble, originated under N portion of Halemaumau.

February 26, 6:11 pm, very feeble, probably originated in Kohala area about 4.0 miles N of Kawaihae. 20° 5′ N; 155° 50.0′ W.

March 4, 3:18 am, very feeble, originated in NE portion of Kilauea Crater.

March 5, 1:11 am, very feeble, 15.0 miles deep in Mauna Loa NE rift, 7.0 miles NW of Kulani Cone. 19° 35.4′ N; 155° 21.6′ W.

March 8, 10:33 am, very feeble, 22.0 miles deep in Mauna Loa NE rift near Pukauahi Cone. 19° 33.0′ N; 155° 31.2′ W.

March 13, 9:28 pm, very feeble, 10.0 miles deep under E slope of Mauna Loa, 2.5 miles SE of Mauna Loa seismograph. 19° 27.5′ N; 155° 21.2′ W.

March 14, 6:08 am, very feeble, 2.0 miles deep near Kipuka Puaulu. 19° 26.8′ N; 155° 18.7′ W.

March 14, 9:54 am, slight, 2.3 miles under Halemaumau, Kilauea Crater. 19° 24.6′ N; 155° 17.2′ W.

March 14, 10:56 am, feeble, probably originated in area between Makaopuhi Crater and Hilina Pali.

March 14, 12:10 pm, feeble, of shallow origin in area about 0.8 mile W of Devil's Throat. 19° 22.7′ N; 155° 14.9′ W.

March 20, 12:13 am, very feeble, probably originated in Hilina Pali area about 6.00 miles SE of Makaopuhi.

March 21, 8:47 am, very feeble, of shallow origin in area immediately E of Kilauea Iki. 19° 24.7′ N; 155° 13.6′ W.

March 22, 5:46 am, 40.0 miles deep Mauna Loa NE rift, 8 miles from Summit Crater. 19° 33.0′ N; 155° 30.0′ W.

March 22, 10:57 pm, feeble, 10.0 miles deep Mauna Loa NE rift, 13.0 miles from Hilo. 19° 38.0′ N; 155° 16.0′ W. Reported generally felt in Hilo.

March 24, 8:59 pm, very feeble, 9.0 miles deep in Kau desert area about 2.0 miles S of Puu Ohale. 19° 20.7′ N; 155° 15.0′ W.

March 25, 11:02 pm, very feeble, probably originated in Chain-of-Craters between Devil's Throat and Puhimau Crater.

March 28, 5:36 am, very feeble, 20.0 miles deep, Mauna Loa NE rift near Puu Kulua. 19° 35.2′ N; 155° 26.0′ W.

March 29, 9:47 am, very feeble, of Kilauea Crater origin.

March 30, 9:35 pm, very feeble, originated in NE portion of Kilauea Crater.

Continuous Tremor

Thirty-seven minutes beginning at 8:30 am, January 27. Eleven minutes beginning at 2:02 am, February 18.

Teleseisms

January 18, 11:53 pm, H.S.T., beginning of unidentified portion.

January 24, 5h 15m 41s pm, H.S.T., "P" waves began to register. Shock originated in Chile and was of very destructive nature resulting in estimated loss of over 20,000 human lives, distance from Kilauea 6,435 miles.

January 29, 3h 57m 57s pm, H.S.T., "P" waves began to register. Shock originated in Solomon Islands. Distance from Kilauea 3,800 miles.

February 2, 7h 05m 37s pm, H.S.T., "P" waves began to register. Distance from Kilauea, 3,795 miles.

February 7, 8:26 pm, unidentified portion began recording. No reports have been received concerning this quake either by press or from other stations.

February 24, 4:01 am, unidentified portion.

Microseismic Motion

Microseismic motion of the ground at the Observatory was moderate January 15-21 inclusive and January 29, 30, and 31. It was strong the remainder of the month.

For February it was light on the 20th, 21st, and 25th; moderate on the 12th, 22nd-24th, 26th-28th, and strong the remainder of the month.

During March it was strong 3-5, 17-19, and moderate the remaining dates. All dates inclusive.

H. H. W.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the observatory seismograph and the one at Halemaumau; the algebraic sum toward or away from the pit.

At the Observatory the total accumulated tilt for the year ending January 29, 1939 was 1.15" S and 5.93" W.

For the year ending February 26, it was 1.00" S. and 1.73" W.

For the year ending April 2, it was 3.08" S and 4.85" W.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
Jan. 8	0.43" S 54° E	3.22" S 64° E
" 15	0.55" S 11° E	3.52" S 42° W
" 22	0.91" S 19° W	4.77" N 15° W
" 29	0.97" S 35° W	2.62" N 30° E
Feb. 5	2.00" S 28° W	2.92" N 85° W
" 12	0.77" S 12° W	1.49" S 60° W

Apr. 2	1.20" S 9° W	2.00" from H. H. W.

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory January 21, indicated closing of both the Halemaumau and the crater values compared with similar measurements of December 29. The Halemaumau angle between the pit seismograph and the NW pit BM closed 0.50". The crater angle between the SE crater rim station and Uwekahuna closed 1.58".

Angle values determined on February 15, indicated opening across Halemaumau and closing across the crater. Between January 21 and February 15, the Halemaumau value increased 0.83", and the crater value decreased 1.15".

During March two determinations were made of the angles. These were March 13 and 30. On the first of these two runs, the Halemaumau angle closed 2.25" and the crater angle closed 0.25". Between March 13 and March 30 the Halemaumau angle again decreased (0.59") and the crater angle opened by an amount of 2.24". Total change for the month, Halemaumau angle closed 2.84" and the crater angle opened 2.00".

During the first three months of 1939 the Halemaumau angle has decreased 2.51" and crater angle has decreased 0.84".

These changes agree favorably with current tilt toward Halemaumau.

H. H. W.

Levelling at Kilauea

Since January 1, 1939 two sets of levels have been run over the usual circuit on the floor of Kilauea Crater between the Spit BM on the SE crater rim and the NW Pit BM. The line of levels follows the S-SW-W, rims of Halemaumau.

These determinations were made January 30 and March 21. In both cases the NW Pit showed relative lowering with reference to Spit BM. On the first run, this value amounted to 14.0 millimeters and on the second run, a similar value of 15.0 millimeters. These determinations are in accord with both tilt and horizontal angle determinations.

Since the lava inflow at Halemaumau in September, 1934 the NW Pit BM has showed a total relative lowering with respect to the Spit BM of 0.429 meters or 1.41 feet.

H. H. W.

Chain of Craters, Crack Openings*

At 6:00 am, May 28, 1938 a series of earthquakes of various intensities began to register on the seismographs of the Hawaiian Volcano Observatory. Many were strongly felt in the National Park Headquarters area. Within the ensuing 24-hour period well over 100 earthquakes were recorded as well as several hours of continuous tremor in the early stages of the disturbance. Accompanying this seismic activity were visible ground movements along pre-existing cracks in the Chain-of-Craters between Pauahi and Aloi, roughly four miles SE of Kilauea Crater. Definite evidence of these movements was produced by shattering of the hard surface of the Chain-of-Craters road at approximately 11 different localities. Slides occurred in Pauahi. The largest crack developed near Pauahi where a large section of the roadway was destroyed by caving. A few days later seismic conditions had returned to normal.

On the morning of August 8 at 2:14 o'clock, a similar crisis began. More earthquakes were recorded in the following 24 hours than had occurred in the corresponding period in May. Over 200 earthquakes occurred on August 8 alone. This time there were a number of shocks from Kilauea Crater, several from Hilina Pali and others at various points along the Chain-of-Craters but mostly concentrated near Kokoolau and Devil's Throat. Again visible evidence of the general area of disturbance was indicated by cracks across the Chain-of-Craters road; three groups near Devil's Throat and one near Hiiaka (SW rim). The cracks between Pauahi and Hiiaka showed no appreciable changes.

On August 10 seven representative cracks were chosen for measurement and numbered successively from the large crack (hump) near Devil's Throat to the last large crack near Aloi.

The list is as follows:

No. 101—At the "hump" about 1000 feet W of Devil's Throat.

No. 102—At W side of junction of Chain-of-Craters road with the Hilina Pali road.

No. 103—Near S rim of Hiiaka.

No. 104—Large crack near S rim of Pauahi.

No. 105—About 1000 feet SE of the Chain-of-Craters road and Ainahou Ranch road junction.

No. 106—About 50 feet SE of No. 105.

No. 107—About 750 feet W of W rim of Aloi Crater.

Table of crack measurements on Chain-of-Craters road. (Values in centimeters except No. 104 which is in feet, inches and sixteenths.)

Date	101	102	103	104	105	106	107
August 10	402.05	62.85	101.60	17'8- 8/16"	87.00	88.45	41.00
September 2	402.65	63.90	101.45	17'8-12/16"	87.10	88.60	40.90
October 7	402.80	64.00	101.40	17'8-14/16"	87.15	88.65	40.75
November 4	402.95	64.10	101.40	17'8-15/16"	87.20	88.65	40.65
December 2	403.00	64.10	101.45	17'9.0"	87.15	88.65	40.60
January 6	403.30	64.20	101.45	17'9.0"	87.05	88.65	40.50
February 3	403.45	64.25	101.45	17'9.0"	87.05	88.65	40.45
March 3	403.65	64.30	101.40	17'9- 1/16"	87.10	88.65	40.40
March 31	403.70	64.40	101.35	17'9- 1/16"	87.15	88.65	40.40
Total change in mm.	+16.5	+15.5	—2.5	+10.0	+1.5	+2.0	—6.0
	plus (+)=open			minus (—)=close			

The indications from the above figures are that the greatest amount of movement has been and continues near Devil's Throat with next highest rates of change at Pauahi and Alai respectively.

These measurements are to be continued and will be reported regularly.

THE VOLCANO LETTER

No. 464 Department of the Interior National Park Service April-June, 1939

Edward G. Wingate Superintendent
Hawaii National Park

Hawaiian Volcano Observatory
T. A. Jaggar Volcanologist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

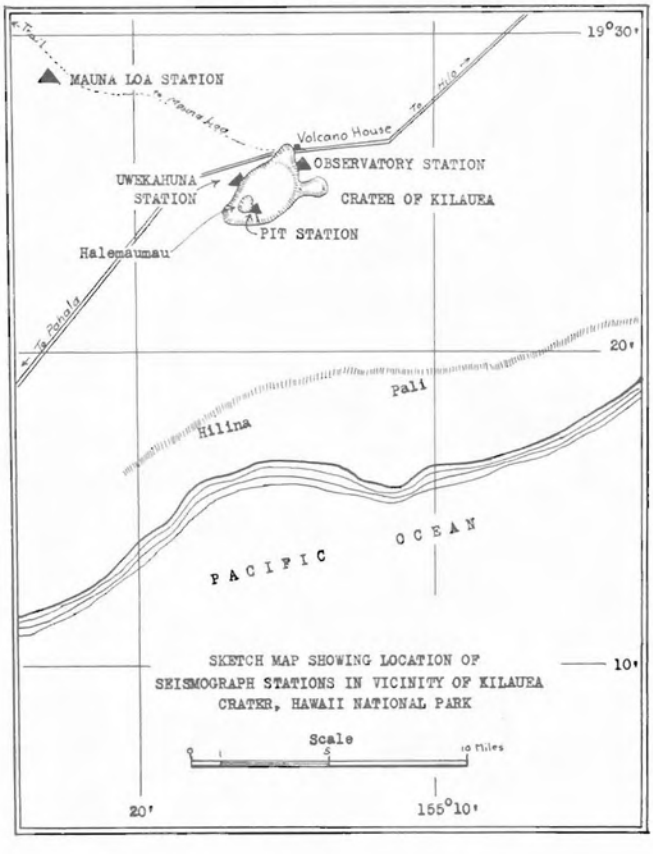
The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, is leased and operated by the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigations.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

TIME CONTROL FOR SEISMOGRAPHS OPERATED BY THE HAWAIIAN VOLCANO OBSERVATORY

HUGH H. WAESCHE, Asst. Geologist



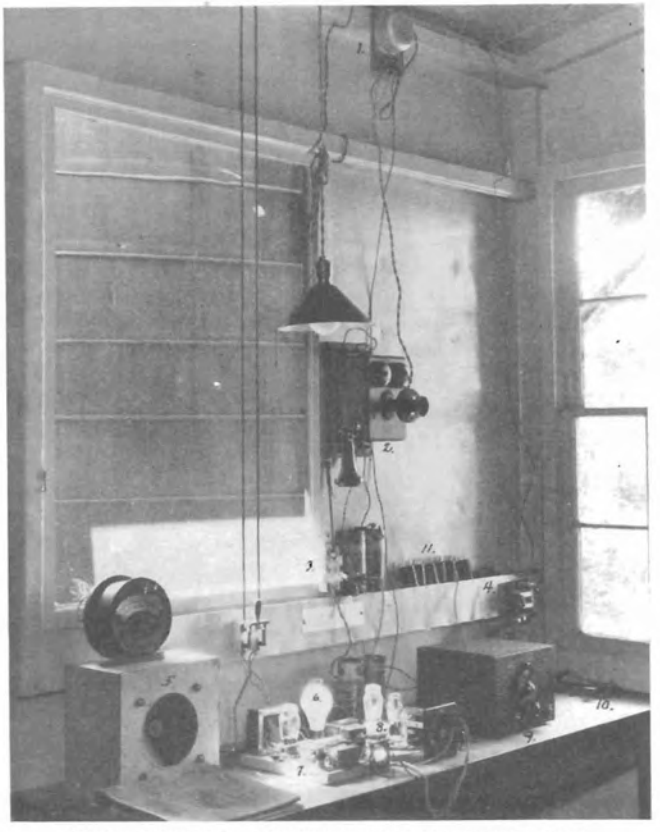
A major problem concerning the operation of any group of seismograph stations is the time control. This is important for widely separated stations but becomes of increasing value for studying travel times between stations separated by distances from one mile to several hundred miles where time errors of tenths of seconds may produce relatively large error in determining earthquake focii.

At Kilauea, seismographs are located at the Observatory, NE rim, Uwekahuna, NW rim and at the SE rim of Halemaumau (see map). At the Observatory there are three instruments, the Bosch-Omori, a vertical component and a low magnification instrument of special design. The entire group has always had a common time control, originating from a pendulum clock (Howard) equipped with electrical contacts for closing the circuit on the fifty-ninth second and breaking on the sixtieth second of every minute and closing for ten seconds during the first minute of each hour. Proper correction of clock is maintained by comparison with radio time signals from NPM and NPG daily at 4:30 pm, H.S.T.

The writing pens are lifted off the smoked drums by a solenoid supported in front of and slightly above each needle. This system has been the most satisfactory method found for indicating the time on the smoked paper. It is true that occasionally important phases are missed in an earthquake but this occurs far more rarely than might be suspected and indicates the time in a reliable manner. The Bosch-Omori low magnification and Uwekahuna recording drums have minutes 50 millimeters in length; all the other records have minute lengths of 30 millimeters.

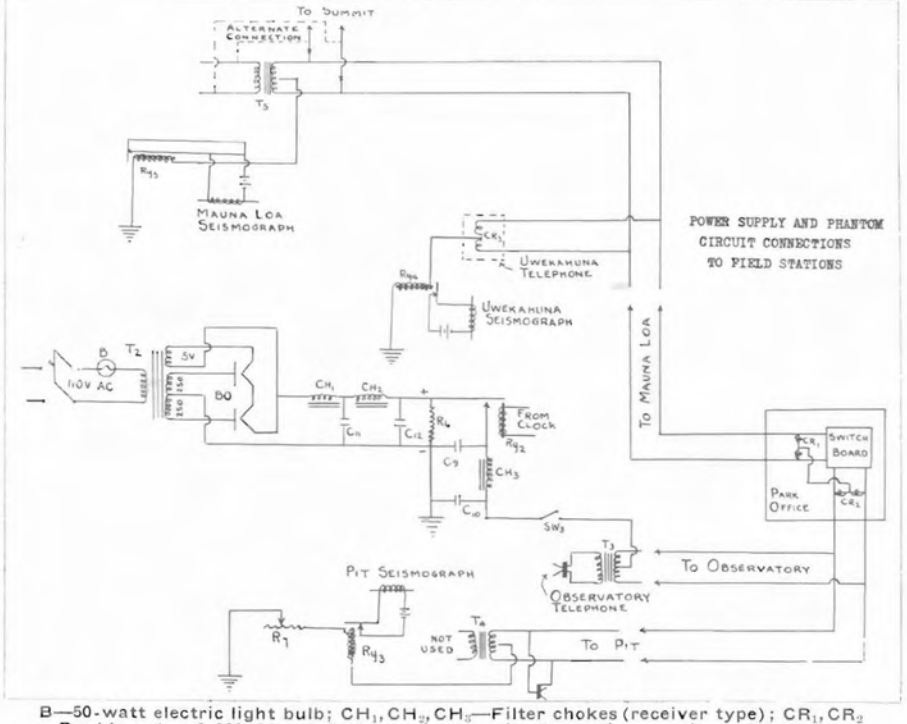
Individual time clocks were installed at Halemaumau and Uwekahuna as well as in the outlying stations at Hilo and Kealakekua. A station using the same system was installed on Mauna Loa in October, 1938. The latter is located about 10.0 miles NW of the Observatory. None of these stations had radio sets for time corrections and were unattended except for daily visits to change the recording drums.

In 1931 Mr. A. E. Jones began studies of travel times in



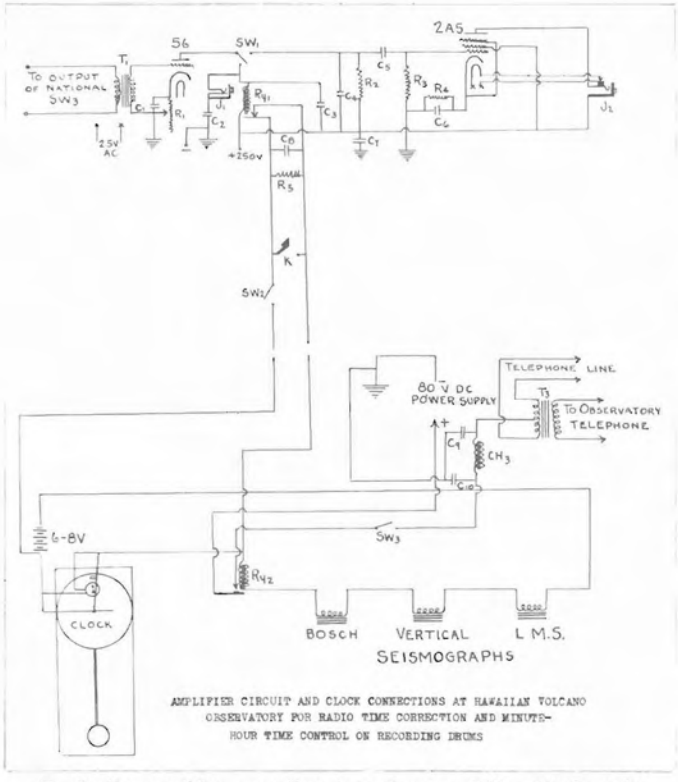
the Hawaiian Islands. Before this, travel times developed by Omori for local shocks in Japan had been used. Mr. Jones found that the Omori travel times did not agree with the seismic facts in Hawaii so immediately set to work developing a set of travel times for the Island. He succeeded in doing this very ingeniously as described in his paper "Hawaiian Travel Times", published in the Bulletin of the Seismological Society of America in January, 1935. During these studies, time comparisons between the Pit and Uwekahuna clocks were made with the clock at the Observatory using a stop watch carried between stations daily. Time corrections at Hilo and Kona were made by listening to the time tone and then as nearly as possible synchronizing this by manual operation of a key which transmitted a signal over the mutual telephone lines to those stations. Lags and other errors of the personal equation as well as unreliability of time clocks in the outlying stations made the system only partially successful and by 1937 all attempts at time control have been given up other than for S-P determinations based on the known speed and dimensions of the recording drum and at the Observatory where close watch could be kept on clocks and radio.

As more earthquakes were recorded, however, there came the conviction that good, reliable time control with all the stations exactly correlated with the clock at the Observatory was a necessity. There was still considerable doubt as to the speed of the compressional and transverse waves from various parts of the Island and earthquakes with good preliminaries at all stations still did not give satisfactory solutions when locations were attempted. Consequently, various plans were considered, varying from radio control from the central station to direct wire connections. Little was done because of the expense of the necessary equipment.



The first step was made in December, 1936, when a sensitive relay and vacuum tube amplifier to operate it were added to the regular short wave receiver then in service. About the same time a rectifier was added to the set, thus utilizing the Hilo power, 110 volts A.C. Previously batteries had been used but had proved expensive. The radio-operated sensitive relay closed the same circuit operated by the time clock and thus indicated the position of true time with reference to the nearest minute. Every day time was checked at 4:30 pm, by an operator tuning the set to the 12,885 kc frequency of NPG or NPM. This was highly successful and probably gave a time correction at the Observatory well under 0.5 sec. for all the instruments operated in that building.

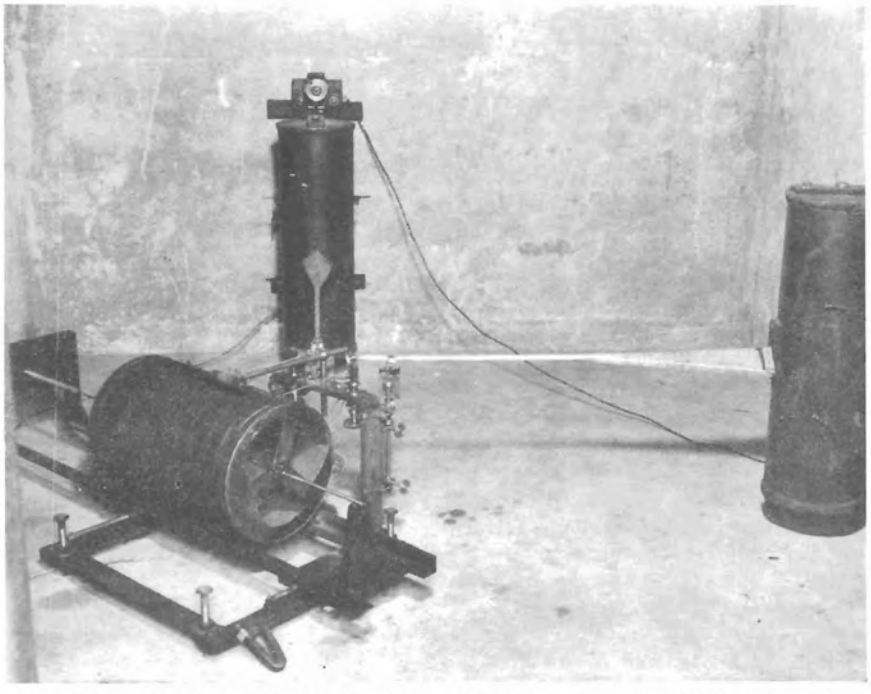
About one year after the relay was installed, the 10,000-ohm coil winding burned out. A new 5,000-ohm coil was wound and operation resumed with little change in the sensitivity of the relay. In attempting to make some mechanical changes in the relay during April of this year, the coil was injured beyond repair. Rather than rewind the relay and take chances on its burning out again, a new relay was constructed, using two 1,250-ohm telephone ringer coils in series. This relay proved sensitive enough (closes on about 0.5 milliamps) and has the added



TIME CONTROL STATION AT THE HAWAIIAN VOLCANO OBSERVATORY

1. Observatory repeating coil; 2. Test telephone set; 3. Anne-mometer switch; 4. Sensitive time relay connected to radio receiver; 5. Loud speaker; 6. 50-watt ballast bulb in series with power transformer; 7. Power unit and rectifier for operation of time control system; 8. Power and amplifier unit for radio receiver; 9. National SW3 radio receiver; 10. Key for manual control of circuits; 11. Wave band coils for radio receiver.

B—50-watt electric light bulb; CH_1, CH_2, CH_3—Filter chokes (receiver type); CR_1, CR_2—Double sets of 800-Ohm telephone ringer coil; CR_3—Ringer coil on Uwekahuna telephone; T_2—Power transformer 250-250 secondary and 5 V for rectifier; T_3, T_4, T_5—Repeating coils; Ry_2—Relay of low resistance in Observatory circuit; Ry_3, Ry_4, Ry_5—1250-Ohm relays at seismograph stations; SW_3—Single pole, single throw switch for cutting off phantom circuit; $C_9, C_{10}, C_{11}, C_{12}$—8 mfd filter condensers; R_6—50,000-Ohm bleeder resistor; R_7—5000-Ohm wire wound variable impedence (not found necessary).



AMPLIFIER CIRCUIT AND CLOCK CONNECTIONS AT HAWAIIAN VOLCANO OBSERVATORY FOR RADIO TIME CORRECTION AND MINUTE-HOUR TIME CONTROL ON RECORDING DRUMS

T—Audio-amplifier, coupling transformer; SW_1—Single pole double throw toggle switch; J_1, J_2—Jacks for connecting speaker; C_1—4 mfd; C_2—0.2 mfd; C_3—0.1 mfd; C_4—0.002 mfd; C_5—0.1 mfd; C_6—10 mfd; C_7—0.25 mfd, relay sparking filter; C_8—0.5 mfd; R_1—50,000-Ohm potentiometer DC component control; R_2—30,000-Ohm 1 watt carbon; R_3—75,000-Ohm 1 watt carbon; R_4—300-Ohm 2 watt carbon; R_5—500-Ohm 1 watt carbon relay sparking filter; Ry_1—Home-made relay 2500-Ohm; K—Key for manual operation; SW_2—Single pole single throw switch to disconnect amplifier from clock; SW_3—Single pole single throw switch to disconnect power from telephone line; C_9, C_{10}—8 mfd electrolytic filter condenser; Ry_2—Relay operated by clock circuit, closes time circuit to other stations; T_3—Repeating coil.

advantage of having readily replaceable coils of which there always are some in stock as the Hawaii National Park keeps a supply for replacement purposes in their telephones.

The U. S. National Park Service, for purposes of protection and convenience, operates its own telephones and necessary lines in the Park. There is a small exchange at Park Headquarters through which are connected three trunk lines, all of which are metallic, that is, two wire and ungrounded. One line is connected to the Observatory and also serves the southern part of the Park, including Halemaumau. A second line serves the Park employee, residential area and the third line serves Uwekahuna Museum, the Hotel, Military Camp and the Mauna Loa line extending to the summit. For some time these lines had been thought of as potential connecting links between the seismograph stations with direct time control from the Observatory clock. A plan was evolved using center tapped resistors across the line, one at the Observatory and one at the Pit seismograph station. This would produce a phantom circuit on the metallic line with a ground return. A relay was to be activated by the clock simultaneously with the Observatory seismographs. The contact circuit of the relay would then be made to send a direct current of sufficient voltage over the phantom circuit to operate a relay at the Pit station. Theoretically this circuit would not interfere with the telephone circuits as the current on the metallic line would be balanced and moving in the same direction over the lines. Before trying this arrangement Mr. L. W. Branch, local manager of the Mutual Telephone Company, was consulted. His opinion was that such a circuit would be effective but recommended the use of standard telephone repeating coils instead.

In December two of the repeating coils were purchased from the telephone company. One of these was placed in the Observatory and the other was placed at the Pit and connected as indicated in the accompanying diagram. Ninety volts of "B" battery were the source of power. The trial was successful in that the time was transmitted and synchronized with the Observatory. However, it was discovered that each time the circuit was closed or opened, an unbearably strong popping noise was heard on all phones on that line or others connected through the switch-board. A filter circuit consisting of the conventional 8 mfd condenser—filter choke and 8 mfd of condenser inserted in the phantom alleviated the situation so that the phones were usable; but this did not completely clear up the situation. The lines were undoubtedly either unbalanced or one wire was grounded. Furthermore, the batteries soon become exhausted. As batteries were short-lived and therefore impractical a power pact similar to those used regularly on radios was constructed. This was connected to the regular 110-volt A.C. power. The transformer was that from an old radio receiver and an 80 rectifier tube was used. A 50-watt electric light bulb was hooked in series with the primary of the transformer as an indicating device and safety precaution in case any of the circuits should become shorted. The flash of this bulb every minute showed that the circuit was operating and continuous bright glow of the bulb showed that something was wrong with the circuit. When the high voltage power was idling and only the filament current for the rectifier

MAUNA LOA SEISMOGRAPH STATION SHOWING LARGE DRUM FOR 48-HOUR CONTINUOUS OPERATION. N-S COMPONENT TO RIGHT; E-W TO LEFT.

tube was being drawn, only a dull red glow showed from the bulb in the darkness.

For about three months the test circuit operated consistently but the disturbance to the phones, though not bad, continued. Finally the relay at the Pit stopped. Current tests showed that the line drew 150 milliamperes. It was evident that at least one line was shorted. A careful check showed that the short was at a place near the Pit station, where insulation had been worn from a wire running through a portion of the line which had been put in a pipe below ground. Correction of this fault cleared the telephones of all noise and the relay responded vigorously. The trial circuit was then a complete success and the Pit station was considered permanently time-coupled to the Observatory.

The problem was now to add the Mauna Loa and Uwekahuna stations to the circuit. This could be done by putting repeating coils at the switch-board terminals of the Observatory-Pit line and the Mauna Loa line. A repeating coil with one side of the transformer burned out was available in the Park. Cost of more transformers made them impractical. The burned out transformer was placed at the Pit and the good side used. The transformer from there was transferred to the Mauna Loa station. To offset the lack of repeating coils at the switchboard two sets of two 800-ohm ringer coils were used. One set was connected across the Mauna Loa line and the other set across the Observatory line. The two coils in each set were connected in series. This connecting wire was equivalent to a center tap so a jumper was connected from the link on one pair of coils to the link on the other. This made a phantom circuit path for the time signal whether the two lines were directly connected through the switchboard or not. Effective resistance across the metallic line was that of two telephones at 1,600 ohms each, but offered only a total of 800 ohms in the timing circuit. The relays at the Pit and on Mauna Loa had 150-ohm coils. They were replaced by 1,250-ohm telephone ringer coils. This made them much more sensitive and reduced current consumption materially and even allowed for considerable current loss through line leakage in wet weather or from other causes.

A third relay patterned after the one at the Pit was installed at Uwekahuna. No more repeating coils were available so the phantom circuit was tapped from the connecting link between the two ringer coils on the regular Uwekahuna telephone. This was found to be a satisfactory arrangement with the relays responding consistently and without interfering in any way with the telephone service.

With the telephone lines clear all three relays in the circuit operating and a 50-watt bulb in series with the power transformer primary, the current drawn is 60 milliamperes at about 80 volts.

The results have been very gratifying. The only interruption was caused by an accidental short on the line to Mauna Loa by linemen placing a grounded cable against a guy wire which in turn was bent across a service line. When this short was in existence, the Mauna Loa and Uwekahuna relays responded only when the switchboard was connected through from 4:00 pm to 8:00 am, daily. A few days before the short was discovered, all the relays were out of operation. Since this trouble was cleared up the circuit has performed perfectly.

No careful studies have been made of the results on the seismograms yet, but preliminary observations indicate that the arrangement is extremely worthwhile and gives direct time correlation for the entire circuit. Extra work involved in making time corrections has been eliminated and the uncertainty of S-P values has been corrected.

The remaining problem now is to obtain accurate time correlation for the Hilo and Kona stations. Specially designed semi-automatic radios have been requested and it is hoped they will be available in the near future. There will be much value and satisfaction to a completely coordinated set of seismograph stations. When this is accomplished accurate travel times for the area may be determined and possibly more knowledge obtained of the underground structure in Hawaii.

Hawaiian Volcano Observatory Report for April-June 1939

VOLCANOLOGY

April 1939

The Volcanic Observatory recorded a cold and rainy April, with low seismicity and some Halemaumau slides. A rock slide from the northwest wall of Halemaumau occurred at 9:50 a.m. April 5 and several unusually large newly fallen boulders were seen at the foot of the northeast talus at 10:00 a.m. April 7. On April 16 a slide from the southwest rim at 9:32 a.m. continued for about five minutes. It left a mark on the Pit wall and produced tremor at the Halemaumau seismograph. Marks on the Pit walls indicated other slides.

Crack measurements at the twenty-eight marked localities around Halemaumau showed decline from the measurements of March during the first week of April, there was increase of opening the second week, and thereafter the crack movement notably declined and for the whole month there was strong decrease of crack-opening.

Mauna Loa was visited by the northeast trail April 20, and no visible changes in the conditions of that volcano were observed.

Of the sixty-six shocks and tremors registered on the seismographs for April, fifteen were located by seismometric method, and of these eleven were under Kilauea mountain, three were Mauna Loa and one was Hualalai.

The following are the local data for April:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
April 9	2	6.0 mm.	19
" 16	1	10.5 mm.	16
" 23	0	3.0 mm.	18
" 30	0	2.5 mm.	13

May 1939

The month of May appears to have been strongly seismic and volcanic all over the world with press reports of a destructive earthquake in Japan and of increase of volcanic activity in Alaska, Costa Rica, Italy and Java. Hawaii showed steady increase of numbers of earthquakes reaching a peak of seismic activity May 31 with three strongish shocks near Hilina Pali and Kilauea. Exceptionally strong tides with high waves altered the black sand beach at Kaimu May 19 and 20, measured cracks near Chain-of-Craters road both opened and closed, relative height of the road humps on this road increased, and slides occurred at Makaopuhi, Devil's Throat and Hilina Pali.

Rock slides occurred in Halemaumau at northwest rim 8:47 a.m. and 9:02 a.m. May 3. At 12:47 p.m. May 11 a slide fell from the northwest wall. The strongish earthquake of 10:27 a.m. May 15 was accompanied by slides from the northern and western walls 10:28 a.m. and 10:29 a.m. Sliding at northwest wall occurred 11:23 a.m. May 15. Along

with earthquakes approximately fifteen slides occurred in Halemaumau as follows:

May 23, southwest wall, 2:14 and 2.31 p.m. ;
24, northeast and northwest rims 1:11 p.m. and north rim 2:30 and 5:50 p.m.;
26, north wall, 8:17, 8:20, 8:40 a.m. and 4:29 p.m.;
27, northwest rim, 2:20 and 2:40 p.m.;
28, northern rim, 8:38, 8:59, 10:15 and 11:05 a.m.

At Makaopuhi Crater a scar indicating fresh slide from the north rim was seen on May 5, and the Devil's Throat continues to fracture and break away along the west and north rims. Several slides from the cliffs in the Hilina Pali region occurred about 2:05 p.m. May 18.

Of one hundred eighty-four seismic disturbances twenty-three indicated place of origin. Of these, six were from Kilauea, six from Hilina Pali and six from Mauna Loa. One each was from Hualalai and Chain-of-Craters. One was near Honolulu, one west of Maui and one from Mountain View.

The following are the local data for May:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
May 7	2	7.5 mm.	12
" 14	1	3.5 mm.	38
" 21	3	13.0 mm.	39
" 28	15	8.5 mm.	95

June 1939

After the second week of June the seismic activity dwindled. The maximum of the different types of activity, including seismic frequency, was the second week of June, but the greatest intensity of quaking had been at the end of May. A strongish shock occurred June 12 and another June 19, both fairly deep under Kilauea; a peculiar shock June 24 was like a blast, of shallow origin under the northeast rim of Kilauea crater. Of late, Veniaminof has been active on the Alaskan peninsula, Poas and Irazu volcanoes in Costa Rica, Vesuvius excited some press report, and so did Krakatoa. Eleven distant earthquakes have been registered from New Caledonia, northeastern Asia, Solomon Islands, Lower California, Aleutian Islands, Tonga Islands, and a near shock about ninety miles from us.

Rock slides at Halemaumau were reported June 7, north wall, 12:53 p.m.; June 8, northern walls, 12:53 p.m.; and from northwest wall on June 9; June 14 a slide wth large boulders from high up west wall 3:25 p.m. Dust clouds indicated slides at northwest wall June 12, 1:36 p.m.; June 16, 2:12 and 2:13 p.m. A slide from northwest wall was reported June 26 11:15 a.m.

That the working of the fault benches southeast of Kilauea is a distributed movement was shown by discovery June 12 of a fresh landslip on Pali Lele O Kalihipaa four miles south of the center of Kilauea.

Of a total of three hundred thirty-seven local seismic disturbances in June, thirty-one had their centers located, of which twenty-two were under Kilauea, five along Chain-of-Craters, three at Hilina Pali and one between Kilauea and Hilo. It is remarkable that Mauna Loa and Hualalai were not heard from. There was some seismic activity near Maui.

The following are the local data for June.

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
June 4	0	8.5 mm.	36
" 11	3	10.5 mm.	124
" 18	8	4.5 mm.	88
" 25	0	4.0 mm.	58
July 2	1	5.5 mm.	31

* Including teleseisms or earthquakes over 5000 km from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

April 4, 9:03 pm, very feeble, probably originated near center of Kilauea Crater.

April 5, 3:04 am, very feeble, 3.0 miles deep, Kilauea near W rim of Halemaumau (SW rift). 19° 24.6'N; 155° 17.8' W.

April 6, 9:09 pm, very feeble, Mauna Loa NE rift near Puu Ulaula.

April 12, 4:18 am, slight, 18.0 miles deep NE slope of Kilauea about midway between the crater and Glenwood. 19° 27.0' N; 155° 14.0' W. Reported felt in Hilo, Olaa and Hawaii National Park.

April 13, 2:53 pm, very feeble, probably originated in Twin Craters area E rim of Kilauea Crater.

April 15, 9:48 pm, slight, felt by many persons in Hawaii National Park. Located 1.3 miles deep in Kilauea Crater, NE rim of Halemaumau. 19° 25.0' N; 155° 16.9' W.

April 16, 6:14 pm, very feeble, probably originated in Hilina fault system S of Makaopuhi Crater.

April 16, 10.57 pm, very feeble, probably of shallow origin near center of Kilauea Crater.

April 17, 1:08 pm, very feeble, of Kilauea Crater origin, near center.

A shock was reported felt in Hilo at 10:24 pm, April 17. This corresponded with the registration time of a tremor at the Observatory. It apparently originated 13.0 miles from Hilo in the NE rift of Mauna Loa.

April 20, 6:42 am, very feeble, Kilauea Crater near NE rim of Halemaumau.

April 20, 8:49 am, very feeble, NE portion of Kilauea Crater.

April 24, 2.51 pm, very feeble, Kilauea SW rift about 18.0 miles from Kilauea near sea.

April 25, 2:21 am, very feeble, 22.0 miles deep under Hualalai area. 19° 41.5' N; 155° 46.0' W.

April 29, 9:57 pm, very feeble, Mauna Loa NE rift, 5.0 miles deep and 5.0 miles NE of the summit crater. 19° 31.6' N; 155° 26.0' W.

May 1, 5:15 pm, very feeble, originated under Halemaumau.

May 8, 7:03 am., slight, probably originated in Hilina fault system about 20.0 miles deep and 4.0 miles S of Makaopuhi Crater.

May 11, 7:51 am, very feeble, probably originated 7.0 miles under Kilauea Crater.

May 13, a tremor at the Observatory recording at 3.32 pm corresponded with time of an earthquake reported felt in Honolulu.

May 14, 5:37 am, very feeble, of Kilauea Crater or Chain-of-Craters origin.

May 15, 10:28 am, moderate to strong, strongly felt over entire Island of Hawaii with exception of Kohala district. Probably most strongly felt in Hilo where there was slight damage to some masonry structures and plaster work. Also quite strongly felt in Hawaii National Park. Located 10.0 miles deep, 2.5 miles E of Makaopuhi Crater. 19° 22.0′ N; 155° 08.0′ W.

May 18, 8:48 pm, very feeble, 10.0 miles deep in Hilina Pali area, 4.0 miles S of Makaopuhi. 19° 19.0′ N; 155° 9.0′ W.

May 20, 2:05 am, very feeble, Kilauea Crater near NE rim of Halemaumau.

May 20, 10:18 am, very feeble, probable origin, Hilina fault system about 4.0 miles S of Puu Huluhulu.

May 23, 2:14 pm, moderate to strong, felt over entire Island of Hawaii and registered on University of Hawaii seismograph at 2h 16m 03s pm. All instruments at the Observatory except the strong motion seismograph were dismantled. Subsidiary stations at Hilo, Kona on Mauna Loa and around Kilauea Crater likewise were dismantled. Source of origin was apparently 7.5 miles NW of Kilauea Crater from a depth of 12.0 miles. 19° 28.5′ N; 155° 22.0′ W.

May 24, 12:59 pm, moderate to strong. Similar to quake of preceding day in that it was felt throughout Island of Hawaii and dismantled all seismographs except strong motion instrument at the Observatory. Registered at Unversity of Hawaii, Honolulu, "S" wave at 01h 00m 29s pm. Location 15.0 miles deep, 2.5 miles SE of Observatory, E rim of Kilauea Crater. 19° 25.0′ N; 155° 14.0′ W.

May 24, 1:09 pm, slight, probably same epicenter as preceding but possibly 5.0 miles deeper.

May 25, 3:39 am, very feeble, probably originated in Hilina fault system.

May 25, 8:54 am, very feeble, probable epicenter same as moderate shock of May 23, 2:14 pm.

May 26, 10:40 pm, very feeble, probable origin, Hualalai.

May 27, 4:29 pm, very feeble, probable origin, about 5.0 miles from Summit Crater, Mauna Loa, NE rift, about 8.0 miles deep.

May 28, 3:48 am, very feeble, probable origin, about 15.0 miles under Mauna Loa Summit Crater.

May 28, 6:34 am, very feeble, probable origin, Mauna Loa SW rift, 15.0 miles under area near 1907 source cones.

May 29, 7:15 pm, very feeble, registered on Honolulu seismograph "P" wave at 07h 15m 09s pm. Reported widely felt on Oahu and on Maui. Located 20-30 miles deep, 90.0 miles S of Lanai, 19° 30′ N; 156° 50′ W.

May 29, 11:45 pm, very feeble, probable origin, Chain-of-Craters near Devil's Throat.

May 31, 3:10 pm, moderate to strong, 11.0 miles deep in Hilina fault system, 8.0 miles S of Kilauea iki. Dismantled seismographs at Observatory and Pit but no others. 19° 18.5′ N; 155° 14.5′ W. This shock was peculiar in that there were no reports of it being felt. Members of the Observatory staff were conscious that earthquake was taking place through a special electric signal system, yet experienced no sensation of earth motion.

May 31, 8:38 pm, slight, felt in Hilo and Hawaii National Park, 12.0 miles deep, Mauna Loa NE rift, 13.0 miles SW of Hilo. 19° 37.5′ N; 155° 15.5′ W.

May 31, 8:51 pm, moderate to strong, reported felt throughout Kau and Hilo districts as well as other parts of Island of Hawaii but was particularly strong in Hawaii National Park and moderately so in Hilo. Location of source of origin, 11.0 miles deep, area 4.0 miles W of Mountain View. 19° 34.0′ N; 155° 10.5′ W.

June 2, 11:38 am, very feeble; Hilina fault system near SW rift was probable origin.

June 5, 2:06 am, very feeble, probable origin, under Kapoho area about 7.0 miles E of Pahoa, E extremity of Island.

June 5, 7:01 pm, very feeble, probably originated under sea floor off SE coast of Hawaii near Kalapana.

June 6, 4:07 pm, very feeble, 4.0 miles deep in Kilauea SW rift at Crater Junction. 19° 24.1′ N; 155° 18.0′ W.

June 7, 1:34 pm, very feeble, origin similar to that of moderate quake of 3:10 pm, May 31.

June 7, 10:47 pm, very feeble, NE portion of Kilauea Crater.

June 8, 10:45 pm, very feeble, 1.1 miles deep, 1.0 mile W of Puhimau Crater. 19° 23.6′ N; 155° 15.9′ W.

June 9, 2:25 am, very feeble, 3.0 miles deep, 0.5 mile NW of Pit seismograph station, Kilauea Crater. 19° 24.8′ N; 155° 17.1′ W.

June 9, 9:29 am, very feeble, probably of relatively deep origin, Hilina Fault system, 10.0 miles SE of Observatory.

June 9, 2:06 pm, very feeble, of shallow origin, cracks 0.7 mile N of Puu Ohale. 19° 21.9′ N; 155° 16.7′ W.

June 10, 5.41 am, very feeble, 1.1 miles deep, E rim of Kilauea Crater in vicinity of Kilauea iki. 19° 25.0′ N; 155° 15.6′ W. Felt slightly by a few persons in Hawaii National Park.

June 10, 10:10 am, very feeble, about 3.0 miles deep, 1.0 mile SW of Kamokukolau. 19° 22.5′ N; 155° 16.9′ W.

June 10, 8:51 am, feeble, 3.0 miles deep, about 0.5 mile W of Ahua Kamokukolau. 19° 23.0′ N; 155° 16.6′ W.

June 11, 11:18 am, very feeble, probable origin deep under Hilina fault system about 8.0 miles S of Observatory.

June 11, 10:45 pm, very feeble, 2.5 miles deep, about 2.1 miles W of center of Halemaumau. 19° 24.6′ N; 155° 19.0′ W.

June 12, 1:11 am, moderate to strong, 13.0 miles deep in Kau Desert area near Koae and Puu Ohale. Felt generally on the Island of Hawaii but apparently with greatest intensity in Hilo and Hawaii National Park areas. Dismantled Observatory, Pit and Mauna Loa seismographs.

June 12, 5.47 pm, feeble, 3.7 miles deep, 2.0 miles W of Pit seismograph under SW rim, Kilauea Crater. 19° 24.4′ N; 155° 18.5′ W.

June 12, 6:26 pm, very feeble, of shallow origin (0.5 mile ±), approximately 0.5 mile N of Uwekahuna. 19° 26.0′ N; 155° 17.4′ W.

June 13, 10:47 pm, very feeble, probably originated near SE rim of Kilauea Crater.

June 14, 1:04 am, slight, approximately 2.0 miles deep, Kilauea Crater between SE rim of Halemaumau and SE rim of Crater. 19° 24.5′ N; 155° 17.8′ W.

June 14, 2:06 am, very feeble, probably originated near SE rim of Kilauea Crater.

June 14, 6:27 am, very feeble, 2.3 miles deep, Kilauea SW rift near Cone Peak. 19° 23.7' N; 155° 18.5' W.

June 14, 10:02 am, slight, 2.1 miles deep, S rim of Kilauea Crater, 1.3 miles SE of Center of Halemaumau. 19° 23.6' N; 155° 16.5' W.

June 15, 3:18 pm, very feeble, 15.0 miles deep, S rim area of Kilauea Crater. 19° 23.5' N; 155° 15.5' W.

June 15, 5:46 pm, very feeble, probably originated near Kilauea iki.

June 16, 11:35 am, very feeble, Kilauea Crater origin near Halemaumau.

June 18, 5:12 pm, very feeble, of shallow origin near NE portion of Halemaumau.

June 19, 4:49 am, moderate, 15.0 miles deep in area E of Kilauea Crater approximately 2.0 miles SE of Observatory. 19° 25.3' N; 155° 15.0' W. Felt in Hilo and Hawaii National Park, where many persons were awakened. Dismantled E-W component of Bosch seismograph at Observatory and both components at Pit.

June 20, 4:10 am, very feeble, of shallow origin, Kilauea Crater near SE portion of Halemaumau.

June 20, 3:01 pm, slight, 13.0 miles deep, Puna rift near Makaopuhi. 19° 22.0' N; 155° 10.0' W.

June 24, 2:04 pm, slight, Bosch seismogram at Observatory indicated no S-P phase interval but began abruptly with "M" phase. In immediate vicinity of this station (Hawaii National Park headquarters) the shock was reported felt as a sudden vibration similar to that produced by nearby blasting. Many persons thought it actually was a heavy blast. On this evidence it was assumed the quake originated in the faulted area NE rim of Kilauea Crater. Examination of the Pit and Uwekahuna seismograms confirmed this assumption and the point of origin was so placed and considered of shallow origin. 19° 25.8' N; 155° 16.6' W.

July 1, 12:20 am, moderate, 11.0 miles deep, Chain-of-Craters near Puu Huluhulu and Alealea Crater. 19° 23.0' N; 155° 11.5' W. Reported felt by many persons in Hilo, where a large number were awakened. In Hawaii National Park the shock was reported felt as a prolonged and persistent swaying motion lasting 15 ± seconds. Here, too, a number of persons were awakened. E-W component of Bosch seismograph was dismantled as was the same component at Halemaumau.

Teleseisms

April 5, "P" waves began recording at 6h 21m 58s am, 3,755 miles from Kilauea. Reports from the Jesuit Seismological Association place the origin in the vicinity of New Caledonia. 27° S; 167° E.

April 17, unidentified portion at 8h 16m 33s pm.

April 20, "eP" at 6h 08m 17s pm, distance 3,630 miles. Jesuit Seismological Association reports 500 km deep, NE Asia. 48.6° N; 138° E.

April 21, "eP?" at 9h 42m 35s am, no distance determined and no reports from other localities received.

April 29, "eP" at 4h 34m 49s pm, distance 3,730 miles. Reports from U. S. C. and G. S. give origin as 11° S; 158° E. Solomon Islands.

May 2, "eS?", 3h 01m 26s am, U. S. C. and G. S. report—off coast of Lower California as place of origin. 29.5° N; 113.8° W.

May 9, "ePr?" at 9h 21m 27.0s pm, U. S. C. and G. S. location given as Aleutian Islands. 41° N; 179° W.

June 1, "iP" at 5h 15m 10s pm, no distance, no reports.

June 8, "eP" at 10h 24m 31s am, U. S. C. and G. S. reported location between Samoa and Tongas. 15° S; 173° W.

June 11, "eP?" at 5h 01m 13s ± am, no distance, no location reported.

On June 16, at 4:20 am, a tremor registered on the Observatory seismograph having the appearance of a near shock. Kona seismograms indicated a distance of 66 miles; the Mauna Loa seismograph indicated a distance of 93.0 miles.

Microseismic Motion

April

Light—10, 11, 13, 14, and 25.
Moderate—9, 12, 15, 16, 19, 21-24, 26-28.
Strong—3-8, 17, 18, 20, 29, 30.

May

Light—2, 6, 7, 19, 20.
Moderate—3-5, 8-13, 16-18, 21-31.
Strong—1, 14, 15.

June

Light—2-9, 13-16, 18, 21-30 inclusive.
Moderate—1, 10, 11, 12, 17, 19, 20.
Strong—None.

Time used throughout is Hawaiian Standard, 10h 30m slower than G. C. T.

Tilting of the Ground

The following tables show tilt by weeks recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum toward or away from the Pit as indicated by tilt stations on the W and SE rims respectively.

At the Observatory the total accumulated tilt for the year ending April 30, was 4.0" S and 5.35" W.

For the year ending May 28, it was 3.92" S and 4.75" W.

For the year ending July 2, it was 3.75" S and 2.6" W.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
April 9	1.61" S 83° W	1.85" N 5° E
" 16	0.93" N 72° E	3.73" N 87° W
" 23	0.25" N 83° E	1.49" S
" 30	0.47" S 60° W	2.53" W
May 7	0.45" N 22° E	6.11" N 69° W
" 14	2.19" S 61° W	7.09" S 79° W
" 21	0.92" N 73° E	11.62" S 64° W
" 28	0.31" N 25° E	15.44" N 41° W
June 4	0.43" N 19° E	3.37" S 85° W
" 11	0.48" N 36° E	3.99" W
" 18	0.17" N 45° E	11.18" N 72° W
" 25	0.88" N 11° E	4.41" S 50° E
July 2	0.42" N 21° E	11.62" N 48° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
April 9	6.48" N 63° W	5.97" toward
" 16	15.91" W	5.82" toward
" 23	15.31" W	9.09" toward
" 30	6.12" N 41° W	3.63" toward
May 9	4.99" N	1.62" from
" 14	5.67" N 21° E	3.93" from
" 21	12.15" N 40° E	7.96" from

June 4	16.85" S 74° E	17.04" from
" 11	8.42" N 37° W	4.41" toward
" 18	1.72" S 41° W	10.46" from
" 25	2.75" N 11° W	4.75" toward
July 2	6.45" S 89° W	8.38" from

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory, April 15, indicated closing of both the Halemaumau and the Crater values compared with similar measurements of March 30. The Halemaumau angles between the Pit seismograph and the NW Pit BM closed 0.91". The crater angle between the SE crater rim station and Uwekahuna closed 1.16".

During May two determinations were made of the same angles. These were May 6 and 26. On May 6 the Halemaumau angle had opened 1.59" and the Crater angle had closed 1.17". Between May 6 and 26 the Halemaumau angle closed 0.34" and the Crater angle opened 0.75". Total change for the month, Halemaumau angle opened 1.25" and the Crater angle closed 0.42".

Angle values determined June 17 indicated closing of the Halemaumau and closing of the Crater angle. Halemaumau value decreased 3.33". Crater value decreased 0.38".

Total change at Halemaumau, March 30 to June 17, 2.99", closing; across Crater 1.16" closing.

Chain-of-Craters Road Cracks

Date	101	102	103	104	105	106	107
April 28	403.70	64.40	101.35	17'19/8	87.15	88.60	40.35
June 2	404.00	64.40	101.45	X	87.20	88.60	39.75
June 30	404.35	64.50	101.45	X	87.25	88.75	39.70
Total change in mm.	+ 6.5	+ 1.0	+ 1.0	——	+ 1.0	+ 1.5	—6.5

Plus (+) = open. Minus (—) = close.

In 104, near Pauahi was temporarily discontinued. Large size makes it difficult to measure but determinations will be resumed in near future.

There was no change between March 30 of last report and April 28 of this report.

It is obvious that these cracks were greatly accelerated in their openings during the month of May, when seismic activity likewise increased. Cracks around Halemaumau showed relatively large increase in same period. This demonstrates the probability that the cracks around Halemaumau, although greatly activated by gravity, are also moved by volcanic changes, i.e., seismic changes.

THE VOLCANO LETTER

No. 465 Department of the Interior National Park Service July-September, 1939

PUBLISHED BY THE UNIVERSITY OF HAWAII

Edward G. Wingate, Superintendent
Hawaii National Park

Hawaiian Volcano Observatory
T. A. Jaggar, Volcanologist

EXPEDITION TO LAVA-BOMBING SITE

T. A. JAGGAR

This expedition to the north slope of Mauna Loa was conducted by the volcanologist of Hawaii National Park in cooperation with the Territorial Department of Forestry and Agriculture. The scientific members of the party were T. A. Jaggar, L. W. Bryan and H. H. Waesche. Cordial assistance came from Parker Ranch through Joseph Ignacio, who prepared trail and camp ground at 7,000 feet elevation on the north slope of Mauna Loa. The objects were to photograph the exact spots where bombs fell to deflect the 1935 lava flow, to delimit the flow area, to note the bomb effects, to map some older flows and to start a campaign to study more closely Mauna Loa on its danger slope above Hilo.

Fig. 1—Bomb crater with upstanding edges and pahoehoe ring and torrent of released lava; Target 2, elevation 8,200 feet. Arrow shows crater. Photo by Jaggar.

Camp was made August 30, 1939; the Bryan party studied the middle of the flow September 1 and the source region at 8,900 feet September 2. The Jaggar party joined them, and mapped and photographed the bomb craters September 3 and 6, taking color and monochromatic pictures. On September 5 a study was made of the 1899 flow about 8,000 feet, and on September 7-8 a heavy black aa flow in contact with the 1935 flow on its east side was found to be very fresh and to check perfectly in age and position with the western 1880 flow, **never hitherto mapped,** but described succinctly by Coan, Baker and Hitchcock as sweeping from Puka Uahi twelve miles towards Mauna Kea the first week of November 1880. This becomes of very great importance in studying the source of the 1935 Humuula flow that was bombed, for the 1935 outburst was between this relatively recent flow and the 1843 flow and was guided by the depression between them. The contact between the aa lavas of this 1880 branch and 1935 was found, 1935 red and free from vegetation, 1880 black with some lichens and with large concretionary "snow-ball" boulders on its surface (Figure 8).

The exploration of the bomb craters was started by Forester Bryan and carried forward by Dr. Jaggar, Mr. Waesche and Ranger Jess, so that most of the twenty demolition bombs dropped by the army squadrons were accounted for in the mile of lava-source cracks and tunnels between Target A and Target B. (See Volcano Letter 442.) Fragments of shrapnel, rusty red, were found in profusion; several of the "pointer" bombs of black powder and sand were discovered; one large "dud" bomb was found with end torn off and several hundred pounds of TNT exposed (Figure 3); and pieces of casing, vanes, covers and detonator tubes were picked up (Figure 6). The pointer bomb casings contained Hilo beach sand. The TNT was lighted and burned, first piecemeal, then as a whole with a newspaper fuse, while the party retreated down the mountain. After twenty-five minutes of flame and black smoke, the remains of the explosive were detonated by the fire perhaps reaching the war-head mechanism, and a quarry blast ended the perform-

ance. The place was revisited and photographed by Mr. Jess, who found a 3-foot depression, and fragments 100 feet away.

About sixteen of the bomb-holes were identified, one a perfect oval one hundred feet long by forty feet wide, crowned by a ring of upturned fragments of the rim, the interior a pit forty feet deep to a lava tunnel below. Liquid lova had splashed up and out in great sheets and gushes of molten glass. Seventy-five per cent of the holes found had exposed liquid lava. Four holes were off the stream line and in pairs, making bomb craters of broken rock (Figure 2), circular soucers twenty feet across and six feet deep.

In one case melted glass clung to shell fragments. In another a winged bomb had plunged through a thin crust, possibly into liquid lava (Figure 4), and was intact, its nose exposed protruding down into a tunnel below. Great blobs of glassy lava lay on the surface of pahoehoe silvery tongues, where explosions had flung them high. Rivers of liquid lava had escaped from some of the deep tunnel punctures, where the explosion had opened the tube. Other places had halos fifty or sixty feet wide, platforms of black glass, around an immense circular hole, where the bomb had released an artesian well of lava. The edge of the hole was scalloped like a tiara (Figure 4). The upper Target A was thickly strewn with pieces of rusty steel, from a quarter-inch to ten inches across, thin and thick, terribly jagged shrapnel torn from the big 600-pound shells like so much pasteboard.

The source region one mile below its upper limit had been studied by Jaggar and Waesche on foot in March 1936. They had found the lower bomb-craters, recognized the slabs and upwellings, but had not found any iron fragments. The actual source at Target A is a channel twenty feet across bordered by a bank of froth lava, meandering slightly, and lined

Fig. 3—Demolition bomb fragments with protruding TNT; near Target 1. Photo by Waesche.

Fig. 4—Pointer bomb of black powder near Tarket 1 with nose in cavern beneath; and Forester L. W. Bryan. Photo by Jaggar.

by a glassy pahoehoe floor, with windows revealing frozen streams and tunnel beneath. This channel begins abruptly at a ten-foot inclined shaft and transverse cracks. Up the mountain is a hill or flow-front of pasty-mixed lava of non-identifiable age. Down the mountain the torrent flowed in the channel, sometimes on the surface, sometimes deep in a tube. Mostly the margins are silver pahoehoe, but aa patches occur. Farther down a gush of pahoehoe begins and spreads in a fan. This is repeated five times in three miles. Underneath all this is a flow of aa. Down at Humuula the pahoehoe gushes unite at a river bending into a lake. They bend around the front of two large feather-shaped deltas of the aa of mid-December, 1935.

A striking feature of the bombed area was the existence upstream from some bomb-holes (Figure 5), of tunnel-openings where pudgy, pasty, stiff semi-aa lava welled up as a heap or pudding. The smashing of the tunnel had cooled the oncoming liquid so that it dammed itself. This confirmed the theory that the bombing solidified the tunnel lava back into the heart of the mountain. With twelve river hits out of sixteen, and liquid flung up hundreds of feet, there can be no question whatever that the bombing stopped the flow. The tunnels farther down the hillslope from the artificial damming were full of liquid which poured on for a week. But the bombardment of the river targets had cooled, dammed, solidified and freed from gas an enormous volume of slag, which froze where it lay, and the

very smallness of the natural vents proves how large was the artificial effect of this human achievement. The whole flow was in a single pipe, and the collective bomb craters were much bigger than that pipe. The pipe was a natural sewer tunnel twenty to forty feet underground and ten to fifteen feet across. A single one of sixteen bomb punctures was eighty feet across and forty feet deep to the roofed-over flow. No slag-stream full of gas could take such a bombardment, flinging up its substance, with several tons of high explosive, distributed along a mile of stream-way, and fail to thicken and solidify.

The source stream of the Humuula flow when active, at elevation 8,900 feet, glowed and steamed in a line of vents that were pahoehoe where the lava emerged, and this heap was visited by Ranger G. E. Olson, Philips and Ignacio November 25, 1935, as is shown by the photograph, Figure 7. An air photograph by Dod at the same period shows that the line of vapors ended abruptly against older dark lava uphill. This was the lower glow-spot, Figure 5, Volcano Letter 429, and the upper limit of bombed stream, Volcano Letter 442 frontispiece. The conclusion is that this channel and tunnel was a crack in the mountain that vomited out the Humuula flow of 1935, and that the dark lava uphill is part of the cold 1880 torrent. The line of vapors and glows ended against this older lava, and the crack beneath emerged downhill from it but did not break it.

The event was on December 27, 1935, when the front of the lava flow was pushing toward Hilo a mile a day, twelve miles from the city, and fifteen miles downhill from this source tunnel. The United States Army Air Corps all day long bombed the two targets of the source tunnel from the air. The next day the front slowed down, and five days later it stopped.

This camping trip of a week shows that the scientists can live in the high lava of Mauna Loa in comfort, that the danger

Fig. 5.—Pasty lava plug welled up, as result of bomb damming, in main stream tunnel; Mauna Kea in distance; Target 1. Photo by Jaggar.

slope above Hilo can be critically studied with new markers and air photographs, and with the proposed barriers for deflection of the most rapid flows that may rush to the sea near Hilo, we can eventually, if supported with men and trails and additional upper Mauna Loa lands in the Park, make the inhabitants of this fair land take pride in their defense against volcanoes.

Hawaiian Volcano Observatory Report for July-September 1939

VOLCANOLOGY

July 1939

Halemaumau had few rock slides, but the month showed uneasy working of fault blocks on Chain of Craters, and at Hilina Cliff south of Kilauea fresh avalanche scars were found July 13. A strongish shock July 14 originated there five miles underground. Three slides on Hilina Cliff July 25 occurred about 4:20 p.m. A slide from the northwest wall of Halemaumau July 30, 11:30 a.m., made a cloud of dust.

The cracks parallel to Halemaumau rim, of which 28 are measured weekly, showed aggregate closing for the first and third weeks of July, a condition not recorded since October, 1938. It is of interest that Chain of Craters measured fault cracks, four miles southeast, also closed for these weeks.

Sulphur fume was reported July 7 on Mauna Loa trail as an odor one mile below 1935 cone. Fuming in Halemaumau bottom has decreased, but was observed at the stain southeast the second week, and on July 28.

Messrs. Bullard, Schulz and others camped at Mokauweoweo rest house, summit of Mauna Loa, July 20-21. Abundant fumes were found on the crater floor, heat was rising from the summit part of 1935 rift northeast, and sulphur was being deposited in cavities on southwest flank of 1935 cone at 11,000 feet.

The numbers of local and distant seismic disturbances recently, by months, have been:

	Local	Distant
April	66	5
May	184	3
June	337	3
July	203	3
August	287	2
September	101	1

The swarm of June-July is evident, but the July disturbances were mostly tremors. Sixteen Kilauea shocks and five from Mauna Loa were located for July, two of the latter 35 miles deep. A distant earthquake of July 6, 3,550 miles away, was reported as 550 km. deep between Fiji and Tonga.

Of the 203 shocks and tremors of local origin registered on the seismographs for July, 21 were located by seismometric method, and, of these, 10 were under Kilauea crater, 5 were under Mauna Loa, 3 under Kilauea rifts, and 3 at the Hilina Cliffs.

The following are the local data for July:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
July 9	0	3.0 mm. closed	40
" 16	0	7.5 mm. opened	56
" 23	0	2.0 mm. closed	70
" 30	1	3.5 mm. opened	37

August 1939

The month at Kilauea crater exhibited some movement in the Hilina-Chain of Craters fault blocks which border the Kilauea rift on the southeast. (See map Volcano Letter 462.) A roadside crack at the edge of Aloi pit opened 2 feet in an hour of the early afternoon August 2, and extended 20 feet in depth. The motion did not continue.

The next event was a swarm of earthquakes about August 17, several of them felt, centering at the Hilina Pali fault system, including greatly increased frequency of very feeble movements and tremors.

A remarkable feature of this period, enduring for two weeks, was cumulative closing instead of opening, of the 27 concentric rim cracks around Halemaumau edge which are measured once a week. On the week ended August 18, of the rim cracks 19 closed, 8 were unchanged, and none opened, with aggregate closing of 15 millimeters. Along Chain of Craters, also, the measured cracks showed temporary closing of 8.5 millimeters. As these measurements were made the day after the Hilina disturbances, and the following week showed restorative opening of cracks, it appears that the fault movements caused this unusual compression normal to the fault planes, and both Halemaumau and the Chain of Craters took the squeeze, as both are on the major Kilauea rift.

Of two distant earthquakes both in New Hebrides region, 3,270 and 3,500 miles away, August 11 and 17, the second coincided in date with the moderate local earthquakes, preceding them by about six hours.

Slides in August were observed as follows:

August 2, 10:20 a.m., at north wall of Pauahi Pit;
" 2, 10:00 a.m., west wall Halemaumau, small;
" 6, Kilauea Iki scars north wall;
" 15, north wall Halemaumau, 11:19 a.m.;
" 17, scars in Pauahi crater.
" 20, north wall Halemaumau, 3:17 p.m.;
" 27, dust streaks north and west walls Halemaumau.

Of the 287 local shocks and tremors counted on the seismograms for August, 20 were located, and of these 7 were from Hilina Cliffs, 6 from Kilauea crater, 3 from Mauna Loa, 1 each from Kilauea southwest rift, Kona, Kohala and Hualalai.

The following are the local data for August:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
August 6	1	2.5 mm. opened	57
" 13	0	1.5 mm. closed	50
" 20	2	15.0 mm. closed	86
" 27	0	11.0 mm. opened	52
Sept. 3	0	5.0 mm. opened	42

September 1939

For six weeks following August 20 the decline in local earthquake frequency, and in numbers of tremors that determine technical seismicity, was steady and progressive. There were some feeble earthquakes felt that preceded equinox. Nothing volcanic was remarkable. An earthquake near Kamchatka under Bering Sea occurred September 8, 2,800 miles from Kilauea station.

Slides in September were observed as follows:

September 8, 12:40 and 12:59 p.m., northwest wall Halemaumau;
" 29, 10:33 a.m., north rim Halemaumau;
" 29, fresh fall of debris in road crack Pauahi Pit.

There was gradual movement detectable along the fractured rim of Devil's Throat, and humps in the road increased slightly between Hiiaka and Aloi pits. Blue fume is notably less at Halemaumau. Gas collections were made by Dr. Ballard of the University of Hawaii in Mokuaweoweo September 14. The three members of the expedition felt a sharp earthquake on the Mauna Loa crater floor at 10:07 a.m. of that date. This registered as a tremor at Kilauea seismographs.

Fig. 7—Pahoehoe steaming heap with glow-hole in foreground, November 25, 1935, at 8,900 feet elevation, Humuula. Photo by Olson.

Of the 101 local shocks and tremors recorded in September, 16 were located, and of these 6 were from Kilauea crater, 4 from Mauna Loa, 3 from Kilauea rifts, 2 from Hualalai, and 1 from Hilina Cliff region.

The following are the local data for September:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
September 10	2	2.0 mm. opened	39
" 17	0	1.5 mm. opened	28
" 24	0	3.0 mm. opened	19
October 1	1	2.0 mm. opened	15

* Including teleseisms or earthquakes over 5,000 km from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the station operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

July 5, 12:20 am, slight, 12.0 miles deep in Hilina Pali area 2.5 miles S of Makaopulii 19° 20.2′ N., 155° 10.2′ W. Felt slightly in Hilo and by a few persons in Hawaii National Park.

July 7, 5:46 pm, very feeble, probably originated in SE rim area of Kilauea Crater.

July 7, 7:23 pm, very feeble, probably originated in SE rim area of Kilauea Crater.

July 7, 8:04 pm, feeble, probably originated in E rim area of Kilauea Crater.

July 8, 3:32 pm, very feeble, probably originated Kilauea SE rift near Kalapana.

July 11, 5:51 pm, very feeble, of Kilauea Crater origin.

July 12, 11:30 pm, very feeble, of Kilauea Crater origin.

July 14, 3:51 am, moderate to strong, 5.0 miles deep, Hilina fault system about 5.0 miles SE of Makaopuhi. 19° 19.5′ N; 155° 07.0′ W. All instruments at the Observatory were dismantled with the exception of the strong motion seismograph. The quake was generally felt on the island with the greatest internicity centered in the Kau-Puna area. Most sleepers were awakened in Hawaii National Park and in Hilo. Reported unusually strong at Pahoa.

July 15, 9:46 pm, very feeble, of shallow origin in Kilauea Crater E of Halemaumau.

July 16, 7:14 am, very feeble, about 35.0 miles deep, Mauna Loa NE rift, 13.0 miles NE of Summit Crater. 19° 33.5′ N; 155° 25.5′ W.

July 16, 3:57 pm, very feeble, probable origin Hilina Fault system about 3.5 miles S of Makaopuhi Crater.

July 19, 11:38 am, very feeble, 1.5 miles deep, Chain of Craters, near Puhimau. 19° 23.6′ N; 155° 14.9′ W.

July 19, 10:15 pm, very feeble, 1.4 miles deep, 1.3 miles W of Hiiaka Crater. 19° 22.6′ N; 155° 15.1′ W.

July 21, 9:04 pm, very feeble, Mauna Loa NE rift about 12 miles SW of Hilo.

July 25, 11:00 am, very feeble, originated about 1.7 miles NW of Volcano Observatory, 4.2 miles deep. 19° 26.9′ N; 155° 16.3′ W.

July 25, 11:45 am, very feeble, 35.0 miles deep, Mauna Loa NE rift, 16.0 miles NE of Summit Crater.

July 27, 2:02 am, very feeble, 23.0 miles deep on W slope of Mauna Loa, 14.0 miles W by S of Mauna Loa Summit Crater. 19° 26.0′ N; 155° 48.0′ W.

July 28, 5:12 pm, very feeble, probably originated in Kilauea Crater 1.3 miles SW of Observatory.

July 31, 8:58 am, very feeble, of shallow origin Mauna Loa NE rift 16 miles from Summit Crater.

July 31, 8:18 pm, very feeble, probably originated in Kilauea Crater near Halemaumau.

July 31, 8:21 pm, very feeble, of shallow origin, Kilauea Crater rim area near Kilauea Iki. 19° 25.1′ N; 155° 15.3′ W. Reported felt by few persons in Hawaii National Park and dismantled NS component of Pit seismograph.

August 4, 3:16 pm, very feeble, of shallow origin near S rim of Keanakakoi Crater. 19° 24.1′ N; 155° 16.0′ W.

August 4, 11:56 pm, very feeble, 2.2 miles deep, 4.0 miles NW of the Observatory. 19° 28.5′ N; 155° 18.8′ W.

August 5, 1:46 pm, very feeble, 8.0 miles deep, 5.0 miles SW of Kailua. 19° 31.0′ N; 156° 02.0′ W. Reported felt at Holualoa and Hookena.

August 6, 5:09 pm, very feeble, origin was 40.0 miles under Hualalai. 19° 41.5′ N; 155° 35′ W.

August 7, 7:19 am, very feeble, probably originated under N rim area of Kilauea Crater.

August 8, 4:32 am, feeble, originated in Hilina Fault system, 3.0 miles N of Apua Point, 6.0 miles deep. 19° 18.0′ N; 155° 11.5′ W. Reported felt in Hilo.

August 8, 6:50 am, feeble, 10.0 miles deep in Hilina Fault system 4.0 miles S of Makaopuhi. 19° 19.0′ N; 155° 10.0′ W. Reported felt in Hilo.

August 11, 6:39 pm, very feeble, probably originated in Kilauea SW rift near sea coast.

August 15, 2:52 pm, very feeble, probably originated in Mauna Loa NE rift.

August 16, 10:29 am, very feeble, originated in area between Makaopuhi and Hilina Fault.

August 16, 2:20 pm, very feeble, originated near Uwekahuna, NW rim, Kilauea Crater. 19° 25.5′ N; 155° 17.6′ W.

August 16, 2:40 pm, very feeble, Mauna Loa NE rift about 5.0 miles SW of Puu Ulaula.

August 17, 5:57 am, moderate, 8.0 miles deep in Hilina Fault system, 4.5 miles SE of Makaopuhi. 19° 19.5′ N; 155° 06.5′ W. Unusual in that it was not reported felt.

August 17, 6:18 am, moderate, 4.0 miles deep in Hilina Fault system, 4.0 miles ESE of Makaopuhi. 19° 21.5′ N; 155° 07.0′ W. Not reported felt.

August 17, 6:58 am, very feeble, probably in Hilina Fault system, about 15.0 miles deep and N of Keahou Point.

August 17, 11:51 pm, slight, probably of shallow origin in Hilina Fault system 3.5 miles S of Puu Ohale.

August 18, 9:03 pm, very feeble, probably originated under NE portion of Mauna Loa Summit Crater.

August 20, 10:01 am, very feeble, 12.0 miles deep, 3.0 miles W of Kulani Cone near NE rift of Mauna Loa. 19° 31.7′ N; 155° 21.0′ W.

August 27, 4:19 pm, very feeble, NE rim area of Kilauea Crater.

August 28, 6:21 pm, very feeble, probably originated in Kohala district.

September 3, 6:17 am, very feeble, Mauna Loa Summit Crater origin.

September 3, 6:54 am, very feeble, of shallow origin in Chain of Craters near Kokoolau and Devil's Throat. 19° 23.0′ N.; 155° 14.7′ W.

September 3, 8:10 pm, feeble, 7.0 miles deep, Mauna Loa NE rift, 3.0 miles SE of Puu Ulaula. 19° 30.0′ N; 155° 26.0′ W. Reported felt at Kilauea Military Camp accompanied by mild roaring noise.

September 4, 12:28 am, very feeble, 5.0 miles deep, Mauna Loa NE rift near Pukauahi Crater. 19° 31.5′ N; 155° 31.0′ W.

September 7, 1:32 am, feeble, 15.0 miles deep, Hualalai Volcano. 19° 41.0′ N; 155° 51.0′ W. Reported strongly felt at Puu Waawaa.

September 7, 10:46 am, very feeble, 4.0 miles deep under Waldron Ledge, NE rim Kilauea Crater. 19° 24.4′ N; 155° 15.4′ W.

September 8, 1:39 pm, very feeble, NE portion of Kilauea Crater.

September 13, 6:49 am, feeble, 9.0 miles deep Kilauea SW rift, 6.0 miles from the Observatory. 19° 24.0′ N; 155° 20.0′ W.

September 13, 4:20 pm, feeble, 13.0 miles deep Hilina Pali about 4.0 miles N of Apua Point. 19° 18.0′ N; 155° 10.0′ W.

September 14, 10:07 am, a tremor, reported felt on Mauna Loa.

September 14, 12:10 pm, very feeble, probably originated from relatively great depth under Hualalai.

September 15, 6:13 pm, very feeble, NW rim of Kilauea Crater, 0.6 mile N of Uwekahuna. 19° 25.9′ N; 155° 17.5′ W.

September 17, 3:33 am, very feeble, of shallow depth, Kilauea Crater near Halemaumau.

September 20, 10:41 am, very feeble, about 2.5 miles deep in Kilauea Crater near Halemaumau.

September 27, 11:24 am, very feeble, Kilauea SW rift.

September 28, 9:11 am, very feeble, probably from SW portion of Kilauea Crater.

Teleseisms

July 6, "P" waves began recording at 12h 18m 54.0s pm. This was reported by the Jesuit Seismological Society as a deep earthquake (550 km) which originated in the area between the Fiji and Tonga groups of the S. Pacific. 24° S; 18° W. Distance from Kilauea approximately 3,550 miles.

July 17, unidentified portion at 5h 11m 36s pm. No reports received.

July 23, 5h 03m am, unidentified portion.

August 11, "P" waves, 3h 46m 11s pm, J. S. A. location in vicinity of New Hebrides 13° S; 169° E. Distance from Kilauea, 3,270 miles.

August 17, surface (L) waves at 12:10 am, U. S. C. and G. S. location 18° S; 168° E in New Hebrides area. Distance from Kilauea, 3,500 miles.

September 8, 1h 42m 19s am, "P" waves began. U. S. C. and G. S. location near Kamchatka in Bering Sea. 51° N; 175° E. 2,800 miles from Kilauea.

Microseismic Motion

Moderate—4, 13-17, 20, 23, 24, 26, 30.
Strong—19, 21, 22, 25.
Time used throughout is Hawaiian Standard, 10h 30m slower than G. C. T.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum toward or away from the Pit as indicated by tilt stations on the W and SE rims respectively.

At the Observatory the total accumulated tilt for the year ending July 30, was 2.05" S and 4.0" W.

For the year ending August 27, it was 1.53" S and 3.43" W.

For the year ending October 1, it was 1.24" S and 3.20" W.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
July 9	0.50" N 20° E	6.97" S 26° W
" 16	0.97" N 26° E	3.13" S 23° W
" 23	0.66" N 21° W	2.98" N 79° W

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory were made twice during the month of July. On July 7, these measurements indicated opening of 0.58" for the Halemaumau value and closing of 0.61" for the Crater value compared with similar measurements of June 17. Between July 7 and July 29, the Halemaumau value showed closing of 2.73" and the Crater value showed opening of 1.58". Total, June 17 to July 29: Pit closed 2.25" and Crater opened 0.97". The Halemaumau value is measured between the seismograph station on the SE rim and the NW Pit bench mark. The Crater value is measured between a station on the SE rim of Kilauea Crater and the Uwekahuna station.

Angle values August 17, indicated opening of the Halemaumau value of 4.42" and closing of the Crater angle of 2.75".

Two measurements were made during September. On September 12, the Halemaumau angle had closed 0.17" and the Crater angle had closed 0.25". Between September 12 and September 27, Halemaumau value closed 2.41" and Crater value opened 2.41". Total change August 17 to September 27, Halemaumau closed 2.58" and the Crater opened 2.16".

Total change at Halemaumau, June 17 to September 27: Halemaumau closed 0.41" and the Crater opened 0.38".

Spirit Levelling around Halemaumau

Between August 25 and 30, a line of levels on Kilauea Crater floor was run for a complete circuit around Halemaumau. Comparison with a similar run made March 20-21, 1939 shows that the NW Pit BM had lowered since that period 4.4 centimeters relative to the Spit B. M.

Sept. 29	404.65	64.55	101.55	17'19⅛"	87.30	88.75	39.65
Total change in mm. since June 30..	+3.0 mm.	+0.5	+1.0		+0.5		

Plus (+) = open. Minus (—) = close.

New cracks developed in the side of the road nearest Aloi Crater and on its S rim. One crack was parallel to the road and the other was across the road surface. Measurement of these two cracks was started August 2, 1939. They were designated 108 and 109 respectively. On September 29 No. 108 had opened from 102.55 cm to 102.70 cm, a total of 1.5 millimeters. No. 109 remained unchanged at 97.70 cm.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, is leased and operated by the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigations.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

1935 LAVA IN MOKUAWEOWEO CRATER

By HUGH H. WAESCHE, Assistant Geologist

In the evening of November 21, 1935 about 6:30 p.m., Hawaiian Time, Mauna Loa began on eruption which was to lost well over six weeks and which was to exhibit oll phases of activity common to Mauna Loa eruptions. The major portion of the activity was a spectoculor outflow with large streams of lavo descending the north slope of the mountain into the saddle between Mauna Loa and Mauno Kea.

Just what occurred in the eorly hours of the eruption is vague. It was a cloudy evening and the activity was not visible from the Observatory until about 10:00 p.m. At that time a minimum of 8 fountains were playing olong the northeast slope af the mountain from the summit crater to a point about five miles along the rift. Apparently the NE rift had cracked open over this distance. By 2:00 a.m. oll of the upper fountoins had diminished slightly and the octivity was concentrating at the two lowest fountains near the 12,000 foot elevation. At approximotely 6:00 a.m., Lt. Carl Truesdole of the United States Army Air Corps flew over the Crater of Mokuaweoweo and reported some activity there still in progress. By 10:00 a.m. when the writer flew over the area af activity with Lt. Campbell all activity in the Summit Crater had ceased. The two fountains at 12,000 feet continued for approximately ten days. The remainder of the time, lava issued from what oppeared to be a rift hidden by old lava flows on the north flank of the mountain. At most the crater activity lasted hardly more than twelve hours.

Later when National Park rangers went to the summit af Mauna Loa, they found thot the fissure indicated on the map (near top) had opened within 100 feet of the rest house and that lava had poured into the crater and down the northeast slope in great quantities from it. The lava was a brownish-black, frothy type of pahoehoe indicating that it had probably been highly charged with gases. The Volcano House Trail was covered and eliminated for about three-quarters of a mile. (For photographs see Volcano Letter No. 445, March 1937.) It is possible that the fissure extended southwest toward the center of Mokuaweoeo in the general direction of the 1903 and 1914 cones but was covered by lava pouring into the main crater from the higher elevation bay to the northeast.

Fig. 2—Dr. Jaggar on an exploration of a Mauna Loa rift. Pit in 1881 pahoehoe dome northwest of Puu Ulaula. (October 4)

The attention of olmost everyone had been concentroted on the flows resulting from this eruption so consequently the croter hod received little attention. In 1934 Mr. A. E. Jones had made a detailed map showing the extent of the 1933 crater flow.* Dr. Jaggar has described that eruption. Mr. E. G. Wingate had mapped the 1926 flow. It was desirable thot the series be completed, therefore on July 18, 1939, Dr. Fred M. Bullard, professor of geology at the University of Texas ond temporarily employed by the National Park Service ot the Volcano Observatory, made the trip to the summit. Using a United States Geological Survey preliminory sheet of the area as a base, he mode a Brunton Compass survey of the crater inflow which is indicated by the hatched area toward top of map. The work was done July 19, 20, and 21. Mr. Paul Baldwin, temporary National Park ranger, repeated the work of Dr. Bullard obout three weeks later. His map was identical to Bullard's with the addition of the tongues and other slight modification of the southeast edge of the flow.

Apparently the 1935 lava covered a sizeable portion of the 1933 flow as indicated by the dotted boundaries of the latter flow as mapped by Jones.

The 1935 flow is little more than a veneer over pre-existing flows and has changed the contour of the crater little. It may attain a thickness of 5 feet in a few spots particularly where it adjoins the 1933 flow which in some places is aa in choracter.

Hawaiian Volcano Observatory Report for October-December, 1939

VOLCANOLOGY

October 1939

October had no special volcanic events. For the first week seismic activity increased and northeast tilting of the ground at the observatory was marked but normal for this time of year. The second week this tilt increased as well as the number of earthquakes; one of these was sharply felt on the floor of Mokuaweoweo, the summit crater of Mauna Loa, at 2:27 p.m. October 11, and on the same day at 3:42 p.m. a shock resembling a powder blast was felt at Kilauea. On the 15th a rock slide at 10:32 a.m. sent a dust cloud up the north wall of Halemaumau. The third week held a similar seismicity and thin fume rose from the southeast marginal crack of Halemaumau floor; the northwest solfatara had dimmed in color and ceased to fume. During the last week things quieted down and the measured rim cracks which changed closed instead of opening, just as in July-August.

Distant earthquakes were registered October 3 and October 16, the last located near the New Hebrides. The local shocks were distributed between Mauna Loa and Kilauea with the last most abundant, and one shock of October 19 was from Hualalai or beyond thot mountain.

Exploration of NE Rift of Mauna Loa

Dr. Jaggar, with Mrs. Jaggar and Ranger Jess, camped at Puu Ulaula, 10,000 feet elevation, northeast rest house of Mauna Loa October 2-5, to identify lava flows with those seen in Humuula trip of September, (Volcano Letter No. 465) to collect specimens for spectrograph tests, and to take photographs in Kodachrome and monochrome. Some of the latter are reproduced here. (Figures 2, 3, 4, 5, 6, 7.)

Puu Ulaula is old shell pahoehoe and cinder (Figure 5) with other old cones northeast of it, over the rift line here trending ENE and bifurcating to the NE. Southeast from the hills lying a mile WSW, extends the Kapapala aa flow of November 1880, entirely distinct from the pahoehoe black flow and cones (Figures 3, 6, 7) of 1881 which originate above and to the west of Puu Ulaula and trend NE, dominated by the large square-topped black cone of 1881 at elevation 9,617 feet lying a mile and a half NE of the Rest House, (from summit of which photographs 6 and 7 were taken). The aa lava of 1880 is distinct from the later 1881 source basalt: the former has a red porridge-like surface (Figure 4), its pahoehoe being bronzy and frequently frothed on the surface to coarse brassy pumice.

The 1899 lava is black pahoehoe all around the cone Puka Uahi and overriding the 1880 flows. Just northeast under the 1880 floods are the red and bright-colored cones of 1855 with surfaces of fine-grained brassy pumice a half inch thick. The black, smooth torrent of 1899 flowed off to the north from Puka Uahi, and was explored far to the north in September trip. On the engraved Humuula sheet U.S.G.S. the northeast Hilo flow is misnamed 1880 and the southeast Kapapala flow is misnamed 1881: these names should be exchanged. To all appearances it is possible to ride on the 1899 pahoehoe to Humuula by the routes explored in September.

The black floods of the 1881 Hilo-flow NW of Puu Ulaula are like the Kilauea floor lavas, and extraordinarily like the smooth piles of Mauna Iki in Kau Desert. Figure 2 shows the rim and cavernous overhang of a circular pit 60 feet across, with tumble of debris of collapse, that was in 1881 a lava lake on top of a pahoehoe dome. This was a source-heap over a crack of the NE Mauna Loa rift belt, a half-mile WNW from Puu Ulaula rest house. In the background of the photograph is one of the older cones of possibly 1855 cinder. The general view up the rift belt from the top of the 1881 black cone (elevation 9,617 feet) includes this slag heap near the skyline (Figure 6). The floods of pahoehoe from it fill the picture. The near line of conelets curving to the right, is the 1880-81 rupture. This pahoehoe is the later phase of 1881 that pressed forward in tunnels seven months to Hilo. Among the distant cones on the right is Puka Uahi (11,068 feet). In the early months of the 1880-81, floods of lava that pushed towards Mauna Kea from the Puka Uahi region, and towards the Hilo slope, were all stirred to become aa in the lower lands and some of these came from the Black Cone line of vents. The plexus of cones around Puka Uahi were sources of 1855, 1880, 1881 and 1899.

Before leaving the 1881 Black Cone, let us look at a photograph from its summit to the northeast, Figure 7. This is towards Puu Oo ranch lands, in the extreme distance across the sag of the upper Wailuku drainage above Hilo. In the foreground the open gash of the rift is bordered by pumice cones and aa lava. On the left appears the 1881 pahoehoe which sweeps to the right across the distant lands.

Outside the extreme right of the picture is the source of the aa of 1852 which gushed from a vent only 8,500 feet above the sea, but as always, with pahoehoe at its source and down its middle stream for three miles. Its flowing was short lived, so it never sent its vitreous lava to Hilo by the tunnel method. If its rushing torrent of liquid aa, 13 miles long between elevations 8,300 feet and 3,300 feet, had not been preceded by the emission of great volumes higher up the mountain twice, respectively 6 months, and 3 days, before the lowest Hilo outburst, this 1852 flow would have been in Hilo harbor in a week. The duration of the Hilo flow including decadence was 17 days, February 20 to March 8, the front stopping 12 miles from Hilo shore. As in all the outflows there was an extension of the crack up to the summit, this gushed from summit downwards with tremendous power February 17-18 for forty hours, and these upper 1852 floods are quite unidentified on the landscape of today.

The extension of the mapped crack from its cone at 8,420 feet elevation, takes us past the south side of Puu Ulaula, where a flood of black lava with phenocrysts of feldspar makes a sharkskin type of pahoehoe. This is overlapped by the 1880 Kapapala flow and is shown on the right in Figure 4. It may be part of the upper floods of 1852. A line of conelets heads almost due east from Puu Ulaula to Kulua and Puu Kipu, showing how cracks radiate from Puu Ulaula, as an important subsidiary dome on the ENE rift.

The map of all these features is Humuula Sheet, 1930, County of Hawaii, United States Geological Survey. Any later eruption may bury the lava of any former one. The concretion-ball aa lava supposed 1880 (Figure 8, Volcano Letter 465) discovered in September at elevation 7,000 feet, 4½ miles SSW from Humuula sheep station, came from near Puka Uahi, and its source pahoehoe is obscure in that vicinity until some petrogenic distinction, chemical or mineralogic, is discovered characteristic of date or age. Progressively later date means stage of internal alteration of magma. Age means stage of external weathering. In order to map thoroughly all these flows and recount their histories, specimens for comparison are being collected.

Microscopical petrography is not enough when a single flow may differ more in samples from source to front than two flow specimens of separated ages differ from each other. For this

Fig. 3—Cascades of 1881 pahoehoe along line of cones, north of Puu Ulaula. (October 4)

reason it is proposed to submit samples of known different years to arc vaporization in spectrograph for possible qualitative or quantitative differences in elements, and also to test for hydration and some other analytic distinctions, that may be characteristic of year of emission, apart from chemical or crystal differences exhibited within a single eruption. If discovered, this would mean secular magmatic change throughout a century, and identity of year could be established for two flows reaching different fronts, if both had the same characteristic of a specific date.

Fig. 4—The 1880 flow near source, aa in foreground, on Kapapala side of rift, south of Puu Ulaula, looking north. (October 5)

The color pictures that were taken of the interior brilliant ochre glazes of 1855 ond 1935 vents showed brick red, bronzy green, orange and coffee-colored surfaces within cracks and pits. Similor colors mark the pumices. Here ore gas-fluxing phenomena. Vent basalt can be gas-melted to recrystallization and reglazing like the glazing of pottery. The recrystollization within Hawoiian basalt stalactities, by gas melting, of augite and feldspor shelled over by hematite and magnetite, as described by Edword Dana ("Characteristics of Volcanoes," J. D. Dana, p. 339. The quotation from Brigham of water origin is totally erroneous.) shows that cavern linings remelted by gas heat demonstrate the power of gas fluxing to recrystallize the lava's own substance in a gas-filled chamber. The small droplets on the stalactites and glozes show they were very liquid. The small bubbles on the pumiceaus skin of gassy source lavas agoin show intense liquidity; these by their rainbow tints produce the brass color mentioned.

Geologists do not realize that gas-reactions approoching 1500° C., in enarmaus volumes of suddenly released carbon gases and hydrogen, make the high-energy phase of the dike-rupture colled "o volcanic outbreak". This foaming incandescence and its gas, freed in confinement (pits and caverns), ore melting agents. The gas-tight shell over a flowing lava stream can increase the temperature af that stream, by confining its reacting gases; and those gases can glaze and recrystallize the under-surface of the shell. If such a gas-melt were re-digested by rising lava, we would have a feldspar-augite-iron oxide concentrate assimilated by normal basalt.

Now imagine the inbreak (irruption) of an intrusion in a foreign rock doing the same thing, and gas-fluxing that rock. The rock might be highly siliceous or calcareous. The deep chamber of rupture would be gas-tight and confine the vesiculate foam, but the rise of temperature would be great ond the melting assimilation by basalt would proceed to whatever andesitic crystallinity the final gas-free magma achieved. Just as in the beautiful aggregates of feldspar crystals synthesized in Mauna Loa glazes and stalactites, totally different in grouping, and somewhat in chemical composition, from the lava, so where gas-fluxing melts to dripping a quartzite or shale, it is easy for anyone who has seen in Hawaii glowing caverns, red hot fuming and Mauna Loa fountains, to envisage the evolution of hybrid magmas from pre-existing solid phases when attacked by olivine-basalt glass in process of gas effervescence. There is a field for experiment in solution of gases in such glass, pressure release from solution, and in gas-fluxing various rocks to a glaze.

The following are the local data for October:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
October 8	0	3.0 mm. opened	22
" 15	1	2.0 mm. opened	33
" 22	0	2.5 mm. opened	44
" 29	0	6.5 mm. closed	19

Fig. 5—Summit of Puu Ulaula, showing flag, wind gauge, and azimuth plate. (October 5)

November 1939

The month of November was notable for steady decline of the seismic index. The first week showed a slight increase over the end of the preceding month in seismic activity of both Mauna Loa and Kilauea. Fresh rocks on the floor of Makaopuhi Crater indicated there had been small slides from the southwest wall. There was a return to the opening of Halemaumau rim cracks, whereas the previous week had been extraordinary in that none had opened. Tilting af the ground at the Observatory was away from the crater. A slight shock November 3 and a feeble one November 4 were of Kilauea origin but not reported felt.

The second week produced a moderate rock slide sending up dust at the north

Fig. 6—Looking up rift from 1881 Black Cone; Puu Ulaula on left skyline.

wall of Halemaumau 10:22 a.m. November 10. There was one feeble earthquake under Kilauea Volcano and felt there. Tilting of the ground at the Observatory was away from the crater.

The third week recorded one rock slide Halemaumau north rim 10:20 a.m., November 14. Earthquakes were very feeble. The rim cracks resumed excessive closing. Tilting of the ground continued NNE.

The fourth week showed excessive microseismic activity along with a storm at sea causing waves to wash over Hilo breakwater. Seismic activity was locally very small though earthquakes were reported all over the world. Observatory tilt was still away from the crater.

The following are the local data for November:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
November 5	0	8.0 mm. opened	25
" 12	1	4.0 mm. opened	21
" 19	1	1.5 mm. closed	19
" 26	0	2.0 mm. opened	13

December 1939

The month of December was seismically quiet and, in accordance with the habit of the last five years, the solstice week about December 21 was particularly peaceful. This is the more remarkable in that during the active years of the last two cycles December has been the eruption month. Seismic activity increased at the beginning of the month and Observatory tilt changed to the crater direction. The second week fume was noted in Halemaumau probably from the solfatara along SE edge of floor. On December 8 at 10:35 a.m. rocks were heard falling at Halemaumau wall NW. Distances of earthquakes indicated Hualalai, Mauna Loa and Kilauea. Tilting was resumed away from Kilauea Crater. The third week produced a moderate slide at 2:55 p.m. December 12 making noise and sending out dust at Halemaumau NW wall and two other slides from the rim N and NE occurred at 3:25 and 3:29 p.m. A very feeble earthquake under Halemaumau completely dismantled the seismograph there, was felt at Uwekahuna but registered as very feeble. Observatory tilt was towards the crater.

The fourth week with earthquakes reported from Costa Rica, Manila, London, Kamchatka and the Celebes nothing happened at the Observatory except registration of some distant shocks and a feeble earthquake near noon December 23 indicating origin 15 miles deep under Mauna Loa northeast rift with epicenter eight miles from Mokuaweoweo. Sources at this locality command close attention because of the menace to Hilo. Observatory tilt was away from the crater. The end of the year produced outbreaks of disastrous earthquakes in Turkey. Some fume could be seen over Halemaumau on calm humid days, rim cracks closed and Observatory tilt was inward.

The following are the local data for December:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
December 3	0	3.5 mm. opened	26
" 10	1	0.5 mm. opened	18
" 17	3	0.5 mm. closed	33
" 24	0	5.5 mm. opened	18
" 31	0	0.5 mm. closed	20

Change of Annual Tilt

A significant change of importance is indicated by the following table showing in seconds the amount of tilt and its direction at the Observatory, NE rim of Kilauea Crater, for the year preceding the date indicated respectively in north-south azimuth and east-west azimuth at the seismographs.

January 29, 1939	S 1.15 seconds	W 5.93 seconds
February 26, 1939	S 1.0 "	W 1.73 "
April 2, 1939	S 3.08 "	W 4.85 "
April 30, 1939	S 4.0 "	W 5.35 "
May 28, 1939	S 3.92 "	W 4.75 "
July 2, 1939	S 3.75 "	W 2.60 "
July 30, 1939	S 2.05 "	W 4.00 "
August 27, 1939	S 1.53 "	W 3.43 "
October 1, 1939	S 1.24 "	W 3.20 "
October 29, 1939	S 1.15 "	W 1.48 "
December 3, 1939	N 2.20 "	W 1.56 "
December 31,1939	N 1.70 "	W 1.35 "

Fig. 7—From summit of 1881 Black Cone looking toward Puu Oo ranch lands.

This record of tilt south and west, or toward Kilauea Crater at the top of the NE wall of that crater, throughout the year 1939 as representative of the preceding twelvemonth for the end of each month, was also characteristic of many preceding years, checked by levels and readings of horizontal angles towards Kilauea and Halemaumau that hove all agreed in indicating since the explosive eruption of 1924 that the general trend has been downward and inward. Individual Halemaumau eruptions have produced temporary tiltings awoy from the crater, but the annual record for repeated monthly summaries has appeored to imply that the ground around Halemaumau pit was continuing to lower as it did in 1924, but in less angular amount.

Beginning with the record of December 3, 1939 the north-south component suddenly shows a change from the preceding month of o totol of 3.35 seconds from the record of October 29, and this substantial northerly tilt for the year preceding the date of record is retained on December 31 as nearly two seconds to the north or away from Halemaumau. When a record of this kind is a resultant of accumuloted change for an entire year it is much more significant of a change of habit in underground workings of the volcano than the mere tilt from one month to the next. It should be remembered that the spring and summer of 1938 produced first a big earthquake in Maui and then a visible rupture along Chain-of-Craters, east rift of Kilauea in May, with renewal of movement there in August 1938 and some seismic sequences of the same disturbance in 1939. As the average interval for Kilauea outbreaks in this century was about a year and a half up to 1934, it appears that an eruption was omitted in 1936, and was about due in 1938. This Chain-of-Craters disturbance may have been the equivalent of that eruption, absorbed in subterranean intrusion, and representative of the return of lava from the seaward direction to the east, where there was submarine outflow in 1924. This submarine outflow as o fundamental disturber of the mountain, producing intense subsidence, may have continued that subsidence by sluggish flow until the backing up of the lava achieved the 1938 intrusion. Meantime the succession of gushes on the Halemaumau bottom may have been offshoots from Mauna Loa. If now the change in tilt at the Observatory means a resumption of swelling and elevation of Kilauea Crater, the lava that returns to Halemaumau about 1940 may have enduring characteristics more like the Kilauea activity of aforetime.—T.A.J.

* Including teleseisms or earthquakes over 5,000 km from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the islond of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus hos been made.

October 3, 4:12 p.m., very feeble, probably originated Mauna Loa NE rift neor summit crater.

October 5, 5:52 p.m., very feeble, probably originated in area south of Kilauea Crater neor junctian of Poli Lele o Kalinipaa ond Pali Kalanaokuaiki.

October 8, 10:35 a.m., very feeble, originated in vicinity of NE rim of Kilauea Crater.

October 11, 1:11 a.m., feeble, probably originated in Hilina Fault system about 4.0 miles southeast of Makaopuhi.

October 11, 2:27 p.m., feeble, 8.0 miles deep, Mauna Loa NE rift about 3.0 miles SW of Puu Ulaula. 19° 30.5′ N; 155° 29.0′ W. Reported sharply felt at Mauna Loa resthouse.

October 11, 3:42 p.m., feeble, 0.8 mile deep, east portion of Kilauea Crater. 19° 24.7′ N; 155° 16.0′ W. Reported felt in Hawaii National Park.

October 14, 3:55 p.m., very feeble, originated near eost central portion of Kilauea Crater.

October 15, 4:38 a.m., very feeble, originated 22.0 miles under Mauna Loa summit crater, 19° 28.5′ N; 155° 36.0′ W.

October 15, 11:03 a.m., very feeble, east central portian of Kilauea Crater.

October 16, 10:25 a.m., very feeble, of Kilauea Crater origin.

October 16, 1:35 p.m., very feeble, of Kilauea Crater origin.

October 17, 6:33 a.m., very feeble, probably originated in Chain-of-Craters near Puhimau.

October 19, 7:33 p.m., very feeble, under west slope of Hualalai, 5.0 miles NNW of Kailua, 19° 42.0′ N; 156° 01.0′ W.

October 26, 6:18 p.m., very feeble, probably originated in Mauna Loa NE rift about 10.0 miles SW of Hilo.

October 29, 12:02 a.m., very feeble, about 7.0 miles deep, Mauna Loa NE rift, 19° 35.5′ N; 155° 23.0′ W.

November 1, 2:38 p.m., very feeble, of shallow origin about 0.6 mile west of Kokoolau Crater, 19° 23.2′ N; 155° 16.0′ W.

November 3, 12:15 a.m., very feeble, probably originated in Hilina Fault system, near Laeapuki.

November 3, 3:38 p.m., slight, 3.0 miles deep in the vicinity of Cone Peak along Kilauea SW rift. 19° 23.5′ N; 155° 18.3′ W.

November 4, 3:07 a.m., feeble, probably of same origin as preceding shock.

November 4, 3:54 p.m., a tremor at the Observatory recorded on Mauna Loa as a feeble shock probably originating in the NE rift.

November 4, 10:58 p.m., very feeble, 25.0 miles deep under Mauna Loa 8.0 miles NW of Pahala. 19° 17.5′ N; 155° 34.0′ W. Reported felt in Pahala.

November 7, 5:34 a.m., very feeble, 2.7 miles deep, 1.4 miles east of Puu O Hale in Kalanaokuaiki Pali near junction with Pali Lele O Kalihipaa. 19° 21.4′ N; 155° 15.4′ W.

November 8, 11:23 p.m., very feeble, of shallow origin east central portion of Kilauea Crater. 19° 25.0′ N; 155° 16.0′ W.

November 10, 7:06 a.m., feeble, of shallow origin east rim of Kilauea Crater under SW portion of Kilauea Iki. 19° 25.0′ N; 155° 15.0′ W.

November 10, 11:06 a.m., very feeble, probably of same origin as preceding quake.

November 13, 1:02 a.m., very feeble, of Kilauea origin.

November 13, 1:59 p.m., very feeble, of shallow origin east central portion of Kilauea Crater.

November 14, 7:55 a.m., very feeble, from Mauna Loa NE rift about four miles from Summit Crater.

November 14, 9:56 a.m., very feeble, of Kilauea origin, probably Hilina Fault system south of Makaopuhi Crater.

November 19, 3:21 a.m., very feeble, of relatively shallow origin under Summit Crater of Mauna Loa.

November 19, 6:08 a.m., very feeble, of Mauna Loa NE rift near Summit Crater.

November 19, 7:23 a.m., very feeble, of shallow origin, SE rim of Halemaumau in Kilauea Crater.

November 20, 4:29 p.m., very feeble, 7.0 miles deep, Mauna Loa NE rift about 5.0 miles from Summit Crater. 19° 31.0′ N; 155° 31.5′ W.

November 24, 5:34 a.m., very feeble, from Hilina Fault Zone, 5.0 miles west of Kalapana.

November 27, 10:30 p.m., very feeble, of shallow origin, Kilauea Crater, 1.0 mile NE of Pit seismograph.

December 1, 12:35 p.m., very feeble, probably originated in Mauna Loa NE rift.

December 2, 8:48 a.m., very feeble, 0.8 mile deep, 1.0 mile SSE of Halemaumau. 19° 23.5′ N; 155° 16.6′ W.

December 3, 5:21 a.m., very feeble, 18.0 miles deep under Mauna Loa Summit Crater. 19° 31.0′ N; 155° 32.5′ W.

December 5, 6:29 a.m., very feeble, probably originated under ocean floor to SE of Island of Hawaii.

December 6, 10:56 p.m., very feeble, of shallow origin Mauna Loa NE rift 5.0 miles from center of Summit Crater.

December 8, 12:18 a.m., very feeble, probably originated under sea floor to SE of Island of Hawaii.

December 8, 3:49 a.m., very feeble, of shallow origin, NE rim of Mauna Loa Summit Crater. 19° 30.0′ N; 155° 34.3′ W.

December 8, 11:54 p.m., very feeble, from Chain-of-Craters near Devil's Throat.

December 10, 2:24 p.m., very feeble, of shallow origin 1.0 mile SE of Pit seismograph. 19° 23.8′ N; 155° 16.3′ W.

December 13, 1:56 a.m., very feeble, probably originated under sea floor about 23 miles west of Hualalai.

December 17, 2:48 p.m., very feeble, of shallow origin, south rim of Kilauea Crater, 1.0 mile south by east of Pit seismograph. 19° 23.5′ N; 155° 16.8′ W. Dismantled both components of Pit seismograph and reported felt in residential area of Hawaii National Park.

December 19, 1:11 p.m., very feeble, of shallow origin, Kilauea Crater.

December 21, 8:15 a.m., very feeble, about 20.0 miles deep and 12.0 miles south of Mauna Loa Summit Crater, 8.0 miles NW of Pahala. 19° 17.5′ N; 155° 34.0′ W.

December 22, 5:36 a.m., feeble, 9.0 miles deep, 8.0 miles SE of Summit Crater of Mauna Loa. 19° 24.4′ N; 155° 29.0′ W. Reported strongly felt at Kapapala Ranch House.

December 23, 12:06 p.m., feeble, 15.0 miles deep, Mauna Loa NE rift, 8.0 miles from Summit Crater. 19° 32.0′ N; 155° 29.0′ W.

December 23, 10:54 p.m., very feeble, 1.7 miles deep, 0.7 mile SE by south of Pit seismograph. 19° 23.8′ N; 155° 16.4′ W.

December 26, 8:50 p.m., very feeble, Kilauea SW rift near junction with Hilina Pali. 10.0 miles deep. 19° 15.5′ N; 155° 23.0′ W.

December 13, 8 minutes of continuous tremor began recording 6:02 a.m.

Teleseisms

October 3, 3h 18m 40.0s, a.m., "P" waves? Distance undetermined.

October 17, 8h 01m, p.m., located in New Hebrides area. Reported to have originated at a depth of 100 km. Distance from Kilauea, about 3,500 miles. Epicenter 16° S; 168° E, by U.S.C. and G.S.

December 16, 12h 25m 48s, a.m., "P" waves. Distance undetermined.

December 21, 10h 42m 55s, a.m., "P" waves. Distance from Kilauea approximately 5,505 miles, probably originated in Celebes.

December 21, 6h 25m 13s, p.m., "P" waves. Distance from Kilauea, approximately 4,625 miles. No reports received on location.

December 26, 2h 16m, p.m., surface waves. Distance undetermined; origin the disaster near Erzerum in Asiatic Turkey.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau the algebraic sum toward or away from the Pit as indicated by tilt stations on the W and SE rims respectively.

At the Observatory the total accumulated tilt for the year ending October 29, was 1.15" S and 1.48" W.

December 3, 2:20" N and 1.56" W.

December 31, 1.70" N and 1.35" W.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
October 8	1.85" N 45° E	4.47" S 60° W
" 15	1.45" N 52° E	5.16" N 15° W
" 22	0.50" S 58° W	0.00 ——
" 29	0.77" N 79° E	2.98" W
November 5	1.43" N 35° E	3.81" N 53° W
" 12	0.56" N 30° E	4.41" N 74° W
" 19	0.74" N 11° E	0.00 ——
" 26	0.00 ——	0.00 ——
December 3	0.60" N 53° W	0.00 ——
" 10	0.27" W	3.13" S 55° W
" 17	0.27" S 6° E	5.99" S 30° E
" 24	0.21" N 67° E	4.47" N
" 31	1.17" S 48° W	0.00 ——

Week Ending	Halemaumou Southeast Station	Halemaumau Resultant
October 8	4.86" S 50° E	8.55" from
" 15	9.23" N 47° E	0.09" toward
" 22	4.96" N 67° E	0.97" from
" 29	15.10" N 83° W	6.90" toward
November 5	3.79" N 25° E	0.90" from

" 17	6.58" S 17° W	1.52" from
" 24	6.48" N 30° W	6.93" toward
" 31	6.48" S 30° E	6.48" from

Crater Angles

Measurements of horizontal angles across Kilauea Crater from the Observatory were made October 10 and 26, November 15 and December 7 and 19. On October 10 the measurements indicated opening of 1.16" for the Halemaumau value and opening of 0.92" for the Crater value, compared with similar measurements made on September 27. Between October 10 and October 26 the Halemaumau angle remained unchanged and the crater angle closed 2.08". Total, September 27 to October 26, Pit opened 1.16" and Crater closed 1.16". The Halemaumau volue is measured between the seismograph station on the SE rim and the NW Pit bench mark. The crater value is measured between a station on the SE rim of Kilauea Crater and the Uwekahuna Station.

Angles November 15 had changed by the Halemaumau value opening 0.59" and the Crater value opening 0.24" compared with October 26 determinations.

Two more angle determinations were made during December. On December 7, the Halemaumau angle had opened 0.16" and the Crater angle had opened 1.09" since November 15. Between December 7 and 19, the Pit angle closed 1.25" and the Crater angle remained unchanged. Total change November 15 to December 19; Halemaumau angle closed 1.09" and the Crater angle opened 1.09".

For the period September 27 to December 19, both ongles showed on increase. The Halemaumau value increased 0.66" and the Crater value increased 0.17".

Chain-of-Craters Road Cracks

Date	101	102	103	104	105	106	107
October 27	404.65	64.55	101.50	17'9⅛"	87.30	88.75	39.55
November 24	404.60	64.60	101.50	same	87.35	88.75	39.60
December 29	404.55	64.60	101.55	same	87.35	88.75	39.50
Total change in mm. since September 29	—1.0	+0.5	.....	.....	+0.5	.....	—1.5

The two cracks which opened at the road edge of Aloi Crater rim during August showed no changes in the past three months.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, is leased and operated by the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigations.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

TILT CHANGES AT KILAUEA

By HUGH H. WAESCHE,
Asst. Geologist

Tilt has been defined by T. A. Jaggar and R. H. Finch as "a change in the angular relation between a portion of the earth's surface and the plumb line". This change is measured on "tilt-sensitive" seismographs or on instruments often called clinoscopes built exclusively for tilt measurement. Usually they are pendulum devices. Horizontal pendulums of several seconds period are particularly tilt sensitive. At Kilauea the Bosch-Omori seismograph located on the NE rim of Kilauea Crater is the principal instrument used for tilt determinations. In addition there are two clinoscopes, one on the southeast rim and the other on the west rim of Halemaumau. For other tilt studies, values are also obtained from the Mauna Loa, Hilo and Pit seismographs. The Bosch-Omori seismograph consists of two components N-S and E-W, recording on a single drum. A fixed pen is made to record a reference line each time a new, smoked paper record is started. Daily measurements from this line to the second line of the regular seismograph recording, in millimeters, give the migration of the recording pens caused by ground tilt. The drums are changed each morning and evening usually at 8:00 a.m. and 8:00 p.m., thus two tilt readings per day are obtained although it has been found necessary to use only one, which is the evening reading. The Bosch-Omori seismograph at the Observatory with a static magnification of about 115 and a period of seven seconds is sensitive enough to record a depression of 1 centimeter in 16 kilometers or 0.4 inch in 10 miles. For reference, 1 second of arc is equivalent to 0.272 inches depression or elevation at a distance of 1 mile. Charts derived from measurements of tilt changes recorded by the Bosch-Omori seismograph at the Observatory are the only ones discussed in this article.

Early studies of volcanic eruptions and earthquakes in Japan drew attention to ground tilt as a factor of great importance preceding, during and after the respective disturbances. Pioneers in tilt studies in that country were the late Professor Omori and Director Emeritus Akitune Imamura his successor at the Imperial University in Tokyo. In 1930, Dr. Imamura[1] discussed at length, "Topographical Changes Accompanying Earthquakes or Volcanic eruptions". In that publication he deals in some detail with fourteen earthquakes between the Tosa earthquakes of the year 684 A.D. and the Formosa earthquake of 1906 A.D. where evidences of ground tilt have occurred but where no instrumental check was available. Tilt changes of twelve other earthquakes between 1891 and 1927 were checked by precise levelling. In addition, tilt changes associated with the volcanic eruption of Usu in 1910 and the Sakurajima eruption of 1914 are described. One of the principal conclusions drawn was that with all earthquakes and all volcanic eruptions there occur topographic changes (with emphasis on ground tilt) whether they are observed or not. Conclusions of that nature only served to emphasize the importance of tilt studies and development of instruments for determining tilt as a source of data supplementing other geophysical investigations. Such data might be of great value in predicting future earthquakes or volcanic eruptions and are particularly important from that point of view in Japan and California as well as other localities subject to sudden terrestrial changes. The Japanese seismologists have developed a wide variety of tilt measuring devices and are obtaining data in quantity from both volcanic and seismic areas with most attention probably centered on the Tokyo area, scene of the very destructive Kwanto Earthquake of September 1923. Results have proven instructive and gratifying and undoubtedly, as more knowledge is gained, will play an important role in predictions both volcanic and seismic.

In California, ground tilt is being carefully studied by the staff of Pasadena Seismological Laboratory of the Carnegie Institution, the seismological laboratory of the University of California and the United States Coast and Geodetic Survey. These groups are especially interested in tilt associated with the great earthquake-making faults of the west coast as an indicator of the approach of potential, property and life damaging earthquakes.

In Hawaii, H. O. Wood first noticed pronounced ground tilt at the Observatory with the establishment of the seismographs on the NE rim of Kilauea Crater in 1913. However, tilt was not given an important place in the study of Hawaiian Volcanoes until 1917 when Romberg and Jaggar began the systematic recording and studying of daily and seasonal tilt changes and their relationship to Kilauea and Mauna Loa. Their work has been carried on and is now considered one of the more important studies in volcanic research.

Apparently Hawaii, Japan and California are the only places in the world where tilt studies have been a serious part of the

[1] "Publications of the Earthquake Investigation Committee in Foreign Languages, No. 25."

volcanic and seismic research program. Interest in this phase of earth movement is gaining rapidly though as its importance is more generally realized. The positive results obtained are of great value in volcanologic studies.

In order that the ground tilt might be better visualized, results of the daily readings are plotted on coordinate paper lined ten to the inch. One millimeter change on the seismogram is plotted to 1/10 inch so that 1 inch on the paper is equal to 1.21 seconds of arc. The latter value is determined from the constants of the seismograph. An arbitrary numerical value was assigned to the starting point and all tilt has been plotted on this base since. The E-W migrations of the seismograph pen are plotted as abscissa and the N-S as the ordinates. During the 27 years of measurement, it has been found that tilt on the NE rim of Kilauea Crater, considered as the path of the top of a vertical rod describes an annual loop of from 5 to 20 seconds of rotational arc with the loop elongated in a NNE-SSW direction, the greater axis usually being about twice the length of the shorter one. In the course of producing the major loop many minor ones occur and both, almost without exception, progress in a clockwise direction. In general, tilt is southwesterly during the warmer summer and fall months and northeasterly during the cooler late winter and spring months. Jaggar and Finch[2] have shown that seasonal temperature changes and tilt at Kilauea are correlated; at the same time loading due to rainfall is not related. A direct relation to lava eruption, confirming tilt changes was shown by precise levelling results by R. M. Wilson in 1921 and 1927.[3] Lava movements apparently affect tilt directly. This is shown in irregularities of the annual curve and in accumulated tilt from year to year. Accumulated tilt may be thought of as relative average change of position or migration of the annual loop, or relative displacement at corresponding periods of successive years.

Three types of tilt graphs are regularly plotted at the Hawaii Volcano Observatory. One is simply a daily curve derived from lines connecting points plotted as described. This produces a rather irregular diagram at times confusing. In order to straighten out and smooth the annual curve a system of overlapping 7-day means is used for the second type. This makes any plotted point a 7-day average. The next value to be plotted is obtained by subtracting the seismogram measurement of the first date used in the average summation and then adding the value succeeding the seventh measured. As tilt moves the seismograph pens beyond normal registration range, the instrument is adjusted to realign the recording pens and proper corrections added or subtracted from the last measured tilt value depending on direction of adjustment. The third system used two separate graphs for N-S and E-W components, representing direction in one plane only. In this system the dates are on the abscissa and amount of tilt in millimeters, ordinates. Millimeter graph paper is used with the millimeter divisions used for days and millimeters of tilt as measured on the seismograph record. The advantage of this type of graph is that it shows the marked excess of N-S tilt compared with that of the E or W.

The center of Halemaumau is S 50° W and the center of

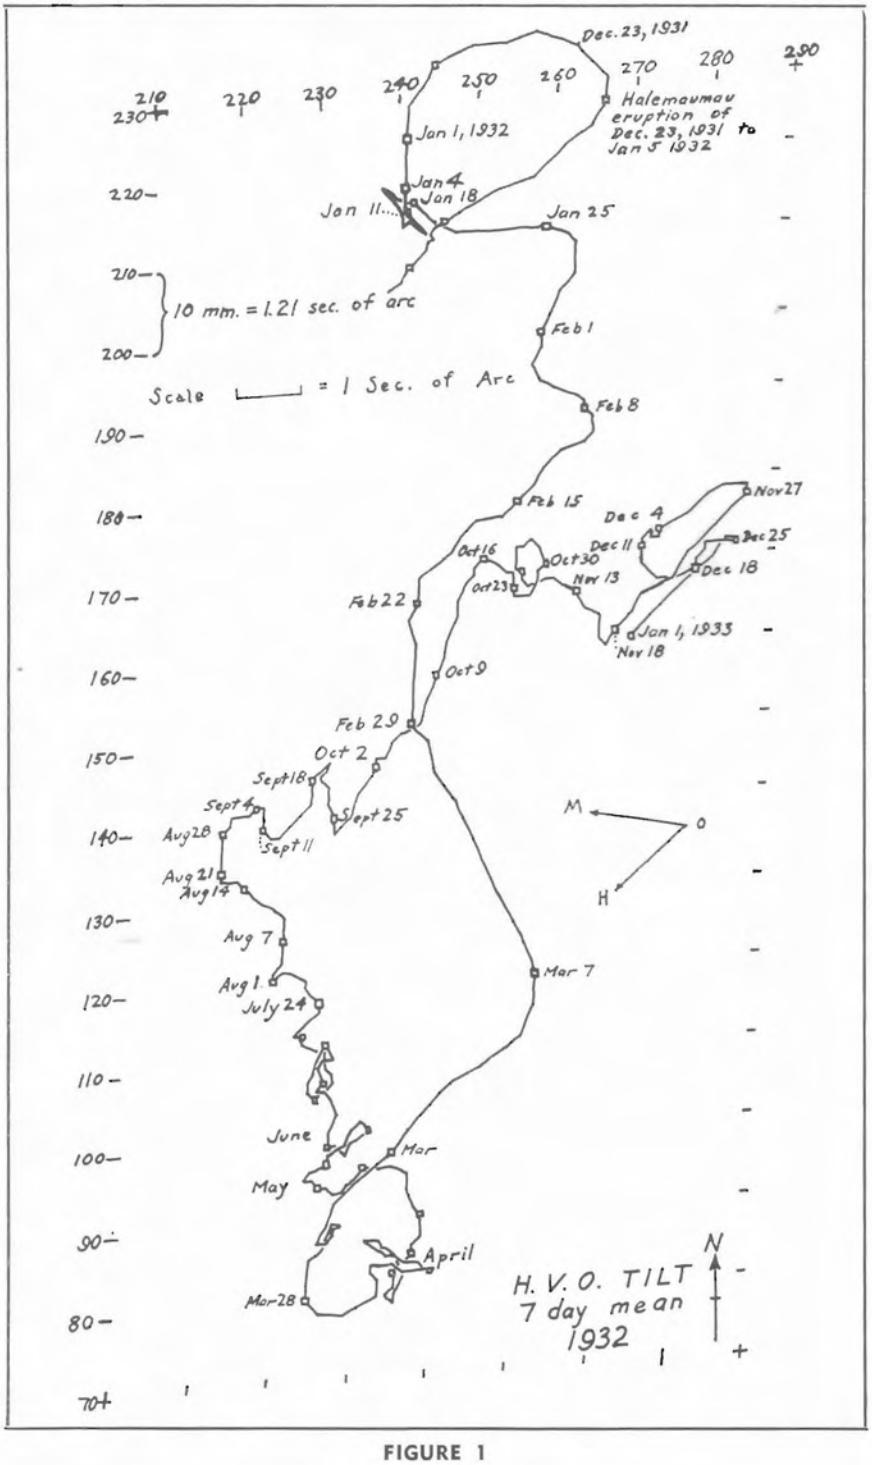

FIGURE 1

[2] Tilt Records for Thirteen years at the Hawaiian Volcano Observatory; Bulletin of the Seismological Society of America, Vol. 19, No. 1, March 1929.

[3] Ground Surface Movements at Kilauea Volcano, University of Hawaii Research Publications, Number 10, 1935.

Kilauea Crater is S 40° W from the Observatory. The longer axes of the annual loops average S 30° W. The figures suggest that factors other than concentric tumescence around either Halemaumau or Kilauea influence the direction of tilt at the Observatory. The factors may be topographic and/or structural. It seems likely that the area S of the Observatory is made up of a series of fault blocks stepped downward toward the sea and roughly paralleling the Hilina Fault system and the Mauna Loa rift system. If this is true there would be the SW Kilauea rift as indicated by the fractures in the SW Crater wall and dykes in Halemaumau, and another rift running to the east through Kilauea Iki. The Keanakakoi-Chain of Craters rift would be echelon connecting the Kilauea Crater with the Hilina Pali toward Puna. Such a fault block system might easily explain the lack of E-W tilt on the NE Kilauea Crater rim, which would tip more to its N than E with reference to the direction of greatest ease of ground movement.

The accompanying charts are copies of original plats which have been made at the Observatory. Figure 1 shows the Bosch-Omori, 7-day mean, tilt path for 1932. The yearly loop was very irregular. Apparently during 1931 the lava-gas pressure under Kilauea Crater had forced the tilt well to the N and E. This effect continued until December 23 when Halemaumau inflow began. As the eruption continued, pressure was released resulting in the westerly and southerly tilt lasting until January 18. After that easterly tilt of 2 seconds of arc occurred presumably because some pressure built up after the vent had sealed off. During the sealing period, probably January 4 to 18, irregularities which may have been sympathetic to resulting pressure changes in the crater occurred. The pressure release as a result of the eruption allowed considerable southerly tilt to occur. However, reference to figure 2 shows that the more easterly accumulated tilt of 1932 was a forerunner of the building up of pressure under Mauna Loa preceding the eruption of the summit crater December 2 to 18, 1933 almost due west of the Observatory. Simultaneously Kilauea Crater was no doubt adding to the increased easterly tilt.

In Figure 2, south and easterly tilt began building up about October 29, 1933. A maximum was reached about November 26. On December 2, Mauna Loa erupted at the summit crater. Tilt showed sympathetic reactions between December 3 and December 24. The "jog" in the line, December 17, corresponds to the sealing off and end of the eruption December 18. Tilt continued west and north until December 24 when it moved east and north, possibly because of increases of pressure under Kilauea resulting from termination of the Mauna Loa activity. It is of interest to note that 1933-tilt ended to the N and W of its starting point—indicating that tilt had accumulated to the N from Kilauea pressure and probably had altered to the W as a result of pressure release from Mauna Loa.

Figure 3 is a continuation of the 1933 chart (Fig. 2). Starting with January 7, the general progress of

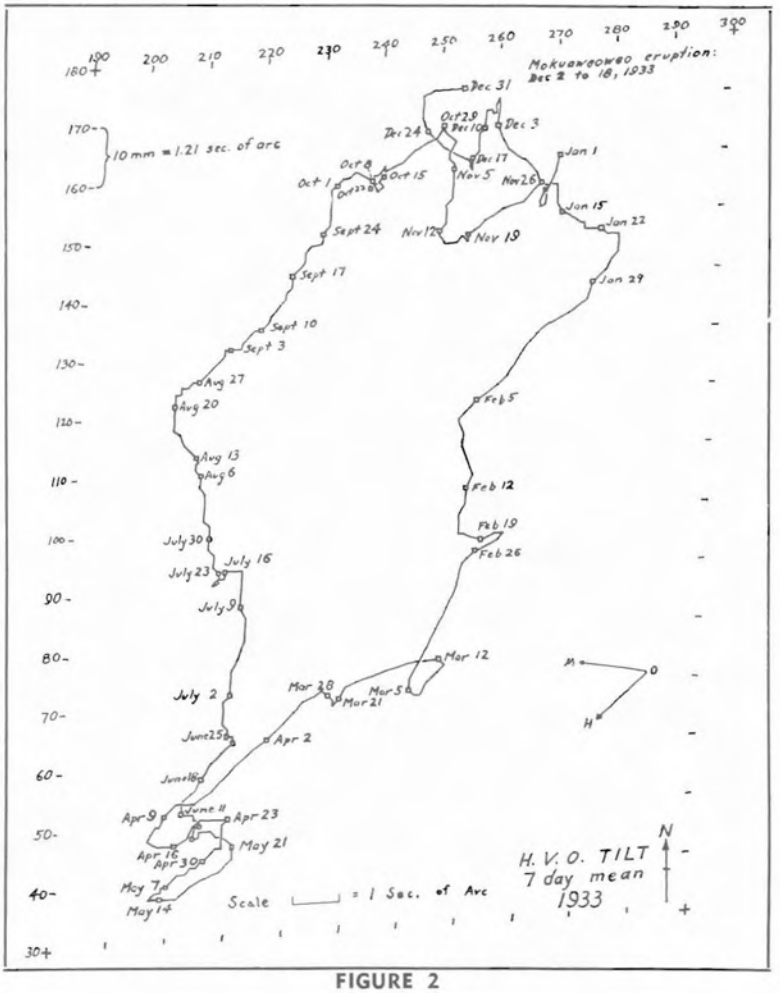

FIGURE 2

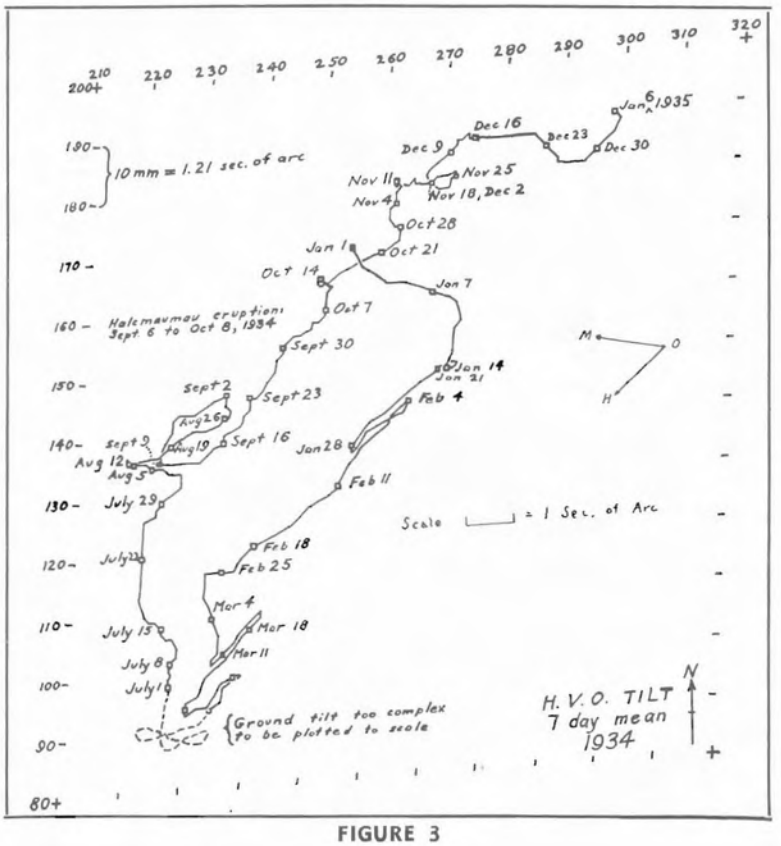

FIGURE 3

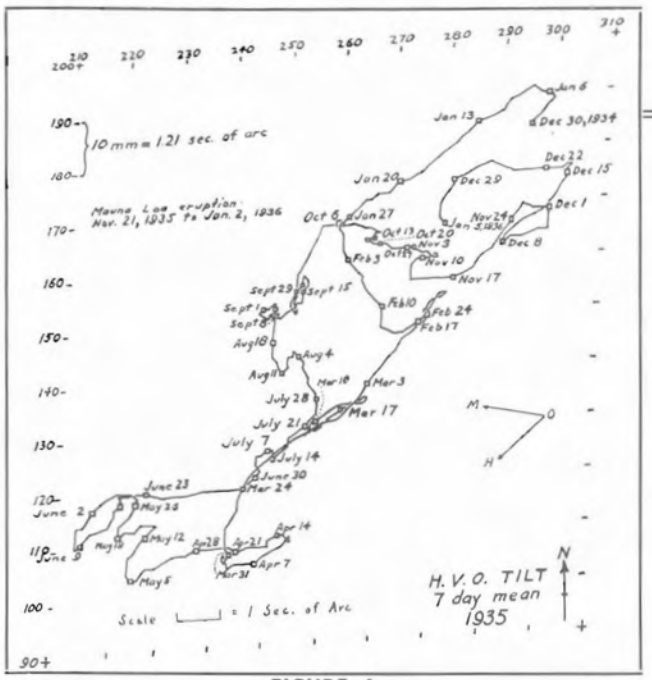

FIGURE 4

the annual loop is to the south and west in normal fashion. The interesting point however is that the southwesterly tilt ceased about five and one half seconds from the low of 1933 and moved steadily north until August 5 when irregularities began to occur. Halemaumau began erupting in the early morning hours of September 6. Tilting to the SW followed until September 9 when recovery started and the normal trend continued in a northeasterly direction until January 6, 1935. At that time the ground on the NE rim of Kilauea had tilted approximately three seconds of arc northeast of its position at the same date the preceding two years. In other words, in 1933 and 1934 tilt had accumulated to the north and east.

Figure 4, 1935 continues from the preceding chart and marks the last tilt-eruption curve. This curve is highly irregular. In June, some two seconds of arc had again accumulated to the northeast over a similar period in the preceding year. On October 6, southeasterly tilt began, continuing until November 17 when Mauna Loa summit crater and N E rift began an eruption which continued until January 2, 1936. The tilt

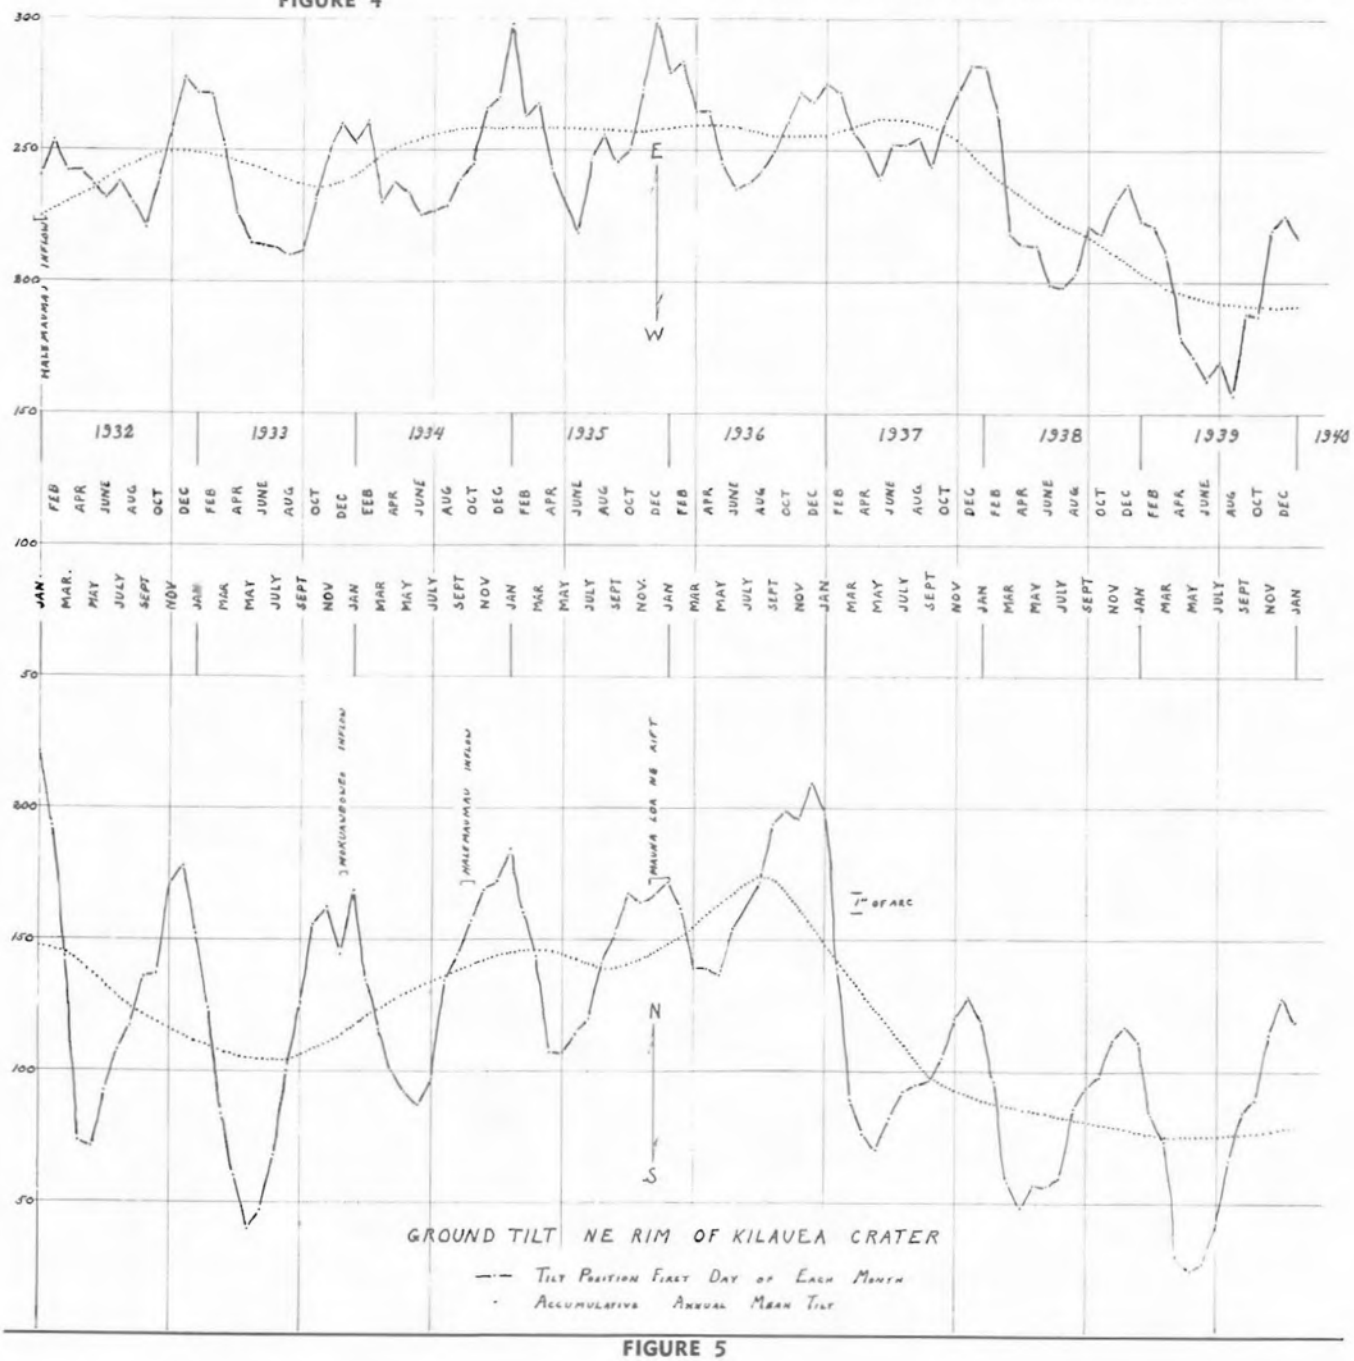

FIGURE 5

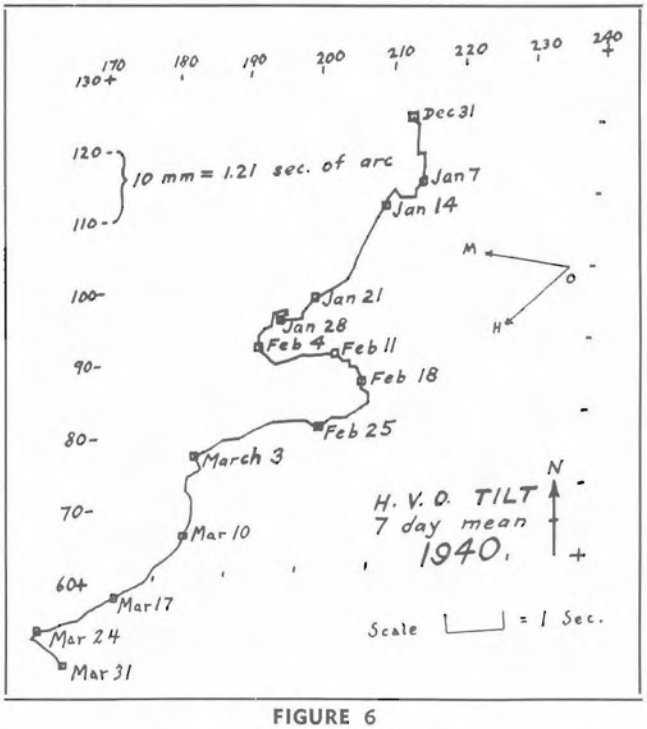

FIGURE 6

recovered most of its northerly trend which would be normal for Kilauea and then moved rapidly to the west December 22 to December 29, during the decline of the Mauna Loa eruption. It is striking that northerly tilt did not recover as it had done in preceding years. Possibly sympathetic pressure under Kilauea had been reduced with the Mauna Loa eruption.

Reference to Figure 5 will show relations which followed. Accumulated tilt increased in 1936 and then steadily receded during 1937 and 1938 but began to recover during the last six months of 1939. By December 1939, northerly tilt had recovered beyond that of the same period in 1937 although easterly tilt had not so recovered. The dotted line marking mean annual tilt indicates a definite recovery corresponding roughly with the peaks. Furthermore, the plotted 7-day mean loops of 1937, 1938 and 1939 were open and relatively regular.

Figure 6 shows the tilt for the first quarter of 1940. On March 31, 1940 the tilt position was 2.6 seconds N and 1.37" W of the same relative position for preceding year. Northerly tilt has recovered much but easterly tilt has lost. However, the strong northerly trend in contrast to condition of three preceding years may be strongly significant of volcanic changes to come.

Figure 7 illustrates the appearance of the tilt curve plotted on a daily basis rather than as a smoothed curve. Sharp irregularities are diurnal in nature and may be related to temperature changes between day and night. It covers the same period as Figure 6.

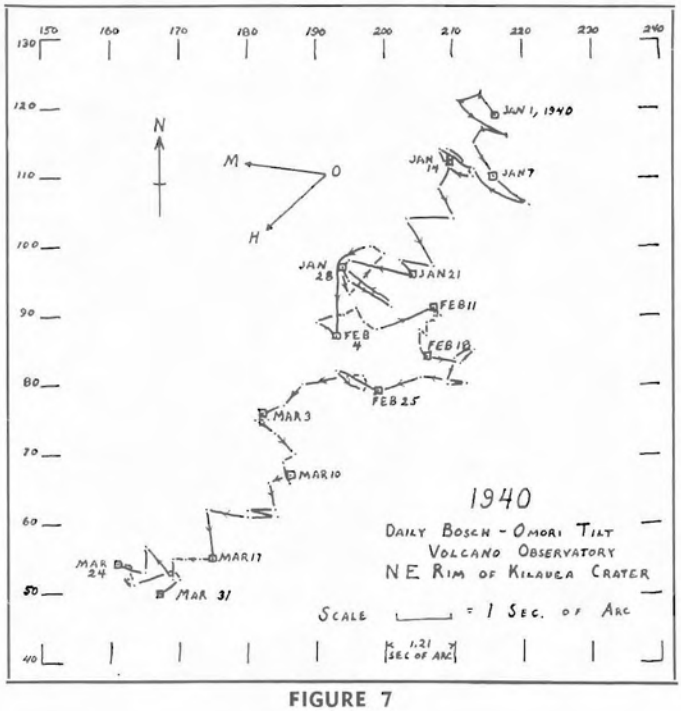
In the smooth curves, dates of tilt changes do not correspond exactly to visible or other volcanic changes as they are affected by possible sudden changes three days before or after the date concerned which are of course not clearly shown because of the smoothing by overlapping means.

The most interesting chart of the entire group is Figure 8 which gives a general picture of tilt changes at the NE rim of Kilauea Crater from 1913 to the end of 1939. In this case average monthly tilt has been determined and these values plotted as overlapping means in groups of five in the same manner that the daily Bosch-Omori tilt was plotted by 7-day means. The relative position of each month is represented by a square and in order to simplify the resulting maze, each yearly trace is given a different design. During a large portion of each of the two years, 1916 and 1917, tilt records either were not kept or were lost. That period is indicated by a dotted line using an X for each month rather than a square. The major loop progresses counter-clockwise but all others are of normal clockwise movement. That part of the plat from 1913 to 1931 inclusive was worked up and plotted by Dr. H. A. Powers, the remainder by the author.

Changes in ground tilt represented by Figure 8 bear a direct relation to volcanic activity during the same period. A direct relation also was found to exist between the tilt and ground surface changes determined by surveys of precise levels and triangulation in 1912, 1921 and 1927 as described by R. M. Wilson.

Reference to Figure 8 shows that there was strong easterly tilt from July 1913 to July 1918 with only slight westerly recession in 1919. Mauna Loa summit crater erupted in 1914; the SW rift was active in 1916 and in 1919 it produced the Alika flow. The flows were progressively bigger. From March to August 1919 there was considerable westerly tilt. This continued until August 1924 when marked easterly tilt developed. In 1926 the Hoopoloa flow from the SW rift of Mauna Loa occurred. In 1928 and 1929 there was recession to the west again but recovery to the east was resumed in 1930 which continued until 1936. During that period there occurred the Mauna Loa summit eruption of 1933 and the NE rift eruption of 1935-36. Westward tilt followed in 1937, 1938 and 1939. Relative E-W position at the beginning of 1940 is about the same as 1914 and 1926 indicating that pressure conditions from Mauna Loa as affecting tilt at Kilauea at no period have been less than at present and on this basis do not alter its eruptive possibilities, compared with the years referred to.

The proximity of Kilauea makes its effects on the Observatory tilt more striking. It should and apparently does affect the NE Crater rim tilt more in the N-S direction than in the E-W direction. In 1913, 1914, 1915, 1916 and 1917 there was pronounced annual fall tilt. Lava rising occurred simulta-



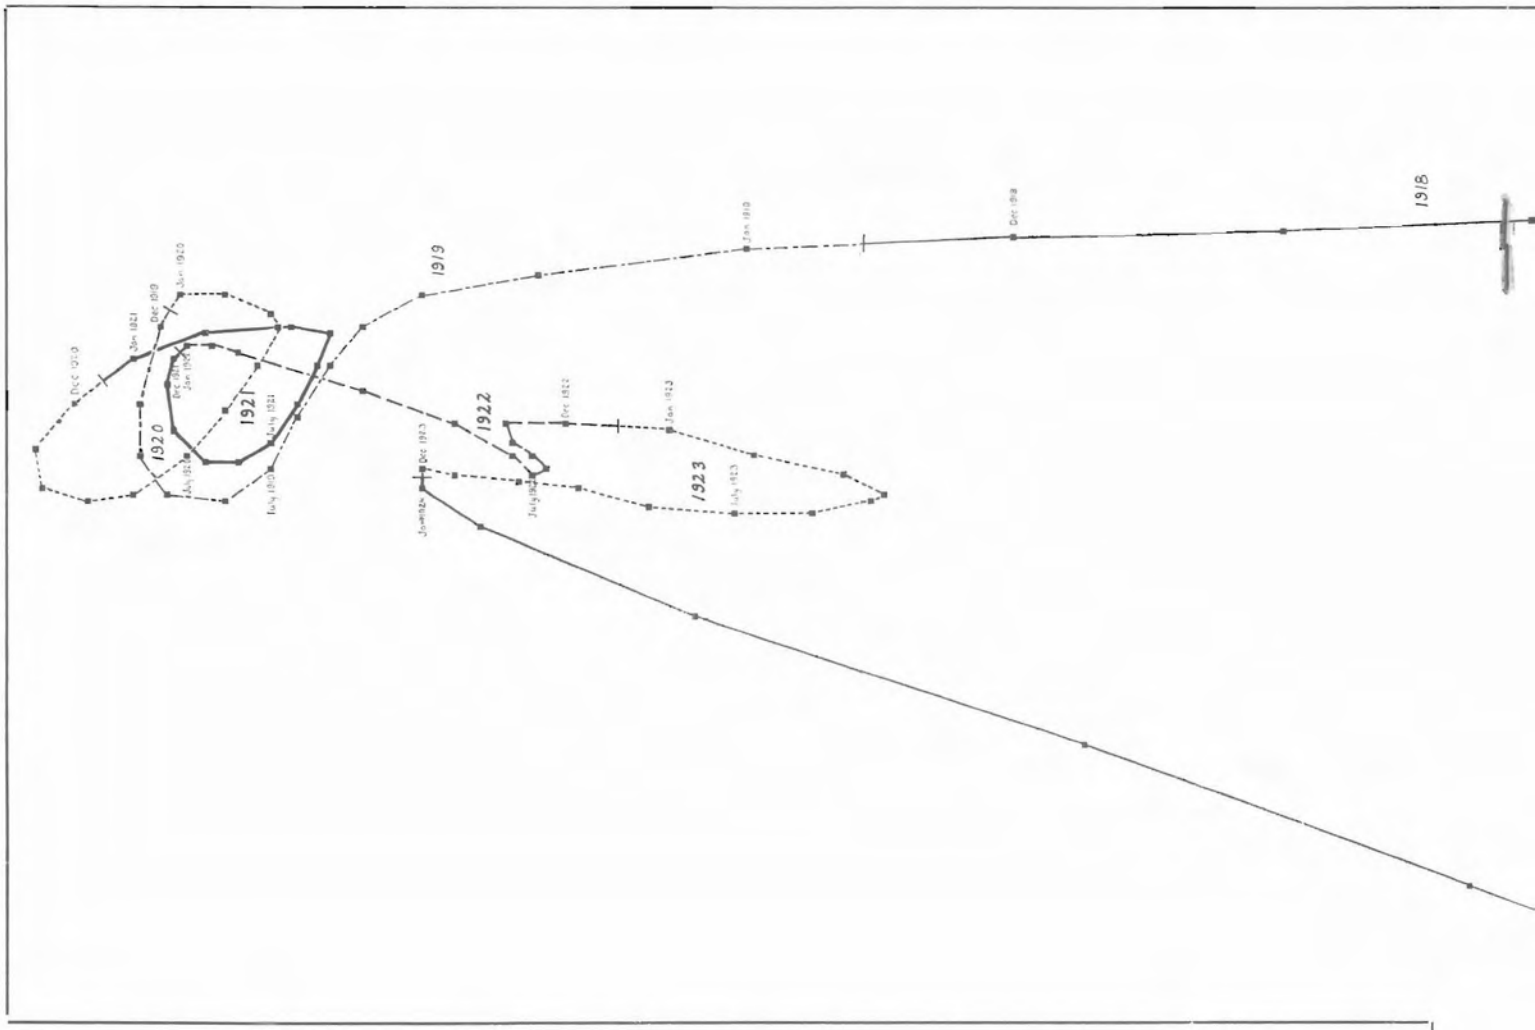


FIGURE 7

neously in Halemaumau and this in turn was apparently sympathetic to increases of pressure under Mauna Loa. Beginning in 1918 the Mauna Loa influence is submerged by the great changes taking place within the Kilauea dome reflected by rising lava in Halemaumau and fifty-three seconds of northerly tilt between May and January of that year. Strong northerly tilt continued until August 1919 culminating simultaneously with Halemaumau lava overflow. In 1920 outflows occurred in the Kau Desert and Halemaumau overflows occurred again in 1921. After this there was lava recession with outflow in vicinity of Makaopuhi during 1922 and 1923. Southerly tilt was marked during those two years. However, in the fall of 1923 there was recovery of north tilt with an accompanying rise in lava in Halemaumau. This was followed by strong southerly tilt of eighty-one seconds between January and July, 1924. In May 1924, lava in Halemaumau receded to unknown depths and activity reached a culmination during that month by steam blast explosion and finally collapse of Halemaumau and to some extent the entire dome of Kilauea. After this, Kilauea Crater was only periodically active with Halemaumau inflows which occurred in July 1924, July 1927, January 1928, February and July 1929, November-December 1930, December-January 1931-32 and September-October 1934. Southerly accumulative tilt continued during 1925 and 1926 but recovered in 1927 to the north. Southerly tilt again occurred for 1928 and 1929 with little change during 1930-31. Slight southerly tilt accumulated during 1932, 1933 and then recovered in 1934 to a point north of the two preceding years. Halemaumau inflow of September, 1934 was the last Kilauea extensive activity to date. Northerly tilt continued during 1935 and 1936. During 1937, 1938 and 1939 southerly tilt steadily accumulated and, with the exception of the Chain-of-Craters seismic crisis of May and July 1938, Kilauea has had its quietest period of the current cycle of events. However, 1939 ended with accumulated tilt again to the north and the first three months of 1940 have borne out the suggestion that a new cycle of northerly tilt may have started and with it the possibility of a coming change in volcanic activity somewhere in the Hawaiian system of eruptive vents.

R. M. Wilson's work has confirmed the major changes described. Precise levels were run from Hilo to Kilauea in 1912, 1921 and 1927. These showed that apparently between 1912 and 1921 the Volcano House B. M. was elevated about two feet and between 1921 and 1927 it was lowered about 3.5 feet. Comparison with Figure 8 shows that the values coincide with tilt changes both in time and relative amounts.

Levels have been run periodically around the SW rim of Halemaumau from the Spit B. M. on the SE Crater rim to a B. M. on the NW rim of Halemaumau. Since 1934 there had been relative lowering of the NW Pit B. M. of 2.02 feet by April 1940. If it is assumed that the Spit has remained more or less stationary, then the Crater floor of Kilauea has settled, and accumulated tilt should be to the south. All other evidence confirms this condition.

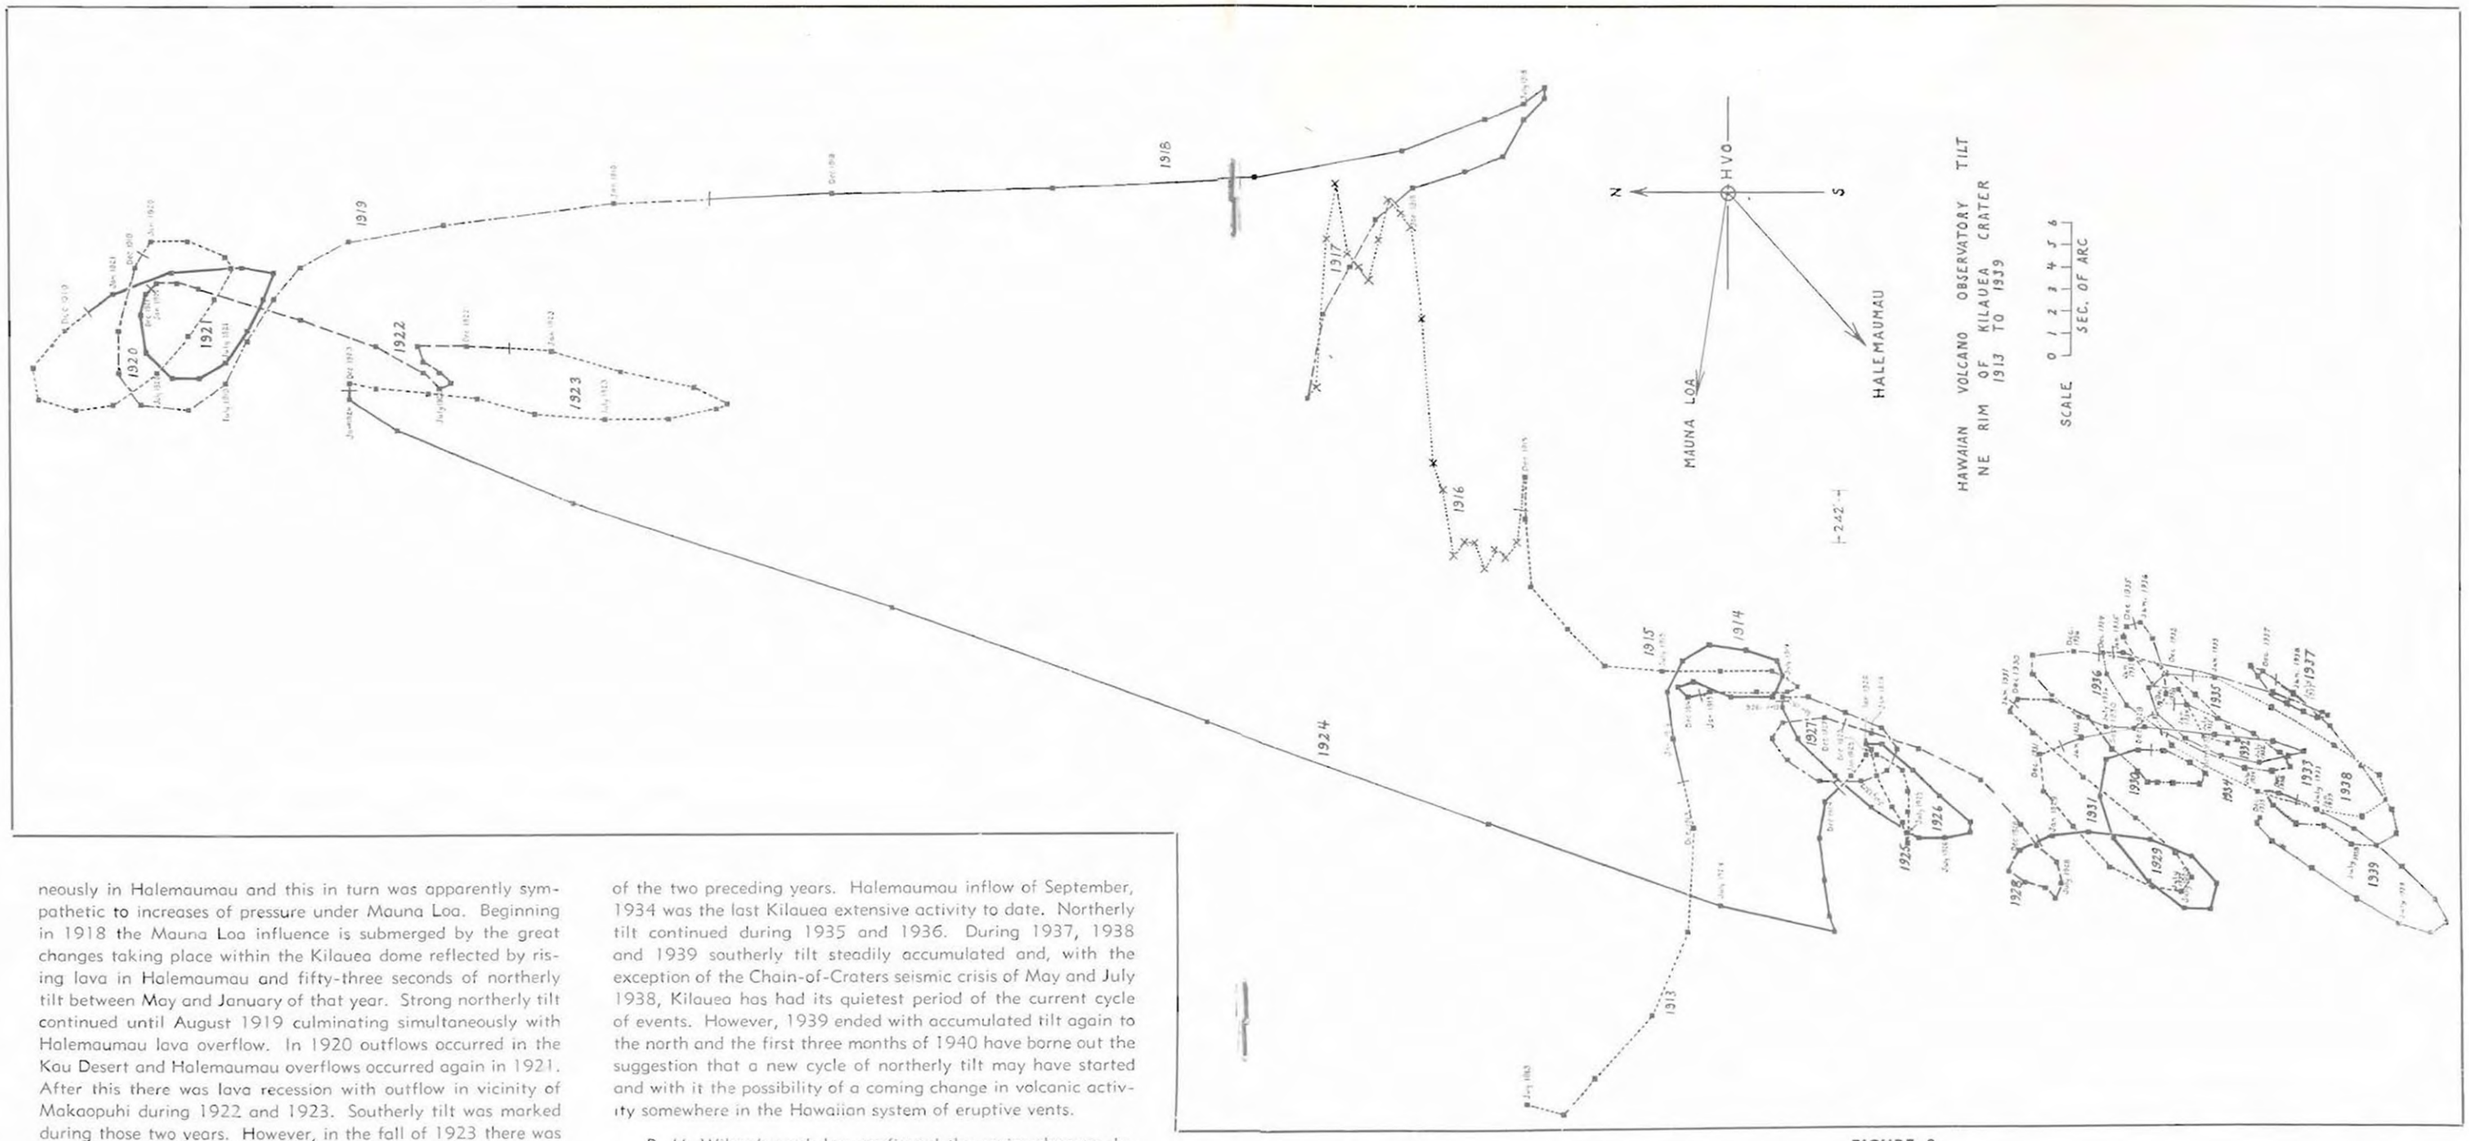

FIGURE 8

neously in Halemaumau and this in turn was apparently sympathetic to increases of pressure under Mauna Loa. Beginning in 1918 the Mauna Loa influence is submerged by the great changes taking place within the Kilauea dome reflected by rising lava in Halemaumau and fifty-three seconds of northerly tilt between May and January of that year. Strong northerly tilt continued until August 1919 culminating simultaneously with Halemaumau lava overflow. Southerly accumulative tilt continued during 1925 and 1926 but recovered in 1927 to the north. Southerly tilt again occurred for 1928 and 1929 with little change during 1930-31. Slight southerly tilt accumulated during 1932, 1933 and then recovered in 1934 to a point north of the two preceding years. Halemaumau inflow of September, 1934 was the last Kilauea extensive activity to date. Northerly tilt continued during 1935 and 1936. During 1937, 1938 and 1939 southerly tilt steadily accumulated and, with the exception of the Chain-of-Craters seismic crisis of May and July 1938, Kilauea has had its quietest period of the current cycle of events. However, 1939 ended with accumulated tilt again to the north and the first three months of 1940 have borne out the suggestion that a new cycle of northerly tilt may have started and with it the possibility of a coming change in volcanic activity somewhere in the Hawaiian system of eruptive vents.

R. M. Wilson's work has confirmed the major changes described. Precise levels were run from Hilo to Kilauea in 1912, 1921 and 1927. These showed that apparently between 1912 and 1921 the Volcano House B. M. was elevated about two feet and between 1921 and 1927 it was lowered about 3.5 feet. Comparison with Figure 8 shows that the values coincide with tilt changes both in time and relative amounts.

Levels have been run periodically around the SW rim of Halemaumau from the Spit B. M. on the SE Crater rim to a B. M. on the NW rim of Halemaumau. Since 1934 there had been relative lowering of the NW Pit B. M. of 2.02 feet by April 1940. If it is assumed that the Spit has remained more or less stationary, then the Crater floor of Kilauea has settled, and accumulated tilt should be to the south. All other evidence confirms this condition.

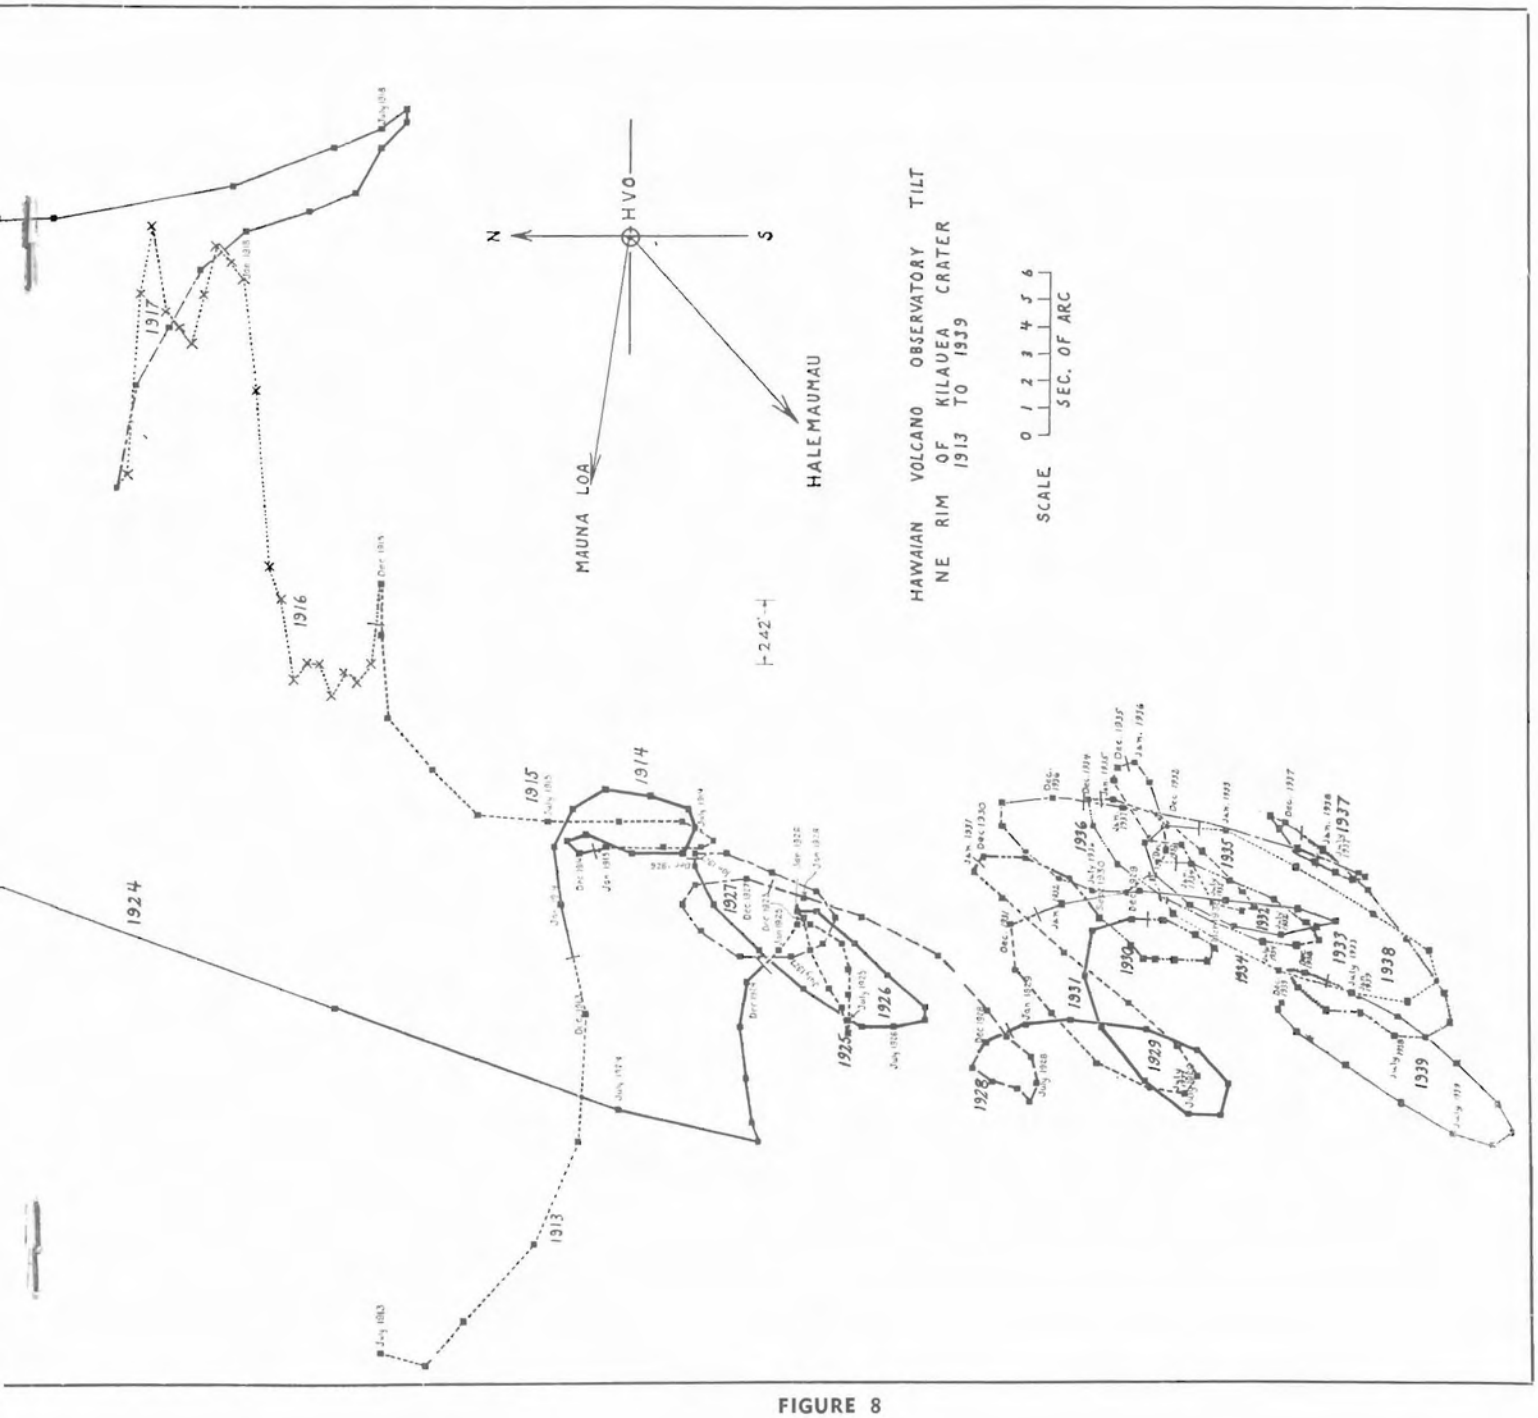

FIGURE 8

From the facts here illustrated and discussed it seems obvious that ground tilt is an extremely revealing as well as important factor in volcanic studies. More instruments should be developed. Dr. Willard H. Eller of the University of Hawaii Physics Department, in cooperation with the Volcano Observatory, is working on the problem and several new instruments have been developed which are promising. The need is for a self recording "tiltmeter" little affected by temperature which will give a clear picture of ground movement in any direction. Such instruments well placed and in sufficient numbers would not only be useful in determining changes in lava movements but would also be of help in straightening out the complicated structural relations of the Hawaiian Volcanoes.

In acknowledgment, the author wishes to thank Mr. P. E. Schulz of Hawaii National Park for tracings made of charts Nos. 1, 3, 4 and 6 and used for reproductions here illustrated, and to Dr. H. A. Powers and Mr. A. E. Jones for figures and computations on earlier charts.

Hawaiian Volcano Observatory Report for January-March 1940

VOLCANOLOGY

January 1940

The month of January began with still less seismicity than December but the third and fourth weeks produced excess of disturbances on the Mauna Loa seismograph, and the half of these recorded at Kilauea were mostly of Mauna Loa origin (29 out of 31 shocks third week). Nothing is known to have happened at the craters, and the island was going through a period of excessive drouth with very light southerly winds and calms. Humps in the Chain-of-Craters road were increasing in number between Devil's Throat and Aloi pit.

The following are the local data for January:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
January 7	2	4.0 mm. closed	11
" 14	0	2.0 mm. opened	18
" 21	0	2.5 mm. opened	31
" 28	0	4.0 mm. closed	26

Two rock slides from the southeast rim of Halemaumau down the interior wall were indicated by dust clouds seen from the Uwekahuna Museum January 4 at 9:45 a.m. and 9:57 a.m.

February 1940

The month of February was without unusual volcanic events. The drouth continued and the burning down of Volcano House February 6 produced danger to the wooden Observatory a few hundred feet away. A peculiar tremor on the seismograph was recorded between 6:15 a.m. and 7:10 a.m. while the fire was at its height, possibly correlated with flame pulsations of the conflagration as well as related traffic movement.

The first week of the month at Mauna Loa seismograph continued to show more very feeble earthquakes than the one at Kilauea but this peculiarity was declining. Of the feeble and very feeble earthquakes of the month, 31 in number, only 10 were from distances corresponding to Mauna Loa or beyond, the others chiefly Kilauea shocks.

No slides were reported at Halemaumau. Inspection February 17 showed a thin blue haze reflecting sunlight between 10:00 a.m. and noon. For the first time a bright orange-yellow spot was observed on the floor between the center and the southeast rim wall, making a faint plume of fume, with yellow-lined cracks adjacent. Presumably sulphur was being deposited.

The following are the local data for February:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
February 4	0	2.5 mm.	43
" 11	0	3.0 mm.	42
" 18	0	2.0 mm.	50
" 25	0	2.5 mm.	34

March 1940

The month of March produced notable increase in Mauna Loa earthquakes, solfataric stains were increasing on the Halemaumau floor and some feeble earthquakes were felt during the month. Of 26 feeble and very feeble local earthquakes registered during the month 13 were from Mauna Loa distances and two were reported felt.

In Halemaumau on March 1 there was faintly visible fume and much white and yellow stain along the southeast edge of the pit floor. The solfatara at the base of the west wall is apparently dead. Accompanying a felt earthquake at 9:47 a.m. March 2 rocks fell from the WNW wall of Halemaumau and there was a scar of recent sliding at the south. A moderate slide sent up a dust cloud lasting 10 minutes at NE wall of Halemaumau 5:28 p.m. March 4. The end of the month produced a few rock slides and the fuming and yellow spots were still in evidence at the southeast in Halemaumau. Observation at Devil's Throat March 30 showed fresh rocks on the floor from the west wall.

The Mauna Loa seismograph showed a spell of seismic activity more intense than that at Kilauea for forty-eight hours between noon March 8 and noon March 10. Approximately 40 seismic disturbances were registered, whereas Kilauea recorded only 23. All but two at Kilauea were tremors, whereas Mauna Loa registered 15 as very feeble earthquakes. Apparently Mauna Loa was in local agitation under the northeast rift, and Mauna Loa was again focus of swarms of small earthquakes at the end of the month. This was precursory to the outbreak of Mauna Loa of April 7, and these interesting demonstrations of how differently two seismographs behaved only 9.4 miles (15 km.) apart show how desirable are multiple instruments of simple design over a uniform net of locations, recording time and intensity at a central station.

The following are the local data for March:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
March 3	1	1.0 mm. opened	52
" 10	1	2.5 mm. closed	45
" 17	0	5.5 mm. opened	22
" 24	0	0.5 mm. closed	24
" 31	few	7.0 mm. opened	26

Change of Annual Tilt

Referring to the notable change of tilt at the end of each month for the year next preceding, tabulated in page 5 of Volcano Letter No. 466, it is of interest to exhibit a general continuance of tilt to the west and north at the Observatory northeast rim of Kilauea Crater, for the year preceding the date indicated, respectively in north-south azimuth and east-west azimuth at the Bosch-Omori seismograph.

January 28, 1940	S 0.88 seconds	W 3.27 seconds
February 25, 1940	N 0.97 seconds	W 1.34 seconds
March 31, 1940	N 2.6 seconds	W 1.37 seconds

All of this is in contrast to a strongly southwesterly tilt of over 5 seconds between May and July 1939, this changing to an aggregate of about 3 seconds of northwesterly tilt between December 1, 1939 and March 31, 1940.

* Including teleseisms or earthquakes over 5000 km. from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the Island of Hawaii. Kilauea earthquakes were located by means of the seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible a determination of depth of focus has been made.

January 9, 7:47 pm, very feeble, probably originated in Kilauea SW rift about 8.0 miles SW of Halemaumau.

January 16, 11:06 pm, feeble, of shallow origin Mauna Loa summit crater, 19° 28.0' N; 155° 37.5' W.

January 16, 11:08 pm, very feeble, same location as preceding quake.

January 16, 11:32 pm, very feeble, 9.0 miles deep in area 4.5 miles W of Kilauea crater (Kaoiki Pali). 19° 25.2' N; 155° 20.5' W.

January 16, 11:45 pm, very feeble, probably originated in Kilauea SW rift.

January 17, 10:50 am, probably of Hualalai origin.

January 20, 12:34 am, very feeble, probably originated in Hilina Fault about 3.5 miles SW of Kamakaia Hills.

January 28, 1:06 am, very feeble, 2.3 miles deep, Kilauea SW rift, 0.8 mile NE of Cone Peak. 19° 23.9' N; 155° 17.9' W.

January 28, 6:18 pm, very feeble, Mauna Loa NE rift about 6.5 miles NE of Puu Ulaula.

January 28, 9:14 pm, very feeble, Mauna Loa NE rift about 3.0 miles NE of Pohaka Hanalei.

January 29, 8:06 am, very feeble, probably originated under N slope of Mauna Loa.

January 30, 1:11 am, very feeble, Mauna Loa NE rift about 3.0 miles NE of Pohaka Hanalei.

January 30, 11:32 am, very feeble, 1.1 miles deep, SE rim area of Halemaumau. 19° 24.4 ' N; 155° 16.6' W.

January 30, 1:54 pm, very feeble, Mauna Loa NE rift 6.0 miles NE of Puu Ulaula.

January 31, 2:19 am, very feeble, 1.1 miles deep, near SW rim junction of Kilauea Crater with SW rift. 19° 23.9' N: 155° 17.6' W.

February 2, 12:29 am, very feeble, of shallow origin, SE rim of Halemaumau. 19° 24.5' N; 155° 16.9' W.

February 2, 9:14 am, very feeble, from central portion of Kilauea Crater.

February 3, 12:49 pm, very feeble, probably originated in vicinity of Ahua Kamokukolau.

February 5, 7:50 pm, very feeble, E rim area of Kilauea Crater near Byron Ledge.

February 7, 11:43 am, very feeble, of shallow origin, Mauna Loa NE rift 5.0 miles SW of Puu Ulaula. 19° 31.0' N; 155° 31.0' W.

February 8, 7:19 am, very feeble, 11.0 miles deep, near junction of Hilina Pali fault with Kilauea SW rift. 19° 15.0' N; 155° 21.5' W.

February 8, 10:42 am, very feeble, of shallow origin, Kilauea Crater 0.9 mile NE of center of Halemaumau. 19° 24.9' N; 155° 16.4' W.

February 9, 7:42 am, very feeble, probably originated in Chain-of-Craters near Puhimau.

February 9, 10:47 pm, very feeble, probably originated under E rim of Kilauea Crater.

February 10, 4:44 am, very feeble, originated under Halemaumau not over 0.3 mile in depth and near SE rim. 19° 24.3' N; 155° 17.2' W.

February 12, 11:18 pm, very feeble, NE rim area of Kilauea Crater.

February 14, 8:54 pm, very feeble, NE portion of Kilauea Crater.

February 15, 3:03 am, very feeble, 11.0 miles deep near junction of Hilina Fault with SW rift of Kilauea. 19° 13.5' N; 155° 21.5' W.

February 16, 9:12 am, very feeble, probably originated 13.0 miles from the Observatory in the Kilauea SW rift.

February 16, 4:09 pm, very feeble, 2.3 miles deep under NE rim of Kilauea.

February 17, 7:03 am, feeble, 4.2 miles deep in rifts 0.9 mile S of Ahua Kamokukolau. 19° 22.2' N; 155° 15.9' W.

February 28, 10:38 am, very feeble, probably originated in Kilauea SW rift.

March 1, 1:58 am, very feeble, 12.0 miles deep, Mauna Loa NE rift, 8.0 miles NE Puu Ulaula and 18.0 miles SW of Hilo. 19° 36.0' N; 155° 22.0' W.

March 2, 9:47 am, feeble, of shallow origin SE rim area of Kilauea Crater. 19° 23.8' N; 155° 16.5' W. Dismantled N.S. component of Pit seismograph and reported sharply felt on SW rim of Halemaumau.

March 2, 10:20 am, very feeble, some origin as preceding quake.

March 4, 8:15 pm, very feeble, probably originated under SW end of Mauna Loa summit crater.

March 8, 10:40 pm, very feeble, Mauna Loa NE rift.

March 9, 4:00 pm, Mauna Loa summit crater.

March 10, 4:06 pm, feeble, 17.0 miles deep, Mauna Loa NE rift about 4.0 miles NE of Puu Ulaula. 19° 34.0' N; 155° 24.5' W. Reported felt at Uwekahuna.

March 11, 11:43 pm, feeble, of shallow origin under Byron Ledge, E rim of Kilauea crater. 19° 24.8' N; 155° 15.7' W.

March 14, 11:26 am, very feeble, probably originated in cracks 0.8 mile NE of Puu Ohale.

March 18, 3:27 am, very feeble, 18.0 miles deep under Hualalai. 19° 40.0' N; 155° 48.0' W.

March 20, 7:46 pm, feeble, 11.0 miles deep, Hilina Pali, 4.0 miles S SE of Makaopuhi. 19° 19.0' N; 155° 09.0' W.

March 21, 11:11 pm, very feeble, probably originated under Mauna Kea area.

March 22, 3:23 am, very feeble, probably originated in Hilina Pali.

March 26, 12:45 am, very feeble, NE slope of Mauna Loa, 4.0 miles SW of Hilo seismograph.

March 27, 7:27 am, very feeble, 18.0 miles deep under Mauna Loa summit crater. 19° 28.0' N; 155° 37.0' W.

March 27, 5:54 pm, very feeble, Mauna Loa NE rift near Mauna Loa seismograph station.

March 27, 6:50 pm, very feeble, of shallow origin, Kilauea Crater, 0.4 mile E of east rim of Halemaumau. 19° 24.5' N; 155° 16.5' W.

March 28, 2:31 am, very feeble, 18.0 miles deep, Mauna Loa NE rift, 2.0 miles SW of Puu Ulaula. 19° 31.0' N; 155° 29.0' W.

Teleseisms

January 2, 1h 06m 34s am, unidentified portion registered. Location by U.S.C. and G.S. Vicinity of Easter Island. 31° S; 108° W.

January 6, 3h 42m 51s am, "P" waves registered. 3775 miles from Kilauea in vicinity of New Hebrides and Loyalty Islands. 22° S; 170° E.

January 16, 2h 54m 18s pm, "P" waves registered. 3700 miles from Kilauea in vicinity of Marianas Trough. 17° N; 148° E.

February 7, 6h 53m 37s am, "P" waves. 2810 miles from Kilauea in the Aleutian Islands. 52° N; 174.5° E.

February 8, 1h 09m pm, unidentified portion. No information concerning point of origin obtained.

February 11, 9h 59m 17s pm, "P" waves. 3115 miles from Kilauea in vicinity of Tonga Trough. 22.6° S; 177.5° W.

February 11, 10h 53m 04s pm, unidentified portion recorded. Originated in Aleutian Trough. 54° N; 160° W.

February 19, 3h 56m 56s pm, "P" waves. 3250 miles from Kilauea in Solomon Islands. 12° S; 167° E.

February 24, 1h 40m 54s, am, "P" waves.

March 27, 2h 18m am, unidentified portion.

Time used throughout is Hawaiian Standard, 10h 30m slower than G. C. T.

Tilting of the Ground

The following tables show tilt by weeks as recorded on the Observatory seismograph, NE rim of Kilauea Crater and at Halemaumau, the algebraic sum toward or away from the Pit as indicated by stations on the W and SE rims respectively.

At the Observatory the total accumulated tilt for the year ending January 28, was 0.88" S and 3.27" W.

For the year ending February 25, was 0.97" N and 1.34" W.

For the year ending March 31, was 2.6" N and 1.37" W.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
January 7	1.12" S 10° E	0.00
" 14	0.77" S 56° W	0.00
" 21	1.94" S 37° W	0.00
" 28	0.73" S 59° W	1.58" N 71° W
February 4	0.63" S 39° W	4.23" N
" 11	1.34" S 88° E	0.98" N 79° W
" 18	0.66" S 45° E	1.37" N 16° E
" 25	1.09" S 44° W	1.72" S 20° W
March 3	2.15" S 76° W	0.00
" 10	1.41" S 8° W	1.19" S 71° W
" 17	1.68" S 48° W	2.38" N 56° E
" 24	1.46" S 66° W	1.04" N 49° W
" 31	0.77" S 39° E	0.51" S 72° W

Week Ending	Halemaumau Southeast Station	Halemaumau Resultant
January 7	12.77" S 36° E	12.79" from
" 14	6.48" S 80° W	4.86" toward
" 21	3.89" S 39° W	0.98" from
" 28	3.82" N 68° W	1.59" toward
February 4	0.74" S 70° W	1.95" toward

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory was made once during the month of January. On January 11, the measurement indicated closing of 0.42" for the Halemaumau value and closing of 0.41" for the Crater value compared with similar measurements of December 19.

Angle values February 8, indicated closing of 0.08" for Halemaumau and opening of 1.41" for the Crater. February 28, Halemaumau angle had closed 2.19" and Crater angle had opened 2.06". Change January 11 to February 28, closing of 2.17" for Halemaumau and opening of 2.45" for Kilauea Crater.

Angle values March 16, indicated opening of 2.00" for Halemaumau and closing of 1.39" for the Crater. March 28, Halemaumau angle had opened 0.26" and Crater angle had opened 1.59". Change February 28 to March 28, Halemaumau opened 2.26" and Crater closed 1.56".

Total change December 19 to March 28. Halemaumau angle from Pit seismograph to NW Pit BM, closed 0.33"; Crater angle from SE rim station to Uwekahuna opened 1.50".

Spirit Levelling Around Halemaumau

On February 9, a line of levels was run from the Spit B.M., SE rim of Kilauea Crater to the NW Pit B.M., on the NW rim of Halemaumau. Compared with a similar run made August 30, 1939, the NW Pit B.M., had lowered 0.067 meters with reference to Spit. This relative lowering, since July 2, 1934 has amounted to 0.697 meters or 2.26 feet.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, is leased and operated by the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigations.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

MAUNA LOA SUMMIT CRATER ERUPTION 1940

By HUGH H. WAESCHE
Acting Principal Scientist

Historical Background

With very little immediate warning, Mauna Loa became active with a summit crater outbreak during the late evening hours of April 7, 1940. That event was not unexpected as numerous data had indicated the possibility of volcanic activity and only a few weeks before, Dr. T. A. Jaggar had publicly stated that Mauna Loa should produce activity, probably in the summit crater, about May 1, 1940. This statement was based principally on known periodicity of Mauna Loa outflows and on average lengths of periods between eruptions during the current century compared with corresponding similarity of events in the nineteenth century. The first eruption of Mauna Loa reported observed was that of 1832; the next, and well observed, was the northeast rift flow of 1843. The similarity of conditions during the 1843 eruption and that of 1935 is striking. Both issued from the same approximate elevations and were accompanied by minor activity in Mokuaweoweo at the outbreak. Bath were active with fountains in the vicinity of twelve thousand feet for a week or ten days and later produced voluminous flows from much lower elevations on the northern flank of Mauna Loa. The course of the 1935 flow would undoubtedly have been that of 1843 if it had not been interfered with and diverted by the earlier flow. The parallel was carried over by the recent 1940 summit eruption. The 1843 outbreak was followed 6 years and 4 months later by a Mokuaweoweo outflow; the one of 1940 followed the 1935 activity in 4 years and 5 months. Like 1849, the activity of 1940 was remarkably free of seismic effects which are normally expected before and with any eruption. The 1935 eruption is thought to have been stopped by bombing. If this is true the inactive period which followed may have been shortened accordingly to keep the parallelism, and also may have allowed a more rapid build-up of lava pressure under the mountain. If, on the other hand, average periodicity of eruption for Mauna Loa is considered, it will be observed that that alone was sufficient for expected activity at approximately the time it occurred. Seismic activity and tilt also suggested coming volcanic changes.

Since 1899 there have been 9 Mauna Loa eruptions. Of these 4 have been purely summit activity while the other 5 have been flank outflows accompanied for the first few hours by activity in Mokuaweoweo. Eruptions of this century and their respective sources are as follows:

1899—July 4, summit 4 days, northeast rift 19 days
1903—October 6, summit 2 months
1907—January 9, summit short, southwest rift 15 days
1914—November 25, summit 6 weeks
1916—May 19, southwest rift 2 weeks
1919—September 29, summit short, southwest rift 6 weeks
1926—April 10, summit short, southwest rift 2 weeks
1933—December 2, summit 17 days
1935—November 21, summit short, northeast rift 42 days
1940—April 7, summit 19 weeks

Tilt Change Diagrams Volcano Letter 467

The millimeter divisions of original chart make non-rectangular coordinate lines at side and top of some of the figures by the angular amount the seismograph booms were permanently set oblique to the N-S and E-W azimuths.

Study of this list shows that with the exception of the 1916-1926 eruptions, summit eruptions have alternated with flank outflows. In general the same relations seems to have existed during the nineteenth century and this may be accepted as the normal succession although by no means an iron-clad rule.

The average period of quiescence between eruptions since 1899 has been 4 years, 6 months with a maximum interval of 7 years and 10 months between 1907 and 1914 and a minimum between 1914 and 1916 of one year and 6 months. If the average interval had occurred between 1935 and 1940, the latter eruption would have begun, probably late in May. Actually it came nearly two months ahead. The 4 years and 3 months-period between 1899 and 1903 was very close to the average and the 1935-40 interval. Another interesting relation is the time interval between a summit eruption and a rift flow. The average is 25 months, with the shortest, 16 months between 1914 and 1916 and the longest, 37 months between 1903 and 1907. The 25-month average for this century is close to the 28-month average value from 1849 to the present. This suggests that the time interval between summit and flank eruptions of the same volcanic episode stays fairly constant within close limits.

Seismic Events

Although there was a remarkable absence of seismic phenomena associated with the 1940 period of activity, there was no lack of earthquakes in the 12-month period which preceded the outbreak. All eruptions are preceded by premonitory seismic disturbances and also are succeeded by after effects of a similar nature. It is difficult to distinguish where earthquakes associated with one eruption end, and those of the next begin. Then too, there are other shocks which probably have no direct relation to the subterranean lava movements.

In 1935 premonitory earthquakes of the Mauna Loa eruption, which came in November, probably began with the strong shock which caused some damage in Hilo, June 28, at 9:00 a.m. It was located in the Mauna Loa northeast rift about 10 miles from Hilo. Mauna Loa shocks increased in number and reached a climax on the night of September 30-October 1 when 1 strong (11:58 p.m. strongest recorded at Observatory in over 5 years), 3 moderate, 2 slight, 3 feeble and 20 very feeble earthquakes registered within a period of 12 hours from 10:00 p.m. to 10:00 a.m. They originated at points scattered throughout the Mauna Loa rift system from Hoopuloa to Hilo. At 1:11 a.m., November 21, a moderate earthquake originating at a point 5.0 miles from the summit crater in Mauna Loa northeast rift marked the locality from which, 17 hours later, floods of lava were to issue. With the outbreak there were 2 slight, 2 feeble, 2 very feeble earthquakes and then a period of 3,198 minutes of tremor. During that eruption there were almost no earthquakes. One hundred twenty-five earthquakes, from very feeble to strong, had been located in 1935, and of these 23 were of Mauna Loa origin with 4 locations in southwest rift, 9 near Mokuaweoweo and the remainder from the northeast rift. In 1936, after the Mauna Loa eruption, there were no notable earthquakes of Mauna Loa origin and about the normal number from Kilauea.

The figures for the years 1935 to 1939 inclusive are tabulated as follows:

Year	Total Locations	Mauna Loa Total	Mokua-weoweo	SW Rift	NE Rift
1935	125	23	9	4	10
1936	195	10	3	1	0
1937	257	20	4	1	15
1938	386	32	6	2	24
1939	217	47	14	1	32
1940, to June 30.....	106	20	9	0	11
Jan. 1 to Mar. 31.....	50	16	7	0	9

These figures fit in very well with the known volcanic developments; 1935 was the year succeeding the last Kilauea outflow.

The Observatory seismographs are located on the northeast rim of Kilauea Crater and show the very large excess of recorded Kilauea earthquakes over those from Mauna Loa. That also explains the increase of total locations of epicenters in successive years from the low of 1935 (Kilauea in repose following the 1934 eruption) to the high of 1938 which was the year of the Kilauea Chain of Craters crisis in May and August. The approaching Mauna Loa activity probably explains the slower decline in seismic activity after 1938 compared with the rise preceding that year. The Mauna Loa column is clear-cut in its significance; 1935 relatively high wtih Mauna Loa in eruption, then a low in 1936 with repose of lava movement. Starting in 1937, Mauna Loa seismic disturbances steadily increased with their highest increment (last figure in column 6) between January and April, 1940. In the first half of 1940 there were 20 Mauna Loa earthquakes located with 16 of these in the first quarter. Thus for the first quarter of 1940 the Mauna Loa earthquake rate at the Observatory was an increase in ratio over 1939 of 64 to 47. During the period of activity following the release of initial energy there were only 4 located Mauna Loa shocks by the end of the second quarter. The remaining three columns are identified with the sites of eruption and outflow. The 1935 northeast rift activity was the first from that source since 1899. That 1899 eruption high on the slope (12,500±) was the last of the nineteenth century series which had successively sealed the northeast rift from the vicinity of Kulani Cone. It was followed by 1907, 1916, 1919, and 1926 flows, successively higher on the Mauna Loa southwest rift effectively sealing that section which was the only part of the rift open after 1899. Many more earthquakes occurred to the southwest than to the northeast in those years and they were still plentiful through 1933. Four earthquakes in 1935 were

Fig. 2.—Fountains and rift in Mokuaweoweo the morning of April 8. Note small fountain to the north of Na Puu Waenakonu, left center; 1914 cone in right foreground, later center of activity. Photo by 18th Air Base Photo Laboratory, A.C., Wheeler Field, T. H.

located in the southwest rift including a very heavy shock the night of September 30-October 1. Intrusion at least was probably going on then in the southwest rift. After that year there were almost no southwest rift earthquakes and this was borne out by the Kona seismograph at Kealakekua.

By far the greater proportion of the earthquakes from Mauna Loa originated in the northeast rift which is probably "open" and "working." Theory here fits with fact. The "liveness" of the Mauna Loa northeast rift was confirmed by the registration in January and March, 1940, of earthquake swarms on the Mauna Loa seismograph, which is located at an elevation of about seven thousand feet and 6 miles southeast of Puu Uloula on the northeast rift. In 48 hours, January 16-18, more than 60 seismic disturbances registered. They were of tremor or very feeble classification, most of which did not register at the Observatory. Distances indicated were such as to give locations along the rift toward the summit crater. The Volcano Weekly Report No. 1462 of the week ending Jonuary 28 says, "The Mauna Loa seismograph has continued to show more earth disturbances than the seismographs at the Observatary . . . . Evidence still points to some movement along the Mauna Loa northeast rift. Between noon, March 8 and the same time March 10 (48 hours), 40 seismic disturbances registered on Mauna Loa compared with 23 at Kilauea. Fifteen of these were very feeble earthquakes."

Seismic activity is usually more intense before pending eruptions and with the possible exception of the one of 1849 the current activity has probably the lowest record of seismic disturbance before and during the activity. The strong earthquake of January 22, 1938, felt throughout the Island group, as well as registered all over the world, may well have been the beginning of the Chain of Craters crisis at Kilauea during the summer of 1938 and the beginning of the summit eruption of 1940 on Mauna Loa. In any case, such earthquakes, located a hundred or more miles from the Observatory and under the sea floor to the north and west of Hawaii have been usual rather than unusual in the past history of Hawaii and its volcanoes. In 1912 there were 2, and one each in 1913 and 1914. The last preceded the 1914 eruption by 3 months. In 1916 (Mauna Loa year) there were 3 earthquakes; 2 in 1918; 3 in 1919 (Mauna Loa year); one in 1923; one in 1926 (which preceded Mauna Loa eruption by 3 weeks); and, in 1927 there were 2 (1929 was Hualalai earthquake year).

Unless the relatively heavy earthquake shocks of May, June, and July, 1939, may be similarly classed there were no unusual seismic events leading up to the 1940 eruption other than an increase in numbers. It is possible that the heavy seismic activity (intensity not quantity) of 1935 so shattered the northeast rift and summit cracks that the lava could later rise and flow along them without producing any great amount of crustal disturbance. Also the 1935 eruption may have been artificially halted leaving the magma column well up in the volcanic system ready to break through at the slightest increase of pressure.

Activity on Mauna Loa was first observed as bright glow from summit fountains of lava the evening of April 7, 1940, at about 11:30 p.m. On the seismograph, the usual harmonic type of tremor began at 10:59 p.m. and continued until 4:00 a.m., April 8; this latter time corresponded with a visible diminishing of glow and fume. The tremor was interrupted by very feeble earthquakes at 11:09, 11:21, 11:35 and 11:38 p.m. Apparently these were felt by no one. Other than o feeble earthquake at 12:07 p.m., May 17, felt widely on the Island of Hawaii and a slight to moderate one at 5:32 p.m., June 11, also reported felt, there was no other seismic disturbance of importance that could have been said to originate under Mauna Loa. Practically no shocks were reported by observers stationed near the scene of activity. Probably indirectly connected with the summit eruption was the strong earthquake, felt throughout the Island group and of world-wide registration which recorded at 11:57 p.m., June 16. The Pasadena seismological

laboratory classified this shock as grade 7, a major earthquake. It was followed by many after shocks of various intensities.

Tilt

The possibility of some volcanic change either at Kilauea or Mauna Loa was suggested by the fact that the annual Observatory ground tilt of Kilauea showed accumulation to the north for the first time since 1936 in December, 1939. This northerly accumulation was increased during the first three months and all southerly tilt ceased in April as usual. However, there were erratic changes from normal westerly tilt to easterly tilt in February and March when there should be almost exclusively westerly tilt and a relatively smooth curve when plotted.

Outbreak

Between 11:30 p.m. and midnight April 7, residents of the Hawaii National Park heard a great amount of squawking by pheasants in nearby groves of ohias and ferns. This peculiarity is usually significant of earth disturbances and in this case indicated that the seismic effects of the Mauna Loa outbreak were detected by the birds but in no case seem to have affected any humans. A roar like the sound of a distant automobile motor was distinctly heard about 11:45 p.m. by one resident who dismissed the sound as that. Telephone communications from the Kona section of the Island to the Park superintendent announced that Mauna Loa was in eruption. That occurred at or about 12:10 a.m., April 8. At 12:30 a.m. a bright orange red glow, illuminating the entire western sky, was visible from the National Park residential area. From the Volcano Observatory a clear view of the glow from fountains, fume column and red reflection from nearby clouds, was obtainable. Extent of the fountaining area appeared to be from the northeast rim of the summit crater to a point well over the summit curve to the southwest. Measurements by transit from the Observatory bench mark indicated that activity was from the north bay of Mokuaweoweo to a point in the region west of Lua Hohonu, the second pit crater to the southwest. A more accurate location could not be determined from that point; however, airplane pictures made of the summit about 4:30 a.m., April 8, showed fountains extending along a crack from about the center of the main crater, southwestward across the south lunate platform, through the southwest rim and along old rifts toward Kahuku, a total distance of about three and one half miles. Terminals were approximately 1903 cones (Na Puu Waenakonu) at north, and cracks west of Lua Hohonu. The line of the rift was S 23° W and was in direct line of connection between cones of 1903, and those of 1914 and 1926. It seems likely that the wider glowing expanse measured by transit from the Observatory included fresh lava flows which may have flowed over the northern half of Mokuaweoweo with great rapidity in the first few hours of activity when the lava is always most fluid. If there were fountains in the northern half of the Crater, no pictures show them. However, soldiers who left the north rim at 2:30 p.m., April 8, reported fountains in the north bay with lava rising rapidly and at that time within five feet of the rest house on the northeast brink of the north bay. In spite of this it is doubtful if deep-seated fountains actually developed north of the center of Mokuaweoweo.

At 1:15 a.m., the light from 6 main fountaining areas was readily discernible with their accompanying columns of fume. Smaller fountains and fume columns were interspersed with the larger ones. Most intense glow seemed toward north with others slightly less toward center of body of glowing region; to the south light was fainter and fume thinner. At 2:00 a.m., 8 fountaining areas were visible but by 4:00 a.m., they had dwindled to 4 with largest still at center and to north. Fume columns were still faintly visible to south.

During these first few hours, pahoehoe lava streams covered practically the entire floor of Mokuaweoweo with the

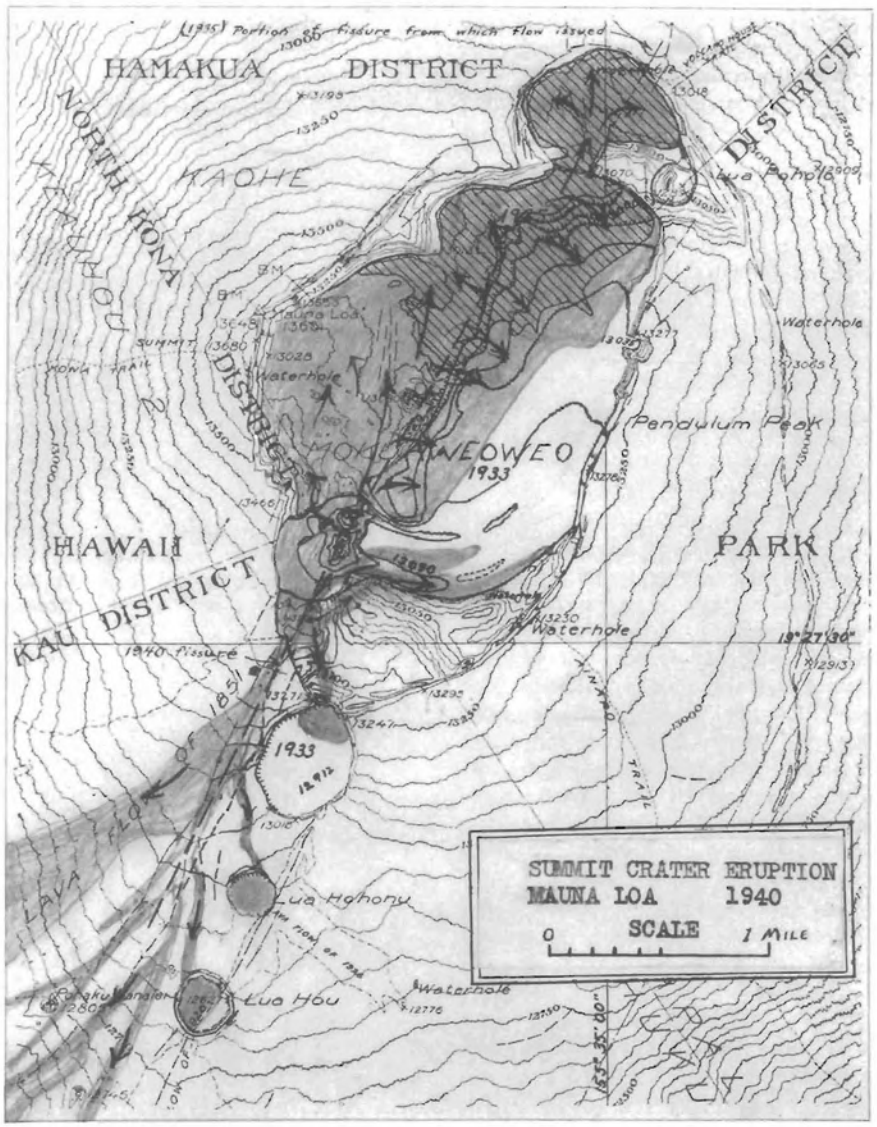

Fig. 4.—Map of Mokuaweoweo, 1940. Shaded areas show approximate extent of lava flows during the first twenty-four hours of activity. Arrows indicate direction of flow. Hatched area to north is 1935 lava. Light area to southeast is 1933 aa, extensively covered by later flows during May and June. Base map, U. S. Geological Survey, preliminary sheet of 1926.

exception of the southeast portion which was partially filled with 1933 aa preventing extension there of the new flows. One flow, however, which originated at the fountains on the south lunate platform, moved north to cascade into the main crater and then turned eastward across the 1933 aa nearly reaching the east well of the Crater before the source fountains ceased and stopped its further progress. Another flow from same source cascaded into the first pit crater to the southwest. Undoubtedly all of these flows were extremely fluid, highly gas-charged, and covered the floor of Mokuaweoweo with extreme rapidity as is characteristic of the early hours of all eruptions.

To the southwest of the Crater, on the outer slope of Mauna Loa, pahoehoe streams turned into aa further down the slope and cascaded from the rift into all three of the pit craters with the greater part of the activity taking place in the vicinity of Lua Hohonu. Greatest extent of this flow seems to have been about four miles.

At 9:00 a.m., April 8, a large column of fume was visible over Mauna Loa summit rising vertically from two areas to a great height, possibly ten to fifteen thousand feet above summit where it bent sharply to the east and extended in a long broad zone to the horizon southeast of Kilauea. The fume was of the usual bluish tint in reflected light and amber in direct light. The denser of the two contributing fume columns was to the south in contrast to relative values of preceding night. This confirms the air picture which showed the most active fountains near the center of the crater although the first party to reach the summit found the activity concentrated in the southwest portion where it remained for the rest of the eruption. The main fountaining apparently changed from the region of the northeast 1903 canes to the vicinity of the 1914 cones within the first 18 hours, just as the extra-crateral fountaining did from southwest to the 1914 cones.

A party from the National Park went to the summit the first day. On the way up a fume column of whitish-amber color was plainly visible. Its rate of emission was variable with some puffs being given off with a great amount of energy. At Puu Ulaula rest house a rumbling noise came from the direction of the activity resembling the pounding of surf on a distant shore. The morning after the outbreak, Pele's hair was found distributed over the entire southern portion of the island, including the vegetable gardens northeast of Kilauea.

Initial Crater Phase

By the time the first party had reached the summit crater at 6:10 p.m., April 8, all activity had become concentrated in a series of fountains toward the southwest end of Mokuaweoweo between the 1903 cones and the south lunate platform. Their exact position could not be identified at first as they were observed end on. The north bay had been partially filled with black pahoehoe which had reached a level about 10 or 15 feet below the rest house ledge. This already had cooled enough to slump downward 5 to 10 feet by shrinkage and probably by some runoff of liquid lava below the surface. Where the crust had fractured, glowing cracks and caverns were produced; faint bluish fumes hung over the entire crater. There was no conclusive evidence that fountains had been active in the north bay. A tongue of pahoehoe had moved along a crack toward the pit crater Lua Poholo but had stopped on its rim. Pele's hair was seen floating in large quantities in the air.

There was now only one fume column and the fountains at its base were extremely active, of orange red color and were playing two to three hundred feet above the crater floor throwing out liquid, lava spatter but apparently few cinders; there had been practically no cone building at this stage. Heat waves caused all objects in the crater to appear to waver considerably and the glowing flow fronts moving north and west looked like many small fountains. Much snow clung in patches to the crater walls.

On the morning of April 9, there was little apparent change. Observations from the west rim showed the main fountaining concentrated in a portion of the rift about 1,400 feet long with its northern extremity between the 1914 and 1933 source cones. A crack in the crater floor was plainly visible extending from the fuming 1903 cones south-southwest to a point on the rim near the first south pit crater. At the main fountaining area there were 6 jets or centers of activity with the most energetic to the north. The largest jets played to heights of 300 feet and relative intensity remained almost constant. To the south of the main fountain there were 5 smaller, independent fountaining areas of diminishing size. The largest may have been 50 feet in height. Other fountains which had been active on the south lunate platform were producing fume only. The 5 smaller fountains between the main fountaining area and the south lunate platform apparently stopped after this date

as they were not mentioned in later reports, although the jets of the large fountaining area continued and even increased in size during later periods of the eruption.

Two main lava flows issued from the large fountain; one from its south side flowed west and a second from the north side to the north. They were producing pahoehoe. Near the fountain the two streams were extremely fluid and flowed with rapidity. Although the front of the flow was dark and black, the remainder was of a light bronze color. These flows were covering black pahoehoe of an earlier stage of the 1940 eruption, probably first night outpourings contemporaneous with lava of the north boy. The pahoehoe fronts advanced in a normal manner by the projection of advancing arms and toes. No gas vents similar to those seen at the 1935 eruption were noticed. Occasionolly bright flashes of lava issued from the flanks, near the base of the old cones.

During the afternoon of April 9, the north lava flow front advanced to within a half mile of the north bay. Movement along the front was plainly visible from the rest house and by the morning of the tenth had advanced to within a quarter of a mile of the north bay. However, the low gradient of the crater floor and the increased distance from the cones had resulted in a slowing down of the flow's advance; accompanying this was the beginning of the next phase of crater activity, the formation of pressure ridges, dome building and cone development at the vents. By 8:30 a.m., April 10, the front of the flow moving to the north had increased from about five feet in thickness to 10 or 20 feet.

Pressure Ridges and High Fountains

Continual observation of eruption progress was meanwhile being made and there was an unbroken line of daily reports throughout the continuously visible activity.

By 6:00 p.m., April 11, the pahoehoe front had reached the gap between the main crater and the north bay. There the general shape of the crater was such that the forward movement of the lava for the next few days was deflected with a curved front to the east. This slowed down the actual flow front to a standstill where it had a chance to cool and form a resistant dam to farther advances into the north bay. Meanwhile, great volumes of liquid lava were pouring northward behind this front and as a result enormous horizontal pressures were produced between the hydraulic effect of the liquid lava and the crater walls. Great sections of the floor in the northern end of the main crater were ruptured, slipped over lower layers, and piled into ridges sometimes 50 feet in height. Blocks of dense lava 15 or 20 feet across and several feet thick were stacked in heaps and along ridges like molehills. In places where the uppermost crust of the crater floor had slid over lower layers lava had been ground to a pink rock flour. A chaotic condition over the greater portion of the crater was the result and this made most of the area nearly inaccessible. This type of activity continued through April 19, when most of the flow to the north ceased along with a general decrease in activity.

The fountains continued with little change through noon, April 12. Most energetic portion of the fountain was at north end of a series of 8 jets, and played to heights of 300 feet, throwing out molten spatter. By 2:30 p.m., there was a notable increase with ejecta from the north jet going to heights of 500 feet. During the remainder of the afternoon the intensity increased until at 6:00 p.m., spatter, pumice and cinders were being thrown to heights of 600 feet. From then on through April 19, this type of activity, pulsating in character, was a daily occurrence with the fountains reaching a low, liquid lava stage in the morning and then gradually reaching a climax in the late afternoon. The high fountains produced much pumice accompanied by increased cone construction; the low fountain periods produced almost exclusively liquid spatter. The cone had developed to a height of about 175 feet and was still most active at the north jet.

On April 15, 11:00 a.m., from an airplane, one large jet was seen to be active with 4 smaller ones of diminishing intensity to southwest. The large fountain had built up a cone which had by now almost completely covered the 1914 and 1933 cones. Fountains were pulsating considerably and producing pumice. These pulsations apparently became more erratic and at greater intervals with the passing of the next few days.

Period of Crateral Flow and Cone building

After April 19, there was a rapid decline in fountain activity and almost no lava movement until on April 23 only a faint fume column was visible and a report of "no glow visible" at the cinder cone was received from the observer at the summit. The afternoon of April 24, a party made its woy one mile into the main crater. From there much fume was visible at the cone but no incandescent material was in evidence. However, many hot, glowing cracks were encountered in northeast portion of crater and in most cases the glow was at least 5 feet below the surface. Aa was found, confirming the earlier reports of that type of flow being produced at north bay gap and in northeast portion of main crater where it was forced through frozen pahoehoe crust April 20 and 21.

At 6:30 p.m., April 24, glow from the cone indicated activity was continuing in spite of apparent lull of preceding day and pasty lava spatter "sloshed" from the mouth of the vent and splashed fluidly down the cone slopes. On the morning of the twenty-fifth, observations from the west rim of Mokuaweoweo showed considerable activity at the portion of the cone to south in contrast to the previous greatest intensity point to the north. Lava was agitated in the mouth of vent and from time to time

Fig. 11.—Cone as seen from west rim, 8:30 a.m., April 25. Note pressure ridges in foreground. Photo by Hagerlund.

splashed over the north rim. The vent to the north subsided entirely within the next few days and all activity became centered in the more southerly one. A small pahoehoe flow issued from the west flank of the cone through the cinders and fanned out toward the west wall. Every five to ten minutes lava was thrown from the vent with greater than average violence and accompanied by booming, explosive noises. The 1903 cones had been almost buried by 1940 lava. This general type of activity continued with little change until May 9, adding cinders and spatter to the cone and gradually increasing lava accumulations on the crater floor to the north and west. The fountains rarely played more than 50 feet above the cone summit.

Beginning May 9, explosions occurred within the vent of varying intensities, some quite violent, and general activity appeared to increase with the fountains at times playing to heights of 100 feet above the cone crest. A new flow developed from the north base of the cone May 11. This type of activity continued with unusually heavy explosions May 13, at 12:30 a.m., and May 15, at 4:30 p.m., both of which ruptured and altered the shape of the cinder cone. On May 25, the cone apparently split open near the center of its ridge to form a transverse east-west rift. Three lava streams issued as a result, flowing east, west and south with great rapidity. The east stream coalesced with the south flow and nearly inundated a small spatter cone formed during earlier stages of eruption, about one quarter of a mile to the southwest. The west flow then swung south to join the other two and a new flow developed to the north which at 5:00 p.m. was rapidly advancing. On May 26 most of the flow was to the east with tongues of pahoehoe advancing across the 1933 aa and at several points contacting the east wall. This type of activity continued with flows constantly spreading to east and north of the center of activity and the fountain playing with little change. During May 27, 28, and 29 there was much puddling of lava to east and north, forming a large lake near the center of the crater. The contributing lava stream cascaded down the east slope of the high portion of the cone. On June 5, a flow was moving over 1933 aa toward the east wall; the fountain increased in height and appeared to be producing more pumiceous material. At 6:00 p.m. new flows developed to east and west, and east rim of cone partially foundered; a small spatter cone developed several hundred feet to east of main vent. At this time fume increased considerably and a dense column was visible from Kilauea daily.

A large rounded lava dome, like Mauna Iki in Kau Desert, had formed around and under the cone by May 8. It measured possibly 75 to 85 feet above the average crater floor and was surmounted by the still active cinder cone which was about 190 feet in height with the greatest length south-southwest-north-northeast, at its base, about 1400 feet. With flows moving east, north and at times to the west and with almost continuous fountaining to heights of 50 to 100 feet there was little change until June 19, when there began periods of intermittent quiet and renewed activity which continued the remainder of the month of June.

Areal Extent and Volume

Between April 7 and June 30, the almost continuous outpouring of lava within the summit crater of Mauna Loa resulted in an enormous volume of filling over practically the entire crater floor. The greatest fill was in the vicinity of the center of activity to the southwest. Next in order were the west and north portions of the crater followed by the north bay and finally the east portion, probably far below the other areas in quantity because of the presence of the higher 1933 fill. If the greatest fill was 90 feet apart from cone and zero taken as the minimum, it would be reasonably safe to say that the fill of 1940 had an average depth of 45 feet for all of Mokuaweoweo. Forty-five feet are equivalent to approximately 14 meters. The area of Mokuaweoweo is about thirty-two million square meters. Then the total volume of new lava in Mokuaweoweo should be about four hundred and forty-eight million cubic meters. The 1933 eruption was estimated to have produced sixty-eight million cubic meters. The 1940 figures do not include the flows in the pits to the southwest or along the rift.

Kilauea Reaction

Throughout the Mauna Loa eruption, Kilauea showed little or no sympathetic effects. Crack openings increased somewhat but were not abnormal. Levelling showed Kilauea floor to be still lowering relative to Spit B M. It has shown no appreciable changes since.

Conclusion

The Mauna Loa eruption of 1940 was expected and its location in the summit crater was normal based on observations of previous eruptions. Earthquakes show the northeast rift still to be restless and the southwest rift to be quiet. Mauna Loa summit eruptions are invariably followed by flank eruptions. They usually come within 2 years, occasionally less than one, and at other times at periods os great as 3 years. It is not altogether impossible that alternation of flows might take place and that the next outflow may be on the Kona side. It seems more likely it will be on the Hilo side and there is no doubt but what a flow will come in the not too distant future.

The 1940 Mauna Loa eruption was the longest duration of summit crater activity of any such since 1873-74.

The author is indebted to the National Park summit observers for their daily reports, which contributed much of the data here used, and to Dr. T. A. Jaggar for his helpful comments and criticism.

Hawaiian Volcano Observatory Report for April-June 1940

VOLCANOLOGY

April 1940

In April an eruption of the summit crater of Mauna Loa began about 11:00 p.m. April 7 and continued throughout the month. The number of earthquakes was unusually small for a time of lava eruption. Nothing notable happened at Kilauea. The Observatory staff and the Park rangers visited the summit camp of Mokuaweaweo in relays, so that this was the best observed Mauna Loa source in action on record.

The outbreak fulfills expectations in that Mauna Loa intervals have been somewhat over four years average for this century, and the last eruption ended in January, 1936. The lack of earthquakes resembles the 1849 summit eruption. This followed 1843 which like 1935 had flowed in the Humuula saddle. The partial outflows of 1940 south of Mokuaweoweo, just where 1851 erupted, strongly suggests that the next decade will have voluminous outflow at the north, like the decade that followed 1851. That also was a time of no mention of earthquakes, and as the 1940 eruption proved to be a long one in the summit crater like 1849, the danger of a Hilo outflow within the next few years is considerable. There is every reason to acquire the whole summit region of Mauna Loa for the National Park and to build there stations for scientific observation.

Army airplane photographs by Brig. Gen. W. F. Frank, Capt. M. W. Kaye, Col. G. W. Fitzgerald's party and others were in port taken the first night and morning, developed and printed in Honolulu, and delivered at the Volcano Observatory at 6 p.m. the same day. The Park telephone to the summit and Puu Ulaula camps kept the Observatory in constant touch with the activities as never before. Color photographs both in motion and still, some of them by the Park staff, are among the most remarkable that were ever taken of Hawaiian activity. Ranger Olson and party spent the night at the actual fountains inside Mokuaweoweo Crater April 17-18, and their experiences almost duplicated the descriptions of the several active cones of October, 1919 as published in Observatory Bulletin. On April 12 Dr. S. S. Ballard collected gases at the summit, for analysis at the University of Hawaii, returning to Honolulu April 14. As the summit crater camp had been threatened by rising lava the first day it was torn down with a view to rebuilding it later on the east margin.

The eruption is fully reported in Hugh H. Waesche's article herewith. It began along the rift from the plateau of the 1851 source west of the south pits of Mokuaweoweo, with first seismic record 10:59 p.m. April 7, and extended its crack through the 1914 and 1903 cone (Puu Waenakonu) regions of the main crater. Intensity declined throughout the month with floods of lava into the main bowl. Streams of pahoehoe the first night flowed southwest from the upland into Kahuku and South Kona, turning into aa further down. Streams also cascaded into the southern pits. Flows outside of the crater stopped within half a day. Inside the crater torrents of frothy pahoehoe flowed around all the cones, but mostly at the west.

There was from a distant view the usual broad band of lighted fume the first night, dwindling until April 18, when the fume was seen best in afternoon light with the sun behind it. At the end of April, glow and fume were visible chiefly at the summit station. There the fountain April 17-21 occasionally jetted up 700-900 feet through vents, becoming clogged along a fissure line of seven jets heaping up a ridge of basaltic pumice, from about the 1914 cone position southward. The concentrated building of a dome inside the crater centered between the 1914 and 1933 cones in the southwestern part of Mokuaweoweo sink. The old cones were buried under the new accumulations. The April eruption closely resembled that of 1933, but did most of its filling on the west side of the crater, whereas the December, 1933 eruption had been to the east. The first pahoehoe fills of the north bay, and the central crater became ruptured by aa lava rising up cracks, making pressure ridges so as to leave a chaotic floor. At the end of April there were fountains 50 feet high. Absence of felt earthquakes at the Mauna Loa camps was remarkable.

There was continuous tremor at the beginning of the Mauna Loa eruption lasting five hours. A feeble shock, felt as a jolt like blasting, occurred at Kilauea Crater April 16 and a slight shock also felt near Kilauea occurred April 21; a deeper shock April 26 was located under the Kilauea-Puna rift near the east point of the island.

The following are the local data for April, counting tremor spasms as single seismic disturbances:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
April 7	0	1.5 mm. closed	24
" 14	0	2.0 mm. "	26
" 21	3	1.5 mm. opened	16
" 28	several	8.0 mm. "	11

May 1940

Throughout the month the eruption of the summit crater of Mauna Loa built up a large heap of pahoehoe lava in the southwest part of the main bowl of Mokuaweoweo, so that from a side channel in the top of the heap a cascade overflowed the 1933 lava at the east side of the floor. This process continued into June. Nothing notable happened at Kilauea. Parties of rangers and workers built a trail from the end of the northeast trail around the northeast side of the crater to the flat plateau of the Wilkes Camp of 1840 where it is planned to rebuild the summit resthouse.

There was a seeming lull in the activity the middle of May, with only slight visibility of fume and no glow as seen from Kilauea. There was marked revival at the end of the month with glow at night plainly visible, and fume column showing at times the amber or cinnamon color of the early days. After two months of activity the fountain source produced more heavy pahoehoe and less pumice, and the pahoehoe was now burying part of the earlier pumice beds, and part of the pressure ridges and aa that welled up cracks, but still leaving the Mokuaweoweo floor very rough.

There was said to be increased heat and fume coming up the cracks in such early surfaces of the eruption as the fill of the north bay near the older resthouse location. This suggested that intrusive lava was penetrating under the earlier crater fillings, as in the case of Halemaumau in October, 1934, when also the fountaining of the cone center became pulsatory with gushing at intervals. The local seismic index of only 4 to 5 at Kilauea for each week was remarkably small for a period of continuing eruption. The measured earthquakes in National Park station were mostly at Mauna Loa distances, and nothing happened to suggest any change at Halemaumau.

A feeble earthquake May 17 was strongly felt at Kapapolo

Ranch and feebly felt at Hilo. There was continuous tremor for six minutes the evening of May 21, but there is no reason to correlate these later spasms with Mauna Loa. The Mauna Loa seismograph on east flank of mountain did not show them. This quarter was a time of many distant earthquakes, especially the month of May, with disturbances in the Philippines, Aleutian Islands, Imperial Valley of California, Peru, and northwest Canada, all of these around the Pacific Ocean.

The following are the local data for May, counting tremor spasms as single seismic disturbances:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
May 5	1	2.5 mm. closed	17
" 12	0	3.5 mm. "	14
" 19	0	0.5 mm. opened	15
" 26	0	2.5 mm. "	15

June 1940

The month of June found the Mauna Loa summit eruption continuing with the large slag heap growing in Mokuaweoweo Crater, and the tendency to alternation between gushes and intrusions increasing. Nothing notable happened at Kilauea. Observers lived at the summit of Mauna Loa continuously. A new feature of great importance, which has happened before in connection with eruptions of the Hawaiian volcanic system, was a strong and perhaps relatively deep earthquake on June 16, followed by many aftershocks for a fortnight, and centering about the ocean deep northwest of Maui and about 185 miles east of Honolulu.

It happens that in this general vicinity there is a deep trench of 3,000 fathoms bordering the southwest side of a large triangular plateau in the ocean bottom 170 nautical miles long, containing a high peak rising 8,000 feet above it, 240 miles northeast of Honolulu. The deep trench is between this seemingly submerged island and Maui, and it is in this trench 75 miles north of Ookala that the disturbances occurred which generated these earthquakes. The earthquake of June 16 was strong and profound enough to register on the seismographs of Pasadena as a teleseism.

From past experience there seems to be good reason to connect such earthquakes as this with the reactions of magma pressing upward under the larger Hawaiian ridge, in some way related to the clogging effects of the cooling and restraining plug that was solidifying in the Mauna Loa crater and bringing the eruption to a close after three months of outpouring. There is here matter for a seismological study worthy of extended investigation.

Mauna Loa in June showed a succession of lulls followed by outbursts at or near the top of the new inner dome of floor in Mokuaweoweo Crater. Apparently the lowerings were times of intrusion, as on May 27-29, when glow-cracks developed even as far away from the center as the north bay. Then at the cone center May 29 the liquid lava came up with fountaining, and overflows of the inner dome occurred, mostly to the east. The alternations were, down June 1-4, up after June 5, down June 10-12, up June 13-16, down June 17-24, up June 25-26, down June 27-July 2, and up July 3-5.

The duration of the gushes decreased from four days to two days; the duration of the intrusive spells increased from two days to eight days. The intervals between gushes increased from five to twelve days between the end of May and June 25: the intervals between intrusive spells increased from five to ten days in the same period. There was a pronounced quake felt in Kona during the low level following June 10, and the large earthquake northeast of Maui of June 16-17 near midnight was felt even in Honolulu and accompanied the quiescence of Mauna Loa lava that began June 17.

The gushing spells were accompanied by rupture and caving in of the summit craterlet, followed by fountains spurting 50 to 100 feet above the top of the dome, along with strong glow and fume as seen from Kilauea, and cascading torrents of lava to both west and east sides of the Mokuaweoweo floor, but mostly to the east. The structure built up stands more than 300 feet above the floor of 1939, it surmounts in height the east wall of Mokuaweoweo, and the recurrence of heat and glow was marked under the floor of the north bay of the greater crater during June, suggesting intrusive confinement of gas.

The following are the local data for June, counting tremor spasms as minutes of duration:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
June 2	0	0.0 mm. opened	15
" 9	1	1.5 mm. closed	10
" 16	0	2.5 mm. opened	10
" 23	0	1.0 mm. closed	119
" 30	0	1.0 mm. opened	25

Felt earthquakes occurred June 11, June 16, June 17 twice, and tremor spasms were notably small the first half of June, the 144 minutes of tremor indicated being recorded during the fortnight of aftershocks following the large earthquake.

* Including teleseisms or earthquakes over 5,000 km from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

April 3, 2:49 pm, very feeble, originated under NE rim of Kilauea Crater.

April 4, 4:29 pm, very feeble, 8.0 miles deep, Hilina Fault, 3.6 miles S of Puoialua. 19° 19.0′ N; 155° 09.2′ W.

April 4, 11:08 pm, very feeble, 6.0 miles deep, Mauna Loa NE rift 5.0 miles NE of Puu Ulaula. 19° 34.0′ N; 155° 24.0′ W.

April 4, 11:24 pm, very feeble, 0.9 mile deep, SE portion of Halemaumou. 19° 24.5′ N; 155° 17.0′ W.

April 7, 11:09 pm, very feeble, of shallow origin, Mauna Loa summit crater. Associated with outbreak of eruption. Others followed at 11:21 pm, 11:35 pm and 11:38 pm.

April 10, 2:00 pm, very feeble, from Mokuaweoweo.

April 11, 2:33 pm, very feeble, 10.0 miles deep, Mauna Loa NE rift, vicinity of Puu Ulaula. 19° 32.0′ N; 155° 28.6′ W.

April 14, 12:46 am, very feeble, of shallow origin, 0.5 mile E of Ahua Kamakukolau. 19° 22.9′ N; 155° 15.6′ W.

April 14, 8:10 pm, very feeble, same source as preceding.

April 15, 12:00 noon, feeble, 4.2 miles deep, vicinity of Cone Peak, Kilauea SW rift. 19° 23.6′ N; 155° 18.4′ W.

April 16, 6:06 am, very feeble, 0.6 mile deep, SE portion of Kilauea Crater 0.6 mile E of Pit Seismograph. 19° 24.3′ N; 155° 16.4′ W.

April 16, 8:51 am, very feeble, from E rim of Kilauea Crater (Byron Ledge).

April 16, 4:53 pm, feeble, of shallow origin, NE rim of Kilauea Crater, 19° 15.6′ N; 155° 15.9′ W. Felt by residents in Hawaii National Park headquarters area as a sharp hump similar to heavy blasting.

April 20, 5:06 pm, very feeble, of shallow origin in cracks between Kokoolau Crater and Ahua Kamokukolau.

April 21, 1:06 am, slight, 0.4 mile deep, Kilauea Crater, 0.9 mile E of center of Halemaumau. 19° 14.5′ N; 155° 16.3′ W. Felt by few persons in Hawaii National Park. Dismantled Pit seismograph.

April 21, 12:32 pm, very feeble, from vicinity of Puhimau and Kokoolau Craters.

April 22, 11:01 pm, very feeble, 5.0 miles deep, 6.0 miles S of Pahoa, Kilauea Puna rift. 19° 25.0′ N; 154° 57.0′ W.

April 23, 1:16 am, very feeble, 12.0 miles deep, Kilauea SW rift, 6.6 miles SW of Pit seismograph. 19° 21.0′ N; 155° 22.0′ W.

April 23, 9:38 am, very feeble, Kilauea Crater, 0.7 mile, NE of Pit seismograph.

April 26, 11:56 am, feeble, probably 15.0 miles deep, Kilauea-Puna rift near Cape Kumukahi.

May 5, 10:13 am, very feeble, probably originated off coast of Hawaii in vicinity of Laupahoehoe. Reported felt at Paauhau.

May 5, 8:47 pm, very feeble, about 15.0 miles deep off coast of Hawaii, 4.0 miles NE of Ninole. 19° 58.0′ N; 155° 07.0′ W. Reported felt at Paauhau.

May 10, 12:37 pm, very feeble, 2-5 miles deep under Mokuaweoweo, summit crater of Mauna Loa. 19° 28.0′ N; 155° 35.5′ W.

May 17, 5:41 am, very feeble, of shallow origin, 5 miles off seacoast near Punalulu. 19° 04.5′ N; 155° 29.5′ W. Reported felt at Pahala and Kapapala Ranch.

May 17, 12:06 pm, feeble, of relatively shallow origin, under Mauna Loa summit crater. 19° 28.0′ N; 155° 35.0′ W. Reported felt at Kapapala Ranch and Hilo.

May 18, 10:56 am, very feeble, origin probably same as preceding.

May 26, 3:32 am, very feeble, probably originated in E central portion of Kilauea Crater.

May 27, 2:10 am, very feeble, of Halemaumau origin.

May 27, 2:49 am, very feeble, originated in NE portion of Kilauea Crater.

May 28, 11:12 pm, very feeble, 10 miles deep, Kilauea SW rift. 2.0 miles NW of Koae Cone. 19° 22.8′ N; 155° 19.5′ W.

June 11, 5:32 pm, slight to moderate, 18.0 miles deep, Mauna Loa. 19° 26.8′ N; 155° 31.6′ W. Felt in Kona at Hookena and Kealakekua and at Hawaii National Park.

June 13, 11:18 pm, very feeble, Mauna Loa NE rift near Pukauahi Crater.

June 16, origin time 11h 56m 49s pm, a strong earthquake was felt throughout Hawaiian group and particularly Hawaii, Maui and Oahu. No damage reported. Reported as major earthquake of grade 7 by seismological laboratory of California Institute of Technology at Pasadena. All seismographs in Territory dismantled with exception of strong motion instrument at Hawaiian Volcano Observatory. Awakened most sleepers on islands referred to. Most people report roaring noise preceding felt portion. Dogs howled, pheasants squawked and loose objects in or attached to buildings rattled violently. Location as worked out in cooperation with Lt. E. O. Heaton of the U. S. Coast and Geodetic Survey in Honolulu was: depth probably normal; epicenter 21.0° N. latitude; 155.3° W longitude. This would place epicenter approximately 85 miles N of Hilo and 185 miles E of Honolulu.

The main shock was followed by many after shocks chronologically arranged as follows:

June 17, 12:14 am, slight
12:38 am, very feeble
12:40 am, very feeble
3:28 am, very feeble
7:47 am, moderate; felt; Hawaii, Maui, Oahu.
11:20 am, very feeble
11:28 am, very feeble
12:13 pm, very feeble
12:39 pm, slight; felt; Hawaii, Maui, Oahu.
3:47 pm, very feeble
4:27 pm, very feeble
5:04 pm, very feeble
June 18, 11:52 am, very feeble
June 19, 12:20 pm, very feeble
June 23, 1:14 am, very feeble
June 26, 8:44 am, very feeble
10:15 am, very feeble
10:21 am, very feeble
June 28, 7:54 pm, feeble

All of the above were apparently located within an area bounded by lats. 20° 45′ to 21° 15′ N and longs. 155° 0′ to 155° 3′ W. This area would be centered approximately 75.0 miles N of Ookala, NE coast of the Island of Hawaii.

June 17, 1:48 am, very feeble, 1.3 miles deep under cracks, 0.8 mile SE of Ahua Kamokukolau. 19° 22.5′ N; 155° 15.5′ W.

June 19, 1:54 pm, feeble, originated under seacoast area S of Kilauea crater near Keahou landing.

June 19, 4:35 pm, very feeble, of shallow origin Mauna Loa summit crater.

June 21, 6:46 am, very feeble, of shallow origin SE rim area of Halemaumau 19° 24.4′ N; 155° 16.9′ W.

June 21, 7:45 pm, very feeble, 0.6 mile deep, 1.1 mile S of Pit seismograph. 19° 23.5′ N; 155° 16.7′ W.

June 25, 1:33 am, very feeble, originated near center of Kilauea crater to NE of Halemaumau.

Teleseisms:

April 1, 1h 00m 08.0s am, "P" waves. Probably originated in the vicinity of the Philippines.

April 15, 7h 45m 28.0s pm, "P" waves. 2,710 miles from Kilauea in region of Aleutian Islands. 52.6° N; 173.8° W.

May 18, 6h 14m 08.0s pm, "P" waves, probably originated about 2,575 miles from Kilauea; Imperial Valley disaster of California.

May 19, 4h 56m 26s am, "P" waves, distance about 3,200 miles.

May 21, 8h 26m 55s am, "P" waves, distance undetermined.

May 24, 6h 16m 24s am, "P" waves, probably originated near Peru, abaut 5,645 miles distant.

May 24, 12h 10m 31s pm, unidentified portion.

May 27, 11h 22m pm, "P" waves, location of point of origin undetermined.

May 30, 6h 53m pm, unidentified portion.

June 5, 12h 40m am, "P" waves, from NW Canada; 68° N; 138° W.

June 22, 1h 18m 49s am, "P" waves, distance about 5,500 miles.

Continuous tremor:

April 7, 10:59 pm to midnight, 61 minutes and April 8, midnight to 4.00 am, 240 minutes with visible outflow of lava Mauna Loa summit crater; total 301 minutes. May 21, 7:06 pm, 6 minutes of tremor. June 1, 11:20 pm, 3 minutes and 11:52 pm, 4 minutes.

Microseismic Motion:

April:

Light—28, 30.
Moderate—15, 16, 19 to 27, 29.
Strong—1 to 14, 17, 18.

May:

Light—5 to 7, 15 to 30.
Moderate—2, 3, 11, 13, 14, 31.
Strong—1, 2, 8 to 10, 12.

June:

Light—1, 2, 5 to 10, 12, 13, 15 to 18, 21, 23, 28, 29.
Moderate—3, 4, 11, 14, 19, 20, 22, 25, 26, 30.
Strong—24, 27.

Tilting of the Ground:

The following tables show tilt by weeks as recorded on the Observatory seismograph NE rim of Kilauea Crater and at Halemaumau, the algebraic sum toward or away from the Pit as indicated by stations on the W and SE rims respectively.

At the Observatory the total accumulated tilt for the year ending April 28 was 2.58″ N and 0.53″ E.

For the year ending May 26, 3.20″ N and 0.90″ E.

For the year ending June 30, 4.90″ N and 0.33″ E.

Table of Tilt

Week ending	Observatory	Halemaumau West Station
April 7	0.78″ S 13° W	0.00″
" 14	0.73″ S 67° W	1.64″ N 7° E
" 21	0.95″ N 71° E	1.91″ S 20° W

" 23	2.17″ N 9° E	4.44″ toward
" 30	2.17″ S 72° E	1.62″ from

Crater angles

Measurement of horizontol angles across Kilauea Crater from the Observatory was made April 11. At that time the measurement indicated closing of 0.17" for the Halemaumau value and closing of 1.51" for the Crater value compared with similar meosurements made March 28.

Determinations of May 14, indicated closing of 0.42" for Halemaumau and opening of 1.26" for the Crater. Between May 14 and May 29, Holemaumau angle closed 1.08" and Crater angle closed 2.25". Total change April 11 to May 29, Holemaumau angle closed 1.50" and Crater angle closed 0.99".

Final measurements of the quarter was made June 20. May 29 to June 20, Halemaumau angle showed no change and the Crater angle opened 1.25".

Total change March 28 through June 20, Halemaumau angle (Pit seis. to NW Pit BM) closed 1.65" and the Crater angle (SE Crater rim to Uwekahuna) closed 1.25".

Chain-of-Craters Road Cracks

Of the seven principal Chain-of-Craters Road Cracks normally measured, only two have shown any appreciable changes between March 29 and June 28. Numbers 101 and 102, both near Devil's Throat showed increases (openings) of 1.0 millimeter each during thot period.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigations. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

A CHEMICAL STUDY OF KILAUEA SOLFATARIC GASES, 1938-40

By STANLEY S. BALLARD and JOHN H. PAYNE*

The current research project on the collection and analysis of volcanic gases was begun in the fall of 1935. It was the first project under the new cooperative agreement between the University of Hawaii and the Hawaii National Park. Many collections of solfataric gases have been made at Kilauea, and two at Mauna Loa, but as yet there has been no suitable opportunity to collect primary volcanic gases from either vent. A report on the first stages of the investigation appeared in The Volcano Letter[1] over two years ago. Since that article was written, a number of improvements have been made both in the technique of collection and in the method of analysis employed. Also, since September, 1938, we have attempted to make monthly gas collections at the Sulphur Banks wells, or "Kilauea Solfatara," and 23 collections were made in the succeeding two-year period.

There is a dual purpose in making regular analyses of the Sulphur Banks gases. The first is to accumulate a long-time record of the constitution of the gases of a well-established solfatara. This has never been done in America, and its importance has recently been given recognition by the Geological Society of America, which is aiding our project with a research grant from the Penrose fund. The second purpose involves the search for variations in the gases that might correlate with periods of volcanic activity. If such a correlation can be found, another method of prediction will be available and supplementary to the cyclic, seismic and tilt methods that have been used for so many years in Hawaii. Fluctuations in the sulphur dioxide content of the exhalations were indeed noted, but we have not as yet been able to correlate these with any of the volcanic phenomena at Kilauea. However, just prior to the 1940 eruption of Mauna Loa, hydrogen sulphide was noted for the first time at the Sulphur Banks.[2]

From September, 1938, to August, 1939, gas was collected by the "vertical wet" method described elsewhere.[1] This setup is pictured on page 2 of The Volcano Letter, No. 453 (November, 1937). The objection to this method was that when two or three tubes were collected in succession on the same day, considerable variation was found from tube to tube. One tube was used in determining sulphur dioxide, and the remaining one or two tubes in determining the sulphur dioxide plus carbon dioxide total. In view of the possible variation between the tubes of a given collection, this introduced considerable doubt as to the reliability of the results. Also, the collections of May, June, and July, 1939, seemed to be of progressively poorer quality. Therefore a new method of making collections was introduced in September, 1939. As shown in Figs. 1 and 2, three tubes were mounted in series, and the gas reached them only after being drawn through a long copper coil which was immersed in an ice bath. Because of the high thermal conductivity of copper, practically all steam was condensed before the gas left the upper end of the coil, and any condensate that might have been drawn through the coil was trapped in a flask mounted between the coil and the tubes. The gas finally collected in the three tubes was free from condensate, and if care was taken in making the collection, gas samples from the three tubes were of uniform composition.

The analytical methods described previously[1] involved the determination of all constituents by the absorption pipette method. It was realized in the spring of 1938, however, that this method was giving incorrect results, since the absorbent for sulphur dioxide also absorbed large percentages of the much more abundant carbon dioxide. The results of the analyses as previously reported[1, 3] were hence in error. During the summer of 1938 we introduced the present analytical method in which the sulphur dioxide is determined gravimetrically by precipitation as barium sulphate; the sulphur dioxide plus carbon dioxide total is determined by absorption in caustic potash solution; and, the carbon dioxide is computed by difference. The only other regular constituent is air; oxygen is determined by absorption in alkaline pyrogallol and the residuum is regarded as

* Research Associates in Geophysics and Geochemistry, respectively, Hawaii National Park.

nitrogen. Spectroscopic tests[1] confirmed the identity of the nitrogen and failed to show any other gases in the residuum except traces of argon. Combustibles have been sought in every analysis by the combustion pipette method but have never been detected. The volume percentages of the chief constituents, air, sulphur dioxide, and carbon dioxide in the various samples, are presented in Table I. Two or three 250-cubic-centimeter tubes of gas were collected an each date, but because of the analyticol methods employed, only a single set of percentages was obtained in some cases. It is seen that the proportion of air varies widely, between zero and 40 per cent. It seems to us that this gives an indication of the quolity of the collection, and that in satisfactory collections the air content should be one per cent or less. The wide variation of sulphur dioxide, from 0.5 to 18 per cent, is much too large to be occasioned by possible analytical errors. Figure 3 is a graph showing the fluctuation of the sulphur dioxide during the two-year period starting September, 1938. The percentage of sulphur dioxide showed a sudden rise to approximotely 15 per cent in the Januory, 1939, collection. This high value remained fairly constant for a period of five months, after which it dropped to the previous lower value of about 2 per cent. A second increase occurred in October, 1939, but lasted for only o month. There appears to be no regularity about this variation, and the wirters have not been able to find any correlation between it and any of the volcanic or meteorological phenomena measured regularly at the Hawaiian Volcano Observatory.

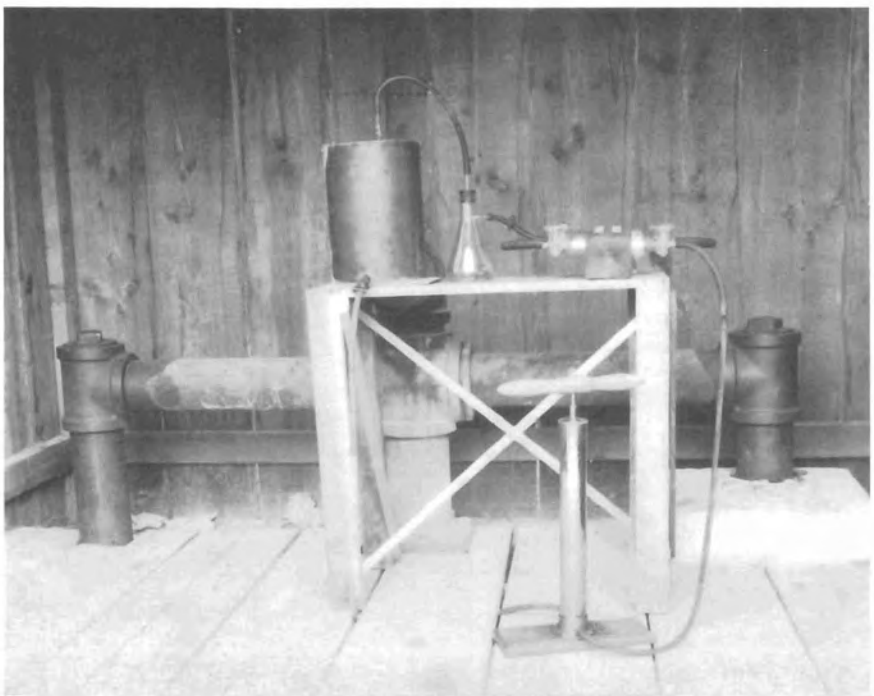

Fig. 1.—Gas collecting setup used at Sulphur Banks wells from September, 1939, to September, 1940. Photo by Fagerlund.

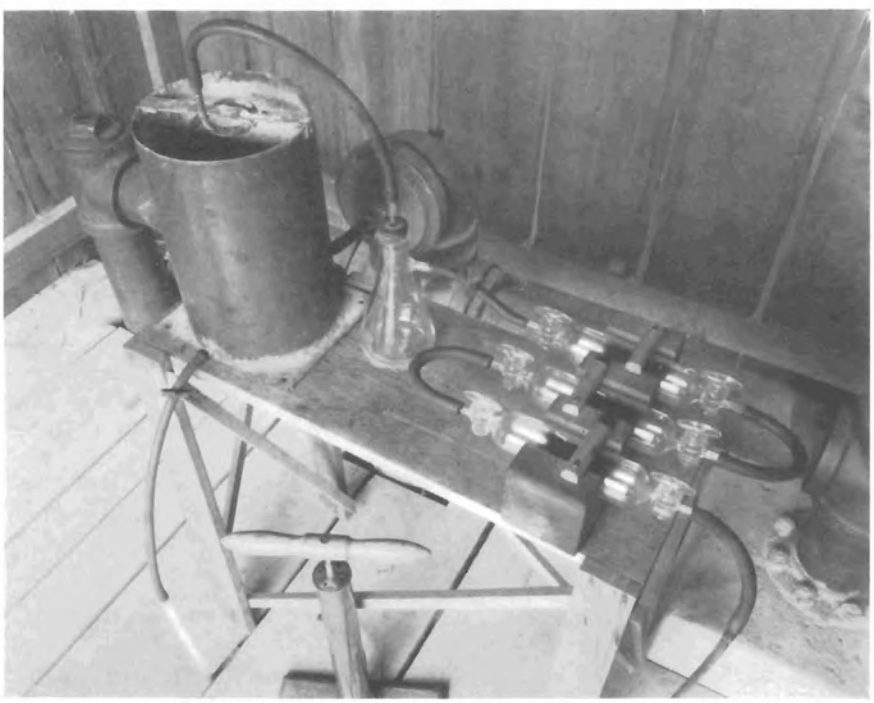

Fig. 2.—Top view of apparatus shown in Fig. 1. When gas is being collected, the copper coil is cooled by filling the brass drum with ice and water. Photo by Fagerlund.

In the collection of March 14, 1940, hydrogen sulphide appeared for the first time. It was easily detected qualitatively by odor, by the darkening of lead acetate paper, and by the formation of yellow cadmium sulphide when the gas was passed into cadmium sulphate solution. There was not sufficient hydrogen sulphide to make its quantitative determination possible. On April 7, 1940, volcanic activity broke out at the summit of Mauna Loa. Samples of gas collected at Kilauea an April 11 and on April 21 contained hydrogen sulphide, but none was found in the collections of May 10 and June 18, even though Mauna Loa was still erupting, although with greatly lessened activity.

The appearance of hydrogen sulphide in the Kilauea solfataric gases just prior to Mauna Loa activity may have been a premonitory sign. If so, this appears to afford an exceedingly valuable methad of forecasting volcanic outbreaks. Furthermore, its occurrence suggests a close relationship between solfataric activity and primary volcanism.

The only previous analyses of these gases were made by Brun[4] and by Allen[5]. Brun's analyses were only partial. Allen determined the steam content to be 96.2 per cent. He found 0.1 per cent sulphur dioxide, traces of sulphur vapor and of

hydrochloric acid, and 3.7 per cent of "fixed gases." It appears from our analyses that Allen's "fixed gases" consisted of air or carbon dioxide or both. We have not as yet determined the steam content of these exhalations.

Further improvements were made in the collection methods in September, 1940. We are also starting to investigate different analytical methods, including especially the possibility of determining sulphur dioxide by the thermal conductivity method.

Many of the gas collections were made by members of the Park staff; we wish to acknowledge particularly the assistance of H. H. Waesche and P. E. Schulz in this regard. Thanks are due L. M. Foster for assistance in making the analyses.

Hawaiian Volcano Observatory Report for July-September 1940

VOLCANOLOGY

July 1940

The Mauna Loa eruption at the summit crater waned to a seeming standstill with decreasing intervals and decreasing activities. Observation of it by Park employees continued, and nothing new happened at Kilauea.

The alternations between activity and quiet in Mokuaweoweo, the summit crater of Mauna Loa, to which the outflow of lava was confined, were as follows:

Quiet	00 a.m.	July 1	to	8:30 a.m.	July 4
Active	8:30 a.m.	July 4	to	8:00 a.m.	July 10
Quiet	8:00 a.m.	July 10	to	6:00 p.m.	July 18
Active	6:00 p.m.	July 18	to	9:30 a.m.	July 21
Quiet	9:30 a.m.	July 21	to	9:15 a.m.	July 23
Active	9:15 a.m.	July 23	to	8:00 a.m.	July 24
Quiet	8:00 a.m.	July 24	to	4:15 p.m.	July 26
Active	4:15 p.m.	July 26	to	6:00 p.m.	July 26
Quiet	6:00 p.m.	July 26	to	12:00 noon	July 27

Only activity after 12:00 noon July 27 was feeble glow the nights of July 27 and July 28 followed by quiet thereafter.

The duration of active spells in sequence according to this table appears to be 24, 64, 23, 2, 36 hours.

The duration of quiet spells appears to be 202, 48, 56, 18, 36-plus hours.

The activity was from the vent in the top of the new inner summit lava cone of Mokuaweoweo southwest of the center of the crater, with fume from internal fountains rising from that vent all the time, and outflows from the cone as indicated. After July 4, flows within Mokuaweoweo streamed to the north, east, west and south from fountains 50 to 75 feet high. On July 8, there was one fountain at the cone center, two in a lake northwest of the cone. On July 18, a fountain in the cone vent shot up 150 feet, and made a strong roar at midnight July 18-19. The fountain was again 150 feet high July 23 at 12:55 p.m., and a strong flow poured into the lake north of the cone in Mokuaweoweo. On July 26, at 5:00 p.m., flowing lava was seen in a crack at the northeast base of the inner Mokuaweoweo cone.

The only slide at Halemaumau reported for July was at 6:34 p.m., July 3, when thin dust rose above the northern half of the pit. There was unusual closing of rim cracks around Halemaumau in the first and last weeks of the month. An important near shock felt from Honolulu to Hawaii at 4:48 p.m., July 15, was located under the sea floor 90 miles east of Maui like the one a month before; there were four other shocks located in this vicinity during the quarter-year.

The following are the local data for July, counting tremor spasms as seismic disturbance for each minute of duration:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
July 7	1	2.5 mm. closed	28
" 14	0	2.5 mm. opened	26
" 21	0	3.5 mm. opened	57
" 28	0	6.5 mm. closed	50

August 1940

After 18 days of seeming quiet, Mauna Loa resumed gushing of lava through the summit inner cone of Mokuaweoweo crater during the afternoon of August 15 about 5:00-6:00 p.m. At 9:30 p.m. the same date, a strong fume column, colored bright red with reflected light of the fountain, rose several thousand feet above the Mauna Loa summit. On August 16, a fume column hung over Mauna Loa throughout the day and red glow was faintly visible through clouds in the evening. This kind of activity continued, but declined August 17-18, and observers at the summit rest camp reported one large fountain in the inner cone and a north flow during the evening on the Mokuaweoweo floor. The fume column was less dense August 18 and a pulsating glow was visible over Mauna Loa as seen from Kilauea. This period of activity came to an end during the night August 18-19, some fume was seen at 7:00 a.m., August 21, and no further lava activity was observed.

Rocks were heard falling from the northeast, east and southeast walls of Halemaumau 10:00 to 11:00 a.m., August 25 and a period of continuous tremor lasted five minutes after 6:19 p.m., August 21. During the last week of the month rocks fell at Halemaumau frequently, and a larger slide at the northeast wall occurred at 3:35 p.m., August 31.

A sharp increase in local seismic activity followed the cessation of lava gushing at Mokuaweoweo. Another moderate earthquake was felt slightly in Hawaii National Park at 10:15 p.m., September 1, originating 117 miles from the Observatory with center probably at the sea-floor east of Maui like the felt, stronger shocks of June 16 and July 15. A very feeble shock from a similar distance occurred August 27.

The following are the local data for August:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
Aug. 4	0	2.5 mm. opened	33
" 11	0	2.5 mm. opened	25
" 18	0	3.0 mm. opened	28
" 25	3	1.0 mm. opened	19
Sept. 1	6	0.5 mm. opened	45

September 1940

During the first week of the month Mauna Loa and Kilauea were quiet, two earthquake shocks were felt and all but one of the feeble shocks were under Kilauea. Tilting of the ground away from the crater became pronounced at the Kilauea Observatory in August and September.

The second week indicated concentrations of seismic activity in the Chain-of-Craters where the highway has shown some increased movement. The third week produced earthquake shock from various distances, and the same may be said of the fourth week, with no notable changes at the crater of Kilauea.

The following are the local data for September:

Week Ending	Halemaumau Slides	Halemaumau Crack Openings	Seismic Disturbances
Sept. 8	0	0.0 mm.	45
" 15	0	5.0 mm. opened	21
" 22	0	0.5 mm. opened	19
" 29	0	0.5 mm. opened	21

* Including teleseisms or earthquakes over 5,000 km from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

July 1, 4:23 pm, very feeble, probably originated in E central portion of Kilauea Crater.

July 4, 3:55 pm, feeble, probably originated 40.0 miles NE of Hilo.

July 6, 2:54 am, feeble, 1.8 miles deep in area between Devil's Throat and Puu Ohale. 19° 22.0′ N; 155° 15.4′ W.

July 9, 7:30 pm, very feeble, probably originated off NE coast of Hawaii about 12 miles E of Ookala.

July 12, 10:14 am, very feeble, Mauna Loa NE rift near Puu Kulua.

July 14, 12:39 am, very feeble, associated with earthquake of 4:48 pm, July 15, and others listed as follows:

July 14, 10:40 pm, very feeble.

July 15, 9:13 pm, very feeble (reported felt in Hamakua at Paauhau and on Maui at Ulupalakua).

July 16, 3:48 pm, very feeble.

August 16, 11:27 pm, very feeble.

August 27, 2:35 pm, very feeble.

September 20, 10:29 am, very feeble.

All of these originated in area under the sea floor about 80 miles N of Hilo bounded as follows: 20° 45′ to 21° .00′ N and 155° to 155° 15′ E.

July 15, 4:48 pm, moderate, probably of normal depth located 65.0 miles N of Laupahoehoe and about 90 miles E of Kahului, Maui. 20° 54′ N; 155° 08.0′ N. Felt generally over all the Islands with the exception of Kauai.

July 19, 7:42 am, very feeble, off sea coast in vicinity of Kawaihae Bay. Reported felt in Kahala.

July 24, 10:50 am, very feeble, of shallow origin, NW rim area of Kilauea Crater 0.6 mile NE of Uwekahuna. 19° 25.6′ N; 155° 17.0′ W.

July 26, 3:49 am, very feeble, Hilina Fault zone S of Puaialua.

July 26, 4:24 am, feeble, 8.0 miles deep, Hilina Fault system, 4.0 miles SSE of Puu Ohale. 19° 18.5′ N; 155° 14.6′ W.

July 26, 4:26 am, very feeble, Hilina Fault, same general locality as preceding.

July 26, 5:34 am, very feeble, Hilina Fault, 3.0 miles NW of Apua point. 19° 17.0′ N; 155° 15.0′ W.

July 26, 11:52 am, feeble, located 11.0 miles deep off sea coast S of Hilina Fault near Apua Point. 19° 16.3′ N; 155° 09.0′ W.

August 1, 1:49 pm, very feeble, 6.0 miles deep on E slope of Mauna Loa, 5.0 miles E of the Pit Crater, Lua Hohonu. 19° 27.0′ N; 155° 31.6′ W.

August 5, 3:27 am, slight, 0.4 mile deep, NE rim of Kilauea Crater near the National Park Headquarters. 19° 25.7′ N; 155° 15.5′ W. Most persons in immediate vicinity of epicenter were awakened by this earthquake.

August 5, 7:31 am, feeble, of shallow origin near junction of Byron and Waldron Ledges, NE rim of Kilauea Crater. 19° 25.5′ N; 155° 15.5′ W. Reported felt in Hawaii National Park.

August 7, 5:51 am, very feeble, Mauna Loa summit crater.

August 10, 1:44 pm, very feeble, 3.0 miles deep near center of Kilauea Crater. 19° 25.2′ N; 155° 16.5′ W.

August 10, 5:34 pm, very feeble, 12.0 miles deep under S coast of Hawaii 9.0 miles E of Pahala. 19° 12.0′ N; 155° 20.6′ W.

August 12, 10:04 pm, very feeble, probably originated in vicinity of Pahala or adjoining sea coast area.

August 14, 2:32 pm, very feeble, 25.0 miles deep, Hualalai, 8.0 miles E of summit. 19° 40.0′ N; 155° 45.0′ W.

August 30, 5:02 am, very feeble, NE portion of Kilauea Crater.

August 30, 1:09 pm, very feeble, 2.4 miles deep under SW rim of Kilauea Crater 0.6 mile W of center of Halemaumau. 19° 24.6′ N; 155° 17.8′ W.

August 30, 5:33 pm, very feeble, of shallow origin, Byron Ledge. 19° 24.6′ N; 155° 15.7′ W.

August 30, 6:35 pm, very feeble, 0.4 mile deep, E portion of Kilauea Crater near Kilauea Iki gap. 19° 24.8′ N; 155° 15.8′ W.

August 31, 6:18 pm, very feeble, of shallow origin, area near junction of Hilina Fault and SW rift (Kilauea). 19° 17.5′ N; 155° 21.0′ W.

September 1, 4:53 am, very feeble, probably originated SE rim area of Kilauea Crater.

September 1, 3:02 pm, very feeble, located 0.5 mile deep under E rim of Halemaumau. 19° 24.5′ N; 155° 16.7′ W.

September 1, 10:15 pm, moderate, 90.0 miles NNW of Hilo. 21° 00.0′ N; 155° 16.0′ W. Reported felt generally on Island of Hawaii.

September 2, 1:43 am, very feeble, of shallow origin near center of Kilauea Crater. 19° 24.7′ N; 155° 16.6′ W.

September 2, 5:12 pm, feeble, 13.0 miles deep, Hilina Fault, 3.0 miles N by E of Keahou Point. 19° 18.5′ N; 155° 13.3′ W.

September 4, 4:02 am, very feeble, originated in rift zone about 1.5 mile W of Devil's Throat.

September 4, 11:48 am, very feeble, Hilina Fault, 4.0 miles SE of Kamakaia Hills.

September 4, 10:44 pm, very feeble, 1.3 miles NE of Puu Ohale.

September 5, 1:07 am, very feeble, Chain-of-Craters near Pauahi.

September 5, 3:11 am, very feeble, Mauna Loa NE rift between Pukauahi Crater and Puu Ulaula.

September 5, 10:09 am, feeble, 0.8 mile deep, 0.4 mile N of Puhimau Crater (Chain-of-Craters). 19° 24.1′ N; 155° 15.1′ W.

September 6, 9:09 am, very feeble, Kilauea NE crater rim.

September 6, 2:01 pm, very feeble, 3.5 miles NW of Hawaiian Volcano Observatory.

September 6, 10:24 pm, feeble, SE rim of Kilauea Crater, of shallow origin, 0.6 mile SE of Pit seismograph. 19° 24.0′ N; 155° 16.5′ W.

September 9, 10:09 am, very feeble, S rim area of Kilauea Crater about 0.7 mile S of Pit seismograph.

September 10, 3:03 pm, very feeble, 1.7 miles deep, 1.4 miles NE of Puu Ohale. 19° 21.6′ N; 155° 16.0′ W.

September 12, 9:59 am, very feeble, 1.3 miles deep, Kilauea SE crater rim near Keanakakoi. 19° 24.3′ N; 155° 15.8′ W.

September 12, 10:07 am, very feeble, of shallow origin, Kilauea E crater rim (Byron Ledge). 19° 24.9′ N; 155° 15.9′ W.

September 12, 4:31 pm, feeble, 1.5 miles deep, 3.5 miles NW of Volcano Observatory. 19° 28.4′ N; 155° 17.6′ W. Reported felt in Hawaii National Park.

September 14, 5:25 pm, feeble, 5.0 miles deep, SW rim of Kilauea Crater at junction with SW rift. 19° 24.0′ N; 155° 17.8′ W.

September 16, 6:06 am, very feeble, of Halemaumau origin.

September 17, 9:35 pm, very feeble, of Halemaumau origin.

September 18, 3:24 am, very feeble, S portion of Kilauea Crater.

September 21, 5:18 pm, feeble, 12.0 miles deep, Hilina Fault, 4.0 miles SE of Kamakaia Hills. 19° 17.7′ N; 155° 18.5′ W.

September 24, 12:56 pm, very feeble, 5.0 miles deep, E slope of Mauna Loa, 7.0 miles SE by S of Mokuaweoweo. 19° 23.0′ N; 155° 32.0′ W.

September 26, 6:14 pm, very feeble, probably same general location as preceding.

September 26, 6:47 pm, slight, of Kilauea origin.

September 27, 12:21 am, very feeble, 3.0 miles deep near center of Kilauea Crater. 19° 25.1′ N; 155° 16.4′ W.

September 27, 11:14 am, very feeble, of shallow origin, Halemaumau. 19° 24.5′ N; 155° 17.2′ W.

Continuous Tremor:

July 17, 9:28 to 9:50 pm, 22 minutes.

August 21, 6:20 to 6:25 pm, 5 minutes.

August 26, 9:34 to 9:52 am, 18 minutes.

Teleseisms

July 2, 8h 56m am, unidentified portion.

July 13, 7h 30m 16s pm, "P" waves, distance 2,620 miles. Located in Aleutian Island region, 52.7° N; 177.6° W. Reported by Jesuit Seismological Association.

July 27, 3h 12m 40s am, "P" waves. 13.7° N; 91.3° W. Honduras.

August 1, 4h 48m 32s am, "P" waves, distance 4,165 miles; Island of Hokkaido, northernmost of Japan group, 44.0° N; 139.6° E.

August 20, 8h 54m 30s am, unidentified portion.

August 21, 5h 04m 04s pm, "P" waves, distance 2,285 miles.

September 12, 2h 56m 51s am, "P" waves, distance 4,060 miles.

September 19, 8h 14m 05s am, "P" waves, distance 3,525 miles.

September 22, 12h 33m 00s am, "P" waves, distance 4,700 miles.

All time H.S.T. (10h 30m slower than Greenwich).

Microseismic Motion

July:

Light: 2, 3, 24, 26, 27, 29.

Moderate: 1, 5, 6, 8, 10 to 14, 16 to 18, 22, 23, 25, 28, 30, 31.

Strong: 4, 7, 9, 15, 19 to 21.

August:

Light: 2 to 5, 12 to 14, 18, 19, 23, 25 to 27.

Moderate: 1, 8, 10, 11, 15 to 17, 20 to 22, 24, 28 to 31.

Strong: 6, 7, 9.

September:

Light: 17 to 20.

Moderate: 2 to 5, 11 to 16, 21, 22, 28, 29.

Strong: 1, 6 to 10, 23 to 27, 30.

All dates inclusive.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending July 28, 1940, was 5.50" N and 1.21" W.

For the year ending September 1, it was 7.22" N. and 1.1" E.

For the year ending September 29, it was 7.05" N and 2.18" E.

Table of Tilt

Week ending	Observatory	Halemaumau West Station
July 7	1.08" N 8° W	0.00
" 14	1.55" N 13° W	0.54" N 75° E
" 21	0.63" N 8° W	0.45" S 70° E

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory June 20 indicated closing of the Halemaumau value and opening of the Crater value compared with similar measurements May 29. The Halemaumau angle between the Pit seismograph station and the NW Pit BM decreased 2.50" and the crater angle between the SE rim station and Uwekahuna increased 1.75".

Angle determinations August 7, showed that the Halemaumau value decreased 1.65" and the Crater value increased 0.85" between that date and June 20.

On September 4, the Halemaumau angle had increased 1.81" and the Crater angle had increased 0.23".

Total Halemaumau change, June 20 to September 4: 0.16" increase; Crater: 1.0" increase.

Levelling at Kilauea

The level circuit on Kilauea Crater floor from the Spit BM on the S Crater rim to the NW Halemaumau rim BM was run September 18, 1940. Compared with determinations of April 18, there was only 5.0 millimeters lowering of the NW Pit BM relative to the Spit BM.

The Crater floor has been apparently settling since the 1934 Kilauea eruption and with the exception of a short period during the 1935 Mauna Loa eruption this is the first run in the last 5 years that such a slight change has occurred. It would seem that Kilauea Crater floor had reached a more stable condition or that lava pressure has increased under Kilauea since April 18.

Chain-of-Craters Crack Measurements

June 28 to October 4: 101—increased 2.0 millimeters; there were no changes in the others during this period.

At Devil's Throat, one crack on the SE rim increased 4.0 millimeters.

It appears that the only measurable movement in the Chain-of-Craters region is taking place in the vicinity of Devil's Throat (No. 101 is about one-quarter of a mile to the NW).

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigations. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE VOLCANO LETTER

No. 470 Department of the Interior National Park Service October-December 1940

ENGULFMENT AT KILAUEA VOLCANO

By R. H. FINCH

The amount of engulfment at the time of the explosive eruption at Kilauea in 1924 was computed by T. A. Jaggar[1] and the writer. T. A. Jaggar in the same bulletin (p. 119), discussed the volume of Kilauea Crater fill for the first century of its recorded history.

In this paper the computations have been extended to include the volume of engulfment at the time of each major collapse, as in 1823, 1832, 1840, 1868, 1886, 1891, 1894, 1916, 1919, and 1922. In most cases the collapse occurred at the time of a Kilauea lava flow at a lower elevation, or immediately followed the cessation of a Mauna Loa outbreak. It is suspected that if we had more complete data on subterranean and submarine lava flows, the correlation between flow and collapse would be nearly one hundred per cent. There were other years with rapid drop in the lava column, notably in 1849, 1855, 1871, 1879, and 1913, but the volumes involved for the most part were not large.

In attempting to compute the volume relations for 1823, the first recorded collapse at Kilauea, we quickly found that the accounts as given by Ellis,[2] Brigham,[3] Dana,[4] and Hitchcock[5] gave widely varying values for the depth of the crater.

Ellis, the first to give a written account of Kilauea, in August, 1823, observed a black ledge about 400 feet below the crater rim and 300-400 feet above the main floor. He wrote, "It was evident that the large crater had been recently filled with liquid lava up to the black ledge, and had, by some subterranean canal, emptied itself into the sea or upon the lower land on the shore." There had been a lava flow from the southwest rift of Kilauea near sea level shortly prior to his visit.

Edward Loomis, in a letter published by Brigham (p. 42), indicates there were several small pits in 1824 with a depth of 200-300 feet which probably had been full of molten lava in 1823. The total depth of Kilauea, referred to Uwekahuna, in 1824 must have been about 1,315 feet. If the computations for volume of engulfment were made for 1824 instead of 1823, the value would be changed by only a small percentage. Loomis made the depth of the main floor 600 feet below the rim where he descended. Malden's depth figures, as given by Dana, are 1,300 feet (p. 51) and 1,700 feet (p. 127). Let us set the various estimates and measurements in tabular form, in order to arrive at a probable figure for the depth of the crater.

Authority	Elevation of rim at place of estimate	Elevation of crater floor	Elevation of black ledge
Ellis, 1823.....	3800 feet	3000 feet	3400 feet
Loomis, 1824	3625 "	3025 "	3325 "
Chamberlin, 1824	.....	3000 "	.....
Malden, 1825	4090? "	2790 "	3190 "
Bingham, 1830 ..	4000? "	3000 "	3400 "
Alexander, 1833..	4000? "	2000 "	Not mentioned
Douglas, 1834	4090 "	2975 "	3375 "
Wilkes, 1840	4000? "	3010 "	3350 "

Ellis made an attempt to check his estimate, first with a string 100 feet long and then with one 230 feet in length. He commented that the string of 100-feet "did not appear to reach near half way to the black ledge of lava." Loomis made his estimate at the lowest point on the rim where the dimensions were small, and, knowing that he measured the width of the black ledge, one can assume that his estimate is not seriously in error. Dana found serious errors in Malden's computation and it may well be that there was an error in his base line. Subsequent careful measurements are in close agreement with the Loomis estimate.

Goodrich estimated that by 1832 the black ledge had been covered with 50 feet of new lava. Subtracting this 50 feet from the Douglas elevation of the black ledge in 1834 gives 3,325 feet, the same as the Loomis estimate. It should be noted that this value differs from the Ellis estimate by only 75 feet. It should not be assumed that the black ledge was an exact level surface around the pit, though judging from the sketches and from the type of activity in 1832 and probably in 1823, the ledge had quite uniform height. By 1840 there was a conical mound around Halemaumau 100 feet above the general floor. The total depth of the crater as given by Malden may be

brought into closer agreement with most of the others if we assume that his figures are for one of the several pits in the crater floor at that time.

An interesting item gleaned from the Ellis account is the report of a chasm across the black ledge apparently where the Puna rift cuts the crater wall.

The average drop of the crater floor in 1823 must have been close to 400 feet. As a convenience in computing the area involved, it was divided into two parts: the northern and wider portion with an area of 40,750,000 sq. ft., and the narrow southern portion with an area of 2,550,000 sq. ft., or a total of 43,300,000 sq. ft. With a drop of 400 ft. the volume engulfed would be 17,320,000,000 cu. ft.

The estimates of the depth of the crater in 1832 vary from 2,000 feet (unsupported) to 1100 feet. The area affected by this collapse was but little less than in 1832, or 41,430,000 sq. ft. With a drop of 450 feet, that means an engulfment of 18,640,000,000 cu. ft.

An observation by Goodrich (Dana, p. 55) indicates that the collapse of 1832 may well have occurred in the latter part of July. This would make it coincide with the cessation of the 1832 outbreak of Mauna Loa.

The collapse of 1840 left an inner pit much smaller than that of 1823 or 1832. The estimate of average depth involved for this year is rendered somewhat uncertain by the considerable relief of the crater floor. The total area of collapse was about 22,120,000 sq. ft. With an average drop of 350 feet, the amount engulfed would be 7,752,000,000 cu. ft.

After the drop of 1868, there was considerable difference in level of the crater floor with the most profound sinking at Halemaumau. This was to be expected because, since 1840, the principal seat of activity was at Halemaumau. The great pit had the outline of an inverted frustum of a cone, with an upper diameter of 2,000 feet, and a lower one of 1,500 feet. It was 500 feet deep. This gives the collapse at Halemaumau of 650,000,000 cu. ft. The sunken portion of the crater, less Halemaumau, had an area of 30,000,000 sq. ft. An average drop over this area of 200 feet would mean a volume of 6,000,000,000 cu. ft. The total engulfed in 1868 then was 6,650,000,000 cu. ft.

The collapse in 1886 left a triangular area with sides about 3,350 feet long. There was a sink near the center of the depression 590 feet deep, but it was only 600 feet across and affected the total volume but slightly. The average drop of about 250 feet over an area of 5,600,000 sq. ft. represents a volume of 1,400,000,000 cu. ft. In addition to the above, there may have been some down-warping as indicated by a pronounced crack that opened near the northern end of the crater.

Since 1868 the source of volcanic activity has become quite centralized in the southern end of the crater at Halemaumau, or its immediate vicinity. In 1891 the collapse was confined to Halemaumau. The estimates of the depth of Halemaumau after the collapse of 1891 vary from 500 to 700 feet. The diameter of the pit was 2,500 feet. The average of the computed values of the volume evacuated was 1,200,000,000 cu. ft.

In 1894 the volume represented in the formation of two benches on the rim of the collapsed pit was about 30,000,000 cu. ft. The pit itself had a diameter in one direction of 900 feet and 1,000 feet in the other. After the initial drop in 1894, there was considerable movement at the bottom with some slight infilling. The estimates of depth clustered around 500 feet. The average based on different estimates and measurements and various methods of calculating makes the 1894 engulfment 300,000,000 cu. ft.

The collapse of 1916 left a void that may be thought of as a frustum of a cone with diameters of 1,100 and 375 feet. The drop in level was 400 feet. These figures give the volume displacement in 1916 as 260,000,000 cu. ft.

The 1919 collapse left a void 1,200 feet in diameter at the top and about 200 feet at the bottom, 591 feet below. At a depth of 275 feet, the diameter was 1,060 feet. The void created by a shelf at the north rim was 600,000 cu. ft. The volume of the main pit, computed as upper and lower frusta of cones, was 353,500,000 cu. ft. This gives for 1919 a total of 354,100,000 cu. ft.

Early in May, 1922, the lava was within about 50 feet of the rim of Halemaumau, while crags stood nearly 50 feet above the rim. By the last of the month there was a void 861 feet deep with a width at the rim of 2,000 feet in a NE-SW direction, and 1,485 feet in a NW-SE direction. This void comprised 750,000,000 cu. ft.

A summation of the computations is shown in the following table:

Volume Engulfed by Principal Collapses in Kilauea

Year	Volume in Cu. Ft.
1823	17,320,000,000
1832	18,640,000,000
1840	7,752,000,000
1868	6,650,000,000
1886	1,400,000,000
1891	1,200,000,000
1894	300,000,000
1916	260,000,000
1919	354,100,000
1922	750,000,000
1924	7,120,000,000
Total	61,746,100,000

After each collapse the crater floor was raised by inflows and in some periods, at least, by marked tumescence. During the period under discussion the total filling exceeded the total engulfment.

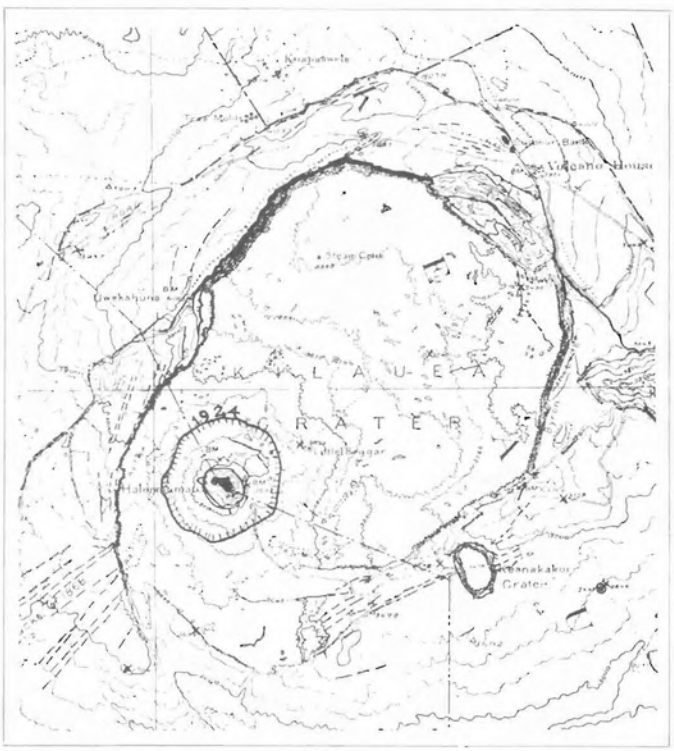

Fig. 1.—Map of Kilauea Crater, 1912 to 1924; enlargement of Halemaumau by engulfment.

Hawaiian Volcano Observatory Report for October-December, 1940

VOLCANOLOGY

October 1940

No glow was visible in the summit crater of Mauna Loa when it was visited on October 14-16, though there was heavy fuming at the 1940 source cone. A portion of the summit of this cone had collapsed.

Kilauea was quiet throughout the month though rock slides were observed on October 18, 29, and 30.

Tilting to the northeast accumulated more than the seasonal normal.

Exceptionally strong microseisms were recorded on October 18 at a time of unusually high waves on Hawaiian shores.

November 1940

There was increase of rock slides from Halemaumau, particularly from the western wall, otherwise Kilauea was quiet in November. Faint bluish fume was noticed over Halemaumau on November 8 and 29.

No activity was observed on Mauna Loa.

December 1940

During the second week of December there was increase in seismicity. The majority of the shakes originated near Kilauea. Rock slides were frequent during the month. A slide at noon December 4 made a large dust cloud.

Tilt for December was to the east. For the year ended December 31, 1940, there was an accumulation of ENE tilt. This tilt indicates that a volcanic low may have been reached in 1939.

The following are the local data for October, November, and December.

Week Ending	Halemaumau Slides	Halemaumau Crack Openings (Millimeters)	Seismic Disturbances

Errata

Volcano Letter No. 467, January-March 1940, "Tilt Changes at Kilauea," p. 2, second paragraph, ninth line, should read: During the 27 years of measurement, it has been found that the tilt on the NE rim of Kilauea Crater, considered as the path of the top of a vertical rod, describes an annual clockwise loop of from 5 to 10 seconds of rotational arc with the loop elongated in a NNE-SSW direction, the greater axis being about twice the length of the shorter one. In the course of producing the major loop many minor ones occur and the latter almost without exception progress in a counter-clockwise direction. In general tilt is **northeasterly** during the warmer summer and fall months and **southwesterly** during the cooler late winter and spring months.

Volcano Letter No. 469, July-September 1940, p. 7, Table of Tilt, Halemaumau resultant Sept. 29: change "5.81" from" to "2.48" from." H.H.W.

* Including teleseisms or earthquakes over 5,000 km from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the Observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and, whenever possible, a determination of depth of focus has been made.

October 7, 5:19 am, feeble, of shallow origin, NE rim of Kilauea Crater not over 0.5 mile from the Observatory. 19° 25.6' N; 155° 15.8' W.

October 11, 11:34 am, very feeble, Mauna Loa NE rift near Pukauahi Crater.

October 16, 3:03 pm, very feeble, probably originated in Mauna Loa NE rift about 5 miles SW of Hilo.

October 22, 3:17 am, feeble, of Kilauea origin, Hilina Fault zone 3.5 miles SE of Kamakaia Hills.

October 26, 7:57 pm, slight, 5.0 miles deep, E slope of Mauna Loa, 7.5 miles E of Pohaka Hanalei. 19° 31.0' N; 155° 26.5' W. Reported felt in Hawaii National Park and sharply felt by many persons at Pohala.

October 28, 9:27 pm, feeble, 15.0 miles deep, in the vicinity of Hilina Fault about midway between Puu Ohale and Keahou Landing. 19° 20.0' N; 155° 16.0' W. Reported felt by a few persons in Hilo.

November 3, 4:36 am, very feeble, probably originated in Kilauea SW rift about 15 miles from the Observatory.

November 4, 11:03 am, very feeble, Hilina Fault, 3.5 miles SW of Kamakaia Hills.

November 6, 5:54 am, very feeble, Hilina Fault system, 5.0 miles deep, 7.0 miles SW of Makaopuhi. 19° 19.5' N; 155° 05.0' W.

November 18, 6:35 am, very feeble, of shallow origin, SE portion of Kilauea Crater, 0.7 mile SE of Pit seismograph. 19° 23.9' N; 155° 16.4' W.

November 22, 5:33 am, very feeble, Mauna Loa NE rift, about 5 miles NE of Mokuaweoweo.

November 24, 11:26 am, very feeble, Hilina Fault system, SE of Makaopuhi.

November 25, 7:34 am, very feeble, 2.0 miles deep, central portion of Kilauea Crater. 19° 25.0' N; 155° 16.7' W.

November 30, 9:52 am, very feeble, of shallow origin under Mauna Loa summit crater.

December 8, 5:48 am, very feeble, Kilauea Puna rift SE of Makaopuhi.

December 9, 1:21 am, very feeble, 1.3 miles deep S rim of Kilauea Crater. 19° 23.8' N; 155° 17.1' W.

December 9, 8:27 am, very feeble, 1.7 miles deep S rim of Kilauea Crater. 19° 24.1' N; 155° 17.2' W.

December 9, 1:24 pm, very feeble, 0.7 mile deep, Kilauea Crater near E rim of Halemaumau. 19° 24.5' N; 155° 16.7' W. Dismantled Pit seismograph.

December 9, 5:05 pm, S rim of Kilauea Crater near Halemaumau.

December 9, 7:35 pm, very feeble, Kilauea SW rift 1.0 mile SW of Halemaumau.

December 11, 9:02 am, feeble, 0.6 mile deep, Kilauea SW rift, 0.3 mile NE of Cone Peak. 19° 24.0' N; 155° 18.4' W.

December 12, 9:52 am, very feeble, 12.0 miles deep, 12 miles NE by N of the Observatory. 19° 30.0' N; 155° 13.0' W.

December 15, 3:26 pm, very feeble, 40 miles ± deep under Mauna Kea. 19° 49.0' N; 155° 29.0' W.

December 19, 1:00 pm, very feeble, of shallow origin, Mauna Loa NE rift near Mokuaweoweo. 19° 31.0' N; 155° 32.0' W.

December 20, 2:48 am, very feeble, 18.0 miles deep, Hilina Fault system, N of Apua Point. 19° 18.3' N; 155° 11.5' W.

December 20, 3:26 am, very feeble, 15.0 miles deep, 8.0 miles S of Kilauea Crater in Hilina Fault system. 19° 18.0' N; 155° 16.5' W.

A number of disturbances, which registered on the Observatory seismograph as tremors, reported elsewhere as follows:

November 8, 5:54 pm, very feeble on Mauna Loa seismograph.

November 12, 1:53 pm, very feeble on Mauna Loa seismograph.

November 16, 8:17 pm, very feeble on Mauna Loa seismograph.

November 25, 4:59 pm, feeble on Mauna Loa seismograph.

November 27, 10:12 pm, reported felt at Paauhau.

December 9, 6:51 am, reported felt at Hookena.

Teleseisms

October 3, 10:08 pm, unidentified portion. Originated in Chile. 19° S; 67° W.

October 26, 7h 37m 40s pm, surface waves. Originated in Central America region. 9.9° N; 84.4° W.

November 16, 5:42 pm, unidentified portion.

December 22, 2:20 am, unidentified portion.

December 28, "P" waves at 6h 17m 15s am. Originated 3,775 miles from Kilauea.

Microseismic Motion

October:

Light: .....
Moderate: 3 to 5, 7, 8, 15, 23, 24.
Strong: 1, 2, 6, 9 to 14, 16 to 22, 25 to 31.

November:

Light: .....
Moderate: 16, 17.
Strong: 1 to 15, 18 to 30.

December:

Light: .....
Moderate: 18, 27 to 31.
Strong: 1 to 17, 19 to 26.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum toward or away from the Pit.

At the Observatory, the total accumulated tilt for the year ending on each of the following dates was:

October 27—8.23" N and 3.60" E.
December 1—5.60" N and 5.30" E.
December 29—7.83" N and 9.90" E.

Table of Tilt

Week ending	Observatory	Halemaumau West Station

" 29	6.38" N 23° E	2.75" from H. H. W.

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory October 1, 1940, indicated closing of both the Halemaumau and the Crater values compared with similar measurements made September 4. The amount of closing of the Halemaumau angle, between the Pit seismograph station and the NW Pit BM, was 0.32" and the crater angle, between the SE rim station and Uwekahuna, was 2.16".

Between October 1 and October 24, the Halemaumau angle opened 0.49" and the crater angle closed 0.92".

October 24 to November 12: Halemaumau angle opened 0.52" and the crater angle opened 3.33".

November 12 to November 29: Halemaumau angle opened 0.08" and the crater angle closed 0.92".

November 29 to December 19: Halemaumau angle closed 0.66" and the crater angle opened 0.69".

Net Halemaumau change, October 1 to December 19: 0.33" open; crater change: 2.16" open. H. H. W.

Chain-of-Craters Crack Measurements

On the Chain-of-Craters Road there have been no appreciable changes in cracks except at No. 108, S rim of Aloi Crater. This crack has opened as follows:

October 4 ..... 97.30
October 25 ..... 97.35
November 29 ..... 97.40
December 27 ..... 97.75

Total opening .... 4.5 millimeters

Crack No. 2, N rim of Devil's Throat opened a total of 2.0 millimeters in the same period. H. H. W.

Time used throughout this report is Hawaiian Standard time, 10h 30m slower than Greenwich.

THE VOLCANO LETTER

No. 471 Department of Interior National Park Service January-March 1941

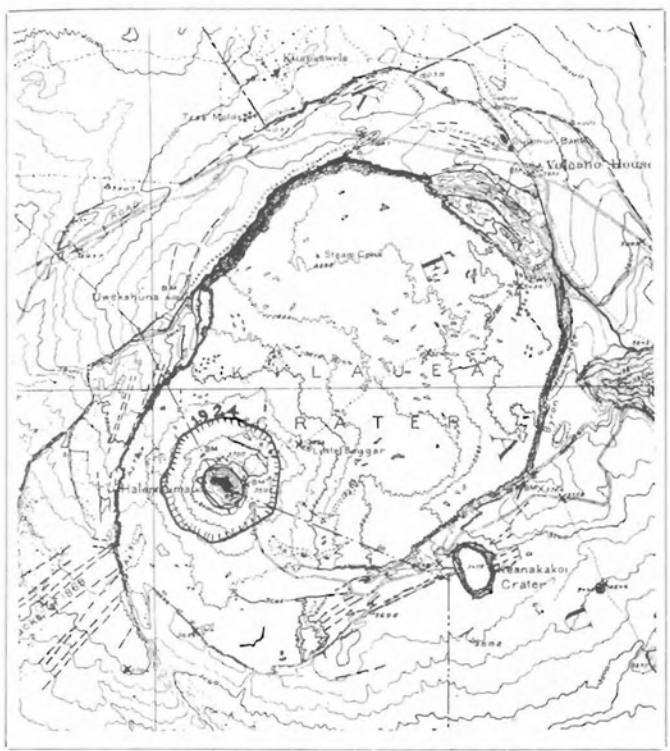
THE FILLING IN OF KILAUEA CRATER

By R. H. FINCH

The net result of the first century of the recorded history of Kilauea Volcano, despite numerous breakdowns, has been a gradual filling of the crater. To facilitate computations of the volume of the uneven filling from 1823 to the present, the areas between convenient contours on the 1922 edition of the Kilauea Crater advance sheet of the U.S. Geological Survey were determined by planimeter. The collapse of 1823 left a comparatively narrow, black ledge around the inner margin of Kilauea Crater. This ledge, 3,400 feet above sea level, was taken as a base. The volume computed from this base plus the amount of the collapse in 1823 would give the total fill since the first recorded visit to Kilauea (in 1823) to the present time. The planimeter measurements indicate that the volumes given in Volcano Letter No. 470 for the collapses in 1823 and 1832 should be increased by about 10 per cent.

The amount of filling can be computed for only a few of the many periods of inflow and tumescence because of lack of adequate data. The volume for the period between 1823 and 1832 would be, to a close approximation, the amount engulfed in 1823 plus a layer 50 feet deep over the entire crater. Just prior to the collapse of 1832, the lava stood 50 feet higher than the black ledge of 1823. The total fill for the period then was about 23,850,000,000 cu. ft. The filling must have taken place within eight years as the lava was at as low a level in 1824 as in 1823, or perhaps a little lower. This would make the average per year about 3,000,000,000 cu. ft. The maximum rate of filling is not readily determinable and was quite likely much higher than the average.

Between 1840 and 1846 a large percentage of the increase in elevation of the crater floor was due to tumescence. However the ratio of the volume due to tumescence to that of inflow cannot readily be determined. In some places a canal or moat that separated the interior platform from the black ledge was 200 feet deep. Because the inner crater was



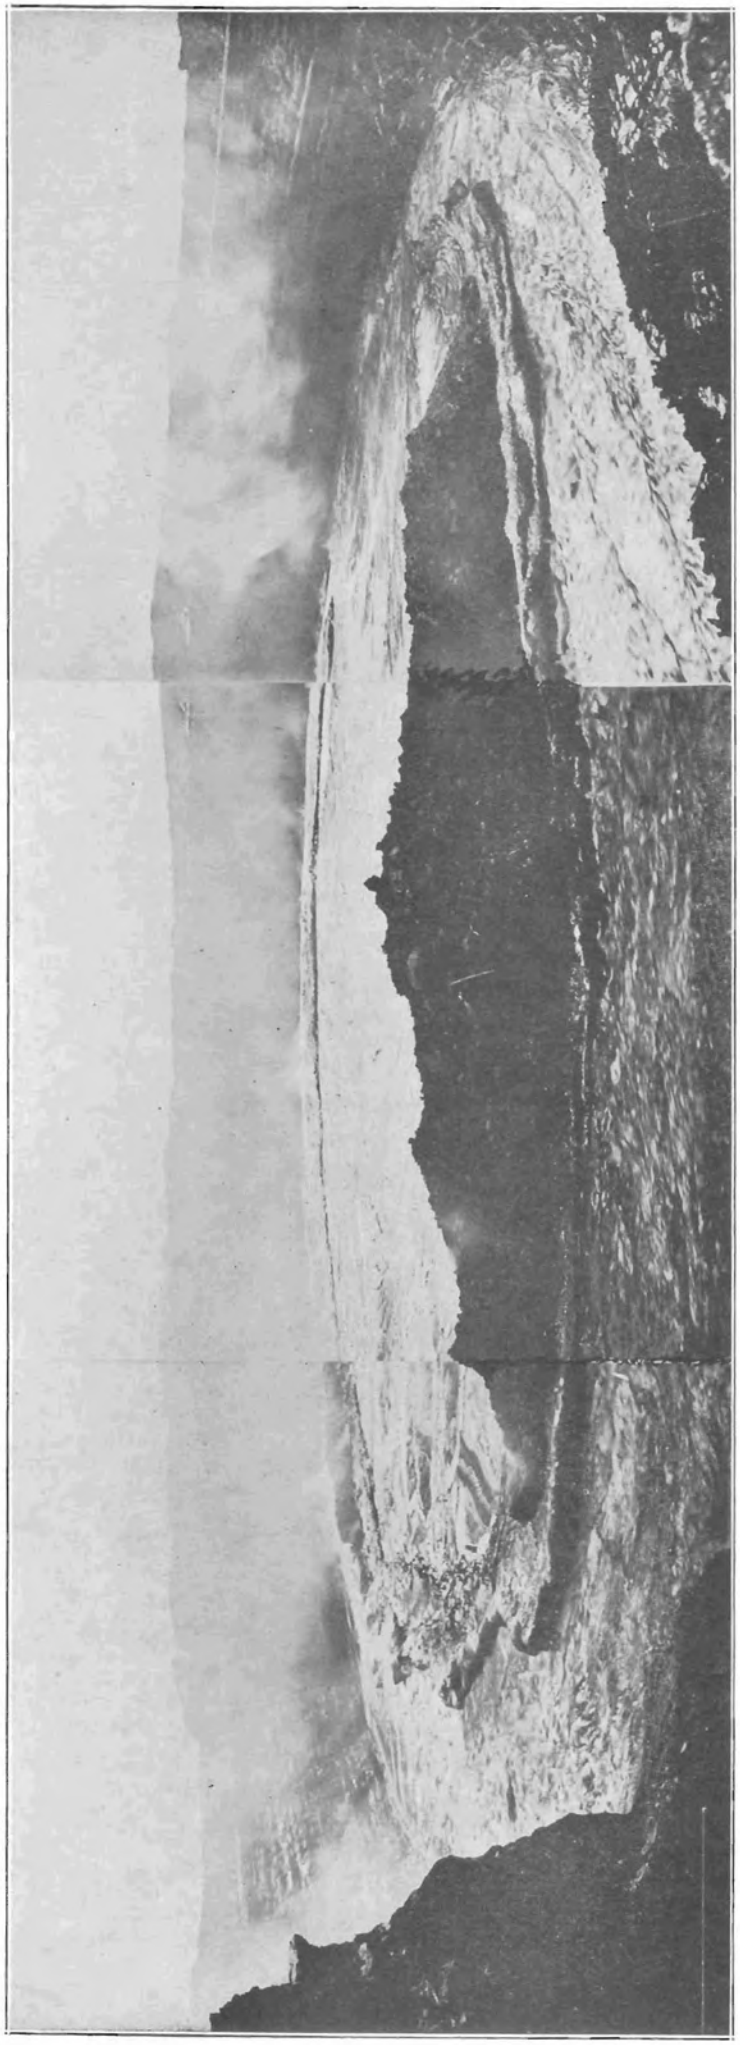


Fig. 1—Map of Kilauea, 1912 to 1924.

funnel-shaped, gaps were left between the resulting interior platform and the walls of the black ledge when the floor was bodily elevated. These gaps were the canals observed in 1844 and 1846 by Titus Coan and Prof. C. S. Lyman. The 200-foot depth of the canal does not necessarily mean that the platform was elevated uniformly through that range. The interior basin may have been elevated much less. Then too, the accumulation of talus blocks around the margin of the lower floor prior to the uplift would have been an important factor in making the margin the highest part of the elevated platform.

Brigham,[1] referring to Lyman's explanation of the canals of 1846, states, "The rise of a cylinder of lava a mile in diameter some 200 feet would be remarkable, but with an overflowing bowl of lava more than a thousand feet in diameter in its very midst the phenomenon would be incomprehensible." But that is exactly what did happen, as correctly explained by Lyman whose visit to Kilauea wos ot about the end of the tumescing period.

A similar phenomenon was the subject of daily measurements by the Hawaiian Volcano Observatory in 1919. Immediately after the collapse of November 28, 1919, it was noted that the bottom of Halemaumau (see map Fig. 1) was being elevated as a unit. In the lava lake was a ring-shaped island surfaced in many places with talus blocks as shown in Fig. 2. This island mantained its identity while the lava column rose vertically 450 feet in 17 days. The upper half of Fig. 3 shows the plan of Halemaumau at the end of the uplift, and the lower half, a section, illustrates the nature of the island and the relation of the superficial lava lakes to the more plastic portions of the lava column. The fact that lava lakes are but comparatively shallow depressions in a pasty plug was not known to Brigham when he wrote.

Tumescing accompanied many, if not all, periods of rapid rise and inflow, but in most cases was not as pronounced as that between 1840 and 1846. The ascensive force of the lava affects not only the more mobile portions of the lava column, but the entire region surrounding Kilauea Crater.[2]

Sometime in 1846 it was observed that the surface of Kilauea was nearly back to its position before the collapse of 1840. This would make the fill of six years about equal to the amount engulfed in 1840, or 7,750,000,000 cu. ft. The averoge per year would be 1,290,000,000 cu. ft.

Dividing the total fill of several years by the number of years obviously does not give a true rate.

[2]T. A. Jaggar and R. H. Finch, **Tilt Records for Thirteen Years at the Hawaiian Volcano Observatory,** p. 43.

Fig. 2—Halemaumau on Dec. 16, 1919, after a rapid rise from a depth of 591 feet. Photo by T. A. Jaggar.

Observations as to the time of beginning and ending of activity are lacking, and also, in some of the longer periods, one or more years may have been periods of inactivity or even recession. Nevertheless, it is a rough measure of activity. In 1919 the rise took place within 17 days, and the average rate fill for this period if continued for an entire year would have amounted to 2.2 cu. mi.

The 1922 map of Kilauea Crater is substantially correct for 1941 save for the 1924 enlargement of Halemaumau and the subsequent inflows. The least elevation change since 1823, unless it be near the southwest rim of Kilauea, is just below Byron's Ledge. There the present surface is but 100 feet above the back ledge of that year. The greatest depth of fill was a little more than 700 feet, at the rim of Halemaumau.

The total fill between 1823 and 1924 was 70,280,000,000 cu. ft. If we subtract the amount engulfed in 1924, 7,120,-000,000 cu. ft., from this total we will have the net fill up to the time of the inflow of July, 1924, or 63,160,000,000 cu. ft. To this net, however, must be added the total volume of the several inflows into Halemaumau from 1924 to 1934. These inflows have lessened the depth of Halemaumau from 1,335 feet below the rim in 1924 to its present depth of 770 feet. Part of the elevation of the Halemaumau floor has been due to the accumulation of landslides from the walls. It is thought that about 800,000,000 cu. ft. was due to inflows. The net fill between 1823 and 1941 then, is 63,960,000,000 cu. ft. The gross filling between 1823 and 1941 would be the above total plus the amount of engulfments from 1832 to 1922 inclusive, or 101,266,000,000 cu. ft.

The history of Kilauea shows that there has been a diminution in size of the volcanic conduit under the crater floor. In 1823 and 1832 nearly the entire crater floor responded to volcanic pressure changes. Between 1840 and 1846, half the crater floor was bodily elevated indicating plastic material under that much of the crater. Most of the inflows of that period, however, came from the site of Halemaumau, and the canal near the southwest end of the crater was obliterated before there were any appreciable flows in the remainder of the canal. The breakdowns of 1868, 1886, and 1891 showed that the mobile portion of the crater got progressively smaller until from 1891 on, it was confined to Halemaumau and the immediate vicinity. That a mobile lava column still exists under Kilauea is indicated by an accumulation of 17 seconds of northeast tilt at the Hawaiian Volcano Observatory since 1939. Northeast tilt at the Observatory means an increase in elevation of Kilauea mountain.

What happened at Kilauea for many years after the explosive eruption of 1790 is not known, but at least by 1823, 33 years afterwards, there was intense activity over the entire crater. The interval of inactivity after 1790 may have been much less than 33 years, for native accounts given in 1823 said that there had been many lava flows but no explosion since 1790.

If Kilauea continues to be periodic in its activity and repeats the conditions following 1790, the 1924 explosion should be followed by a very active Halemaumau in or before the latter part of this decade.

Hawaiian Volcano Observatory Report for January-March, 1941

VOLCANOLOGY

January 1941

An unusual feature of the month was the continuation of northerly tilt until the last week of the month. Seasonal southwesterly tilt normally sets in about the first of the year. The tearing down of a part of the Hawaiian Volcano Observatory should, apparently, have been effective in increasing the normal southwest tilt.

There were no reports of unusual activity on Mauna Loa and surface activity at Kilauea was confined to rock slides from Halemaumau walls which were frequent January 20-22.

February 1941

A light fume column was visible over Mokuaweoweo at 5:15 pm, February 11. On the morning of March 12, Navy aviators reported heavy fume from the same place.

During the two weeks ended February 16 there was a slight southeast tilt instead of the normal southwest tilt for this time of year. The amount was slight but the actual figures do not tell the whole story. To produce an easterly tilt in February it would appear that some deep-seated pressure change, call-

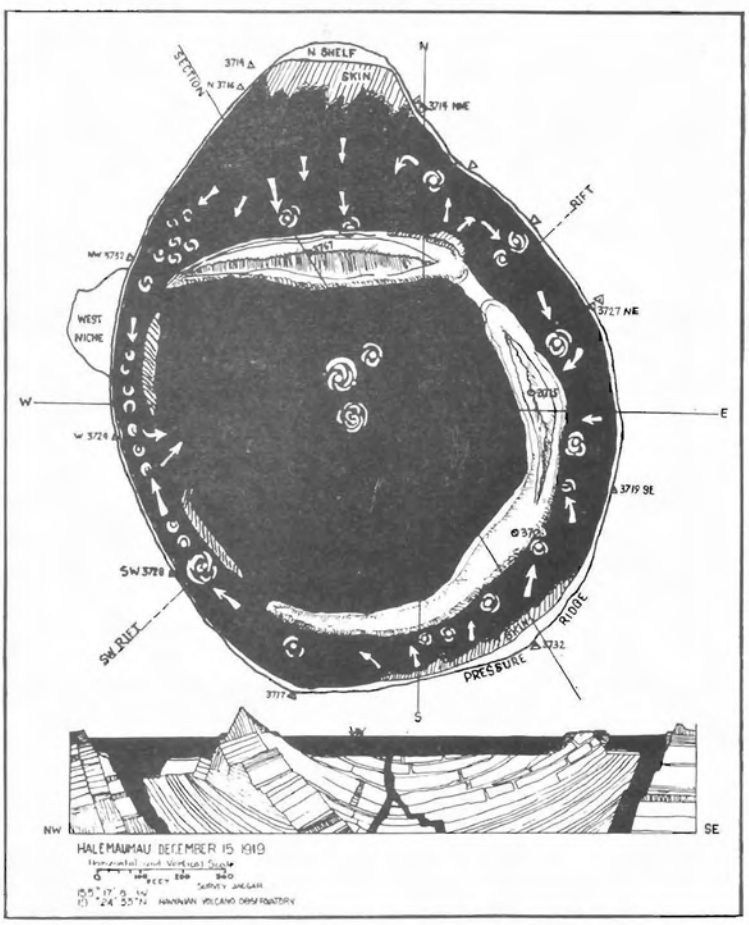

Fig. 3—Plan and section across Halemaumau, Dec. 15, 1919, showing the relation of lava lakes to the viscous and solid material below. From Volcano Observatory records by T. A. Jaggar.

ing for an easterly tilt, must first exceed the seasonal westerly tilt before it can become manifest.

Landslides from Halemaumau have a tendency to occur in groups and this was shown by several on February 17 and 21.

March 1941

Tilting of the ground at the Observatory continued to be erratic in March. In the first ten days the tilt was to the northeast and during the last week it was to the northwest. This means that there will be but little seasonal tilt to the southwest during the first four months of the year. Under normal conditions such a tilt would justify a prediction of volcanic activity but current work on the new hotel adjacent to the seismograph cellar may be affecting the records.

The 1940 Mauna Loa eruption cone was observed to be fuming on March 25.

Some of the local data for January, February, and March are as follows:

* Including teleseisms or earthquakes over 5000 km from Kilauea.
† For local seismicity definition see Volcano Letter 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory on the island of Hawaii. Kilauea earthquakes were located by means of the main seismograph station at the observatory and the two subsidiary stations at Uwekahuna and the SE rim of Halemaumau respectively. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began at the time indicated and whenever possible, a determination of depth of focus has been made.

January 15, 7:45 am, very feeble, 0.8 mile deep, Chain of Craters between Kokoolau and Devil's Throat. 19° 23.0' N; 155° 14.6' W.

January 17, 7:30 am, slight, 14.0 miles deep under W slope of Hualalai near seacoast at Kaiwi Point. 19° 40.3' N; 156° 03.5' W. Reported felt at Naalehu, Kailua, Hookena, Hilo, and strongly felt by everyone at Puuwaawaa.

January 18, 9:34 am, feeble, probably originated about 15 miles N of Papaaloa, in general area of earthquakes of summer of 1940 which originated in same region.

January 19, 6:20 pm, very feeble, 11.0 miles deep under E slope of Mauna Loa, 17 miles W of Kilauea Crater. 19° 25.5' N; 155° 27.8' W.

January 20, 11:01 pm, very feeble, 4.0 miles deep, 1.7 miles SSE of Volcano Observatory; 0.3 mile S of S rim of Kilauea Iki.

January 21, 2:15 am, very feeble, probably originated SW rift of Kilauea near Hilina Fault.

January 21, 7:24 pm, very feeble, 10.0 miles deep, Mauna Loa NE rift near Puu Ulaula. 19° 33.0' N; 155° 28.0' W.

January 22, 3:26 am, very feeble, of shallow origin, Mauna Loa summit crater.

January 25, 3:56 am, very feeble, 15.0 miles deep, 4.0 miles NNW Kailua, W slope of Hualalai on seacoast. 19° 41.0' N; 156° 01.0' W. Reported felt at Kailua and Kealakekua.

January 26, 8:42 am, very feeble, 3.5 miles NE Puu Kulua, Mauna Loa NE rift.

February 3, 2:08 pm, feeble, 14.0 miles deep, E slope Mauna Loa, 5.1 miles W of W rim of Kilauea Crater. 19° 25.0' N; 155° 20.0' W. Reported felt by many persons in Pahala.

February 8, 9:19 am, feeble, located about 37.0 miles N of Hilo under sea floor; 24 miles NE of Ookala. 20° 10.2' N; 155° 0.00' W.

February 11, 9:56 pm, feeble, 60 miles N by E of Hilo. 20° 34.0' N; 154° 49.0' W.

February 13, 12:05 pm, very feeble, Kilauea Puna rift area in general vicinity of Kalapana.

February 18, 11:53 am, slight, 30 miles deep, 14 miles E of summit of Hualalai. 19° 41.0' N; 155° 39.0' W.

February 20, 12:48 am, very feeble, probably originated 8.5 miles SW of Kilauea Crater in vicinity of Kamakaia Hills.

March 1, 12:16 pm, very feeble, Mauna Loa summit crater.

March 1, 3:46 pm, very feeble, Mauna Loa NE rift, 15.0 miles from Hilo.

March 4, 12:37 am, very feeble, Hilina Fault 7.0 miles W of Kalapana.

March 6, 4:28 pm, very feeble, located at base of NE rim of Kilauea Crater and of shallow origin. Sharply felt at Volcano Observatory.

March 8, 9:14 am, very feeble, Kilauea SW rift near junction with Hilina Fault.

March 13, 12:49 pm, very feeble, Hilina Fault N of Apua Point.

March 22, 5:54 pm, very feeble, located under NE rim of Kilauea Crater.

March 25, 5:57 pm, very feeble, probably originated in the vicinity of Punaluu.

March 30, 0:54 pm, very feeble, located on the SW rift of Kilauea, 0.6 mile beyond the SW rim and 0.6 mile NE of Cone Peak. 1.6 miles deep. 19° 24.1' N; 155° 18.3' W.

March 30, 3:42 pm, very feeble, located 20 miles north of Hilo and 8 miles off shore of Laupahoehoe. Depth 20 miles. 20° 00.8' N; 155° 07.3' W.

March 30, 6:54 pm, same location as earthquake of 3:42 pm.

March 30, 9:23 pm, same location as earthquake of 3:42 pm.

March 30, 11:48 pm, same location as earthquake of 3:42 pm.

H. H. Waesche

Teleseisms

January 13, 6h 08m 03s am, probable distance from Kilauea, 3,480 miles.

February 8, 11h 18m 49s am, distance not readily determined, probably 4,540 miles.

Microseismic Motion

January

Light: 1, 4, 5, 8, 9, 15, 16.
Moderate: 3, 6, 7, 10, 14, 17, 19, 25.
Strong: 2, 11 to 13, 18, 20 to 24, 26 to 31.

February

Light: 17 to 22.
Moderate: 6, 7, 14 to 16, 23 to 25.
Strong: 1 to 5, 8 to 13, 26 to 28.

March

Light: 13, 21 to 23.
Moderate: 2 to 4, 6, 12, 18 to 20, 24.
Strong: 1, 5, 7 to 11, 14 to 17, 25 to 31.

Tilting of the Ground

The following tables show tilt by weeks as recorded by the Observatory seismograph and at Halemaumau, the algebraic sum toward or away from the Pit.

At the Observatory the total accumulated tilt for the year ending on each of the following dates was:

January 26 - 12.22" N and 11.16" E.
March 2 - 10.20" N and 12.64" E.
March 30 - 12.58" N and 10.41" E.

Table of Tilt

Week Ending	Observatory	Halemaumau West Station
January 5	0.95" W	0.00 - - -
" 12	1.49" N 6° W	2.77" N 64° W
" 19	1.80" N 76° W	1.61" S 10° E
" 26	0.77" S 21° W	1.31" N 28° E
February 2	0.91" S 14° W	2.90" S 28° E
" 9	1.82" S 72° E	3.19" S 22° W
" 16	0.73" S 13° E	5.42" N 38° E

Crater Angles

Measurement of horizontal angles across Kilauea Crater from the Observatory, January 14, 1941, indicating closing of the Halemaumau value and opening of the Crater value compared with similar measurements made December 19. The amount of closing of the Halemaumau angle was 1.51" and of opening of the Crater value was 1.09".

Between January 14 and January 30, the Halemaumau angle closed 1.24" and the Crater angle closed 1.26".

Between January 30 and February 17, the Halemaumau angle opened 1.16" and the Crater angle opened 0.09".

Between February 17 and March 4, the Halemaumau angle closed 1.57" and the Crater angle closed 2.17".

Net Halemaumau change December 19 to March 4: Halemaumau 2.16" closed; Crater 2.25" closed.

H. H. Waesche

Kilauea Crater Floor Levels.

A level circuit was run from Spit B.M., S rim of Kilauea Crater, to NW Pit B.M., Jonuary 16, 1941. There was no relative change in elevation between these two stations compared with a similar run made September 18, 1940.

Chain-of-Craters Crack Measurements

On the Chain-of-Craters road there have been no appreciable changes in meosured cracks except at #108, S rim of Aloi Crater. This crack has opened as follows:

December	27	measurement was	97.75 cm
January	31	" "	98.25
Februory	28	" "	98.70
March	28	" "	98.90
Total opening			1.15 cm

Devil's Throat rim cracks indicoted only slight chonges.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islonds and around the Pacific Ocean. Its equipment at Kilauea Volcano, Howaii Island, has been transferred to the United States Government, Department of the Interior, National Pork Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** mointain outside seismograph stations and supplement the work of the government with research associotes, instrumental plants and special investigations. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter,** o quarterly record of the Hawaiian volcano laboratories and published by the University of Hawaii, is issued by outhority of the Department of the Interior and supplied to a restricted membership and exchange list of the obove establishments.

THE VOLCANO LETTER

No. 472 **Department of Interior** **National Park Service** **April-June 1941**

• The Volcano Letter, a quarterly record of the Hawaiian volcano laboratories, published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the Hawaiian Volcano Research Association and the University of Hawaii.

• The Hawaiian Volcano Research Association was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, is leased and operated by the United States Government, Department of the Interior, National Park Service.

• The University of Hawaii (T. A. Jaggar, geophysicist) cooperates in maintaining a research laboratory at Hawaii National Park (Edward G. Wingate, superintendent, R. H. Finch, volcanologist). The Association and the University maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants, and special investigations.

CALDERAS AND THEIR ORIGIN, BY WILLIAMS

Review by R. H. FINCH

Calderas and their Origin, by Dr. Howell Williams, [Bulletin of the Department of Geological Sciences, University of California, Vol. 25, No. 6, 107 pages, 1941], offers geologists a thought-provoking and comprehensive discussion on caldera and crater formation. "Calderas are large volcanic depressions, more or less circular or cirque-like in form, the diameters of which are many times greater than those of the included vent or vents, no matter what the steepness of the walls or form of the floor." A crater is limited to "a constructive apparatus from which ejecta escape to build up positive land forms." It follows then that "calderas are almost invariably large volcanic basins produced by engulfment."

He lists six classes of calderas: 1, explosion calderas; 2, collapse calderas; 3, erasion calderas; 4, volcanic graben; 5, volcanic rents or fissure troughs; and 6, major volcano-tectanic depressions. Erosion calderas are probably included for the sake of completeness as they result from modification of other forms. It will be noted that some form of collapse is present in all classes except for the "rare and relatively small explosion calderas."

Uniformity in names such as Dr. Williams proposes would make for clarity, but it will be some time before all volcanologists will cease to use the word crater in the sense of depressions in the surface of the earth caused by volcanic processes. In some ways it would be more in keeping with the ordinary meaning of caldera if the proposed definitions of caldera and crater were interchanged. At Kilauea it is easy to think of Halemaumau as a cauldron in Kilauea crater.

It is gratifying to see proper recognition given to the splendid work of the geologists of the Dutch East Indies, especially Stehn, van Bemmelen, van den Bosch, and Neumann van Padang. The above are included under the term field volcanologists. This would imply that the other class would be library volcanologists. Williams' interest in calderas was aroused by a visit to Kilauea and subsequently he did extensive work on the Brokeoff caldera in California, the Newberry and Crater Lake calderas in Oregon. He also spent considerable time at the calderas in New Zealand, Dutch East Indies, and Japan.

One of the effects of the paper will be to lay forever the idea that explosions by themselves are competent to account for large calderas. In each case discussed, the volume of coarse lithic debris about the rim is strikingly insufficient to account for the material removed. It is surprising that so slight attention has been paid to the scarcity of the old lithic material around each volcano "that blew its head off," for this scarcity was recognized at Santorin by Fouque published in 1879, and by Diller at Crater Lake published in 1902. Van den Bosch is quoted as saying that it is the scarcity of such lithis debris that "explodes the explosion hypothesis."

That small craters may be due to explosions is accepted. Three examples of known small calderas produced by explosion, Rotomahana in New Zealand, Bondai-san in Japan, and Chaos Crags in California are described.

Before discussing 20 illustrative examples of collapse calderas about whose origin there is but little doubt, three calderas doubtfully ascribed to explosion are discussed. They are the Valles caldera in New Mexico, Aniakachak in Alaska, and Mount Multnomah in Oregon. The Valles caldera with diameters of 17 and 18 miles is "probably the largest caldera in the world." The discussion on these three calderas convinces one that Williams was quite conservative in labelling them "doubtfully ascribed to explosion."

These large calderas, often with rim volcanoes, suggest to the reviewer that the great volcanic arcs, such as the Aleutian, mark portions of ancient subsidence basins with rim volcanoes that were many hundreds of miles in diameter.

Krakatau is taken as the type where engulfment follows repeated and usually short-lived explosions of pumice and juvenile ash. An excellent review of the history of Krakatau is given. On page 262 listing some of the possible causes of the activity there, is the statement that the magma prior to 1883 may have been "potentially explosive owing to a high content of dissolved gases, perhaps absorbed from the walls of the reservoir." The mechanism of such an absorption introduces grave difficulties aside from the relatively small volume of gases available from such a source. Escher's gas-caring hypothesis is inadequate to account for the formation of large calderas and comes in for just criticism.

On page 256 occurs the statement that the earlier small explosions of Krakatau of May 20 "were chiefly of vulcanian type —— whereas the culminating explosions were of pelean type, the overwhelming mass of pumice being deposited with great rapidity as glowing avalanches (nuees ardentes)." This seems to be overworking the term nuees ardentes which by many means a more or less downward component of a pumice-charged explosion and not merely a glowing cloud. Ver Beek and Dana long ago assumed that the caldera at Krakatau was produced by engulfment and to this most of the later workers there, Stehn, van Bemmelen, van den Bosch, Neumann van Padang, Reck, and Williams, agree.

The next caldera discussed is Santorin caldera of Greece. The pioneer studies of Fouque have in the main been verified by the comprehensive work of Neumann van Padang and Reck. Fouque's calculation indicated that the ratio of pumice to old lithic material was about 99 to 1.

Eight pages are devoted to the history of Crater Lake which is in fact but a resume of his monograph on that subject which will appear shortly. The arguments that Crater Lake is due

to engulfment should convince the most skeptical of the explosion school. The ancestral cone of Crater Lake is ossumed to have hod a small crater atop its summit at a height of about 12,000 feet. It would seem that a height of about 10,000 feet could account for the glaciotion. The extra 2,000 feet in height would increase the total snowfall but slightly. The top may have been made up of at least two peaks. Such o difference in the originol height would decreose the amount of material that disoppeared from 17 cu. mi. to about 12 cu. mi. The estimate of the volume of the old lava in the ejecta is not over 2 cu. mi. Hence whether the amount engulfed was 12 or 17 cu. mi. affects his orgument not at oll. It is exceedingly hard to follow, however, the argument that the "frothy magma was expelled in so great a volume that instead of being thrown high above the cone it rose but a short distance and falling bock on the slopes of the mountain rushed headlong in a series of glowing clouds (nuees ardentes)." The distributian of the pumice indicates that wind may have been an importont factor in some of the blasts. The "prodigious speed" with which "the avalanches raced down the canyons and spread out on the encircling lowlands for distances as great as 35 miles" may be questioned. Apparently prodigious velocities of translotion were not attoined in the nuees ardentes (horizontal blasts) at Mt. Pele, Soufriere or Lassen. The velocity of the explosian avalanche at Bandai-san was 48 miles an hour.

The four great calderos of Kyusu, Japan, that lie along a north-south line are next token up. Of the numerous calderas to be found in Japan these four receive special treatment because of the greatness of their size and because Aso is the only one well known outside af Japan. The smallest of these, Kikai, has on area of 230 km². Each has a "central cone," though active vent might be a more appropriate term; Sakurajima, for instance, is at the southern rim of the Aira caldera. The subsidence following the 1914 eruption of Sakurajima is nearly symmetrical about the Aira caldera instead of the Sakurajimo cone.

Other cases described under the Krakatau type are Lago di Bolseno in Italy, Mount Gambier in Australia and the Knebel See in Iceland.

Next discussed are calderas whose collopses are occasioned by the lowering of the magma level in the central conduit by dike intrusion injection at depth or lateral outflow at low levels. Kilauea is taken as the type volcano. If explosions accompany the formation of this type, they are phreatic. Sondberg's contention that the walls af Kilauea represent the sides of the originol conduit that has progressively grown smoller until it has reached the very small dimensions of Halemaumau is refuted. In defense of Sandberg's idea, however, it should be remembered that nearly the entire crater was active in 1823 and 1832, not, of course, over a conduit of that size but over a network of feeding fissures. Following a collapse in 1840 involving about one squore mile, the collapsed area rose bodily in some portions at least 200 feet. Since 1891 the active conduit has been restricted to Halemaumau. The sinking of the lovo column in 1919 is attributed to the opening of a lateral fissure. Why not ottribute it to a withdrawal into the depths? If there can be deep-seated pressure increase under a volcano, then why not deep-seated decrease?

Stearns is followed in his belief that Mokuaweoweo is the result of the coalescing of small pit craters fluxed and stopped along the rift zone. However, arguments such as one or more peripheral crocks—not parallel to the rift zone—con be produced pointing to a more widespread collapse at Mokuaweoweo.

Other calderas of the Kilauea type discussed are Nyamlagera in Africo, Batoer on Bali, Medorika in the Kurile Islands, Nemrut Golu in Turkey, and Newberry caldera in Oregan.

Kotmoi is put in a class by itself. The discussion of the volconoes up to Kotmai suggests thot there is a unity in the broader aspects of volcanism. General considerations make one question Fenner's rapid assimilation theory as an explanation of Katmai's activity. This theory is considered a possibility though Fenner himself raised four serious objectians to it.

The discussion of cryptovolcanic calderas is especially interesting as indicating that vestiges of volcanism may still be found in regions long free from orogenic disturbances and quite deeply mantled with sedimentary deposits. Why subterranean explosions are thought to be a necessary accompaniment af such formations is not clear. A decrease of pressure, probably following an increase, and withdrawal of magma into the depth or dike intrusions could account for most of such depressions. The wide distribution of cryptovolcanic calderas is evidenced by the examples offered: Bosumtwi and Nebiewale of the Gold Coast of Africa, the Pretoria Salt Pan af South Africa, the Steinheim Basin and Rieskessel in Germany, and one each in Indiana, Illinois, Kentucky, Ohio, Tennessee, and Utah.

Glen Coe, Scotland, is taken as the type where a caldera results from the collapse af a large cylindrical block along ring fractures. Other calderas described with distinct ring fracture features are those of Ossipee, New Hampshire; Silverton, Colorado; and Buell-Park, New Mexico.

Stromboli is the type for the volcanic sector graben. The sector collapse here has progressed to the northwest producing a series of terrace-like benches. The Somma-vesuvius system is included in this type. As the Vesuvian cone has been built up near the lower western wall of the Somma caldera formed at the time of the 79 A. D. eruption one wonders why it is placed in this group.

Volcanic rents or fissure troughs ore depressions formed on volcanic cones by horizontal movement. Crescentic troughs on several volcanoes of Java appeor to be of this origin.

Some very large depressions related to areal eruptions from extensive fissure systems are classed as major volcano-tectonic depressions. Examples in Sumatra and New Zealand are cited. Such crustal collapses in regions without a large central vent edifice are on a vast scale and not readily apparent as such.

After the discussion of specific volcanoes, 16 pages are devoted to a review af the different theories that have been advanced to account for crater and caldera formations. Serious objections are found to all theories except explosion for small calderas and engulfment for large ones.

This caldera paper is an essential part of the library of every student of volcanoes. No single paper excels it in giving so comprehensive a view of the development of volcanic structures.

Hawaiian Volcano Observatory Report for April-June, 1941.

VOLCANOLOGY

April 1941

There was no visible activity at the Hawaiian Volcanoes during April. A glow was reported over the northeast slope of Mauna Loa the evening of April 1st. It is doubtful if it was of volcanic origin as the moon set at about the time and in the direction of the reported light. There were several earthquakes centering at Kilauea during the last 10 days of the month.

May 1941

Landslides were frequent at Halemaumau during the first half of the month. Pronounced southerly tilting that started on March 10, 1941 continued through April and May.

It appears that many of the Kilauea earthquakes occur at origins deeper than was common at times when molten lava was present as some of the feeble Kilauea shakes are reported as perceptible in Hilo.

June 1941

The 1940 cone in Mokuaweoweo continues to fume quite noticeably. Sulphate and sulphurous deposits are locally conspicuous on last year's lavas.

At Kilauea southwest tilt continued throughout the month. The short period irregularities in the tilt curve and the total accumulated tilt in April, May, and June were greater than common for the past several years. In fact the tilt charts for these months and March resemble those obtained prior to 1924 when there was molten lava in Halemaumau.

Some of the local data for April, May, and June are as follows:

Week Ended	Halemaumau Slides	Halemaumau Crack Openings (Millimeters)	Seismic Disturbances
April 6	1	2.0 closing	13
" 13	0	2.0 opening	9
" 20	3	0.5 "	37
" 27	2	4.0 closing	49
May 4	1	0.5 "	27
" 11	3	1.0 opening	13
" 18	0	0.5 closing	15
" 25	1	1.0 "	28
June 1	0	2.5 opening	14
" 8	2	0.5 "	13
" 15	0	0.0	4
" 22	0	2.5 opening	11
" 29	0	0.5 closing	10

R. H. F.

VOLCANIC ACTIVITY IN THE MARIANAS ISLANDS

An observer reports that on the night of March 28-29, 1941, while passing between the two northernmost islands of the Marianas, fire was observed shooting out of the top and lava flowing down from the volcano on Uracas Island. When first sighted the eruption of this volcano appeared as a bright clear light due to apparent refraction, but later, when closer, it appeared bright near the top and dull red farther down the mountain. It was visible about 40 miles at night. (Hydrographic Bulletin July 2, 1941)

April-June, 1941

SEISMOLOGICAL DATA By P. E. Schulz

* For local seismicity definition see Volcano Letter No. 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory of Hawaii National Park on the island of Hawaii. A new station was established May 22 on Haleokala, Maui, but no disturbances were recorded there during the quarter. Kilauea earthquakes were located by means of the main seismograph station located at the Observatory and the subsidiary stations on Uwekahuna Bluff and near the SE rim of Halemaumau. The more distant shocks were located with the aid of seismograms from Hilo and Kealakekua. The disturbances began recording at the time indicated, and wherever possible a determination of depth of focus has been made.

The number preceding each earthquake date is the serial number of the quake for the current year.

30. April 3, 10:25 am, very feeble, Mauna Loa NE rift near Puu Ulaula.

31. April 6, 5:22 am, very feeble, Mauna Loa NE rift 15 miles from Hilo Bay, depth 20 miles, 19° 38.1' N, 155° 19.3' W.

32. April 6, 5:51 am, very feeble, Mauna Loa NE rift, 19 miles from Hilo Bay, depth 18 miles, 19° 35.5' N, 155° 20.3' W. Reported felt by a few persons in bed at "29 miles," 1.5 miles east of the Observatory.

33. April 20, 1:17 am, very feeble, of Kilauea origin, probably some location as No. 34.

34. April 20, 1:34 am, very feeble, 0.4 mile east of Cone Peak on the Kilauea SW rift, 2.3 miles deep, 19° 23.7' N, 155° 18.3' W.

35. April 20, 2:40 am, slight, location same as No. 34.

36. April 20, 3:33 am, very feeble, location some as No. 34.

37. April 20, 3:51 am, very feeble, Kilauea SW rift, 0.9 mile from Cone Peak at 3,729 foot B. M.

38. April 20, 4:47 am, very feeble, location probably same as No. 37.

39. April 20, 10:46 am, moderate, 0.3 mile sauth of Keanakakoi Crater, depth 1.0 mile, 19° 23.9' N, 155° 16.0' W. Generally felt in the Kilauea area, Kau, and Kano, and by some persons in Hilo.

40. April 22, 6:04 am, very feeble, origin undeterminable.

41. April 24, 7:09 pm, very feeble, central portion of Kilauea Crater.

42. April 25, 2:23 pm, very feeble, location same as No. 41.

43. April 25, 7:36 pm, very feeble, location same as No. 41.

44. April 26, 8:17 am, very feeble, east flank of Mauna Loa about 8.5 miles north of the Volcano Observatory.

45. April 26, 4:10 pm, feeble, Kilauea Crater, 0.9 mile NE of the center of Halemaumau, depth 0.9 mile, 19° 25.1' N, 155° 16.9' W.

46. April 26, 7:13 pm, very feeble, probably Mauna Loa NE rift midway between Hilo and Makuoweoweo. Reported felt by a few persons in Hilo.

47. April 27, 3:08 am, very feeble, SE rim of Kilauea Crater, 1.6 miles deep, 19° 24.4' N, 155° 16.1' W.

48. April 27, 4:47 am, very feeble, SE rim of Kilauea Crater, 0.9 mile deep, 19° 24.4' N, 155° 16.1' W.

49. April 27, 7:16 am, very feeble, center of Kilauea Crater, 1.0 mile deep, 19° 25.0' N, 155° 16.3' W.

50. April 27, 9:12 am, very feeble, probably north of Kilauea Iki.

51. April 28, 1:04 am, very feeble, origin undeterminable.

52. April 29, 7:08 am, very feeble, Kilauea Crater at the 3,646 B. M. just west of Halemaumau, depth 1.0 mile, 19° 24.7' N, 155° 16.8' W.

53. April 30, 10:20 am, very feeble, south rim of Halemaumau, depth 0.8 mile, 19° 24.2' N, 155° 17.2' W.

54. May 1, 9:03 am, very feeble, Kaoiki Pali 2.2 miles SW of the Halfway House on the Momalahoa Highway, depth normal, 19° 20.2' N, 155° 24.3' W.

55. May 1, 8:43 pm, very feeble, probably of Kilouea Crater origin depth fairly great.

56. May 2, 10:53 am, very feeble, adjacent to the Mauna Loa NE rift zone 1.0 mile west of Kiipu Cone, depth normal, 19° 33.3' N, 155° 20.0' W.

57. May 6, 1:46 am, very feeble, Mauna Loa NE rift, 2.5 miles from Mokuaweoweo Crater, depth 7.5 miles, 19° 31.6' N, 155° 31.5' W.

58. May 9, 4:34 am, feeble, east flank of Mauna Loa

half way between Mokuaweaweo and Kilauea Craters, depth about 28 miles, 19° 27.5′ N, 155° 27.6′ W.

59. May 9, 3:23 pm, very feeble, central Mokuaweoweo Crater, depth 15 miles, 19° 29.0′ N, 155° 36.3′ W.

60. May 12, 5:10 am, very feeble, of Kilauea origin, exact locality undeterminable.

61. May 13, 3:47 am, very feeble, about 50 miles from the Observatory, off the SE shore of Hawaii probably on the extension of the Puna rift.

62. May 20, 3:10 am, very feeble, NE rim area of Kilauea Crater.

63. May 21, 8:20 pm, very feeble, junction of the SW rift with the SW rim of Kilauea Crater, depth 1.0 mile, 19° 24.1′ N, 155° 17.7′ W.

64. May 22, 1:59 pm, very feeble, Uwekahuna Bluff of Kilauea Crater, depth 5.0 miles, 19° 25.2′ N, 155° 17.4′ W.

65. May 22, 2:49 pm, very feeble, Kilauea Crater 0.3 mile NE of Halemaumau, depth 2.7 miles, 19° 24.9′ N, 155° 16.8′ W.

66. May 23, 8:25 am, very feeble, of Halemaumau origin, depth shallow.

67. May 23, 9:45 pm, very feeble, 0.8 mile SW of Kilauea Crater, depth 0.8 mile, 19° 24.1′ N, 155° 18.3′ W. Felt by a few persons at "29 miles" and at Hilo.

68. May 24, 11:10 am, very feeble, probably in the north portion of Kilauea Crater.

69. May 24, 6:46 pm, very feeble, east flank of Mauna Loa in the Keawe Wai region.

70. May 25, 6:30 pm, very feeble, 1.4 miles ESE of the Observatory, depth 4.0 miles, 19° 25.8′ N, 155° 14.9′ W. Felt by a very few persons in Hilo.

71. May 26, 1:49 am, very feeble, south of Holemaumau, depth 0.7 mile deep, 19° 24.5′ N, 155° 17.3′ W.

72. June 3, 5:35 pm, very feeble, center of Holemaumau, depth 1.0 mile, 19° 24.5′ N, 155° 17.0′ W.

73. June 4, 7:36 am, very feeble, south of Holemaumau.

74. June 4, 3:18 pm, very feeble, probably near summit of Mauna Loa.

75. June 5, 4:40 pm, very feeble, of Kilauea origin, location undeterminable.

76. June 8, 6:39 pm, very feeble, Mauna Loa NE rift 3 miles SW of Hilo Bay, depth 13.0 miles, 19° 42.7′ N, 155° 07.5′ W. Felt by a few persons in Hilo.

77. June 12, 9:59 pm, very feeble, 10 miles NE of Cape Kunakaki, 17 miles deep, 19° 39.2′ N, 155° 42.5′ W.

78. June 14, 1:33 pm, very feeble, east flank of Mauna Loa probably half way between Mokuaweoweo and Kilauea Craters.

79. June 16, 8:34 pm, very feeble, probably Mauna Loa NE rift in the Puu Kulua area.

80. June 24, 11:22 am, very feeble, of Kilauea origin, exact location undeterminable.

81. June 25, 2:35 am, feeble, SE flank of Mauna Loa, 7.7 miles WNW of the Observatory, depth 2.1 miles, 19° 28.9′ N, 155° 21.6′ W.

82. June 25, 10:54 pm, very feeble, Cone Peak on the Kilauea SW rift, depth 1.3 miles, 19° 23.7′ N, 155° 18.6′ W.

83. June 29, 6:48 am, feeble, Mauna Loa NE rift zone 4.5 miles NE of Puu Ulaula, depth 8.0 miles, 19° 34.5′ N, 155° 26.1′ W. Felt by a few persons at "29 miles."

84. June 29, 8:25 am, feeble, Mauna Loa NE rift 2.0 miles SW of Puu Ulaula, depth 7 miles, 19° 31.7′ N, 155° 26.3′ W.

Teleseisms

April 1, 00h 27m 43s distance undetermined
April 14, 08h 47m 30s distance approximately 3,600 miles

Tilting of the Ground Surface

Several changes have been made in this section of the Seismological Report, which appears at the bottom of this page. It is believed that the changes are justified in that (1) the original data are less manipulated, and (2) the same method is now applied to all 3 tilt stations.

At the Observatory the total accumulated tilt for year ending

April 30: 10.65"N and 10.65"E
May 31: 2.54"N and 10.41"E
June 30: 4.96"S and 7.87"E

MISCELLANEOUS DATA By P. E. Schulz

Crater Angles, Horizontal	Halemaumau Angle	Kilauea Crater Angle
March 4 to April 17	+0.1"	+2.0"
April 17 to May 6	−1.0"	−1.9"
May 6 to June 27	+2.2"	+3.0"
Net Change March 4 to June 27	+1.3"	+3.1"

Kilauea Crack Measurements

During the quarter 3 Halemoumau rim cracks opened 1.0 millimeter each, and 2 opened 1.5 millimeters each; 2 closed 1.0 millimeter each and one closed 1.5 millimeters.

No appreciable changes occurred in the Devil's Throat cracks. Of the remaining Chain of Craters road cracks only #108 parallel to the rim of Alai Crater changed; it opened 1.0 millimeter. Since January 1, 1940, crack #108 has opened 12.5 millimeters.

TILT RECORDINGS AT THE HAWAIIAN VOLCANO OBSERVATORY AND THEIR CONVERSION TO SECONDS OF ARC

By P. E. SCHULZ

The measuring ond plotting of ground tilt is on important factor in volcanologic studies at the Hawaiian Volcano Observatory. The status of this work is summarized in "Tilt Changes ot Kilauea" by H. H. Waesche, Volcono Letter No. 467, January-March 1940.

The purpose of the present article is to show the relationship of the undamped period of the Bosch-Omori seismograph to the conversion factor for stylus displacement to seconds of ground tilt, and the order of mognitude of error in tilt determination which results from the tilting of the instrument itself unless proper corrections are mode.

The curve in Fig. 1 was computed for the Bosch-Omori seismograph from the formula developed in "Tilt Records for Thirteen Years at the Hawaiian Volcono Observatory" by T. A. Jaggor and R. H. Finch, Bulletin of the Seismological Society of Americo, Vol. 19, No. 1, March 1929 which is:

$$\phi = \frac{4\pi^2 L}{g\, T_o^2} \times \frac{D\, s}{A\, l} = \frac{4\pi^2 \times 2.5}{978.236\, T_o^2} \times \frac{1.0 \times .86}{102 \times 24.5} \times 206265$$

where ϕ is the tilt in seconds, L is the reduced length of the pendulum, D is the displacement of the stylus, s and l are the short ond long sides of the pivoted stylus (magnifying arm) respectively, and A is the length of the seismograph boom. The right hand member of the equation is multiplied by 206265 so that the result will be in seconds.

The undamped period of 7.70 seconds of the Bosch-Omori seismograph at Kilouea seems to approach the ideal, for at this value the instrument is a sensitive 2-component tiltmeter whose styli are displaced one centimeter for each 1.21 seconds of tilt, and yet the instrument responds reodily to microseisms, tremors, and local earthquakes. It follows that the registry of teleseisms is not all that could be desired, but the registering of teleseisms is a relatively unimportant part of the work of the Observatory.

Changes in the height of the magnifying lever above the recording drum, which occur from occasional instrumental maintenance, result in slight changes in magnifying lever-stylus length l. In the equation given above for the Bosch-Omori seismograph, however, changes of as much as 5 millimeters in this value do not appreciably alter the conversion factor ϕ.

Tilting of the ground itself, however, may be of sufficient magnitude to change the angle i (between the plumb line and the line joining the 2 suspension points) of the pendulum enough to cause appreciable changes in the undamped period of the instrument, and hence in the conversion factor. This condition exists at Kilauea. The 2 largest tilt-change components for short periods are those of 53 seconds to the narth May 1918 to January 1919, and 81 seconds to the south December 1923 to July 1924. Had the north-south pendulum period been 7.70 seconds at the outset of each, it would have increased or decreased 0.06 and 0.09 seconds respectively depending on whether the pendulum was hung on the south side or the north side of the support. (The Bosch-Omori instrument at the Observatory has its masses suspended on the south and west sides of the supports). From Fig. 1 the conversion factor changes corresponding to 0.06 and 0.09 are 0.03 and 0.04. The net north-south tilting of the ground between the extremes of 1920 and 1939 was 110.0 seconds and the net east-west tilting between the extremes of 1913 and 1918 was 46.4 seconds. The 110.0-second tilt on a 7.70 seconds seismograph period basis causes a change in period of 0.12 seconds with a factor change, from Fig. 1, of 0.06. The 46.4-second tilt results in 0.04-second period increase or decrease in the east-west pendulum with a 0.02 factor change. The approximate averoge annuol range of ground tilt on the northeast rim of Kilauea Crater is 15 seconds north-south and 5 seconds east-west. Even the largest of these figures results in only a 0.02 second period change which does not oppreciobly affect the conversion factor.

The north-south component of the Bosch-Omori seismograph was reoriented July 1, 1941 by rotating it clockwise 7½ degrees into a true east-west position. Since the true tilt varies with cosine of the orientation angle it follows that measured north-south tilt volues were 99 percent of the true north-south tilt values before the reorientation.

The writer is indebted to Mr. R. H. Finch for suggesting the consideration of this subject.

Hawaiian Volcano Observatory Report for July-September, 1941

VOLCANOLOGY

July 1941

The 1940 cone in Mokuaweoweo was observed to be fuming strongly during the latter part of the month. The solfataric deposits on the 1940 lava showed a noticeable increase.

Two earthquakes that occurred on July 8 had their origin at the junction of Waldron and Byron ledges. This would indicate a slight sinking at the northern end of Kilauea Crater. There is evidence in several places that the crater floor has sunk slightly with reference to the crater walls since 1924.

August 1941.

During August, as for the three preceding months, a majority of the earthquakes recorded on the seismographs at the Observatory originated on the northeast slope of Mauna Loa. The rim cracks around Halemaumau showed a distinct opening during the last week of the month. The normal northeast tilt that did not set in until early in July, about two months later than common, continued through most of August.

September 1941

During the first two weeks in September earthquakes of Kilauea origin predominated. An earthquake on September 25 with origin on the east flank of Mauna Loa, about 15 miles from the Observatory, did considerable damage at Kapapala and Pahala. It was strongly felt all over the island of Hawaii and as far northwest as Oahu. The main shaking merged into a continuous tremor that continued for 45 minutes, quite similar in this respect to the shake of September 14, 1919, with about the same indicated origin.—R.H.F.

*For local seismicity definition see Volcano Letter No. 371.

Epicenters of the following local disturbances were determined by means of seismograms from the stations operated by the Hawaiian Volcano Observatory of Hawaii National Park on the islands of Hawaii and Maui. Kilauea earthquakes were located by means of the main seismograph station located at the Observatory and the subsidiary stations on Uwekahuna Bluff and near the SE rim of Halemaumau. The more distant shocks were located with the aid of seismograms from Hilo, Kealakekua, and Haleakala (Maui). The disturbances began recording at the Hawaiian Standard time indicated, and wherever possible, a determination of depth of focus has been made and is given relative to a horizontal plane of 4000 feet elevation passing approximately through the Observatory.

Building construction at the Observatory causing occasional disruptions such as stoppage of the master clock, of the automatic relay circuit, of the seismographs, and of the reception of the radio time signal has rendered the earthquake times given below inaccurate after August 5, 1941.

The number preceding each earthquake date is the serial number of the quake for the current year.

85. July 2, 01:11, very feeble, Mauna Loa NE rift, 1 mile NE of Puu Ulaula, depth 4.8 miles.

86. July 8, 10:14, slight, felt by many persons at Kilauea, NE rim of Kilauea Crater at the junction of Waldron's and Byron's Ledges, depth 0.7 mile.

87. July 8, 20:02, slight, felt generally in the Kilauea area, stronger than No. 86. Location and depth the same.

88. July 9, 15:25, very feeble, NE rim of Kilauea Crater near the Observatory.

89. July 9, 17:53, very feeble, probably on the Mauna Loa NE rift 19 or 20 miles from Hilo.

90. July 11, 21:30, very feeble, probably Mauna Loa NE rift near Hilo, of deep origin.

91. July 12, 17:46, very feeble, SW rim of Kilauea Crater 0.5 mile from the center of Halemaumau, depth 1.0 mile.

92. July 14, 02:40, very feeble, Hilina Pali fault zone about 4 miles south of Kamakaia Hills.

93. July 16, 04:25, very feeble, generally felt in Kona, just north of Akahipuu an the west Hualaloi slope, depth 18.5 miles.

94. July 17, 05:16, very feeble, central portion of Kilauea, of shallow origin.

95. July 18, 05:21, very feeble, Mauna Loa 1.0 mile NE of Kiipu Cone, depth 6 miles.

96. July 19, 07:44, feeble, Mauna Loa NE rift, 20 miles from Hilo, felt by few persons in Hilo, depth 8 miles.

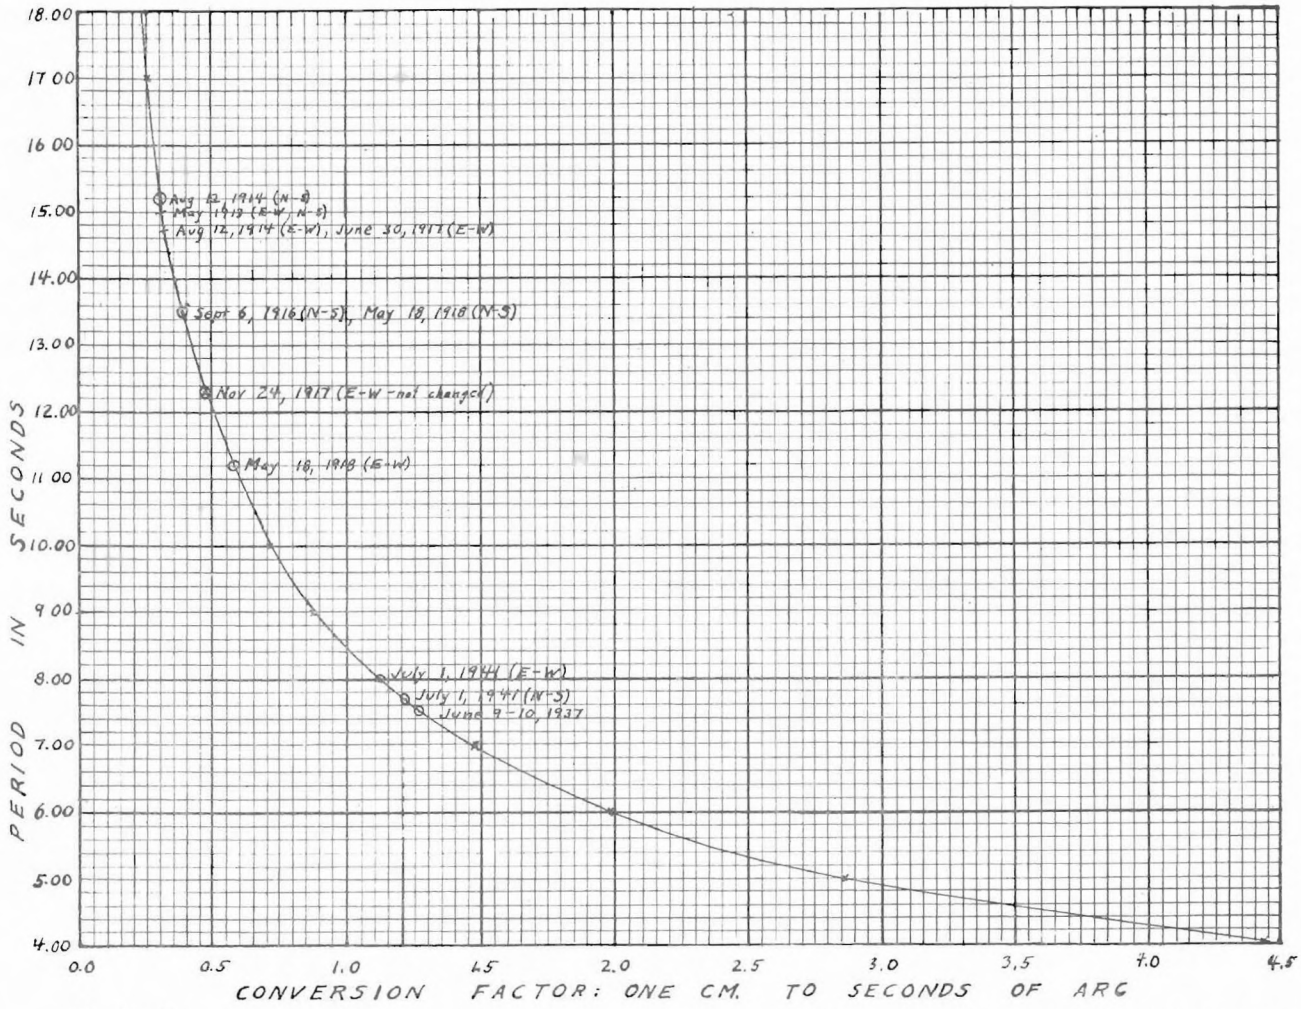

Fig. 1. Curve computed for the Bosch-Omori Seismograph pen arm displacement resulting from tilting of the ground.

97. July 21, 13:20, very feeble, Mauna Loa NE rift, 4 or 5 miles of Puu Ulaula, depth about 8 miles.

98. July 25, 13:31, very feeble, Kaoiki fault, 3.3 miles west of 3913 BM, Kilauea SW rim, depth 2.7 miles.

99. July 28, 03:07, very feeble, 1.1 miles ENE of Puu Ohale, depth 2 miles.

100. July 28, 07:31, very feeble, summit of Mauna Loa, 1.2 miles west of Mokuaweoweo, depth about 15 miles.

101. July 28, 08:32, very feeble, Mauna Loa, probably in the summit area, depth moderate.

102. July 30, 17:14, very feeble, Kilauea Crater area, of shallow origin.

103. August 1, 05:50, very feeble, Hilina Pali fault system, 3.0 miles NW of Apua Point, felt by a few persons in Hilo, depth 9 miles.

104. Aug. 2, 07:56, very feeble, Kilauea Crater, 0.2 mile west of Byron's Ledge, depth 1.0 mile.

105. Aug. 2, 10:30, very feeble, east flank of Mauna Loa, 5.3 miles NW of Uwekahuna, felt by a few persons at "29 miles," 1 mile east of the Observatory, depth 4.3 miles.

106. Aug 2. 13:21, very feeble, of Halemaumau origin, shallow depth.

107. Aug. 2, 20:09, very feeble, SW rim of Kilouea Croter, shallow depth.

108. Aug. 3, 11:16, very feeble, Puna rift, 0.1 mile NW of Devil's Throat, depth 1.5 miles.

109. Aug. 3, 12:43, very feeble, Puna rift, 0.1 mile east of Kokoolou Crater, depth 1.4 miles.

110. Aug. 3, 21:00, very feeble, probably along the Puna Rift near Kilauea Crater.

111. Aug. 3, 23:29, feeble, Puna rift, 0.2 mile north of Kokoolau Crater, depth 1.5 miles.

112. Aug. 4, 01:28, feeble, Puna rift, Kokoolau Croter, of shallow depth.

113. Aug. 4, 01:31, very feeble, Kilauea Crater probably near Byron's Ledge, shallow depth.

114. Aug. 5, 11:14, very feeble, probably Mauna Loo NE rift 4 or 5 miles NE of Puu Ulaula.

115. Aug 6, 17:15, very feeble, of Kilauea origin, possibly near the NW rim of the Crater.

116. Aug. 8, 22:28, very feeble, probably Mauna Loo NE rift area about 5 miles NE of Puu Ulaula.

117. Aug. 10, 09:32, very feeble, summit of Mauna Loa, 1.2 miles NE of Mokuaweoweo Crater, depth 12 miles.

118. Aug. 12, 22:40, very feeble, Mauna Loa NE rift, 8.0 miles NE of Puu Ulaula, depth 6 miles.

119. Aug. 14, 03:09, very feeble, Kilauea east flank 4.0 miles WSW of Pahoa, depth 16 miles.

120. Aug. 15, 17:?, very feeble, Mauna Loa NE rift probably about 6 miles NE of Puu Ulaula.

121. Aug. 17, 00:02, very feeble, Mauna Loa NE rift, Pukauahi Crater, depth 6 miles.

122. Aug. 22, 09:36, very feeble, Kilauea Crater, originated in the Halemaumau area at shallow depth.

123. Aug. 22, 11:04, very feeble, same as No. 122.

124. Aug. 27, 16:10, very feeble, probably in the vicinity of Hilea.

125. Aug. 28, 04:37, very feeble, Hilo 2.3 miles NW of the center, depth about 20 miles, felt by a few persons.

126. Aug. 30, 04:17, very feeble, Kilauea Crater, probably east central portion, of shallow depth.

127. Aug. 30, 17:56, very feeble, Kealakekua Bay, felt by a few persons in Kona, depth probably about 4 miles.

128. Sept. 1, 03:59, very feeble, Kilauea Crater central portion, felt by a few persons at Kilauea and "29 miles," of shallow depth.

129. Sept. 2, 01:10, very feeble, SE rim of Kilauea Crater, depth 0.8 mile.

130. Sept. 2, 10:08, very feeble, central Kilauea Crater, of shallow origin.

131. Sept. 2, 23:47, very feeble, probably 21 miles N of Hilo, depth 10 or 12 miles.

132. Sept. 5, 14:59, very feeble, 2.6 miles W of Uwekahuna near Kaoiki Pali, depth probably 10 miles.

133. Sept. 5, 21:26, very feeble, probably Puna rift near Heiheiahulu Crater.

134. Sept. 6, 18:34, very feeble, SE rim of Kilauea Crater 0.3 mile from Byron's Ledge junction, depth 3.5 miles.

135. Sept. 7, 03:20, very feeble, Kilauea Crater 0.2 mile SW of Halemaumau, depth 1.0 mile.

136. Sept. 7, 14:41, very feeble, pali NW of Kaoiki fault 3.9 miles west of Uwekahuna, depth 3.4 miles.

137. Sept. 7, 19:26, very feeble, Kilauea Crater, 0.2 mile south of 3646 BM, depth 0.8 mile.

138 Sept. 8, 09:20, very feeble, probably east central portion of Kilauea Crater.

139. Sept. 8, 16:25, very feeble, east rim of Keanakoi Crater, depth 2.7 miles.

140. Sept. 8, 17:29, very feeble, NE portion of Kilauea Croter.

141. Sept. 9, 08:35, very feeble, 0.2 mile SE of Kilouea Croter near Keanokakoi, depth 1.5 miles.

142. Sept. 11, 15:17, very feeble, Kau Desert, 0.4 mile north of Cone Peak, depth 6.8 miles.

143. Sept. 14, 11:57, very feeble, probably NE central portion of Kilauea Crater.

144. Sept. 15, 01:48, very feeble, 2.0 miles east of the Observatory.

145. Sept. 16, 01:51, very feeble, 2.0 miles west of the south end of Pauahi Crater, depth 2 miles.

146. Sept. 18, 12:24, very feeble, probably of Halemaumau origin.

147. Sept. 19, 00.04, very feeble, SW portion of Mokuoweoweo Croter, depth 19 miles.

148. Sept. 19, 19:13, very feeble, NE portion Kilauea Crater.

149. Sept. 21, 16:42, very feeble, 0.3 mile SW of the center of Halemaumou, depth 1.7 miles.

150. Sept. 25, 02:07, very feeble, center of Kilauea Crater, depth 1.5 miles.

151. Sept. 25, 07:18, moderate to strong, SE flank of Mauna Loa 4.0 miles north of Kapapala Ranch House, depth 7.0 miles. Felt sharply over the whole island of Hawaii and by some persons in Honolulu. Dismantled all seismographs on the island of Hawaii (low magnification instrument not in operation) and at Haleakala on Maui. Several thousand dollars worth of damage done at Pahala where safes were moved over 1 inch northward, plaster cracked, pipes were sprung, roadfills cracked and some shoulders failed, furniture overthrown and dishes were broken in homes, pharmaceuticals at the Pahala hospital, chemicals in the Pahala Sugar Laboratories and package goods in stores were thrown from shelves. Some persons were injured in flight from houses. At Kapapala Ranch two windows and many dishes were broken, several stone walls were partially thrown down. No disturbance of the sea was reported observed at Punaluu. At Kealakekua a few books were thrown from shelves but no damage was reported. Boulders were shaken loose from steep slopes at the head of Wood Valley and on Hilina Pali. Numerous slides from Halemaumau's walls caused great dust clouds, but no damage was reported in the Kilauea area. Hilo also was strongly shaken but with only slight effect; an old earthquake crack in one building reopened. Residents in the Pahala and Kapapala area were agreed that this earthquake was stronger than any since 1929 and many claimed it was the strongest in 30 to 50 years.

152. Sept. 25, 07:30, feeble, approximately same location as No. 151, but probably deeper, sharply felt at Pahala and Kapapala.

153. Sept. 25, 07:43, feeble, probably near Ainapo, depth perhaps 20 miles, sharply felt at Pahala and Kapapala.

154. Sept. 25, 08:28, very feeble, 2.0 miles NE of Kapapala Ranch house, depth 7.0 miles, felt generally at Pahala and Kapapala.

155. Sept. 25, 09:51, very feeble, Kilauea Crater, probably of shallow Halemaumau origin.

156. Sept. 25, 10:54, very feeble, same as No. 155.

157. Sept. 25, 13:25, very feeble, SE flank of Mauna Loa, 4.0 miles NNW of Kapapala Ranch house, depth 7.0 miles, felt by many persons at Kapapala and Pahala.

158. Sept. 28, 14:11, feeble, Mauna Loa NE rift near Puu Ulaula, depth of the order of 20 miles; felt by some persons in Hilo and at "29 miles."

159. Sept. 30, 11:32, very feeble, Kilauea Kau rift 0.6 mile SE of Cone Peak, depth 2.3 miles.

160. Sept. 30, 11:32, feeble, Kilauea SE rim just SW of Keanakakoi Crater, depth 3.7 miles.

161. Sept. 30, 12:28, slight, Kilauea Kau rift, 1.2 miles SW of Cone Peak, depth 2.0 miles.

Teleseisms: Hawaii Standard time of first wave arrival used; J. S. A. data gives time of origin in Greenwich Time.

July 26, 09: 41 (?), unidentified phase; J. S. A. provisional data 20: 11: 21, 19°.1 N, 142°.2 E.

July 29, 15: 29, weak, undetermined, short period; J. S. A. data 01: 51: 28, 60°.7 N, 149°.5 W, shallow.

Aug. 2, 01: 21, distance 3775 miles; J. S. A. data 11: 41: 25, 30°.3 S, 177°.8 W possibly fairly deep.

Sept. 4, 00: 01, undetermined, recorded at Pasadena.

Sept. 13, 08: 03, undetermined.

Microseismic Motion

	July	August	September
Light	1—31	1—31	1-4, 7-30
Moderate	None	None	5, 6
Strong	None	None	None

Crater Angles, Horizontal: Measured from the 3974-foot bench mark on the NE rim of Kilauea Crater. Between June 27 and July 22, the Halemaumau angle closed 0.5" while the Kilauea Crater angle opened 3.5". Additional measurements were prevented by construction and weather conditions.

Kilauea Crater Levels

A level circuit was run from the SE crater rim to the Spit BM. From thence it was run via the Pit Seismograph counter clockwise around Halemaumau in a complete circuit. The results show an appreciable decrease in elevation of points adjacent to Halemaumau with respect to the Spit BM. Between January 16 and August 14-25, the level changes were:

South side crack #43	— 0.060 meter	(.1969 feet)
NW Pit BM	— 0.035 meter	(.1148 feet)
West Tilt Station	— 0.032 meter	(.1050 feet)
Pit Side Crack #40	— 0.029 meter	(.0952 feet)
Pit Seismograph BM	— 0.031 meter	(.1017 feet)

Crack Changes

On Friday of each week, 28 stations on rim cracks around Halemaumau were measured. During the quarter, there was a general increase in both the number of and amount of crack changes, especially in the case of openings. The total of 41 measured crack openings for the quarter amounted to 34.5 millimeters. Of these the least weekly opening was measured on July 25 and August 1, when in each instance only one crack opened 0.5 millimeter. Largest crack openings were recorded August 29, when 7 cracks opened 4.0 millimeters and September 26, when 7 cracks opened 13.5 millimeters. The largest opening unquestionably resulted from the earthquake of September 25. The total of 38 measured crack closings during the quarter amounted to 21.5 millimeters. July 4 revealed no closing; greatest closing was recorded September 26, when 8 cracks closed 6.5 millimeters.

Monthly measurements of 9 Chain of Craters cracks also showed progressive openings: July 25, none opened, and 3 closed 1.5 millimeters, on August 29, 3 opened 4.5 millimeters, and none closed, and on September 26, 6 opened 5.5 millimeters, and one closed 2.0 millimeters.

The Aloi rim crack showed a uniform rate of opening during the entire quarter save the last week in September when an opening of 7.0 millimeters was recorded due no doubt to the earthquake of September 25. The total opening of this one crack for the quarter was 15.5 millimeters.

The 5 rim cracks around Devil's Throat showed no appreciable change.

Tilt

The following tables give a summary of the tilting of the ground as measured at 3 stations on the summit of Kilauea Volcano. The ** sign indicates approximation only because of loss of tilt records from September 14 to 28 resulting from reconstruction in the seismograph cellar.

LAVA FLOWS IN EASTERN PUNA

By GORDON A. MACDONALD
Associate Geologist, U. S. Geological Survey*

Introduction. Only once since the beginning of written records in Hawaii have lava flows inundated part of eastern Puna. That once was in 1840. But there is ample evidence that in geologically recent times Puna has often been the site of eruption of cinder cones and extensive lava flows. More than sixty cinder and spatter cones dot the east rift zone of Kilauea volcano from the end of the Chain of Craters Road to Cape Kumukahi. Some are 150 to 200 feet high and half a mile or more in diameter, and others are mere hillocks. It is probable that all of the surface lavas throughout this region should be considered geologically Recent, but many of them are of such late date that it is surprising not to find more mention of them in native tradition. Few references to prehistoric lava flows have been preserved by the Hawaiian chroniclers however, perhaps because eruptions were so commonplace.

Much of the northeastern slope of Kilauea between the towns of Olaa and Pahoa is covered by flows of pahoehoe basalt that cannot be more than a few hundred years old. Not only are they nearly devoid of any soil or ash cover, but the vegetation which covers them is often scant and is of the type composed largely of small ahia trees and abundant staghorn fern which characterizes the younger lava flows, such as those of 1793 (?) and 1840. Through these younger lavas protrude **kipukas**, or "islands" of older rock, covered by several inches of ashy soil and the tree-fern jungle which typifies the more mature forests of Puna. Although these late lavas must certainly have been erupted within the time of residence of the present Hawaiian people, who are believed to have arrived in the islands about 1100 A.D.,[1] no mention of them is found in native tradition.

Traditional prehistoric eruptions. A few eruptions recorded by tradition before the arrival of the missionaries in 1820 may be mentioned. The dates are, of course, uncertain. The earliest is an eruption near Kapoho, probably between 1340 and 1380 A.D.[2] This eruption is incorporated in a legend which relates how Pele, goddess of volcanoes, attended in disguise a great **holua**, or sliding contest, held near Kapoho by Kahawali, the chief of the neighborhood. Challenging Kahawali to a race, Pele was badly beaten. She then asked the chief to lend her his sledge so that she might try again. When he refused, the angry goddess stamped upon the earth, and there burst forth showers of heated rocks. Realizing too late the identity of his competitor, the chief fled panic-stricken to Puu Kukii and then northward to the coast, pursued all the way by Pele's magmatic missiles. A crack trending N 60° E, which still exists between Kapoho and Koae, is said to have opened up before him, but he crossed it by laying down his spear for a bridge. Not until he had paddled far out to sea did he escape.

Translating this story into terms of the modern volcanologist, a flank eruption of Kilauea appears to have commenced with the opening of a fissure and the ejection of cinders at Kaholua o Kahawali (Kahawali's holua-slide). As the fissure opened farther and farther down the flank of the mountain the eruption progressively shifted farther seaward, building the line of small cinder and spatter cones which terminates at Kapoho.

Another eruption is said to have occurred near Kaimu in the reign of Alapai, probably between 1730 and 1754.[3] This eruption probably produced the fresh-appearing aa flow crossed by the Pahoa-Kalapana road a mile north of Kaimu. At this altitude the lava is covered only by lichens and moss, and appears as fresh as the 1922 lava in Napau Crater. But farther mountainward, in regions of greater rainfall, it supports thick vegetation, although not much more than the 1793 (?) and 1840 lavas.

Eruption of 1793 (?). When William Ellis, in 1823, questioned the natives about early eruptions of Kilauea, part of the meager information he elicited was mention of an eruption thirty years or so before.[4] The eruption was said to have produced voluminous lava flows contiguous to the cones of Honuaula, Puulena, and Kaliu, along the east rift zone of Kilauea, 3½ to 7 miles southwest of Kapoho. The boundaries of this lava flow as shown in the accompanying figure were mostly mapped by the topographers of the U. S. Geological Survey in 1922 (Kalapana quadrangle), but it was labeled "Lava flow of 1840." However, the distribution of the lava fits so well the traditional description of the 1793 (?) flow that there can be little doubt that it originated at that time. The lava differs in composition from the adjacent flow which reached Nanawale Bay in 1840, and moreover the map prepared by Commodore Wilkes only a few months after the 1840 eruption does not show the 1840 lava approaching within a mile of the line of

cinder cones.[5] The 1793 (?) lava issued from fissure vents and is largely pahoehoe. Lava trees are well preserved along the narrow northern tongue of the flow north of the Pahoa-Kapoho road and northwest of Puu Honuaula.

Eruption of 1840. The only large eruption which has occurred in eastern Puna since the advent of white men in Hawaii is that of 1840. The eruption was not witnessed by white men, but the region was traversed shortly afterward by Father Coan, who for 40 years was the faithful chronicler of Hawaiian volcanoes, and by Commodore Wilkes, Dr. Pickering, James D. Dana, and other members of the United States Exploring Expeditian. The outbreak commenced with the appearance of lavas in Alae Crater, a pit crater near the Chain of Craters Road, on May 30.[6] The lava level rose about 300 feet in the pit crater but fell again when new eruptions appeared on the flanks of the lava cone Kane Nui o Hamo, and north and west of Napau Crater. The spatter left at the "high water mark" in Alae Crater was examined soon afterward by Dr. Pickering. Cracking continued along the east rift zone toward Kapoho, fissures a few inches to 10 or 12 feet wide being opened, but no lava reached the surface. Finally, on June 1, the principal flow commenced near the present Pahoa-Kalapana road. Three days later it reached the sea at Nanawale Bay, and it continued to flow into the sea for three weeks, building out the shore line about a quarter of a mile.

Where the lava encountered sea water, violent steam explasions resulted, and the liquid lava was hurled into the air as by a giant atomizer, to be drifted inland by the wind or heaped into small hills of glassy sand on the fresh lava at the edge of the water. Three of these hills were built, ranging in height from 150 to 250 feet, but because of their unconsolidated nature and their exposure to the full impact of the ocean waves and the nearly constant northeast trade winds, they were rapidly eroded away. There are now only two of them left, and the highest is only 78 feet high.

Coan[7] tells of a man who went to watch the 1840 flow and, wishing to take no chances, stopped some distance away on

open lava, whence he had a good view of the moving stream. He was therefore considerably startled suddenly to find the lava crust rising beneath his feet. Escaping from his dangerous position, he looked back and saw that where he had stood the crust had been buckled up to a height of 15 or 20 feet, and that liquid lava was escaping through crevices. This man appears to have had the unusual experience of standing on an actively developing tumulus.

Hawaiian Volcano Observatory Report for October - December 1941

VOLCANOLOGY

October 1941

Conspicuous fuming at Mokuaweoweo was noted early in the month. The majority of the October earthquakes were of Kilauea origin. The widely felt earthquake of October 25 had its origin near Waimea well down the northwestern slope of Mauna Kea. It was deep seated and may well have originated along the fundamental NW-SE rift of the Hawaiian ridge.

November 1941

As the month progressed it was found that the earthquakes of October 25 and November 8 were premonitory of the swarm of shakes that started at Waimea on the north slope of Mauna Kea on November 13. The shaking was more or less continuous, and by December 7 over 2,000 quakes had been recorded on the Mauna Loa seismograph, the instrument nearest the epicenter. No cracks were observed at the surface in the epicentral area. The characteristics of the shaking indicated that the focus extended into a region with an appreciable degree of mobility. This is not surprising when one considers that the quakes originated 27 miles below the surface.

December 1941

Immediately following the Waimea shakes, which ceased on December 8, there commenced a seismic lull that continued through the rest of December. There are some reasons for thinking that such a seismic lull indicates a high or increasing lava pressure under Hawaiian volcanoes.

* For definition of local seismicity see Volcano Letter No. 371.

The data of the following local disturbances was determined from six seismograph stations operated on the islands of Hawaii and Maui by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. Distances are from Observatory.

The number preceding each earthquake date is the serial number of the quake for the current year.

162. October 7, 14:29, very feeble, distance 14 miles.

163. October 8, 05:24, very feeble, distance 16 miles NE slope, Mauna Loa.

164. October 10, 11:22, very feeble, distance 3 miles SW of Kilauea.

165. October 12, 08:07, very feeble, distance 4 miles SW of Kilauea.

166. October 20, 00:47, very feeble, N slope of Mauna Kea.

167. October 20, 00:51, feeble, near Mokuaweoweo.

168. October 25, 08:54, feeble, N slope of Mauna Kea near Waimea, generally felt on island of Hawaii.

169. October 28, 01:46, very feeble, distance 4 miles.

170. October 28, 08:06, slight, NE rift of Mauna Loa.

171. October 28, 08:07, very feeble, beginning in No. 170.

172. October 28, 08:15, feeble, distance 9 miles.

173-176. October 28, four very feeble shakes during forenoon.

177. October 29, 05:10, very feeble, distance 7 miles.

178. October 29, 08:54, very feeble.

179. October 29, 09:42, feeble, distance 7 miles.

180. October 29, 11:30, very feeble.

181. October 30, 08:31, very feeble.

182. October 30, 18:00, slight, distance 7 miles.

183. October 31, 11:51, slight, distance 7 miles.

184. November 2, 00:20, feeble, P uncertain.

185. November 8, 13:20, very feeble, distance 58 miles.

186. November 9, 05:44, very feeble, distance 16 miles NE slope of Mauna Loa, felt in Hilo.

187. November 11, 02:41, very feeble, distance 16 miles, felt locally.

188. November 13, 20:07, feeble, distance 52 miles, felt in Waimea.

189-196. November 14, 00:51-17:34, eight very feeble shakes, distance 58 miles, felt plainly at Waimea and lightly at widely scattered points on island of Hawaii, depth 27 miles.

197. November 15, 06:53, slight, distance 52 miles, 27 miles deep near Waimea, Hilo instrument dismantled.

198. November 15, 13:27, very feeble, felt in Waimea.

199. November 15, 18:37, feeble, distance 52 miles, felt generally in northern part island of Hawaii.

200. November 16, 02:31, feeble, distance 52 miles, near Waimea, depth 27 miles.

201. November 16, 02:35, very feeble.

202. November 16, 09:41, moderate, origin near Waimea 52 miles away and 27 miles deep, generally felt over island of Hawaii, some slight damage, instruments dismantled.

203-207. November 17, five very feeble shakes originating near Waimea.

208. November 18, 02:56, moderate-strong, strongly felt on entire island and to a lesser degree on Maui, near Waimea, slight damage, 27 miles deep.

209-210. November 18, two very feeble shakes, origin near Waimea.

211. November 18, 10:30, feeble, generally felt over island.

212. November 18, 10:33, feeble, generally felt over island.

213-216. November 18, four very feeble shakes with origin near Waimea.

217. November 19, 07:43, feeble, distance 52 miles, widely felt.

218-219. November 19, two very feeble shakes, origin near Waimea.

220. November 22, 10:04, feeble, near Waimea.

221-222. November 22, two very feeble Waimea shakes.

223. November 22, 21:23, slight, near Waimea, generally felt on island of Hawaii and by a few persons on Maui.

224. November 22, 22:12, very feeble, felt in Waimea.

225. November 24, 18:02, very feeble.

226-228. November 30, three very feeble Waimea shakes.

229. December 4, 09:30, very feeble, distance 52 miles, near Waimea.

230. December 6, 09:44, very feeble, distance 4 miles.

231. December 13, 23:15, very feeble.

232. December 18, 13:00, very feeble.

233. December 20, 15:30, very feeble.

234. December 24, 09:54, feeble, distance 5 miles.

235. December 30, 14:22, feeble, distance 5 miles.

Teleseisms

December 5, 10:29, distance 4,700 miles.

Microseismic Motion

Microseisms were light throughout the quarter.

Crack Changes

Crack movement around Halemaumau and along the Chain of Craters for the quarter was slight. Opening of the crack predominated over closing but most cracks remained unchanged.

Tilting of the Ground

The southeast Halemaumau station showed a slight accumulation of northerly tilt during the quarter. The accumulation of tilt at the west Halemaumau station was very slight to the ENE.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** maintain outside seismograph stations and supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter,** a quarterly record of the Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE VOLCANO LETTER

No. 475 | Department of Interior | National Park Service | January-March, 1942

Published by the University of Hawaii. HAWAII NATIONAL PARK: Edward G. Wingate, Superintendent; R. H. Finch, Volconologist. UNIVERSITY OF HAWAII: T. A. Jaggar, Geophysicist.

THE PHYSICAL PLANT—HAWAIIAN VOLCANO OBSERVATORY

BY P. E. SCHULZ

A new physical set-up is resulting in a material improvement at the Volcano Observatory, Hawaii National Park. The tearing down of the old Observatory buildings on the brink of the northeast rim of Kilauea crater was completed in September. The first unit of the Hawaiian Volcano Observatory was built in 1912 by the Hawaiian Volcano Research Association. Additions were made thereto from time to time in subsequent years. The old structures have been razed to make their site available for the new hotel in Hawaii National Park—the Volcano House. The seismograph cellar, however, remains, and a reinforced concrete slab has been emplaced over it. The slab is covered with about 18 inches of soil. This covering coupled with the location over steam cracks results in a nearly constant temperature cellar. The diurnal variation seldom exceeds 1°F. There the Bosch-Omori seismograph will continue to function in situ as the nucleus of the instruments of the Observatory.

During the wrecking operations and construction, tilt records (pen wanderings with respect to reference lines on seismograms) were lost or useless for 2 weeks in September, 1941, but only 3 days' seismograms were lost. The latter break in record was reasonably well filled by the records from outlying stations. The low magnification and vertical component instruments were taken out of service August 17, 1941. The former will be reinstalled in the old seismograph cellar.

The new quarters of the Hawaiian Volcano Observatory are in the Volcano Observatory and Naturalist Building, which is nearing completion, approximately 610 feet east-northeast of the old site. It will be provided with fireproof rooms for the storage of the official records of the Observatory and with ample office, machine shop, drafting, and library space. A seismograph cellar is also provided, and here the vertical component seismograph has been installed. A simple 2-component horizontal pendulum-type tilt meter is also being installed. This cellar is also built over a steam crack and but slight diurnal and seasonal temperature variations are indicated. In the near future a Hawaiian-type seismograph will be added, possibly to be replaced ultimately with a high magnification instrument.

The new physical set-up is a step forward. The most important implication may be the operation of seismographs and tilt meters in the area about 640 feet from the sheer, 220-foot cliff of Kilauea crater, at the base of which fault blocks and talus descend another 250 feet to the crater floor, and the concurrent maintenance of additional seismographs on the old site only about 30 feet from the cliff. It is expected that there will be a difference in the daily and seasonal tilt, and in the character and amplitude of local earthquakes as recorded in the two locations.

Hawaiian Volcano Observatory Report for January-March, 1942

VOLCANOLOGY

January

The seismic lull that started on December 8, 1941 continued through the month of January. More earthquakes were recorded on Mauna Loa than at Kilauea. There was no surface manifestation of volcanic activity at any Hawaiian volcano during January.

February

The history of Mauna Loa indicates that a flank eruption can be expected during 1942. An earthquake on February 8 on the northeast rift 8 miles southwest of Hilo with a depth of 30 miles was the first definite premonitory symptom in 1942 of such an eruption. A subsurface splitting progressed up the northeast rift, the foci of the earthquakes became progressively shallower. A series of earthquakes on February 21 near the source of the 1852 flow had a depth of 5 miles.

An earthquake at 00:09 February 18 which originated 8 miles under the northern end of Kilauea crater may well have been directly connected with the growing uneasiness of the Mauna Loa-Kilauea system. Coincidental with the occurrence of this shake there commenced a slight northerly tilt at the Observatory that continued until the last of March. It should be borne in mind that before there can be a northerly tilt at this time of year the pressure increase must first be sufficient to overcome the normal southerly tilt.

March

The progressive cracking along the northeast rift of Mauna Loa continued in March, first showing epicenters high up on the northeast rift, then under Mokuaweoweo, and finally on March 21 some distance down the southwest slope. When earthquakes were resumed along the northeast rift on March 28, it seemed safe to predict that Mauna Loa would soon erupt from this rift. Such a forecast was written but not published, owing to war conditions.

Tilt records for March continued and strengthened the indications that Kilauea was reacting sympathetically to Mauna Loa's preparation for an outbreak. The E-W tilt curve for March was marked by pronounced irregularities, which is what might be expected to accompany an increase of internal pressure. Records show that irregularities are more prominent when Halemaumau is active than in times of quiet. The northerly tilt, however, was insufficient to indicate that a breaking of the Halemaumau seal could be expected.—R.H.F.

*For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. Distances are from the Observatory.

The number preceding each earthquake date is the serial number of the quake for the current year.

1. January 2, 13:13, very feeble, felt in Kona.
2. January 9, 13:35, feeble, distance 25 miles.
3. January 9, 14:20, feeble, distance 3 miles, felt locally.
4. January 10, 15:20, very feeble, distance 2 miles.
5. January 12, 15:45, very feeble.
6. January 15, 17:36, very feeble, distance 4 miles.
7. January 18, 05:39, very feeble, distance 17 miles.
8. January 25, 06:13, slight, distance 16 miles, plainly felt locally, broke a few dishes at Kilauea Military Camp.
9. January 26, 22:17, very feeble.
10. January 28, 09:21, very feeble, distance 14 miles.
11. January 29, 09:38, very feeble, northeast rift of Mauna Loa.
12. February 8, 17:48, slight, 8 miles SW of Hilo, 30 miles deep, felt locally, Hilo instruments dismantled.
13. February 8, 19:56, very feeble, same location as No. 12.
14. February 18, 11:09, moderate, 8 miles deep, under northern end of Kilauea crater, awakened many people, dismantled local and Mauna Loa seismographs.
15. February 21, 08:11, moderate, distance 15 miles on NE rift of Mauna Loa, 5 miles deep, all island seismographs dismantled, widely felt.
16. February 21, 08:14, moderate, same as No. 15, only one seismograph recording at beginning.
17. February 21, 08:36, slight, same location as Nos. 15 and 16, E-W dismantled.
18. February 21, 10:01, very feeble.
19. February 21, 20:15, very feeble.
20. February 21, 20:32, feeble, distance 15 miles.
21. February 21, 22:28, very feeble.
22. February 22, 04:12, feeble, distance 14 miles.
23. February 22, 14:47, slight, distance 16 miles.
24. February 22, 15:05, slight, distance 15 miles.
25. February 23, 22:31, very feeble.
26. February 24, 15:34, very feeble.
27. February 26, 14:11, very feeble.
28. March 5, 12:46, very feeble, felt at Kapapala.
29. March 5, 13:14, very feeble.
30. March 7, 06:41, slight, under northern end of Mokuaweoweo.
31. March 13, 21:20, very feeble.
32. March 15, 09:35, slight, E-W dismantled, near southern end of Mokuaweoweo.
33. March 15, 11:00, very feeble.
34. March 15, 12:24, very feeble, southwest of Mokuaweoweo.
35. March 15, 12:39, very feeble.
36. March 15, 23:43, feeble, southwest rift of Mauna Loa, felt in Kona.
37. March 16, 07:08, feeble, near southern end of Mokuaweoweo, felt in Kona.
38. March 16, 21:57, slight, E-W dismantled, near southern end of Mokuaweoweo, felt in Kona.
39. March 18, 11:21, very feeble, SW rift of Mauna Loa.
40. March 18, 15:16, very feeble, northern end of Mokuaweoweo.
41. March 19, 00:17, slight, E-W dismantled, near Mokuaweoweo.
42. March 20, 01:34, very feeble.
43. March 20, 23:05, moderate, dismantled instruments, widely felt, stopped clocks in South Kona, on SW rift of Mauna Loa.
44. March 21, 01:34, very feeble.
45. March 21, 20:14, feeble, SW rift of Mauna Loa, felt in South Kona.
46. March 25, 09:14, very feeble.
47. March 28, 21:55, slight, NE rift of Mauna Loa, felt locally and in Hilo.

Teleseisms

January 19, 20:00, slight.
March 19, 01:46, slight.

Microseismic Motion

Microseisms were very light throughout the quarter.

Tilting of the ground

The southeast Halemaumau station showed a slight NNW tilt for the quarter, while the tilt at the west station was slight to the ENE.

Table of Tilt at Observatory on NE rim of Kilauea

	Week Ended	Amount of tilt	Direction of tilt
January	4	1.21″	S 45° W
	11	1.69″	E
	18	2.06″	N 32° W
	25	1.81″	S 71° E
February	1	2.81″	S 31° W

THE 1942 ERUPTION OF MAUNA LOA

By R. H. FINCH

The expected eruption of Mauna Loa began on April 26, 1942 when a line of fountains appeared in the northern part of Mokuaweoweo and for a short distance down the northeastern rift. The summit of Mauna Loa was obscured by clouds at the beginning of the outbreak, though the recording of continuous tremor on the seismographs indicated that it began a little after 5:00 P.M., daylight-saving time, (4:00 P.M., H.S.T.).

The events leading up to the eruption were of especial interest, as they made it possible to predict both the approximate time and place of the outbreak. The history of Mauna Loa teaches us that it is periodic in its activity. After reviewing the historical record, Dr. T. A. Jaggar wrote in 1937 that a lava flow from the northeast rift of Mauna Loa could be expected anytime from 1942 on. The summit eruption of 1940 made 1942 a year with very definite prospects for a flank eruption. Such a historical background gave one complete confidence that an eruption was imminent when seismological evidence pointed to the same conclusion.

Possibly the seismic prelude to the 1942 eruption may be thought of as starting with the seismic crisis near Waimea in November and December, 1941, when about 2,000 earthquakes with depth of focus of about 27 miles occurred. Such shakes indicate an adjustment along the southeastern part of the fundamental Hawaiian rift, though the records were insufficient to show conclusively whether the shaking accompanied an increase or decrease in pressure. Most of the evidence, however, indicated a pressure increase.

On February 8, 1942, an earthquake occurred 8 miles southwest of Hilo, with an indicated depth of 30 miles. The origin was 37 miles southeast of the Waimea shakes and underneath the extension of the northeast rift of Mauna Loa. There was a progressive movement of the epicenters of the earthquakes up the northeast rift after this date, and on February 21 a series of shakes with depth of origin of about 5 miles originated nearly under the source of the 1852 lava flow or about where the 1942 flank eruption was to break out later. During February, 50 earthquakes were recorded at Kilauea, while 143 were recorded on the Mauna Loa seismograph. The preponderance of Mauna Loa shakes was about the same in March, or 57 at Kilauea, and 136 at Mauna Loa.

After February 21 the epicenters of the earthquakes continued to progress along and up the Mauna Loa rift from northeast to southwest. The northern end of Mokuaweoweo was reached on March 7. A shake on March 20 that originated 5 miles southwest of and across Mokuaweoweo was widely felt over the island of Hawaii. It was especially strong along the Kona coast, where some clocks were stopped and objects thrown from shelves. This shake marked the end of progressive cracking and when earthquakes were resumed along the northeast rift on March 28, it seemed safe to assume that an eruption of Mauna Loa could be expected anytime and that it would occur along the northeast rift. Owing to war conditions, a forecast was not made public, though one was included in the March report of the Observatory to Park Superintendent Edward G. Wingate. Press reports in February and March had called attention to the growing uneasiness of Mauna Loa.

The nature of the splitting action or movement that produced the shakes when the earthquakes were progressing from the northeast to southwest is not clear. A wedging force, applied at a depth of 5 miles or more, from below upward seems indicated. The splitting action down the mountain just preceding a flank eruption produces shallow foci earthquakes and cracks that reach the surface. In many cases the depth of this cracking may well be less than 10,000 feet. The depth of foci of earthquakes and the fact that summit activity nearly always precedes a flank eruption indicate that the ascent of lava at Mauna Loa is restricted to the feeding conduits under Mokuaweoweo.

From observations made after the eruptions, in August, Dr. G. A. Macdonald of the U. S. Geological Survey reports that summit activity originated along a fissure that started near the large bend in the northwestern wall of Mokuaweoweo. After roughly following the northwest wall of the main crater, the fissure crossed the North Bay and extended down the northeast rift for about 2 miles. Within Mokuaweoweo the fissures were, for the most part, well up on the crater wall though they came down to the floor in places. There were several lava cascades into Mokuaweoweo from wall cracks 200 to 300 feet above the crater floor. New lava made an appreciable fill near the western edge of the main crater and covered over half of the North Bay. From the crack outside the crater, a lava flow poured northward for several miles. The upper part of the upper 1935 lava flow was largely buried and the cone of that year entirely surrounded (fig. 1).

By early morning of April 27 the summit activity was about over, and splitting down the rift was in progress as evidenced by numerous perceptible earthquakes. According to G. O. Fagerlund and B. J. Loucks of the Hawaii National Park staff, who arrived at Puu Ulaula at 8:40 A.M. after spending the night on the trail, earthquakes were so frequent that sleep was impossible.

At 3:34 P.M. a vent opened at about 12,000 feet that emitted great quantities of fume. Coincident with the opening of this vent, earthquakes diminished as though the escape of gas had released the pressure to a stage below that necessary for continuance of splitting. The shaking had noticeably increased by 9:00 P.M. and reached a climax at 10:41 P.M. with an earthquake of alarming

proportions. The Mauna Loa seismograph (see map, fig. 1), which is but 6 miles from the epicenter of this shake, suffered considerable damage.

At 4:40 A.M., April 28, lava made its appearance along a crack three-fourths of a mile long, extending from an elevation of 9,500 feet to 9,100 feet. By 9:00 A.M. the upper 500 feet of the fountaining chain was sealing off after having built up a low spatter rampart. By 1:40 P.M. activity had nearly ceased along the next 500-foot stretch, and fountaining was becoming concentrated near the lower end. The lower fountains ejected frothy slag as well as pumice (fig. 2). From the ground it appeared as though there were a distinct northerly bend in the live rift near the lower end. An airplane view by the Army Air Corps indicates that there were two nearly parallel cracks 20 to 30 feet apart, from which lava issued. The lava river from the upper northern crack in joining that from the lower one produced the illusion of a sharp bend.

Airplane observations at 9:30 A.M., April 28, showed that the front of the lava river which issued from the lower end of the fountaining area was obscured by clouds below the Puu Oo trail. This meant a progress of over 6 miles in 5 hours.

As the 1942 flow was partly on top of and moving parallel to the 1852 flow, and thus heading in the general direction of Hilo, its progress was watched with considerable apprehension. Observations of the front of the flow were difficult, owing to its location in a dense jungle and to its being obscured by clouds most of the time. Transit observations by Park Engineer A. L. Jess at 8:00 P.M., April 30, indicated that the front of the flow was at an elevation of 3,500 feet and had progressed nearly 2 miles in the preceding 12 hours.

On May 1, sites for bombing, with a view of diverting lava rivers into new channels and thus making two or more short flows instead of one long one, were selected by A. L. Jess and the writer while flying over the flow in a United States Army airplane. A secondary source,

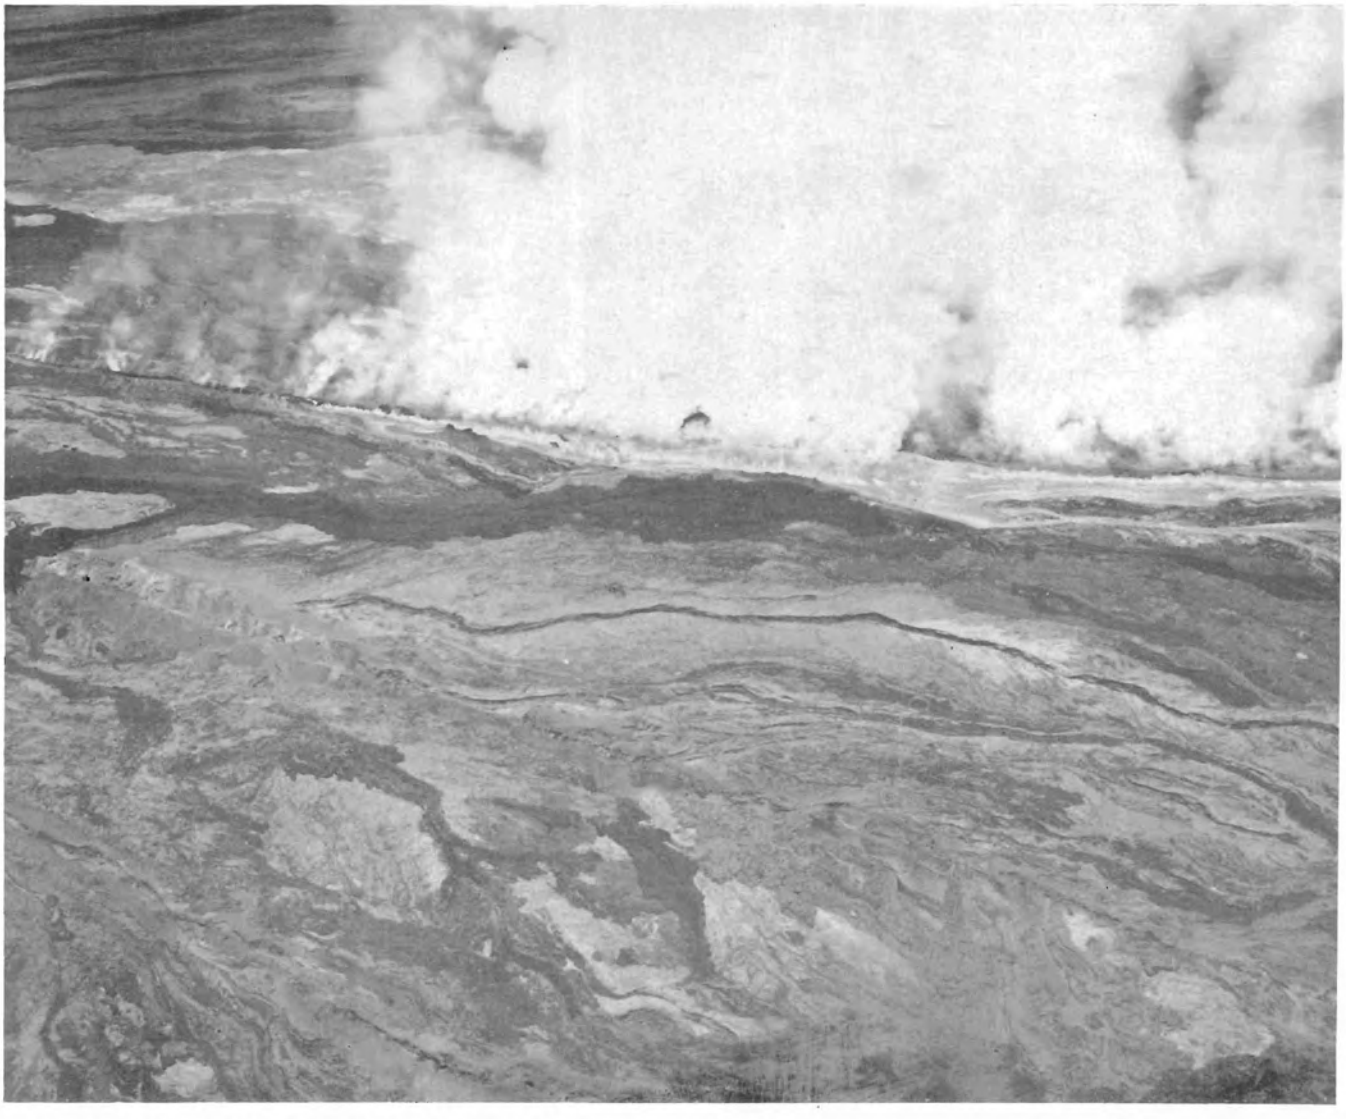

Fig. 2—Looking across the northeast rift of Mauna Loa, April 28, toward the source of the 1942 flank eruption. Though taken early after the outbreak, lava fountains have ceased in the upper 1,000 feet of the fissure. Photo by Base Photo Lab., A. A. F.—A. P. O. No. 953.

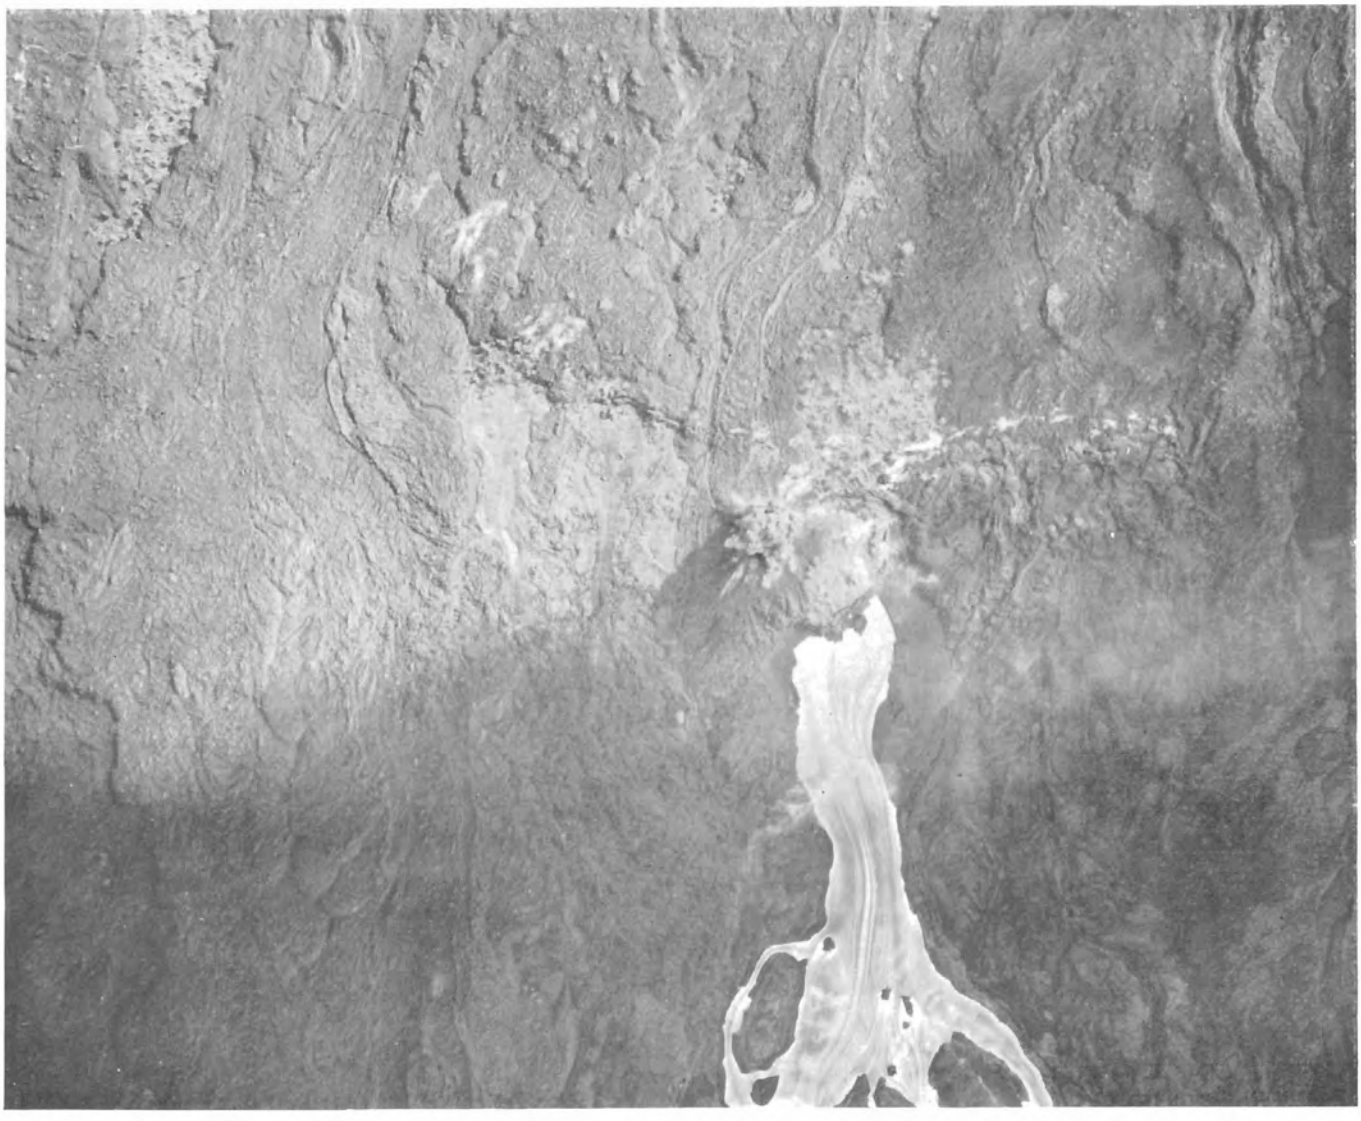

Fig. 3—Lower source 2½ miles below source cone of flow on Mauna Loa, May 1, 1942, with bomb exploding beside it. Photo by Base Photo Lab., A. A. F.—A. P. O. No. 953.

which was suspected on April 30 on account of a noticeably bright spot in the flow area, was found to be in a patch of old reddish-brown lava about 2½ miles below the source cone. A lava river with approximately the same volume as the one from the main source quietly poured out of what appeared to be an old lava tube. There was no fountaining at this source, though fume was issuing from some small cracks aligned at right angles to the northeast rift. Dr. Macdonald examined this area in August and found that there had been three vents along one of these cracks from which lava had issued. The lava emerged from a pahoehoe flow which was overlain by old aa lava. Possibly the crack over which the source cone was located cut across an old tube, and after a little more than a day the tube had become sufficiently heated to allow lava to flow through it. Bombs were dropped alongside this source (fig. 3).

The streams from the 2 sources divided, and for some distance there were 4 or more parallel lava rivers. The 4 rivers came together lower down and continued as pahoehoe for about a mile before becoming an aa stream. This mile of channel seemed to offer the best place for a diversion experiment. Places near the two sources offered other favorable locations. Before a return trip could be made, however, the lower place was obscured by clouds. Several 600-pound bombs were dropped at the upper places during the afternoon of May 1 and on the morning of May 2. At least one stream was diverted, but it returned to its old channel a short distance below. Molten lava cools so rapidly that a diversion lasting but a minute or two is not without appreciable effects on the front of a flow.

Airplane observations by A. L. Jess on the morning of May 2 showed that the front of the flow had widened greatly in the preceding 24 hours and was about 3,000 feet across. The thickness of the front averaged about 25 feet (fig. 4).

On May 1, P. E. Schulz reached the flow by going in from the Kaumana Road to the 1880-81 flow and following up this flow for 3 or 4 miles, thence by more or less following a contour he came to the active front about 1½ miles south of the 1852 flow. Explosions were frequent many

feet back from the edges of the flow. They are caused by the gases resulting from distillation of vegetal matter becoming mixed with air in underground chambers and then ignited. Mr. Schulz reports that they produced billowing black clouds that reached heights of over 500 feet and that the larger explosions produced craters 10 feet across and 2 feet deep. The front of the flow was advancing 300 to 500 feet an hour.

According to observations made by Dr. Macdonald on May 2, the upper 2,000 feet of the active fissure was mainly a fume producer. Blue flames were observed at two localities in the lower part of the inactive fissure. The flame at the lower of these two vents—just above the source cone—was more or less continuous for several days. The extreme upper end of the source cone continuously emitted large volumes of fume. Occasionally, however, pumice was ejected explosively. At other times spindle and ribbon bombs were hurled out. The fume smelled principally of sulphur dioxide. The odor of boric acid was detected over the upper part of the fissure and in the steam from several places in the flow. The main bulk of the fountains averaged nearly 200 feet high, with occasional jets reaching 400 feet.

Nearly all observers noticed fluctuations in fountaining activity. Park Superintendent Wingate at 6:00 P.M., May 3, estimated that the fountains averaged about 100 feet in height, with occasional maxima of about 190 feet. He observed a noticeable increase in activity at 11:00 P.M., which reached a maximum about 2:00 A.M., May 4, when the height of the fountains averaged 140 feet, with occasional jets at least 100 feet higher. The writer on May 5, noticed high fountains in the late afternoon and early evening, a minimum at 11:00 P.M. to 3:00 A.M., May 6, and a noticeable increase in height starting about 5:00 A.M. By 6:00 A.M. the tips of the fountains were reaching heights in excess of 400 feet. It should be noticed that these estimates of height are largely just opposite of what one might expect from the relative visual effects of daylight and darkness. Coincident with the decrease in fountaining, there was an increase in the temperature

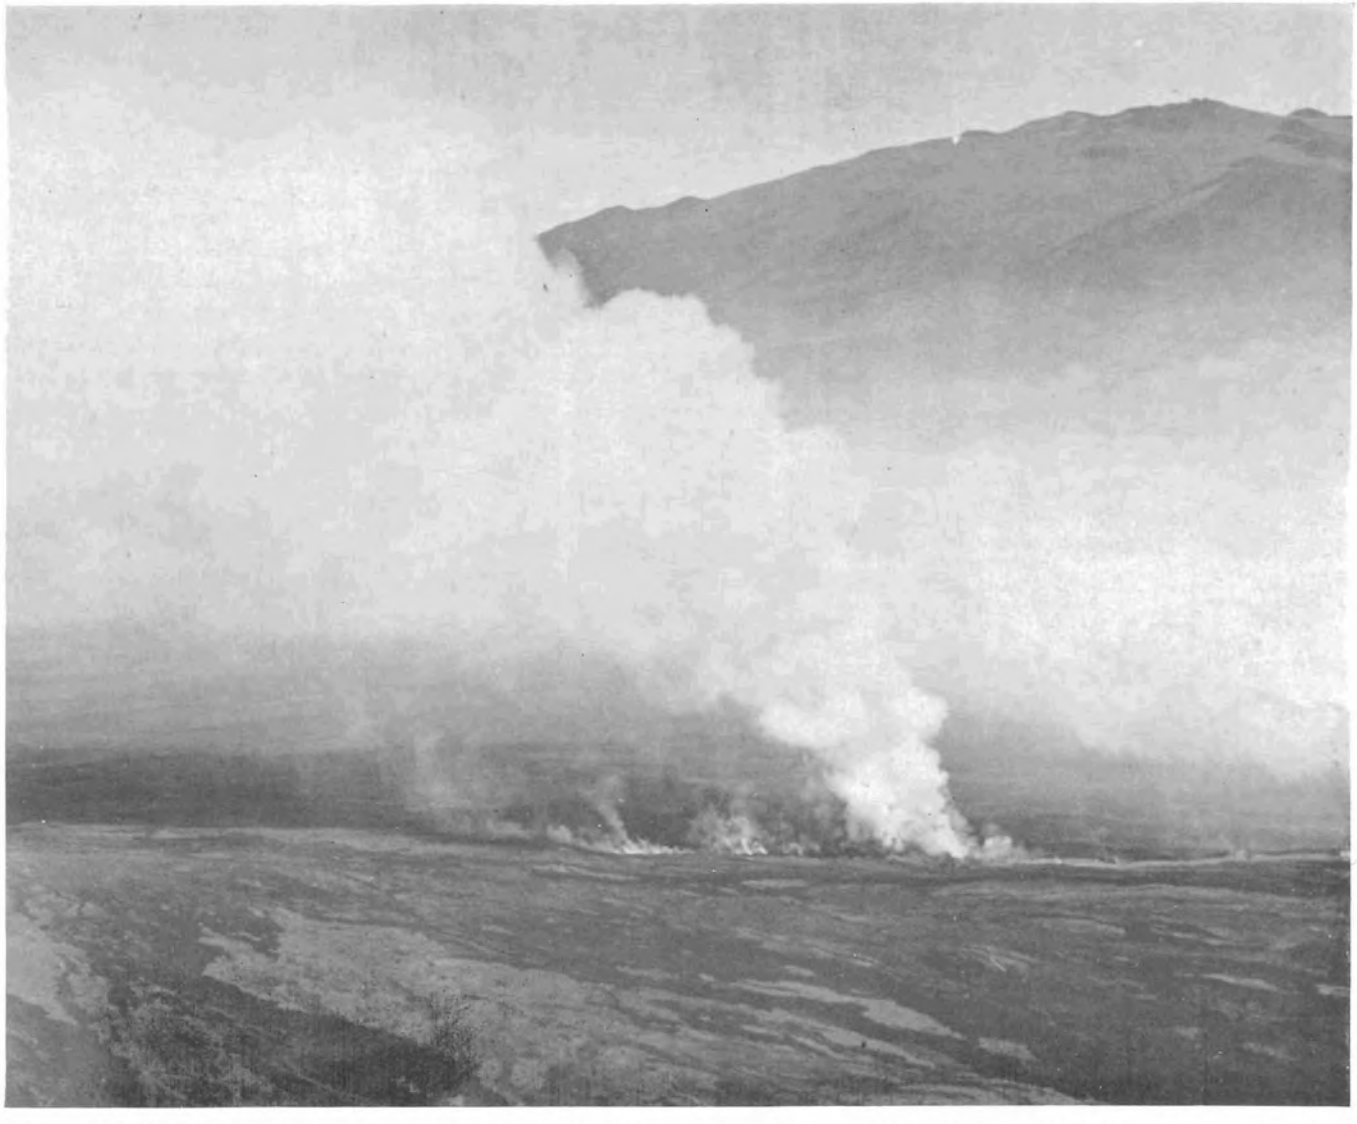

Fig. 4—Northeast slope of Mauna Loa and distant Mauna Kea, showing cone source of 1942 lava flow and live channel, about May 2. Photo by Signal Corps, U.S.A.

Fig. 5—Motion picture photograph close to north side of s ource cone, at about 9,000 feet elevation. Sudden gushing 600-foot fountains jetting southwestward with intense overflow, 1942 eruption of Mauna Loa, 9:00 P.M., May 4. Photo by Lt. Commander F. B. Herman, U.S.N.R.

of the lava river, as evidenced by the decrease in the amount of black skin on the lava and a general increase in brightness. It appeared that the material falling back from the fountains produced a distinct cooling in the lava pool.

The elongated source cone was built up to a height of about 75 feet by deposits of frothy slag and pumice, with the former predominating. This does not necessarily mean that the volume of ejected slag exceeds that of the pumice, for the area around the cone to a distance of about 2,000 feet is mantled with pumice.

During the evening of May 4, Merrill Carlsmith and F. B. Herman witnessed the breaching of the cone in two places, each of which produced large lava rivers (fig. 5). The new river on the northwest side soon reached the old channel, while the one on the southeast side flowed parallel to the old channel and reached a distance of about 6 miles before lateral flows from it, and cooling, stopped forward progress.

The natural diversion accomplished what was expected could be done by further bombing had such a step been necessary, and may have been a backing-up of the May 1 bombing. Progress at the lower front of the flow practically ceased on May 5 at an elevation of 2,750 feet, or a little less than 3¼ miles west of the middle flume house of the Olaa Sugar Company.

The breach on May 4 reached a little over half way down the cone rampart, or low enough for the surging of the lava in the fountaining pool to make a continuous discharge for over a day. If the breaching of the cone had been effected by direct bombing, it might have reached to its base and produced a more voluminous flow. It would appear that the rampart of a source cone offers a favorable place for diversion by bombing.

From May 5 on until activity ceased on May 10, lava outpourings were confined to flows 5 miles or less in length on top of or alongside of the first flows. Glow could be seen in the source rift for several days after May 10. Considerable blue fume was still being emitted from the source area and some distance below it on May 22. Smoke, largely of vegetal origin, was observed over the lower regions of the flow during the latter part of June.

The length of the flank eruption flow was about 17 miles. The area covered with new lava was roughly 5 square miles. An accurate estimate of the volume of the flow is difficult to make without a reasonably good map. Rough calculations, however, indicate that it exceeded 2,000,000,000 cubic feet.

The author is indebted to nearly all members of the Hawaii National Park staff for notes and observations, though but few are mentioned in the text. Of the many others to whom I am indebted for details of the outbreak, especial mention should be made of Dr. G. A. Macdonald of the U. S. Geological Survey. He not only allowed the use of his excellent notes but also read and discussed the manuscript while it was being prepared.

Hawaiian Volcano Observatory Report for April-June, 1942

VOLCANOLOGY

April

That seismicity is often low during the few weeks just preceding a Mauna Loa eruption was again demonstrated in 1942. The premonitory shakes in 1940 preceded the outbreak by 4 weeks. The premonitory shakings in 1942 occurred in Febuary and March. The interval between the earthquakes and the appearance of the lava at the surface accounts for the rather common statement that "Mauna Loa erupted with but little or no seismic warning."

The seismograph not only records the premonitory symptoms of Mauna Loa eruptions but usually accurately times the start of the outbreak. Continuous tremor that began to be recorded a few minutes after 5:00 P.M., April 26, showed that the outbreak began over an hour before it was visible from Kilauea.

Activity at Kilauea was limited to the landslides at Halemaumau caused by several of the stronger Mauna Loa shakes.

May

By May 5, the intensity of the continuous tremor accompanying the Mauna Loa eruption and the rate of outpouring of lava had decreased appreciably. The continuous tremor was recorded on the Mauna Loa seismograph until May 9. The flow stopped during the forenoon of May 10. Considerable fume continued to issue from the source cone and from many places in the flow until the last of the month.

Kilauea continued inactive.

June

Rumors of activity at several places on the recent Mauna Loa flow were common throughout the month. Local adjustments in the 1942 flow, which is over 40 feet thick in many places, may have been the basis of some of the reports, but most were based on local fuming, smoke from vegetal fires at the edges of the flow, or steam clouds following rainstorms. Early in the month smoke from the lower reaches of the flow was sufficient to produce a thin pall of fume over the upper northeast flank of the mountain.

The 1940 cone in Mokuaweoweo was emitting considerable fume on June 30. Local adjustments in the northeast Mauna Loa rift on June 13, 14, and 15, resulted in 92 tremors being recorded on the Mauna Loa seismograph.

Halemaumau remained quiet, though 19 Kilauea tremors were recorded on the Observatory seismograph on June 20 and 21.

*For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. Distances are from the Observatory.

The number preceding each earthquake date is the serial number of the quake for the current year.

48. April 8, 14:23, very feeble, near Mokuaweoweo.

49. April 14, 12:31, feeble, under Kilauea.

50. April 14, 22:11, very feeble.

51. April 19, 22:23, very feeble, Kilauea shake.

April 26, 16:05, start of continuous tremor that continued for 270 minutes, and beginning of summit eruption of Mauna Loa.

52-54. April 26, three very feeble shakes at 20:03, 22:39, and 22:50.

55. April 26, 23:41, moderate, felt locally and Hilo, instruments dismantled, upper NE rift of Mauna Loa, vertical indicates shallow focus.

56. April 27, 00:01, slight, origin same as No. 55.

57. April 27, 04:21, slight, origin same as No. 55.

58. April 27, 08:49, slight, E-W dismantled, upper NE rift of Mauna Loa.

59. April 27, 09:52, slight, near Mokuaweoweo.

60-62. April 27, three very feeble shakes, 10:04 to 10:41.

63. April 27, 11:53, slight, above Puu Ulaula.

64-69. April 27, six very feeble shakes, 11:59 to 13:57.

70. April 27, 14:12, slight, record confused.

71. April 27, 14:15, feeble.

72. April 27, 14:23, slight.

73. April 27, 16:44, slight.

74-78. April 27, five feeble shakes, 16:30 to 21:17.

79. April 27, 21:43, moderate, instruments dismantled, pronounced at Puu Ulaula.

80-87. April 27, eight feeble shakes, 22:01 to 23:50.

88. April 28, 01:45, very feeble, Mauna Loa flank eruption started 1½ miles below Puu Ulaula about this time.

89. April 28, 10:30, feeble.

90. April 29, 06:15, feeble, origin near source of flank outbreak.

91. April 29, 11:10, slight.

92. April 29, 23:14, very feeble.

93. April 30, 02:39, very feeble.

94. April 30, 07:43, slight, flank eruption source.

May 1, eleven shakes recorded on Mauna Loa seismograph but not at Kilauea.

95. May 2, 04:02, very feeble.

96. May 2, 18:00, very feeble.

97. May 2, 19:00, very feeble.

98-100. May 3, three very feeble shakes, 14:41 to 21:43.

101. May 4, 00:26, very feeble, felt at source.

102. May 4, 01:46, very feeble, continuous tremor greatly diminished though prominent on Mauna Loa instrument until 23:00.

103. May 4, 23:54, very feeble.

104. May 14, 22:40, feeble.

105. May 19, 01:34, very feeble NE rift Mauna Loa.

106. May 27, 14:45, very feeble.

107. June 1, 03:45, feeble Kilauea shake accompanied by a rumble.

108. June 18, 08:05, slight, E slope of Mauna Loa.

109. June 21, 05:54, very feeble.

110. June 24, 16:40, very feeble.

111. June 26, 17:10, very feeble.

112. June 30, 19:05, very feeble.

Teleseisms

April 8, 05:26, slight.

May 13, 16:45, moderate.

Microseismic Motion

Microseisms were present, though slight, throughout the quarter.

Tilting of the Ground

The southeast Halemaumau station showed a distinct southeast tilt early in April but practically no movement during the remainder of the quarter. At the west station there has been but little tilt for the past six months.

Tilt

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount of tilt	Direction of tilt
April	5	5.44″	S 67° E
	12	1.94″	S 82° W
	19	1.88″	N 66° W
	23	0.64″	S 13° W
May	3	2.48″	S 81° W
	10	3.39″	N 70° E
	17	1.91″	S 26° W
	24	1.33″	S 29° W
	31	1.82″	N 37° W
June	7	0.36″	N 45° W
	14	2.31″	N 87° W
	21	1.45″	N 21° W
	28	1.03″	N 21° W

Crack Measurements

Crack movement around Halemaumau was distinctly less during April-June than during the preceding 3 months, 16 cracks opened an average of 2.8 millimeters, 11 remained unchanged, and one closed 0.5 millimeters. Movement of the cracks along the Chain of Craters Road was very slight, with the majority showing a slight closing tendency. At the Devils Throat one crack opened 1.5 millimeters, and the others remained unchanged.

THE DUG WELL AT OLAA MILL

By GEORGE DUNCAN

The Olaa Sugar Company recently sank a well shaft 10 feet in diameter in the mill grounds, where the elevation is 220 feet above sea level. Such a shaft gives a detailed exposure of the geologic structure in this part of Puna, where cliffs or other good exposures are lacking, as well as information on the amount of mobile ground water in the vicinity of the conduits of Hawaiian volcanoes.

The author acknowledges his indebtedness to Dr. G. A. Macdonald of the United States Geological Survey and R. H. Finch, Volcanologist, Hawaii National Park, for aid in preparing this article, particularly those parts dealing with geologic interpretation.

The well is located on the northeastern slope of Mauna Loa 3½ miles from the ocean, a little to the north of the Kilauea-Mauna Loa contact. It is thought that most of the lavas exposed in the well are of Mauna Loa origin, though some may be from Kilauea, as in this vicinity there must be some interfingering of Kilauea and Mauna Loa lavas.

The log of the well by Dr. Macdonald, describing each layer, is shown in Table 1.

TABLE 1.

LOG OF OLAA WELL—1941

(On file in Honolulu office of U. S. Geological Survey)

By G. A. Macdonald

Depth	Description
Feet	
0–23	Aa clinker, containing scattered olivine phenocrysts up to 2 mm. across in an aphanitic ground mass.
23–47	Medium-gray sparingly vesicular to dense aa, with moderately abundant phenocrysts of olivine up to 3 mm. long. (Contains hypersthene.)
47–54	Reddened aa clinker, with moderately abundant olivine phenocrysts up to 3 mm. long.
54–56	Fine powdery red ash.
56–61	Moderately vesicular dark-gray pahoehoe with a few small phenocrysts of olivine less than 1 mm. across.
61–64	Dark-gray sparingly to moderately vesicular pahoehoe with a few olivine phenocrysts less than 1 mm. across and scattered phenocrysts up to 1½ mm. long.
Feet	
64–66	Dense to sparingly vesicular light-gray pahoehoe, dikytaxitic, essentially nonporphyritic but with a few olivine phenocrysts less than ½ mm. across.
66-70	Highly to moderately vesicular medium-gray pahoehoe with a few phenocrysts of feldspar up to 1½ mm. long and a very few of olivine less than 1 mm.
70-73	Dark-gray moderately vesicular pahoehoe with a few phenocrysts of feldspar up to 1 mm. or a little more in length. The flow shows a reddened ropy top.
73–81	Dark-gray moderately vesicular pahoehoe, essentially nonporphyritic, but with a few small phenocrysts of olivine and feldspar.

Depth	Description
Feet	
81–88	Moderately to highly vesicular dark-gray pahoehoe, nonporphyritic, approaching clinker in places. Shows ropy flow surfaces.
88–92	Light-gray sparingly to moderately vesicular pahoehoe; some vesicles are as large as 2 mm. across, containing a few phenocrysts of feldspar and olivine up to 1½ mm. Many of the vesicles are lined with platy feldspar crystals.
92–97	Sparingly vesicular to dense light-gray pahoehoe containing scattered small phenocrysts of olivine and feldspar up to 1½ mm. in diameter. (Probably same as above.)
97–107	Moderately vesicular dark-gray pahoehoe with a few phenocrysts of feldspar up to ½ mm. long.
107–115	Sparingly vesicular dark-gray pahoehoe with scattered phenocrysts of feldspar and a few of olivine up to 1 mm. in diameter. (May be same as above.)
115–120	Reddened aa clinker, aphanitic and nonporphyritic.
120–139	Dense to sparingly vesicular medium-gray basalt with a few phenocrysts of olivine up to 1 mm. and feldspar up to 2 mm. across.
139–150	Reddened aa clinker with scattered phenocrysts of feldspar up to 2 mm. Caved badly in shaft.
150–206	Dense medium-gray aa with scattered phenocrysts of feldspar up to 1½ mm. Shows good columnar jointing.
206–217	Aa clinker.

The first 23 feet was composed of aa clinkers so loose that a cement retaining wall was necessary. Retaining walls were also necessary for the ash layer at 54-56 feet and for the clinkery portions of aa flows at 115-120 and 139-150 feet. The massive portion of the aa layer, 150-206 feet, caused real difficulty. It was so abrasive that the best of drills was completely worn out in penetrating 8 to 14 inches of rock.

The ash layer at 54 feet was the only one encountered. The thinness of this layer and the absence of others indicate that this part of the Puna district geologically is comparatively young.

The water in the older drilled wells in the same grounds stands about 17 feet above sea level. Such a level is about what is to be expected, as the normal ground-water-level gradient in regions of moderate to heavy rainfall is about 4 feet for each mile of distance from the shore. At the distance of 3½ miles from the shore, the normal elevation of the ground-water level then would be 14 feet. As the Olaa Mill is located in a region of about 200 inches of rainfall a year, a level averaging a little higher than 14 feet is what is to be expected.

A chamber for housing pumps and motors with a floor 17 feet above sea level was excavated in the massive part of the thick aa flow (150-206 feet, Table 1). After the chamber was excavated and lined with cement, work was commenced to deepen a hole for the sump. The water level was found at 14 feet above sea level. Pumps were installed, and by removing 7,000,000 gallons per day the level of the water was kept at about 6 feet above sea level. A tunnel, the bottom of which was at an elevation of 3¼ feet, was excavated in a northwest direction for about 35 feet in the aa clinker. In view of the fact that pumping was keeping the water at least 8 feet below the normal and that there was a rapid inflow into the tunnel, it appeared too hazardous to continue the excavation. Very rapid rises in the water level that were measured later justified such a belief.

The rise of the water level in the well shows a good correlation with heavy rains. The interval between a heavy rain and the peak of the water level is about 3 days. However, a rain occurring after a dry spell of appreciable length is not followed by a rise in the water level, though it may decrease the rate of lowering. The water of such a rain is used up in saturating the ground. For local rains the rise is very rapid, and the interval a little less than 3 days. For rains higher up the mountain slope the rise is more gradual, and the interval a little more than 3 days. The range of the fluctuation of the water level is considerable. In April 1938 the water reached a height of 22.7 feet and flooded some of the machinery, though most items had been removed before the water reached them. A false floor was installed 6½ feet above the original one. In March 1939 a level of 25.86 feet was reached. Following a dry spell in 1940, the lowest level recorded—13 feet above sea level—was observed. Generally the water level stands at an altitude of about 17 feet.

No evidence of volcanic heat was found anywhere in the shaft. The temperature of the water is constant at 66°F., and the salt content at 0.85 grains per gallon.

No water ran into the shaft even during the heaviest rainfalls. After the shaft was completed and the adit to the pump chamber commenced, there was no sign of water from the sides. This circumstance shows that for 217 feet below the surface there is no impervious ash layer and that the descent of the rainwater is essentially vertical.

The well produces from the lens of fresh water which, owing to its lesser specific gravity, floats on top of the salt ocean water beneath it.

Hawaiian Volcano Observatory Report for July-September, 1942

VOLCANOLOGY

July

Smoke was reported from the 1942 Mauna Loa flow on July 17. This appears to be the last observation of smoke over the flow, though fume continues to be emitted from the source cone.

A landslide from the north rim of Halemaumau on July 16 produced a conspicuous dust cloud.

August

Fume was noticed from the source cones of both 1940 and 1942. More earthquakes were recorded at Kilauea than at Mauna Loa. This relation of earthquake frequency will probably continue for most months until Mauna Loa shows signs of preparing for another eruption.

September

A rainstorm about the middle of the month produced pronounced steam clouds over the lower half of the 1942 Mauna Loa lava flow. The general rise of the steam indicated that nearly all portions of the flow were still hot.

A swarm of Kilauea earthquakes that occurred during the last few days of September may be taken as evidence of subterranean activity. The climax was reached on September 27, when 28 local seismic disturbances were recorded. The tilt curves for July, August, and September indicated that such a swarm of earthquakes was not a premonitory symptom of impending activity.

The September earthquakes caused several landslides from the walls of Halemaumau and one from the southwest wall of Kilauea.

*For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. Distances are from the Observatory.

The number preceding each earthquake date is the serial number of the quake for the current year.

113. July 3, 17:50, very feeble.

114. July 8, 5:15, very feeble, distance 3 miles.

115-117. July 8, 17:27 to 22:33, 3 very feeble shakes.

118. July 9, 3:00, slight, E-W component dismantled, felt locally and strongly in Kohala, in ocean north of Kohala.

119. July 19, 23:30, very feeble, felt at Kapapala.

120. July 29, 06:45, very feeble, Kilauea shake.

121. August 2, 23:05, very feeble, NE rift of Kilauea.

122-123. August 10, 10:35, very feeble, twin shakes.

124. August 15, 06:37, very feeble.

125. August 27, 02:38, very feeble, NW of Mauna Kea.

126. August 27, 10:25, feeble near Mokuaweoweo.

127. September 4, 00:48, very feeble.

128. September 6, 05:20, very feeble.

129. September 9, 21:37, very feeble, Kilauea shake.

130. September 11, 16:50, very feeble, felt in Kohala.

131. September 12, 10:25, slight, Kilauea shake.

132. September 18, 01:51, feeble, felt locally, Kilauea shake.

133. September 19, 09:56, very feeble, distance 2 miles.

134. September 20, 13:31, very feeble.

135. September 20, 14:26, very feeble, Kilauea shake.

136. September 26, 16:55, very feeble, Kilauea shake.

137. September 27, 01:41, feeble, felt locally, distance 2 miles.

138. September 27, 02:57, slight, felt locally.

139-141. September 27, 11:33-13:15, 3 very feeble shakes.

142. September 27, 17:36, slight, felt locally, accompanied by rumble, distance 3 miles.

143-144. September 27, 18:46-19:17, 2 very feeble shakes.

145. September 28, 14:15, feeble, felt locally, distance 3 miles.

146. September 30, 10:20, very feeble.

147. September 30, 10:21, feeble, felt locally.

148. September 30, 10:21, slight, felt locally, E-W dismantled. Accompanied by a landslide from NE wall of Halemaumau.

Teleseisms

July 25, 05:00, slight.
August 6, 13:01, slight, Guatemala.
August 24, 14:36, slight, Peru.
September 8, 15:05, slight.

Microseismic Motion

Microseisms were slight though noticeable throughout the quarter.

Tilting of the Ground

A conspicuous feature was the strong ESE tilt at the Observatory from July 1-10. The E-W tilt curve, which usually is in agreement with the seasonal temperature curve, did not change from westerly to easterly until September 26. Except for the southerly tilt in the first decade of July, tilt in the N-S direction was quite uniformly to the north, or normal for this season of the year.

There were but negligible changes in direction and amount in the tilt at the two stations near the rim of Halemaumau.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount of tilt	Direction of tilt
July	5	2.12″	N 66° E
	12	9.20″	S 46° E
	19	1.04″	N 35° E
	26	0.36″	S
Aug.	2	1.45″	N 45° W
	9	0.71″	S 31° E
	16	0.92″	N 66° W
	23	1.23″	N 11° W
	30	0.12″	N 45° E
Sept.	6	1.04″	N 70° W
	13	0.60″	N 36° E
	20	0.24″	S 45° E
	27	0.71″	N 31° W

Crack Measurements

Crack movement during the quarter was slight. There was no change along the Chain of Craters Road or at the Devil's Throat. At Halemaumau movement was confined to 2 cracks which showed openings of 1 millimeter each.

THE SURFACE ASH DEPOSITS AT KILAUEA VOLCANO

BY R. H. FINCH

The object of this paper is to show that there have been eight, perhaps nine, explosive periods in the geologically recent history of Kilauea. The older ash beds exposed in the walls of the crater and good evidence that at least a portion of the Pahala[1] ash had its origin at Kilauea indicate that explosive eruptions at Kilauea have been rather common through a considerable portion of its history.

A study of the ash deposits indicates that there have been more magmatic than phreatic explosions and that the magmatic explosions were in most cases larger than the phreatic. (A magmatic explosion is one that has fluid or essential material in the ejecta; a phreatic explosion is one without contemporaneous molten lava.)

The area surrounding Kilauea crater is covered with ash to an appreciable depth. At the northeast rim the depth is as much as 6 feet in places; at the southwest end of the crater, depths of 35 feet may be found. The greater depth at the southwest is owing to the prevailing northeast trade winds. A cave-in at an old lava tube half a mile southwest of the Kilauea rim reveals a thickness there of 20 feet of ash (fig. 1). The total depth of the ash deposited can not be determined, as appreciable quantities of most layers were removed by the wind before the next succeeding layer was laid down. The southwest side of the crater is especially susceptible to wind erosion, as it is in the Kau Desert. The deposits on the northeast side are in a region of about 100 inches annual rainfall and are much less subject to wind erosion. At the northeast the terrain is relatively flat and stream erosion has been very slight. At the southwest rim of Kilauea, 5 inches of the ash of that year was still in place one year after the small explosions of 1924. Within a few years it was reduced to a barely discernible trace.

Stone[2] found evidence of at least four carbonaceous or soil layers in the ash around the northern rim. Stearns[3] reports six different vegetal horizons. The six different vegetal horizons in the ash would mean, of course, that there had been seven different explosive periods.

One erosional unconformity is distinct at many places in the ash at the southwest side of Kilauea. If sufficient time had elapsed between explosive eruptions for vegetation and soil layers to develop at the northeastern end of the crater, it seemed that more unconformities could be found at the southwest side. Some time was spent in looking for such unconformities at places favorable for the development of small streams.

Stone[4] reported an ash bed at least 3 feet thick in an open fissure near Cone Peak (fig. 1) that is separated from the surface ash by 12 feet of lava flow. Stearns[5] surmised from discrepancies in the thickness of the ash near Cone Peak that some of the basal layers of ash in this vicinity had been buried by lava flows. On the same page Stearns also mentions a line of driblet cones along a fissure concentric to and 0.7 mile southwest of the Kilauea rim (fig. 1). He found a lava flow from the fissure interbedded in ash. A little study of Figure 1 shows that the drainage pattern has been interrupted by the opening of the crack. As the drainage pattern is in the ash, it is obvious that the fissure opened after at least one ash layer was laid down.

Figure 2 shows a lava flow interbedded in ash in the wall of the fissure. There is a thickness of 132 inches of ash under the flow, and 34 inches over it. At some places near the crack, 10 feet of ash is still in place, though

[1] For a discussion of the Pahala ash which forms the yellow soil layer especially noticeable in the vicinity of Pahala, see Stone and Stearns, references 2 and 3 respectively.

generally the depth is much less. The fact that the ash section containing the flow is thicker than at many places nearer the crater is what is to be expected when one considers that the lava may have protected the covered layers from wind erosion for an appreciable time interval. There were several different lava flows from this fissure, all probably contemporaneous. It is not certain whether these lava flows occurred during the interval that produced the pronounced unconformity shown in the ash beds near the southwest rim, but such may well be the case.

The basal layer of the ash series is a thin, discontinuous, gray, clayey ash readily discernible only at the northern rim. This is not surprising, as any such ash deposited at the southwest, which is in a desert area, would quickly be removed by the wind. Before the next true explosion occurred there must have been a magnificent display of fire fountains, as the country for several miles around the northern part of the crater is covered with a very light pumice—the "thread-lace scoria" of Dana. The basal layer at the southwest is a somewhat indurated bed of yellow, glassy ash. Indications of an unconformity in this layer suggest that it is the product of two explosive periods. Above this layer is another glassy layer with an appreciable percentage of conspicuous pumice fragments. It is probably the product of but one explosive period. Above the pumice charged layer is another one of rather fine glassy texture, in which there is a distinct unconformity; hence it is the product of two different eruptive periods. A rather coarse, gravelly layer is the topmost member. It has heretofore been considered the product of the 1790 explosions, with traces from 1924. Suggestions of unconformities in this layer indicate that the basal portions may have been ejected prior to 1790. Although most of the products of the 1790 eruption are composed of old lithic material, the fact that it contains bombs causes it to be classed either as a magmatic or a mixed explosion. The products of the 1924 eruption contain nothing but old lithic material; hence it was a phreatic explosion.

There are indications, then, of nine different explosive periods in the recent history of Kilauea. The possibility of there having been explosions, the records of which are lost, with intensities comparable to those of 1924, must also be considered. If the floor of Kilauea crater should again be covered by lava flows, but precious little field evidence of there having been an eruption in 1924 would remain.

Sweeping statements that explosions at Hawaiian volcanoes are of the phreatic type are hazardous. Of the last nine indicated explosive eruptions at Kilauea, at least six appear to have been of the magmatic type.

Hawaiian Volcano Observatory Report for October-December, 1942

VOLCANOLOGY

October

There was no visible activity at Hawaiian volcanoes in October. During the first few days of the month there were several small aftershocks from the swarm of Kilauea shakes of September 27. During the remainder of the month, Mauna Loa shakes predominated. The only felt earthquake occurred at 12:43 p.m., October 11. It originated on Mauna Loa and was strong enough to dismantle both the Mauna Loa and Kilauea seismographs.

November

Hawaiian volcanoes continued inactive in November. Forty-five seismic disturbances were recorded at Kilauea, while 56 were registered on the Mauna Loa seismograph.

Strong winds on November 13 raised conspicuous dust clouds on the southwestern floor of Kilauea Crater and in the Kau Desert, although the material of the clouds—ash from the explosive eruption in 1924—was deposited over 18 years before.

December

Observations at Mokuaweoweo on December 17 showed that some fume was escaping from the 1942 vents.

Forty-four earthquakes occurred on December 21. They originated about 2 miles east of Napau Crater along the Puna rift of Kilauea. With a shallow focus 11 miles from Halemaumau, it is believed that they have no special volcanic significance. They probably resulted from local and superficial adjustments along the Puna rift.

*For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. The number preceding each earthquake date is the serial number of the quake for the current year.

149. October 1, 06:04, very feeble, NE rift Mauna Loa.

150. October 5, 23:47, very feeble.

151. October 6, 13:33, very feeble, Kilauea shake.

152. October 11, 11:43, slight, E-W dismantled, both components dismantled, Mauna Loa, northern end of Mokuaweoweo.

153. October 16, 09:21, very feeble.

154. October 29, 22:30, Kilauea shake.

155. November 5, 12:56, feeble.

156. November 8, 00:47, very feeble, SW slope Mauna Loa.

157. November 25, 01:54, feeble, felt locally.

158. November 25, 10:20, very feeble, Kilauea shake.

159. November 26, 03:59, very feeble.

160. December 1, 17:03, very feeble.

161. December 4, 18:28, very feeble, Kilauea shake.

162. December 5, 07:07, very feeble, Kilauea shake.

163. December 6, 12:08, slight, felt from Hilo to S. Kona, in Kahuku near source 1868 flow.

164. December 21, 05:28, slight, instruments dismantled, felt locally and in Hilo, 2 miles east of Napau Crater.

165. December 21, 06:50, feeble, felt locally, same origin as No. 164.

166. December 21, 07:47, feeble, same as No. 164.

167-176. December 21, record confused, 7 very feeble and 3 slight shakes.

177. December 21, 23:57, feeble, same as No. 164.

178. December 22, 07:45, very feeble.

179. December 24, 15:15, feeble, Kilauea Crater.

180. December 26, 10:41, very feeble.

181. December 29, 16:33, very feeble.

Teleseisms

October 21, 06:09, slight, southern California.

November 10, 01:30, moderate, Indian Ocean.

December 9, 12:10, slight.

Microseismic Motion

Microseisms were present, though uniformly slight through October-November.

Tilting of the Ground

There were some slight variations in the direction of tilt, though as a whole there was a slight and rather uniform tilt to the northeast. The direction and amount was normal for this season of the year. The tilt stations at Halemaumau showed almost no movement from October to December, inclusive.

Table of Tilt at Observatory on NE Rim of Kilauea

Week ended		Amount of tilt	Direction of tilt
Oct.	4	1.11″	N 13° E
	11	0.97″	N 29° E
	18	0.17″	S 45° E
	25	0.27″	N 63° W
Nov.	1	0.98″	N 83° E
	8	1.21″	N 45° W
	15	1.95″	N 30° E
	22	0.80″	S 34° E
	29	0.12″	N
Dec.	6	0.39″	N 19° E
	13	0.54″	S 63° E
	20	0.63″	N 45° E
	27	0.63″	N 45° E

Crack Measurements

In October there was no appreciable movement in the cracks around Halemaumau or along the Chain of Craters Road. In November many of the cracks immediately adjacent to the rim of Halemaumau opened slightly, while those farther back and along the Chain of Craters Road showed no movement. Many of the cracks at both places opened slightly in December.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with
UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The Association and the University supplement the work of the government with research associates, instrumental plants and special investigations. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The Volcano Letter, a quarterly record of the Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

LAVA SURGINGS IN HALEMAUMAU AND THE EXPLOSIVE ERUPTIONS IN 1924

By R. H. FINCH

The object of this paper is to show a possible relation between fluctuations in the lava column of Halemaumau and the steam blast eruptions in 1924, as well as to point out the limitations in the quantity of heat and amount of water available for such steam blasts.

A remarkable series of fluctuations in the height of the molten lava in Halemaumau commenced in December 1923 and continued until the lava disappeared on February 21, 1924. The fluctuations suddenly began near the culmination of the steady rise in the lava column that followed the collapse accompanying the small lava flow near Makaopuhi in August 1923. There were short-period fluctuations of approximately 6 to 8 hours, superposed on fluctuations with a period of almost exactly 1 week. The amplitude of the short-period fluctuations was about the same as that of the week-period fluctuations, often amounting to over 60 feet.[1] The general rise in the lava level continued until January 21. Until that date the risings usually exceeded the sinkings. After January 21, however, there was a gradual lowering and the sinkings usually exceeded the rises. This last relation continued until the lava disappeared from view on February 21.

After the disappearance of molten lava in February, harmonic tremor and the smoky condition of the pit, through which glow was occasionally visible, indicated that the lava column remained rather high and nearly stationary until the time of rapid subsidence in the latter part of April. The pasty lava that was revealed at the beginning of this subsidence strengthened such indications.

Previous to the disappearance of the lava, the area of the lava lake that was fluctuating through a range of 50 to 60 feet was about 40 acres. This meant that a large amount of molten lava was involved. In one half-hour period observed, over 10,000,000 cubic feet of lava poured into the lake basin. Some of the withdrawals were even more rapid. If, as seems probable, the total area in cross section of the feeding conduits was small compared to the lava lake, then surgings with similar volume, when confined to the conduits, would mean large vertical ranges. Even if much smaller volumes of lava were involved, the vertical range might well have been much larger than the observed 50 to 60 feet when the upper ends of the conduits terminated in a lake basin.

The possibility of large vertical ranges in the lava surgings being established, indications for such surgings are now required. Harmonic tremor[2]—seismic indications of underground movement of molten lava—furnishes just such evidence. This type of tremor diminished on the seismograms of the Hawaiian Volcano Observatory just before the lava disappeared in February and then was barely visible until April 29, when there was a noticeable increase. Coincidental with the increase in harmonic tremor, a strong southwest tilt and a marked subsidence in the lava column began. Lava drainage into the Puna rift[3,4] may have begun about this time.

A distinct increase in harmonic tremor started on May 7,

just 4 days prior to the onset of the explosions. This type of tremor was moderate to strong until May 17 and slight through the remainder of the explosive period. The maximum in explosive intensity was reached on May 17 to 18, though earthquakes increased in frequency after this date, reaching a maximum on May 24. There is evidence, then, of lava surging prior to and during the explosive period. If the amplitude of the harmonic tremor is an indication of the amplitude of the surgings, the range of movement of the lava column preceding and during the explosions may have exceeded those during the preceding winter.

Dr. T. A. Jaggar has demonstrated that the explosions in May 1924 must have had their origin in steam blasts.[5] The following discussion attempts to indicate in a more detailed way a possible mechanism and the periodicity of the steam blasts. The potency of volcanic heat in producing steam blasts is easily recognized. A cubic foot of water at a pressure of 1 atmosphere and a temperature of 1,700° F. would yield over 5,000 cubic feet of steam, or, if confined, produce a pressure of over 80,000 pounds per square inch. If one considers these figures only, the mechanism of volcanic steam blasts appears rather simple.

Difficulties arise, however, when one considers that with any ingress of water the hot volcano conduit system immediately produces a pressure that greatly retards, if not precludes, further entry of water. If the pressure build-up were at a moderate rate, then some seal to confine the steam before a disruptive pressure was reached would be necessary. (It would appear that landslide material could make but a poor seal, even with optimum arrangement.) If the pressure had built up rapidly, the heat supply would have had distinct limitations. It would have to come from a thin surface layer of the conduit walls and from any landslide material that fell into the conduit, say about one-eighth inch thick. The receding magma must have left appreciable areas of hot wall uncovered. A mechanism producing a very rapid generation of steam and not requiring a thorough seal, such as a "flash boiler," seems indicated.

Before proceeding with the discussion of a "flash boiler" system, a few words concerning the probable height and distribution of ground water in the vicinity of Kilauea seem desirable. For ideas on this subject, the writer acknowledges his indebtedness to Dr. G. A. Macdonald of the United States Geological Survey.

Conditions observed elsewhere in the Hawaiian Islands indicate that large amounts of ground water are trapped in compartments between dikes at relatively high levels. Dr. Macdonald believes that the ground water in some compartments near Kilauea may be as much as 1,500 feet above sea level. The normal elevation of the Ghyben-Herzberg lens of fresh water in the vicinity of Kilauea would be about 35 feet above sea level. The shape and orientation of such compartments in the vicinity of the Kilauea conduit system are probably very irregular. Evidence indicates considerable relatively high-level ground water in close juxtaposition to the volcanic conduits. As lava is a very poor conductor of heat, the horizontal temperature gradient in the conduit walls must thus have been very steep.

[5] Jaggar, T. A. Bulletin, Hawaiian Volcano Observatory, May 1924, page 35.

There can be but little doubt that an abundance of heat was available for the explosions. All that remains is to find a means whereby a considerable volume of ground water could be dropped into hot openings left empty by the receding lava.

The rapid subsidence that started on April 29 was accompanied by many earthquakes of Halemaumau origin. As previously mentioned, the retreat of the lava column was probably made up of fluctuations in which the drops exceeded the rises. The collapse of the entire floor of Halemaumau indicated a series of collapses of the walls of the feeding fissures. The downsurgings of the lava may well have timed the moment of the collapses. Sometime during this pulsating descent of the lava column, a trapped ground-water pocket was encountered, and with the shattering of the conduit walls a comparatively small amount of water gained access to the volcano system. This could account for the first small explosion on May 11. The next indicated withdrawal of lava and collapse of the conduit walls was on May 13, and explosions resulted. If the bottom of the pit was 1,000 feet below the rim, which, in turn, was 3,700 feet above sea level, and if the height of the trapped ground water was 1,500 feet above sea level, then 1,200 feet of fragmental material would have to be lifted to make an appreciable showing in the bottom of the pit. With an average specific gravity of 2 for such a plug, the pressure generated would have to exceed 1,000 pounds per square inch. Pressures of this magnitude should be developed easily. As the explosions progressed, there may have been an increase in the specific gravity of the fragmental material filling the vent because of an increase in the amount of dense material from more deep-seated walls of the conduit and a decrease in the percentage of vesicular lava from the upper walls. If, as is probable, there was a more or less progressive increase in depth of the seat of the explosions, there may not have been a striking increase in the weight of the plug, for there was a gradual increase in the depth of Halemaumau, the maximum being indicated about May 17.

In order to arrive at possible explosion pressures, let us assume probable temperatures and a possible amount of water. If, as has been assumed, most of the explosions occurred just following a downsurge in the lava column, the walls of the conduit had a temperature of about 1,700° F. Let us assume a surface area in the evacuated conduit of 6,000 square feet. An opening 50 feet long and 60 feet deep would furnish such an area. Hot fragmental material that might have fallen into the cracks would also have been an important additional source of heat. Hot volcanic gases would have been a minor contributing factor. If the explosion pressure was developed as a "flash boiler," then the heat available was confined to a layer about one-eighth inch thick in the rock surface. The volume of the rock, if one computes only the surface of the walls of the fissure, would be 62.5 cubic feet. With a specific gravity of 2.5, this volume of rock would weigh about 10,000 pounds. The number of available B.T.U.'s above 210° F. in 10,000 pounds of basalt with an initial temperature of 1,700° F. is 4,470,000, if we assume the specific heat of basalt in this temperature range to be 0.30.

If we assume a final temperature of 900° F. for the boiler system, the available heat in 10,000 pounds of basalt would amount to 2,400,000 B.T.U.'s. This amount of heat would be nearly enough to raise the temperature of 2,000 pounds of water from 66° to 210° F., evaporate it, and then superheat the steam to 900° F. Evaporation, of course, would take up most of the heat. The pressure generated by such a system with a constant volume would be over 3,000 atmospheres. Of course, there was no constant volume system, but the pressure developed must have been many times the minimum requirement of 1,000 pounds per square inch mentioned previously.

Now the question arises as to whether it is possible to inject suddenly an appreciable amount of water into an evacuated conduit. The Olaa well,[6] with a drawdown by continuous pumping of 8 feet, showed a continuous inflow of 80 gallons a second. If a void with the same capacity as that of the sump below the water surface were suddenly created, the amount rushing in during the first half second might well be several times that of any half second after pumping had been in progress for some time. Likewise the discharge during the first half second from water trapped in a dike compartment, when the wall separating it from a volcano conduit is suddenly shattered, might greatly exceed that of any subsequent half second. Furthermore, if the shattering occurred at the same time as a rapid downsurge of the lava, there might be a pressure decrease that would facilitate the inflow of water. A considerable vertical range in the shattered conduit would speed up the inflow of water, for the velocity of inflow varies roughly as the square root of the depth below the surface of the water table.

The temperature of the dust of the explosion column as it cleared the crater rim must have been nearly 900° F., for on several occasions it was observed to have a dull red glow. The expanding steam, then, in the midst of the hot dust, would have had a volume about 3,500 times that of its water equivalent when it reached atmospheric pressure and would have condensed only in the extreme upper and cooler portions of the cloud. Steam was first definitely observed in the explosion cloud on May 14, though whether it had its origin in the explosion or from steaming vents in the crater wall is not known. The amount of condensation of water vapor in the explosion clouds was never striking, in fact, not much more than might be expected from such a column of hot air with appreciable indrafts of humid air. The explosions must have been produced by relatively small amounts of steam.

Although there was no apparent regularity in timing with many of the explosions that occurred during the early part of the explosive period, the most common interval between explosions[7] was 6 to 8 hours. This interval was in accord with observations on lava fluctuations in Halemaumau. The early irregularities might be expected when one considers the possible existence of a network of feeding fissures under Halemaumau that decreased in number with increase of depth and the possibility that collapsing in the different walls may not have taken place simultaneously. Then, too, the explosion pressures themselves may have been the cause of some of the collapses and thus may have resulted in a series of explosions closely following one another. It should be noted that whether there was one feeding conduit with a diameter equal roughly to the bottom of Halemaumau or a series of feeding wells, the preceding discussion is little affected. If there were but one conduit, variation in the timing of the shattering of different portions of the conduit walls could have produced the observed effects.

Two conditions could have prevented further explosions: a lava column that had become stationary and the cessation of the shattering of the walls of the dike-inclosed compartments containing water.

Many of the explosions, perhaps all, produced air-pressure waves preceding the sound waves. This indicates that the onset of the explosions was rapid, like that of dynamite. The idea of a "flash boiler" mechanism to account for the May 1924 explosions of Kilauea does not seem incompatible with possible available heat and ground water nor with the observed facts of the explosions.

AUTHOR'S ACKNOWLEDGMENT: The author is indebted to Dr. T. A. Jaggar and Dr. G. A. Macdonald for reading and criticizing the manuscript, and to Mr. Williard M. Eller of the Hilo Electric Light Company, Ltd., for checking the computations.

COMMENTS

By T. A. JAGGAR

The foregoing discussion on a possible mechanism for comparatively shallow focus explosions is interesting.

I think of the surgings as deeper and place more emphasis on the magmatic furnace than on incandescent walls. With deeper surgings, the wall breakage with each retreat would let in fresh water from the Ghyben-Herzberg lens at the same time that magma was cascading into the evacuated chamber. The effect would be similar to the surface cascade shown in the figures in the Bulletin of the Hawaiian Volcano Observatory for August 1919.

With the Ghyben-Herzberg ground water standing at 35 feet above sea level, the bottom contact with salt water was 1,400 feet below sea level. If the lava outflow undersea was at one-fourth the depth found 40 miles off Cape Kumukahi (east point of the island) and emerged one-fourth the way down the submarine slope at an elevation of about 4,500 feet below sea level, it was 3,000 feet below the bottom of the fresh water lens.

If the rushing lava was cascading past Kilauea from a head relatively high within Mauna Loa, one cascade or rift tunnel could furnish either a continuous or intermittent furnace, such as the cascades and tunnels that were observed for days in 1919 to 1920.

Surgings and drainages would suck down air from the fissured mountain above ground-water level and so increase the

[6] Duncan, George. "The Dug Well at Olaa Mill." Volcano Letter No. 477, July-September 1942.

heat supply with intense gas oxidation. Cascades of retreat are nothing more than excessive convectional fountaining. Far below water level a downsurge of 10,000,000 cubic feet of lava within a half hour cannot leave a vacuum. Evacuated by steam explosions, a shatter chamber, below 1,500 feet of head of water and still lying higher than at least 3,000 feet of head of much heavier rushing lava that sends up a roaring gas furnace through the well, is likely to suck water into the chamber and make steam that pulsatingly escapes. The bulk of the magma rushes on to effervesce into the ocean. With surges of collapse a Bessemer-furnace process would be set up through the collapse debris. Flash-boiler heavings would punctuate the collapse around the deep chamber—collapses having nothing to do with faulting at the surface.

The mechanism may be thought of as a pouring torrent released through a rift tunnel. The geyser shaft was pulsating accordingly as ground water, alternately heated, blasted upward and rushed in cool. The blasts aided rupture for pumping in new water.

I think the end of the explosions resulted because of a backing up of the submarine outflow, the lava filling fracture fissures and losing pressure through satisfying the new rift-system that was generated in the first place by the tumescent stress under the whole island in surgings of 1915 to 1923. This merely makes the tumescence of the upper island extend itself eastward to the submarine island whenever the century-long cycle between steam blast eruptions shifts its surging from high under Mauna Loa to low under Kilauea or Hualalai. The 130-year period for explosions at Kilauea represents something fundamental in the volcano mechanism that cannot be satisfied with superficial relations only.

The arrangements of the 1919 to 1920 flow from Kilauea that built up Mauna Iki serve as a model of the 1924 system. The Mauna Iki flow was fed by a rift tunnel from Halemaumau through an arcade that still shows in the southwest wall. A little way down the slope from Halemaumau was a lava well, with fountaining lava and escaping gas. In 1924 the entrance arcade was somewhere in the depths under Mokuaweoweo; Halemaumau was the well over the rift tunnel; and the lava flow issued somewhere on the submarine slope east of Cape Kumukahi. With such an arrangement we get three possibilities:

(1) That the tunnel is shelled over water tight and lava tight, and the ground water outside like a tubular boiler. This is not possible, as it was recently feeding the pit and in April 1924 was in a belt of shattering.

(2) That the tunnel is a longitudinal rift torrent, open to the pit, its gases rising to the Halemaumau vents in debris; that these vents in turn are water pipes of the shatter belt under hundreds of feet of hydrodynamic head, the water surging downward as the lava fountains surge upward and downward.

(3) That the feeding vent is an independent upright dike under Kilauea, trending to Puna under the openings of 1920 (Mauna Iki), 1921 (Halemaumau), 1922-1923 (Makaopuhi), and April 1924 (Kapoho)—all sealing above and splitting wide open below to rupture a way along the under-ocean dome surface, just as the Kau Desert ruptured in December 1919 to January 1920. The water conditions were the same as (2).

Probably both (2) and (3) are true, the November 28, 1919 sympathy with the end of the Mauna Loa eruption being the beginning of the rupturing downward that fractured open the Kau Desert rifts in 1920. The upsurges of 1923 must have been dike splitting to introduce the dike fillings of the downsurges. A colossal volume of liquid had to go somewhere and come from somewhere, and neither source nor destination appeared.

All the events were a part of the same Mauna Loa-Kilauea pulse series—like 1914, 1916, 1919, 1920, 1921, 1922, and 1923—which left their output on the surface and also within the internal dikes of tumescence. Thus it is only reasonable to believe that the main vent is under Mauna Loa and deep, that the 1923 surgings were the culmination of lava lowering within Mauna Loa, and that the destination was on the same enormous submarine mountain beyond Cape Kumukahi. That Kilauea was internally robbed is proved by Wilson's shrinkage.[1]

Ground water was essential to the occurrence of any explosions at all. When the lava column, its outer armor broken, got below ground water, a phreatic accident was initiated. This means that if the 1942 flow from Mauna Loa, say, had had a head of ground water above, it would have been accompanied or followed by upper-well explosions. Just such explosions are the rule in heavily watered continental volcanoes. This would be particularly the case if the andesites were viscous and the fountaining subterranean. Ergo: Lassen, Vesuvius, Pelee, and Merapi.

Hawaiian Volcano Observatory Report for January-March, 1943

VOLCANOLOGY

January

The beginning of 1943 found both Kilauea and Mauna Loa inactive. Heavy rains during the first week of the month caused conspicuous steam clouds over the 1942 lava flow from Mauna Loa. These clouds started rumors that Mauna Loa was in eruption. A landslide at Halemaumau raised a conspicuous dust cloud at 13:45, January 26. There was an unobserved landslide from the southwest wall of Kilauea. At Kilauea 82 seismic disturbances were recorded and at Mauna Loa 32.

February

Only one of the 83 seismic disturbances recorded at Kilauea was strong enough to be perceptible at the Observatory. On the Mauna Loa seismograph, 33 quakes were registered. There was a perceptible widening of the cracks around Halemaumau.

The thermometer shelter was moved to the new observatory grounds in 1941. The new location, slightly lower than the old, is on the windward side of the northeastern-rim steam cracks; therefore, minimum temperatures now recorded are frequently lower than those at the old location.

March

The preponderance of Kilauea shakes over those of Mauna Loa origin, exhibited in January and February, continued in March. There were 71 shakes at Kilauea and 47 at Mauna Loa. None of the quakes appeared to have any special volcanic significance, and Hawaiian volcanoes remained quiet throughout the month.

* For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the Island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. The number preceding each earthquake date is the serial number of the quake for the current year.

1. January 9, 20:04, very feeble, felt in S Kona.
2. January 11, 14:32, very feeble, Mauna Loa.
3. January 15, 17:41, very feeble.
4. January 16, 03:38, very feeble.
5. January 16, 04:22, very feeble, origin at Kilauea.
6. January 17, 14:08, slight, felt locally, NE rift Mauna Loa.
7. January 19, 02:48, slight, felt locally and in Hilo.
8. January 24, 03:09, feeble, felt in Pahala.
9. January 27, 19:06, very feeble, felt at Kukaiau.
10. January 30, 13:53, very feeble.
11. February 1, 22:10, slight, felt in Hilo, Mauna Loa origin.
12. February 8, 10:35, very feeble.
13. February 15, 06:30, very feeble, felt in Kohala.
14. February 16, 03:59, very feeble.
15. February 27, 07:04, very feeble.
16. March 10, 07:34, feeble, Kilauea shake.
17. March 10, 22:52, feeble, Kilauea shake.
18. March 11, 03:06, very feeble.
19. March 11, 04:11, very feeble.
20. March 11, 10:26, very feeble.
21. March 12, 19:26, very feeble.
22. March 13, 19:25, very feeble.
23. March 15, 12:06, feeble, between Mauna Loa and Mauna Kea.
24. March 16, 01:54, very feeble.
25. March 25, 13:05, slight, Mauna Loa.

TELESEISMS

February 21, 23:00, slight.
March 15, 12:30, very slight.
March 21, 10:10, very slight.

MICROSEISMIC MOTION

Microseisms were present throughout the quarter but especially noticeable on February 13 only.

TILTING OF THE GROUND

The normal southwest tilt prevailed during the quarter save for a slight north-northeast tilt during the last few days of January and the first few days of February. For the past several months the tilt stations at Halemaumau showed almost no movement.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount	Direction
January	3	0.27″	S28° E
	10	1.46″	S42° W
	17	0.48″	S
	24	1.33″	S
	31	0.51″	S13° E
February	7	1.40″	N53° E
	14	0.74″	S80° W
	21	1.17″	N71° W
	28	1.39″	S38° W
March	7	0.57″	N45° E
	14	1.00″	S76° W
	21	0.72″	S
	28	0.84″	W

CRACK MEASUREMENTS

All cracks around Halemaumau except one showed a slight opening during the quarter. One crack along the Chain of Craters Road showed a slight opening; the other crack in this area exhibited no movement.

LAVA RIVERS AND THEIR CHANNELS

By R. H. FINCH

Estimates by reliable authorities of the depth of rapid-flowing lava rivers of Mauna Loa and the observed depth of the channels after flowing has ceased are often in disagreement. The discrepancy arises from the fact that the observed channel depths are too great.

Lava rivers are comparatively narrow streams flowing within well-defined banks. Where such streams flow out onto a relatively flat terrain, especially if the lava is in the aa stage, a slow-moving lava field covering a considerable area may develop. Short-lived lateral overflows often build up the banks of the channel so that frequently lava rivers are appreciably depressed within their banks. Discrepancies persist, however, even after due allowances for such depressions are made. In 1942, for instance, after the Mauna Loa flow had ceased, a channel about 16 feet deep was found where the river was estimated to have been not over 4 to 6 feet deep and depressed within its banks from 3 to 4 feet. This leaves a discrepancy of over 6 feet to be accounted for. In some cases, discrepancies are even greater.

The order of magnitude of the depth of Mauna Loa lava rivers is determined by noting the behavior of a stream at a cascade and by estimating the percentage of the large bank segments that remain visible after having broken off and fallen into the stream. Often lava rivers branch to make braided streams (fig. 1). The majority of these branches persist but a short time and thus offer opportunities to check estimates of depth. Here, estimated and measured depths are in close agreement. The shallow depth of short-lived streams might be taken as an indication that time is an all-important factor in regard to depth and that long-continued rivers erode or melt material to form a deep channel. These possibilities can be discarded, however, as such erosion cannot be appreciable. Moreover, the possibility of lava fusing the bottom of its channel to give the indicated increase in depth is very remote, because the temperature required to fuse lava does not obtain in such a river. Some other explanation must be sought. Furthermore, because lava rivers tend to crust over and the crust tends to become broken into blocks which sink into the melt, one might expect the channel to grow progressively shallower unless there is some mechanism whereby such sunken blocks are continually removed.

Dr. T. A. Jaggar made the first detailed observations on the mechanics of a Mauna Loa lava river at the Alika flow in 1919.[1] Describing the lava river, he stated: "The effect in the lava stream was as though the bottom were everywhere at shallow depth, and perhaps itself shifting downhill at a slower rate than the liquid film on top." In another paragraph he said: "After seeing the marked differentiation between the liquid lava in the channel and the evident semi-solid matter of the channel bottom and sides—the writer surmised that there were here present two kinds of magma, just as in Halemaumau. There we have the sharply differentiated lake magma and bench magma."

Irregularities in the bottom of lava rivers often manifest themselves as stationary waves at the surface. The progressive movement downstream, observed on several occasions, of some of the obstructions causing these stationary waves is a good indication of the dual nature of such streams—that is, of an upper rapid-flowing stream with low viscosity superposed on a sluggish viscous one. The closing stages of Mauna Loa lava rivers fur-

[1] Jaggar, T. A. "Activity of Mauna Loa." Bulletin, Hawaiian Volcano Observatory, October 1919, page 136.

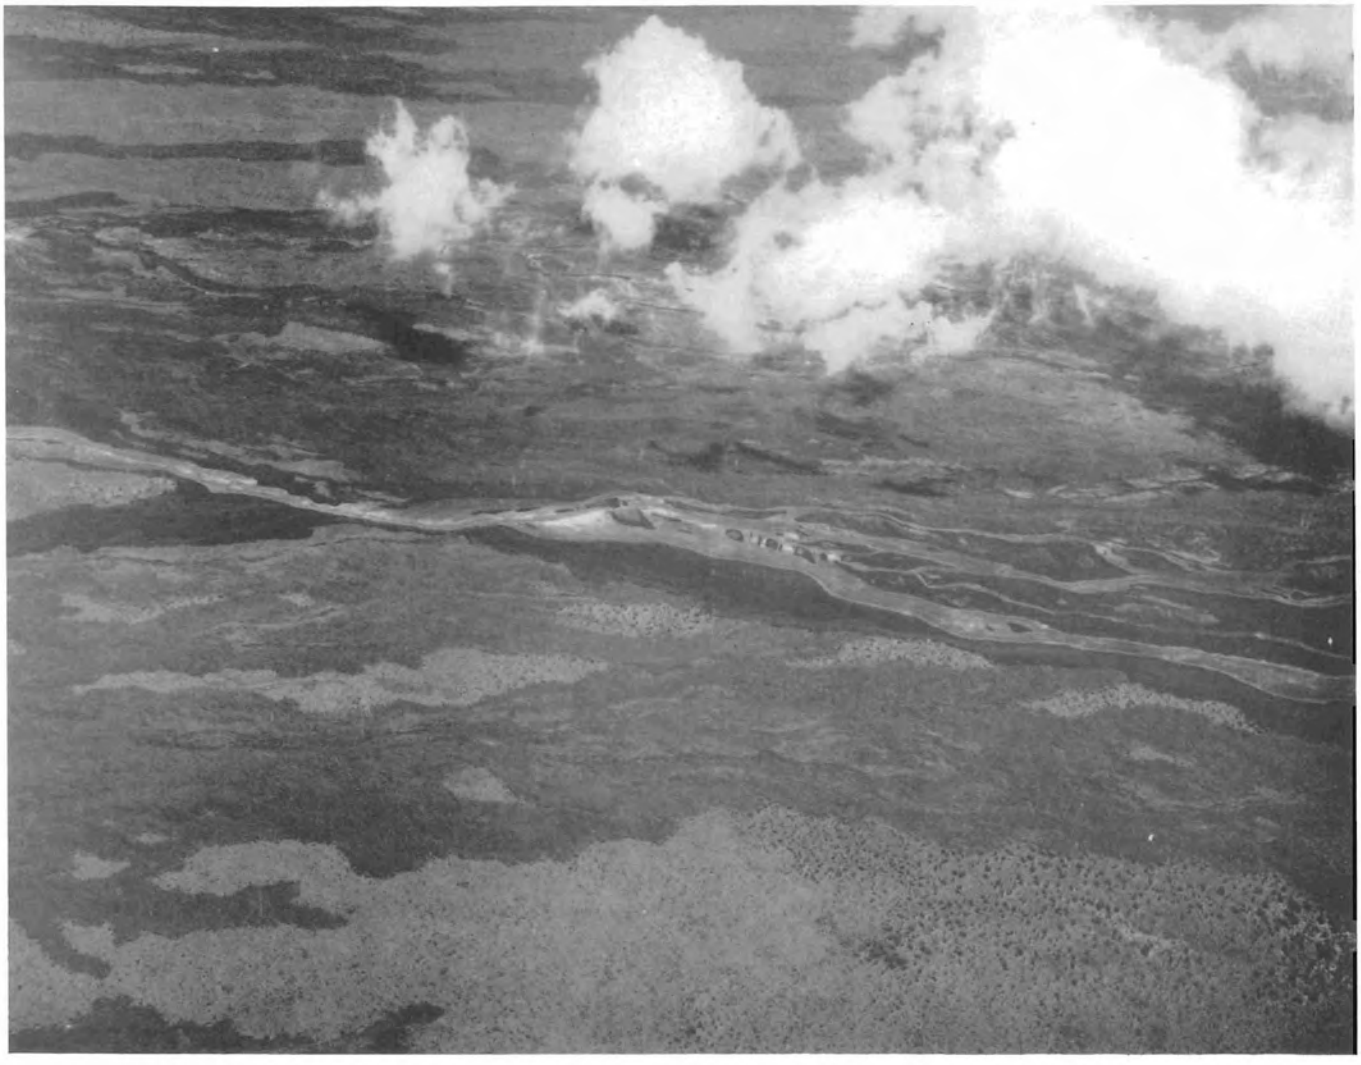

Figure 1—The 1942 Mauna Loa lava river a little below the source cone, where it divided to form a "braided" stream. These branches returned to a single channel lower down. (Photo by Base Photo Laboratory, A.A.F.—APO No. 953.)

nish further evidence on the dual nature of such streams. When diminishing activity at the source cuts off the supply, the material in the upper river quickly drains away, while the slower-moving lower stream continues for some time. Accurate timing of the cessation of the two streams would give some idea of their relative viscosities. Probably, just as perceived by resistance to sounding pipe in Halemaumau, there is gradation of viscosity from liquid vitreous foam on top of the lava rivers to semi-crystalline paste at the bottom. The flowing onward of this paste at the end of an eruption should shallow the delta region stream and deepen the upstream gorge. Exactly this occurred in 1919, 1935 and 1942.

Dr. Jaggar's observation in 1919 that the rapid-flowing Mauna Loa lava rivers are shallow and superposed on slow-moving channel material seems to be justified.

THE VISCOSITY OF MAUNA LOA LAVA FLOWS

By R. H. FINCH

The viscosity of flowing lava is constantly changing. The change is generally to a higher viscosity, because of a decrease in temperature. At the surface of a lava flow, the change is much more marked than in the interior. In pahoehoe flows, the formation of skins gives a very high viscosity for an outer layer. This outer layer, being a good insulator, helps the interior to maintain a high temperature and a relatively low viscosity. The surface granules of an aa flow likewise act as an insulator and allow this type of lava to flow to considerable distances. The rapid cooling of overflows from lava rivers and of the tongue-like extensions by which lava advances causes a rapid change in viscosity within a few seconds.

Because of these factors, one might expect to find a great range in the estimates of the viscosity of lava flows. The data for the estimates of the Alika flow were taken where it crossed the road, which is 9 miles from the source. The apparent viscosity of the lava river changed but slightly in the nine miles, although from the preceding article one might expect that the

volume of the low-viscosity surface portion of the river was relatively greater near the source than at a point 9 miles away. The figure determined by Palmer[1] may be essentially correct for a lava river near the source. Palmer gave the viscosity of the Alika flow as 15 times that of water. Whether the Palmer value is multiplied by 2, or 3, or even 10, it gives us the order of magnitude of the viscosity and is much nearer the truth than the computations of Nichols.[2] The tremendously high viscosity arrived at by Nichols—4,300,000 times that of water—was largely due to erroneous assumptions in regard to field data. For the Alika flow, he made his computations for a river channel and used a depth that was undoubtedly too great. In his computations on the 1887 flow, he had the flow moving as a unit. This, of course, was not the case.

A rough check on the errors in the Nichols' determination is provided by the data he gives on the temperature of dry melt. The formula he used gave the Alika and the 1887 flows higher viscosities than those of dry melts! Now it is well known, although often overlooked, that to reheat lava and get the same degree of mobility that it had when cooling at, say 650° C., it must be heated several hundred degrees higher. Day[3] gives the difference in temperature for lava in which movement can just be detected and the same lava reheated until it will flow under its own weight as 700° C. This is about the same temperature difference that Rittman[4] believed obtains for similar stages in Vesuvian lava. Shepherd[5] has pointed out the importance of small percentages of volatiles in melts and hence the danger of comparing the viscosity of lava flows with the viscosity of reheated devolatilized or partially devolatilized lavas.

The determinations of viscosity made by Nichols appear to be applicable to the tongue of a lava flow that has about ceased moving, but not to Mauna Loa lava rivers. His value may be too low for a moving lava field devolatilized and away from the river.

Hawaiian Volcano Observatory Report for April-June 1943

VOLCANOLOGY

April

April was a month of low seismicity. At Kilauea, 36 seismic disturbances were recorded and at Mauna Loa, 35. None of the shakes was perceptible in the vicinity of the Observatory. The scarcity of earthquakes and a southwest tilt that was less than normal for this season of the year may be taken as indications of rather high internal pressure in the Mauna Loa-Kilauea system. However, despite the scarcity of earthquakes and lack of much tilt, landslides from the walls of Halemaumau were rather frequent.

May

The spell of seismic quiet that marked April continued through May. At Kilauea, 29 seismic disturbances were recorded and at Mauna Loa, 26. An earthquake that originated on the eastern flank of Mauna Loa was felt slightly at widely scattered points in the eastern part of the island of Hawaii at 5:10 a.m. on April 8.

Fume in about the usual amount was observed from the center of Mokuaweoweo on May 29. Several places in the vicinity of the source cone of the 1942 Mauna Loa flow were still quite hot on May 29. The odor of free sulphur was detected at one hot spot about one-quarter mile below the cone. This spot appears to be the place from which conspicuous fume was emitted during the progress of the flow and for a week or two after the eruption ceased.

Along the northwestern edge of the flow, not far from the previously mentioned hot spot, new black aa spatter may be found on the old lava. No cone structure or spatter rampart was built up here and there is little evidence to show where the spatter came from, as the source was buried by a subsequent aa flow. The only clue is the end of a small new crack in the old lava. This crack may be taken as an indication that 1942 lava in an old tube developed sufficient pressure to disrupt the roof at this place and forcibly eject black aa spatter.

June

June is the third month with little seismic activity. At Kilauea, 22 local disturbances were recorded and at Mauna Loa, 15.

After a heavy rain during the latter part of June, the outline of the 1942 Mauna Loa flow was plainly revealed by dense steam clouds. In other words, the 1942 lava, nearly 14 months after the flow ceased, is still hot.

BLOCK LAVA IN THE 1942 FLOW FROM MAUNA LOA

A small patch of block lava may be found in the midst of aa lava near the northwestern edge of the 1942 Mauna Loa flow about one-quarter mile below the source cone.[1] This lava resembles broken brick, having none of the spiny or clinkery surface characteristic of aa. When viewed from a distance, however, its fragmental nature gives it the appearance of aa.

Block lava is distinctly different from slabby pahoehoe. The blocks were formed during the declining days of the eruption by the collapse of the walls of the lava river channel just below the source cone. An appreciable number of the blocks fell upon an aa stream, which transported them to their present position. The uniformity that exists to a greater or lesser degree in the size of the blocks is to be expected when one considers that the thickness of the different flows from which they originated was about the same. Moreover, the larger fragments would be broken during the transportation. R.H.F.

[1] For use of the term block lava, see R. H. Finch, Journal of Geology, October-November 1933, page 769.

* For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the Island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. The number preceding each earthquake date is the serial number of the quake for the current year.

26. May 7, 02:09, feeble, felt Kapapala to Hilo, E slope Mauna Loa.
27. May 8, 04:10, slight, generally felt eastern Hawaii, near Mokuaweoweo.
28. May 9, 02:20, very feeble.
29. May 10, 05:20, very feeble.
30. May 30, 12:53, very feeble.
31. June 14, 03:24, very feeble.
32. June 14, 21:38, slight, widely felt island of Hawaii, near Waimea.

TELESEISMS

April 5, 05:51, moderate.

April 8, 21:25, slight.

May 25, 12:50, moderate, distance 8250 km.

May 26, 00:20, slight.

MICROSEISMS

Microseisms were strong on April 10 and 11, moderate on April 28 to 30 and June 10 and 11, and slight throughout the rest of the quarter.

Tilting of the Ground

During the late winter and spring of the year, the southerly tilt was less than normal. The change to northerly tilt occurred about the middle of June. Westerly tilt, which was normal for the first five months of the year, ceased about the middle of May, and the usual easterly tilt began. There was but little movement at the tilt stations near the rim of Halemaumau during the period April to June.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount	Direction
April	4	0.87″	S34° W
	11	1.37″	N63° W
	18	0.51″	N45° E
	25	0.39″	N71° W
May	2	0.88″	S74° W
	9	0.88″	S56° W
	16	0.51″	N45° W
	23	0.76″	S19° E
	30	0.65″	N68° E
June	6	0.60″	S37° W
	13	0.76″	S72° E
	20	0.76″	N18° W
	27	1.08″	N63° E

Crack Measurements

A majority of the cracks in the vicinity of Halemaumau showed slight openings. The opening near the south rim was appreciable in April and May. In June, one of the cracks along the Chain of Craters Road opened 6 millimeters; no movement was detected at other cracks in this vicinity. R.H.F.

WORK OF UNIVERSITY AND RESEARCH ASSOCIATION

By T. A. JAGGAR

In June, 1938, Dr. T. A. Jaggar, after reviewing twenty-six years of work at the Hawaiian Volcano Observatory, reported in Volcano Letter 460 a planned program for the Hawaiian Volcano Research Association. The plan included making secure the scientific archives, getting the new Observatory building, completing technical publications, creating a publication committee, shifting the volcanologist's work to new hands, and allowing Dr. Jaggar, as Research Associate of the University of Hawaii, to act as editor and writer with the Hawaiian Volcano Research Association collaboration. Various reports on the progress of the plan have been made. Cooperation of the three establishments, Hawaii National Park, University of Hawaii, and Hawaiian Volcano Research Association, was described in Volcano Letter 454, for December, 1937. Dr. Jaggar finished his writing of the "Volcanology" for the quarterly Observatory report of July-September, 1940. "The Physical Plant" of the Hawaiian Volcano Observatory in Hawaii National Park was reviewed by P. E. Schulz in Volcano Letter 475 of January-March, 1942. This issue of the Volcano Letter is a report by the Research Associate of the University of Hawaii on the accomplishments by the University and the Hawaiian Volcano Research Association in accordance with Dr. Jaggar's plan.

The scientific records are being worked over by both R. H. Finch, Volcanologist, and by Dr. Jaggar. The latter has sent two finished memoirs to the Geological Society of America. The new Observatory building at National Park is occupied. The publication committee in Honolulu consists of F. C. Atherton, Gregg M. Sinclair, and T. A. Jaggar. Finch writes, and Jaggar edits the quarterly Volcano Letter published by the University under authority of the National Park Service: its primary function is to maintain a continuous record of the volcano measurements. The making of duplicates of the more valuable volcano records by microfilm, photostat, and carbon copies to be kept at the University has been started.

Some publications appearing later than those listed in Volcano Letter 456 are given below:

WORK OF THE UNIVERSITY

The last lecturing to students by Dr. Jaggar was to a class of 70 in July, 1938, and to audiences of 300 persons in the Adult Education Service in March, 1939. Funds were appropriated for special geophysical research in the University by the Territorial Legislature for the biennia 1939-1941, 1941-1943, and 1943-1945, and Dr. Jaggar was appointed Research Associate in charge, to work in collaboration with University departments, the Hawaii National Park, and the Hawaiian Volcano Research Association. After December, 1941, research manuscripts were compiled (to the number of twelve by 1944) and sent to the Government. At regular intervals reports on the geophysical research, including illustrations and laboratory phases, have been made to the President of the University. Laboratory work on "Abrasion Hardness" of substances has been in progress since July, 1942, in a laboratory and shop created by the Association.

The manuscript reports include inventions used in exploration, in seismology, in mineralogy, and in volcanology, which cover a range of activities of the Hawaiian Volcano Observatory from microscope to mountain top, and under the waters of the ocean, from Alaska to New Zealand, and from Italy to Central America. The manuscripts and their illustrations are voluminous, serving in the laboratories to assemble for University use a compendium of forty years of work in geology, and bringing into system what would otherwise have been loose notes. The compendium is matter for scientific recording; publication is gradually being achieved. Samples of such publication are the papers previously listed on ash, magmatic gases, and tilting of the ground. The effort in all this work has been to aim at the principles of comparative volcanology, and not merely to give local description.

Titles of typescripts (the first fourteen written by Dr. T. A. Jaggar) that have been filed are as follows:

1. "Origin and Development of Craters." 843 pages, 93 plates. (Prepared under a grant from the Geological Society of America.)
2. "Expeditions on Certain Hawaiian Beaches." 11 pages, 1 plate.
3. "Conflagration from Earthquakes." 7 pages, 1 plate.
4. "Exploration of Alaskan Beaches." 21 pages, 1 plate.
5. "Mechanical Features of Vehicles for Exploration." 32 pages, 8 plates.
6. "Aleutian Shorelines." 117 pages, 65 plates.
7. "Volcano Explorations in Japan." 120 pages, 49 plates.
8. "Artificial Defense Against Lava-flow Damage." 139 pages, 12 plates.
9. "Expeditions to New Zealand, Tonga, Samoa, and South Sea Islands." 162 pages, 27 plates.
10. "Journals of Caribbean Earthquake Disasters." 276 pages, 36 plates.
11. "Lava Activity of Hawaii Island." 275 pages, 93 plates.
12. "Steamblast Disasters in Caribbean and Pacific." 284 pages, 39 plates. (Received as a memoir by Geological Society of America.)
13. "Volcanoes Around the Pacific." About 1200 pages, with 100 plates selected.
14. "Abrasion Hardness." About 200 pages, with miscellaneous illustrations. (Is in preliminary typescript and photostat.)
15. "Volcano Warfare," by L. W. de Vis-Norton, Secretary-Treasurer of the Hawaiian Volcano Research Association. 15 chapters, 243 pages.

Number 1 is a memoir embodying twenty-six years of experience at the Hawaiian Volcano Observatory, outlining the field of volcano science, and developing some principles of crater evolution. It assembles observations, maps, sections, diagrams, curves, photographs, reviews, and narrative histories of craters. Numbers 2, 4, and 6 deal with the physical geology of Hawaiian and Alaskan shorelines. Numbers 3 and 7 describe explorations among Japanese volcanoes and some disasters due to earthquakes adjunct to volcanic districts. Numbers 5 and 13 have chapters dealing with instrumental invention and special cross-country vehicles designed to apply power engines in exploration instead of pack animals. These publications also describe Pacific and other volcanic activities. Number 8 is a report on the history in Hawaii of an engineering attempt to protect Hilo harbor from lava-flow damage. Number 9 describes expeditions to New Zealand in 1920, Howland and Baker Islands in 1924, and Niuafoou in Tonga in 1930 by Dr. Jaggar, and to six equatorial islands of the Pacific by H. H. Waesche in 1938. It was in 1938 that an earthquake annunciator was experimented with on two of the islands, just as in New Zealand, on Niuafoou, and on Howland portable shock-recorders had been planted for testing seismicity. Number 10 is a comparative study of two earthquake disasters in the field at opposite ends of the Caribbean Sea—the Cartago shocks of Costa Rica in 1910 and the Montserrat spasms of 1933 to 1936. Number 11 is a condensation of Kilauea record books from 1909 to 1935. Number 12 is based on the author's investigation of the Pelée and Soufrière disasters in Martinique and St. Vincent in 1902, and the comparative volcanology of Kilauea, Tarawera, Sakurajima, Katmai, Taal, and Tomboro volcanoes, with especial reference to the reports of wounded persons. Number 13 is a book on twentieth century volcanology. Number 14 is unfinished and dependent on investigations in progress designed to show that physical hardness is probably a fundamental property of the association of particles measurable in terms of kinetic energy. Number 15 is Mr. Norton's book, a popular exposition of field volcano science, admirably suited to magazine publication if it can be illustrated with pen sketches by a good artist.

A sixteenth typescript of importance is a master's thesis entitled "Chemical Decomposition of Rocks at Kilauea" written by K. T. Mau in June, 1940. It includes 103 pages, 13 tables, and 8 figures. This work awaits publication: it investigates relationship between solfataric alteration and final resulting soil. Rock samples were analyzed chemically, microscopically, and spectroscopically. Natural solfatara alteration is examined with reference to decrease and increase of constituents. Decomposition by hot acid steam prolonged for six months artificially included combinations with air, carbon dioxide, and sulphur dioxide. Sulphur dioxide was proved the most active decomposing agent. Methods of analysis are described critically, and the analyses carried to 24 constituents including nickel, copper, chromium, vanadium, strontium, barium, and zirconium. The spectrographic analysis adds cobalt.

These writings are to be issued as scientific memoirs or books as the occasion to publish arises and are in part on their way into print. Other compilations dealing with field and laboratory notes on experiments with volcanoes, experimental geology, graphical position-finding by stars, simplified earthquake recorders, and Aleutian geology are in various stages of manuscript compilation.

The laboratory and offices of this work for the University are divided between 25 Hawaii Hall Annex, which is Dr. Jaggar's Honolulu office, and the Kilauea Laboratory of the University in Hawaii National Park. Dr. Jaggar's annual routine is divided between six summer months at Kilauea and the six winter months in Honolulu. The research associate's personal instruments, tools, and collections from expedition fields are in Honolulu, and the accumulated instruments and records of thirty or more years of the Volcano Observatory are at Hawaii National Park. Cordial assistance is given by the University departments and by the Hawaii National Park. The immediate cooperation of University departments of chemistry and physics at the Kilauea Laboratory was suspended in 1941.

WORK OF HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In 1941, the Hawaiian Volcano Research Association assisted with materials, equipment, and labor in promoting the duplication of records for the University, and in improving the shop of the Kilauea Laboratory and the Chemical Building in Hawaii National Park when the Volcano Observatory was moved. At that time there was great disruption owing to the moving of the hotel to the old Observatory site. The Association has financed illustrations for manuscripts and preparation of collections. In 1941, Dr. Jaggar's assistant at the University was Sutejiro Sato. In 1942, the assistant was Miss Ruth Baker (Mrs. Burton Loucks) who resigned in 1943. Mr. Sato and Miss Baker typed the numerous manuscripts and did valuable work of classification and labelling, assisted in experiments and compiling, as well as in handling much material that required heavy work in the moves from building to building, and from Kilauea to Honolulu and back. The Kilauea laboratories are two buildings distinct from the new Observatory building. Formerly the property of the Research Association, they have since been rebuilt and transferred to the Park Service for the use of the University workers.

The present Board of Directors of the Hawaiian Volcano Research Association consists of: F. C. Atherton, president; W. F. Dillingham and A. L. Dean, vice-presidents; L. W. de Vis-Norton, secretary and treasurer; and C. M. Cooke, J. R. Farrington, W. F. Frear, G. M. Sinclair, W. W. Thayer, and L. P. Thurston. In 1942, there were sixty members and fourteen donors in the Association.

At that time many boxes of records and specimens from expeditions had accumulated. When the crisis of war activity called for suddenly speeded-up laboratory activity in Honolulu there was no room in which to operate. Accordingly, the Association rented a small building near the University where Dr. Jaggar, as their Scientific Director, placed and classified the collections. These included minerals and implements of his own, formerly the subjects of abrasion hardness investigation at Harvard University and the Massachusetts Institute of Technology. A shop was equipped for rebuilding instruments. Throughout 1942 and 1943 a succession of model sclerometers has been tested on specimens of glasses, minerals, woods, and metals.

A paper on the "Hardness of Hawaiian Woods" was read before the Hawaiian Academy of Science October 16, 1942, and a sclerometer was exhibited in the form of a drill-press with a steel milling tool. It was shown that the hardness of substances varied inversely as the depth of boring during a constant interval, the result having been read by micrometer indicator where the pressure and speed were kept constant.

Such model instruments, used where volume abraded under identical conditions is the end sought, are parallel to the devices employed in metal-working where "machinability" is measured. Complexity of the aggregate of particles, whether atoms, molecules, or granules in a bond, and such qualities as sharpness of tool, toughness, brittleness, and viscosity of substances, all make the investigation a prolonged puzzle. Simple indentation is used in metallurgy as a measuring device. This, however, gives inconsistent results, and is quite inapplicable to minerals, rocks, glasses, and porcelains. Progress has been made since the work on abrasion hardness of woods was made public, and it is believed that a device will be worked out that will be fundamentally sound as a physical implement.

Preparation of a manuscript in connection with the subject of abrasion has proceeded with the assembling of matter from modern reference books. It deals with the great recent extension of the grinding industry and the metallurgy of alloys and welding, a science now so important in ship and airplane construction. There is also much need for abrasion measurement of woods, plastics, earthenware, stones, and minerals. Implements are now in use that deal with wear and degradation in commerce, or with ductile or malleable flow, but the aspect in physics of mutual collision-resistance by molecules appears to have been neglected in elementary textbooks.

The results of founding the Hawaiian Volcano Research Association in 1911 were the creation of the Volcano Observatory at Kilauea, establishment of Hawaii National Park, sending forth of Pacific expeditions, extension of work to California, Alaska, and the Caribbean, and obtaining the increasing cooperation of the Federal Government, the University of Hawaii, and outside research establishments. In volcanology, there is the same need for study of the hot interior earth, including the foundation of three-quarters of the earth's surface under oceans, as there is in astronomy for the physical exploration with instruments of the hot stars of the outer universe. The importance of the Research Association's making such field study possible should be emphasized.

As accented in Volcano Letter 454, the greatest need at present is for a fireproof building for valuable records in the University grounds in Honolulu: the records are now scattered in pine buildings. On February 6, 1940, the total destruction of the hotel by fire at Hawaii National Park taught a lesson. The second need in the current situation is a lava diversion channel, constructed according to surveys which have been finished, to defend Hilo from a Mauna Loa flow: the summit eruption of November, 1943, may be the portent of a coming 1945 outflow.

The Research Association is grateful to E. G. Wingate, superintendent, Hawaii National Park, for construction improving the Kilauea laboratories of chemistry and geophysics for University use. Unfortunately, a grant for critical hydrogen study made in 1941 by the Geological Society of America was suspended by the war crisis.

Summarizing joint activities of the last five years, we report memoirs completed, many thick illustrated and bound reports put into use, laboratories extended, publications issued, physical investigations in progress of service to technology made, records duplicated, a popular book sent to a publisher, and collections of specimens from world localities assembled. These are products of the University of Hawaii and the Hawaiian Volcano Research Association. Likewise, the engineering and scientific staff of Hawaii National Park has continued steadfastly its task of accumulating records and meeting crises in the face of untold reduction of resources.

Hawaiian Volcano Observatory Report for July-September 1943

VOLCANOLOGY

July

The spell of seismic quiet that started in April continued through July. Of the 28 seismic disturbances recorded at Kilauea, 2 are classed as earthquakes and the rest as tremors. Thirty-one seismic disturbances were recorded at Mauna Loa.

Following a heavy rain during the afternoon of July 8, steam clouds were conspicuous over the 1942 flow. The outline of the clouds was so sharp that rumors of a Mauna Loa eruption were started.

August

There was less seismic activity in August than in July. At Kilauea, 21 seismic disturbances were recorded and at Mauna Loa, 26.

Several slides from the walls of Halemaumau were noticed during the first half of the month.

September

Eighteen seismic disturbances were recorded at Kilauea and 20 at Mauna Loa.

September marked the sixth consecutive month in which but very few earthquakes were recorded at the Hawaiian Volcano Observatory. This is the longest period of seismic quiet in the history of the Observatory and is probably the longest in the last 120 years.

The present 6 months period of seismic quiet occurs during the longest period without volcanic activity at Kilauea on record. Nearly 9 years have elapsed since molten lava was visible in Kilauea. For about 6½ years no fume has been visible in Halemaumau, and but very little steam has escaped.

* For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. Distances are from the Observatory. The number preceding each earthquake date is the serial number for the current year.

33. July 1, 01:51, slight, felt locally and at Kapapala, near Ainapo.
34. July 3, 04:26, feeble. NE rift Mauna Loa above Puu Ulaula.
35. August 7, 12:40, Puna rift, 17 miles.
36. August 9, 02:14, very feeble.
37. September 13, 12:34, very feeble, near Mokuaweoweo.
38. September 17, 05:11, very feeble, felt Kohala.
39. September 21, 09:04, very feeble.
40. September 21, 16:17, very feeble, Kilauea crater.
41. September 21, 17:19, slight, Kilauea crater.

TELESEISMS

July 11, 15:49, slight.
July 28, 16:45, moderate, distance 7400 km.
September 13, 16:01, slight.
September 13, 17:45, slight.
September 13, 20:59, moderate, distance 5900 km.
September 19, 14:46, slight.

MICROSEISMS

Microseisms were moderate from July 6 to 9 and on July 19. During the remainder of the quarter microseisms were present though slight.

Tilting of the Ground

Westerly tilt prevailed during July and until the latter part of August when easterly tilt set in and continued through September. There was a slight and more or less continuous northerly tilt during the quarter. After having been nearly stationary for several months, the tilt instruments near the rim of Halemaumau showed some oscillations during the latter part of September.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount	Direction
July	4	0.40″	W
	11	0.74″	N10° E
	18	1.12″	N13° E
	25	0.77″	S51° W
August	1	0.77″	N71° W
	8	0.27″	N27° W
	15	0.27″	N27° W
	22	0.48″	W
	29	0.54″	N26° E
September	5	0.17″	S45° E
	12	0.62″	N79° W
	19	1.45″	N48° E
	26	0.54″	S64° E

Crack Measurements

The majority of the cracks around Halemaumau showed no movement during July while most of those along the Chain of Craters Road closed slightly. With the exception of 1 crack which opened 3 millimeters, there was very little movement at the Halemaumau rim in August. The majority of the cracks along the Chain of Craters Road opened slightly. In September there was but very little movement either at Halemaumau rim or along the Chain of Craters Road. R.H.F.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter**, a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE VOLCANO LETTER

No. 482 **Department of Interior** **National Park Service** **October-December 1943**

PUBLISHED BY THE UNIVERSITY OF HAWAII

HAWAII NATIONAL PARK: Edward G. Wingate, Superintendent; R. H. Finch, Volcanologist

UNIVERSITY OF HAWAII: T. A. Jaggar, Geophysicist

ACTIVITY AT MAUNA LOA IN NOVEMBER 1943

By R. H. FINCH

Conspicuous fume clouds over Mokuaweoweo and spells of continuous tremor on the seismographs indicate that there was slight activity at Mauna Loa in November 1943. The first observation of unusually heavy fume arising from Mokuaweoweo was made on October 10 by A. L. Jess from the summit of Mauna Kea. Steam always rises from the west central part of the crater. Mr. Jess made his observations at 6:45 a.m. and reported heavy fume from the southwestern part.

There had been some indications of a sustained and fairly high pressure under the Kilauea-Mauna Loa volcano system for several months. The indications were chiefly lack of southwest tilt in the spring of 1943 and extraordinarily low seismicity from April to the middle of October. Northeast tilt in the fall of 1943 was about the seasonal normal or, at least, not enough to indicate a return of lava to Kilauea. The number of seismic disturbances at Mauna Loa in October greatly exceeded those at Kilauea; they were 33 and 22, respectively. In November the corresponding numbers of seismic disturbances were 93 and 79. The majority of the November disturbances occurred on the 21st, 22nd, and 23rd. The excess of the number of Mauna Loa shakes over those from Kilauea in October and the observed fume on October 10 were definite indications of a growing uneasiness of Mauna Loa. The indications were not definite enough, however, to indicate impending activity at Mauna Loa.

Further evidence of Mauna Loa's uneasiness was the conspicuous earthquake at 5:22 p.m. (war time) November 10, in which movement of a large block in the southwestern slope of Mauna Loa was involved. Then during the morning of November 11, employees of the Puu Oo ranch on the southeastern slope of Mauna Kea observed conspicuous fume clouds over Mokuaweoweo. During the late afternoon of the same day a conspicuous fume cloud over the southern end of Mokuaweoweo was observed from Park headquarters. The fume was observed from the same place a few times on subsequent days.

Like the spells of continuous tremor, the fuming was intermittent. A National Park party was at the summit of Mauna Loa on November 19, and noticed nothing more than rather heavy steaming from the usual vents in the west central part of the crater. Tremor that continued for several minutes at a time became conspicuous on the seismographs on November 21, reached a maximum on November 22, and practically disappeared on November 23. It is interesting to note that a few reports of glow over Mauna Loa at this time were made on days of maximum spells of continuous tremor. The reports of glow would indicate that cracks heated to incandescence were exposed or else small amounts of molten lava reached the surface. The slight amplitude of the continuous tremor indicates that but a small amount of molten lava was involved, whatever the height the lava may have reached in the Mokuaweoweo conduits.

This quiet November 1943 activity brings to mind the possibility of there having been several unrecorded outbreaks in the past. If such activity had occurred when Kilauea was also active, the continuous tremor on the seismographs might well have been masked by harmonic tremor originating at Halemaumau. The continuous tremor of full-fledged Mauna Loa eruptions, having a much greater amplitude, usually overshadows the harmonic tremor from Kilauea. A conspicuous cloud developed over Mokuaweoweo in March 1921 at a time of intense activity in Halemaumau. There must have been, for a short duration, a pronounced increase in temperature of some of the cracks in the floor of Mokuaweoweo. Whether any molten lava reached the surface at that time is not known.

Apparently most, but not all, Mauna Loa summit eruptions have produced spectacular lava fountains. It is not surprising to find reports of a few outbreaks which produced little or no lava. In 1875 there was a short summit eruption in which pronounced glow was lacking. Starting in December 1887, a fume column was observed over Mokuaweoweo for more than a month. The fact that no glow was reported during this time does not necessarily mean that some short-lived glow would not have been observed had cloud conditions been favorable at the time of observation. From the Volcano House on September 10, 1907, about 8 months after the eruption of that year, a black cloud was observed over Mokuaweoweo that lasted for at least 13¼ hours. Some observers reported a glow in the cloud. At 4:00 a.m. September 11, a glow attributed to a lava flow was reported in the vicinity of Red Hill.

Fume and steam, unless dense, is more conspicuous by transmitted light than by reflected light. For instance there is a steam vent between 11,000 and 12,000 feet on the northeast slope of Mauna Loa whose presence is often plainly revealed at the Observatory by the rays of the setting sun in spring and early summer. At other times of the year the steam is seldom if ever seen. As viewed from the Observatory in June, the sun sets nearly behind the vent. Then the ascending steam is sometimes so conspicuous that it resembles lava fountains. It is interesting to note that the fume clouds of November 1943 were mainly observed by reflected light. That is, their presence was easily observed without the magnifying effect afforded by transmitted light at times of sunrise or sunset.

There is a fairly good correlation between summit eruptions and subsequent flank flows. Whether the fuming of November 1943 is to be interpreted as an added indication of a flank eruption within the next two years remains to be seen.

Hawaiian Volcano Observatory Report for October-December 1943

VOLCANOLOGY

October

The seismic lull that started in April 1943 was interrupted about the middle of October by the occurrence of several shakes, most of which were of Kilauea origin. During the month, 22 seismic disturbances were recorded at Kilauea, and 33 at Mauna Loa.

Large dust clouds from landslides were observed over Halemaumau on October 12 and 20.

November

The preponderance of Mauna Loa shakes over those of Kilauea origin in the latter part of October and the first part of November was the only authentic indication of a growing uneasiness of Mauna Loa. The interpretation of the seismograph records of the earthquake of November 10 suggests a rotational movement of a block in the southwest slope of Mauna Loa. Ninety-three seismic disturbances were recorded on Mauna Loa; 79 were recorded at Kilauea. The majority of the disturbances occurred on November 21, 22, and 23, or at the time of the maximum activity of Mauna Loa.

December

A conspicuous fume cloud was observed over Mokuaweoweo on December 19, first from Kona and later from Waimea. However, there were no signs of continuous tremor on the seismographs on this day. On December 25, steam in somewhat greater amount than usual was observed under the high western wall of Mokuaweoweo, but there was no fuming in the vicinity of the 1940 cone or elsewhere in the crater.

The number of seismic disturbances at Mauna Loa again exceeded that from Kilauea, 52 to 38, respectively.

The data of the following local disturbances were determined from stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard. Distances are from the Observatory. The number preceding each earthquake date is the serial number for the current year.

42. October 7, 08:50, feeble, Kilauea shake.
43. October 16, 02:36, slight east slope Mauna Kea, felt at Hakalau and locally.
44. October 18, 05:06, very feeble, Kilauea shake.
45. October 20, 02:07, slight, felt locally and at Hilo. Five miles deep under southern end of Kilauea crater.
46. October 22, 18:43, very feeble.
47. October 30, 18:23, very feeble, Kilauea shake.
48. October 30, 19:06, very feeble.
49. October 31, 13:28, very feeble, Kilauea shake.
50. November 4, 00:38, very feeble.
51. November 5, 15:35, very feeble.
52. November 8, 14:15, very feeble, felt in Pahala as a sharp jolt.
53. November 10, 16:18, very feeble, felt at Pahala.
54. November 10, 16:22, moderate, dismantled instruments, widely felt southern half island of Hawaii; stonewalls thrown down southwest of Pahala.
55. November 16, 23:26, very feeble.
56. November 21, 22:51, very feeble.
57. November 29, 13:45, feeble.
58. December 1, 19:52, very feeble.
59. December 3, 11:09, very feeble, lower SW rift of Mauna Loa.
60. December 7, 05:47, feeble, NE rift of Mauna Loa.
61. December 13, 19:43, very feeble.
62. December 15, 08:58, feeble, felt at Pahala.
63. December 18, 21:14, very feeble.
64. December 22, 19:50, slight, felt locally and at Hilo, southwest slope of Mauna Loa.
65. December 24, 01:51, very feeble.

TELESEISMS

November 3, 04:12, moderate, Alaska, 4550 km.
November 5, 22:15, slight, 8000 km.
November 20, 08:56, slight.
December 23, 08:45, slight, 6360 km.

MICROSEISM MOTION

Microseisms were strong on October 8, 16, December 9 to 10, and December 26 to 27, and moderate on November 18, 26, and 27. Throughout the rest of the quarter slight microseisms were recorded.

Tilting of the Ground

Normal northeast tilt prevailed during October, November, and until the middle of December except for the pronounced northwest tilt accompanying the distinct earthquake of November 10. The quake produced a permanent offset to the west in the E-W tilt curve. The sharp northerly tilt due to the quake was followed by a southerly tilt of like amount within about a day.

During 1943 there was a slight accumulation of westerly tilt due largely to the quake of November 10. The total northerly tilt for the year slightly exceeded the southerly.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount of Tilt	Direction of Tilt
October	3	1.21″	N54° E
	10	1.02″	N45° E
	17	1.30″	N22° E
	24	0.78″	N52° E
	31	1.18″	S24° W
November	7	1.85″	N31° E
	14	3.87″	N82° W
	21	0.62″	N11° W
	28	0.48″	S
December	5	0.88″	N16° W
	12	1.48″	S81° E
	19	0.84″	S45° W
	26	0.43″	S34° E

Crack Measurements

Crack movement during the quarter was slight. Five cracks near Halemaumau opened an average of 2 millimeters. The rest of the cracks measured near Halemaumau and those along the Chain of Craters Road were stationary.

HARMONIC TREMOR

By R. H. FINCH

Shortly after the seismographs were installed at the Hawaiian Volcano Observatory in 1912 it was noticed that they were recording small tremors continuously.[1] Omori had noticed similar tremors near some of the Japanese volcanoes. From their obvious connection with volcanic activity H. O. Wood called them volcanic vibrations. It was soon noticed, however, that there was no obvious connection between the outbreaks of the periodic fountain, "Old Faithful," in Halemaumau and the tremors as recorded at the Observatory 2.1 miles away. In general the tremors were most conspicuous during times of violent fountaining. The idea that such tremors are due to volcanic activity was confirmed when the seismographs that were installed in Hilo, 22 miles away, failed to record such tremors. When magmatic action totally ceased at Kilauea in 1924 the volcanic vibrations, as was to be expected, disappeared from the seismograms.

After seismograph drums with higher speed were installed at the Observatory in 1918, it was found that there were two types of tremors, one with a quite uniform period and amplitude and the other with a greater range in period and amplitude. To distinguish between the two, Dr. T. A. Jaggar in November, 1918[2] called the more rhythmic vibration "harmonic microtremor." This term was later shortened to "harmonic tremor." The less regular vibrations which often resemble miniature earthquakes were named "spasmodic tremor."[3] Austin E. Jones[4] divides spasmodic tremors into two classes and illustrates the two by idealized sketches. Mixed continuous tremor is recorded at the Observatory during Mauna Loa eruptions even though the source may be 22 miles away.

Harmonic tremor that was recorded under different conditions of the lava column at Halemaumau is shown in figure 1. In most cases the portion reproduced is typical of the tremor as recorded for days preceding and following the sample selected. *A* of figure 1 was taken when the lava lake was high and a flow was pouring on to the southwest floor of Kilauea through a tunnel the intake of which was a small distance below the Halemaumau rim. It is not likely that any of the tremors recorded were due to lava surging in this tunnel. *B* is from the record when lava was flowing at Makaopuhi and Napau craters along the Puna rift. Considering the small scale of these outbreaks and the indicated distance—over 7 miles—it seems probable that the tremors were due to lava surging in conduits under Halemaumau rather than from the seat of the outbreak. *C* shows a portion of the record in 1924 just preceding the explosive eruption of that year and at a time when no molten lava was visible. Numerous earthquakes along the Puna rift, the sinking of the lava column at Halemaumau, and harmonic tremor at this time indicated lava drainage through this rift. *D* is a portion of the record during the short-lived activity at Halemaumau starting on September 6, 1934. The especially large tremors were recorded during some of the most violent fountaining ever observed at Kilauea. Each spell of violent fountaining was usually followed by a rather quiet interval of about 30 minutes as shown by the two comparatively straight lines just below the lower large harmonic tremor. In this case there was a direct correlation between fountaining action in Halemaumau and harmonic tremor. This was due as Dr. T. A. Jaggar has explained[5] to a rather high viscosity of the lava and the inception of the fountains at the bottom of a shaft.

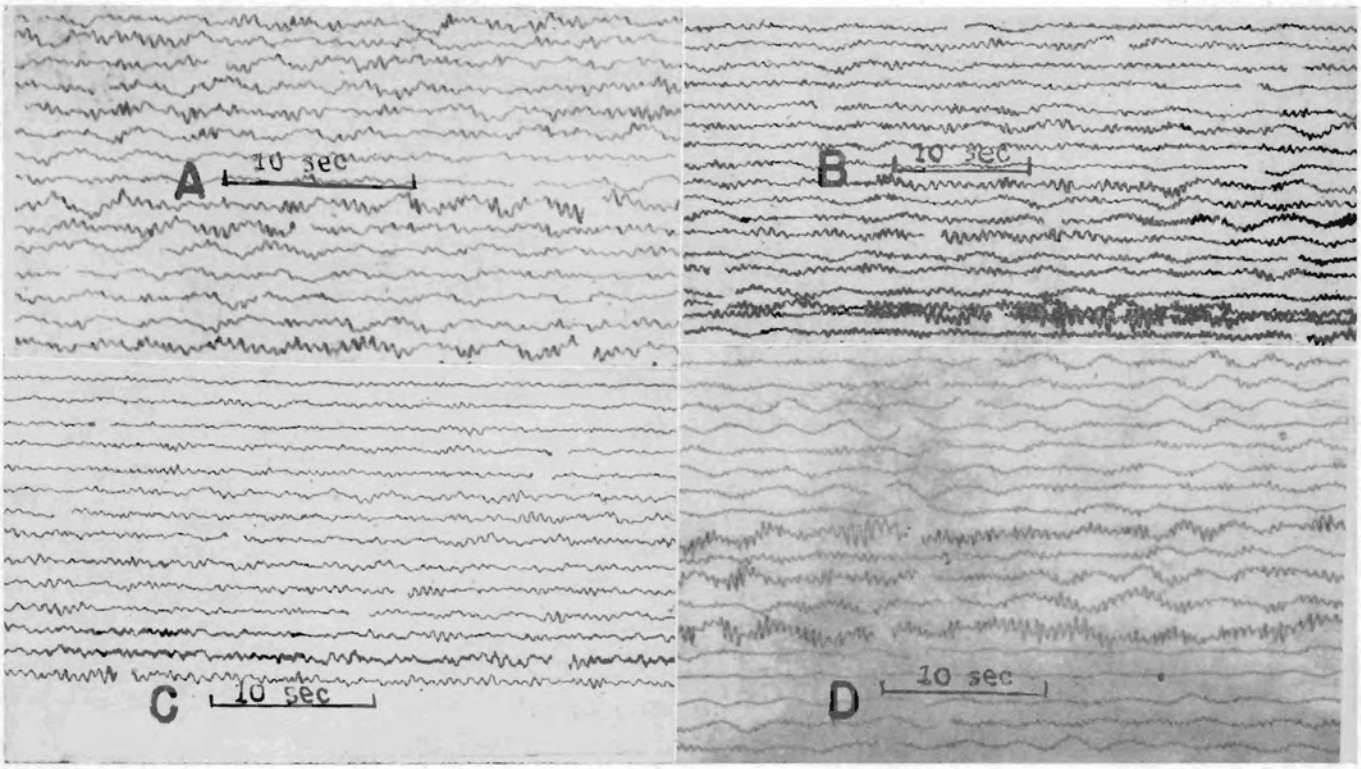

Fig. 1.—Harmonic tremor as recorded on the Bosch-Omori seismograph at Hawaiian Volcano Observatory, 2.1 miles northeast of Halemaumau. Travel from right to left. E-W component.

A. March 26, 1921—lava was high in Halemaumau and flowing in southwest part of Kilauea Crater. ×2½.
B. May 29, 1922—lava was flowing from the Puna rift. No lava was visible in Halemaumau. ×2⅓. Local earthquake is shown in second line from bottom.
C. May 8, 1924—no lava was visible in Halemaumau. Underground movement of lava in the Puna rift was suspected. ×2⅓.
D. September 30, 1934—was taken during lava activity lasting one month in 1934. The especially large tremors accompanied intermittent strong explosive fountaining. ×2½ (magnification of the seismogram, itself magnifying the earth motion about 100 times).

The absence of harmonic tremor at the time of the "False Eruption" on January 11, 1928, strengthens the belief that the small amount of lava which appeared on this date owed its appearance to being squeezed from a crusted pool of 1927 lava by a heavy landslide.

Harmonic tremor at Kilauea appears to be due to underground surging in feeding conduits below Halemaumau. If the surging is induced by the movement of very large gas bubbles in magma, then with a nearly stationary lava lake the bubbles moving through lake magma cannot set up harmonic tremor large enough to be recorded by the Observatory seismographs. When the surging takes place in a conduit of more or less restricted dimensions the solid walls of the conduit may be induced to vibrate with sufficient amplitude to be recorded. In general the tremor is larger when the magma column is falling than when rising.

Harmonic tremor affords good evidence of underground surging of lava whether magma is visible in the pit or not.

Hawaiian Volcano Observatory Report for January-March 1944

VOLCANOLOGY

January

The year opened with both Mauna Loa and Kilauea inactive. The number of Mauna Loa shakes exceeded those from Kilauea; records showed 43 and 39, respectively. The northeast rift of Mauna Loa was more active than the southwest one. The strongest shake during the month, which originated near Puu Ulaula on the NE rift of Mauna Loa on January 23, was generally felt over the southern part of the island of Hawaii.

At 2:00 p.m. on January 15, while on the road between Mauna Loa and Mauna Kea, A. L. Jess observed a distinct fume cloud with a faint yellow tinge over Mokuaweoweo.

Two landslides from the walls of Halemaumau were observed during the afternoon of January 19. Some more slides were observed during the latter part of the same week.

February

Despite the fact that the 4 perceptible earthquakes that occurred during February were of Kilauea origin, more seismic disturbances were recorded at Mauna Loa than at Kilauea; they were 41 and 33, respectively.

Clouds, lacking the characteristics of ordinary cumulus formation that frequently develops over isolated mountain peaks, were observed over Mokuaweoweo during the late afternoon of

February 7. On February 23, a white vapor cloud was visible above the radiation fog which capped Mauna Loa from 8:05 to 8:30 a.m. At other places humps in the fog marked the sites of hot spots in the crater floor.

March

While flying over Mauna Loa on March 30, Ranger Frank Hjort observed blue fume arising from Mokuaweoweo.

A total of 7 seismic disturbances was recorded in about 3 hours during the evening of March 29. Three of the shakes were strong enough to be felt locally. The series of shakes began with the strongest which dismantled the Bosch-Omori seismographs near Park Headquarters. The origin of the shakes was quite deep under the southern end of Kilauea Crater. Forty-four seismic disturbances were recorded at Kilauea and 59 at Mauna Loa.

The strong southerly wind of March 4 raised conspicuous dust clouds over the Kau Desert and adjacent cultivated fields of the Kapapala Ranch. Such winds—opposite in direction from those commonly observed transporting ash in the Kau Desert—though rare, may have been an appreciable factor in developing some soil over portions of the NE slope of Mauna Loa.

* For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake date is the serial number of the quake for the current year.

1. January 4, 02:48, slight, northern end of Kilauea Crater.
2. January 5, 00:05, very feeble, Kilauea shake.
3. January 5, 04:47, very feeble, Kilauea shake.
4. January 7, 09:42, slight. Felt as a sharp jolt, NE end of Kilauea Crater.
5. January 10, 23:25, very feeble, SW part of Mauna Loa.
6. January 12, 20:04, very feeble, shallow focus NE rift of Mauna Loa, 12 miles SW of Hilo.
7. January 17, 01:00, very feeble, SW part of Mauna Loa.
8. January 22, 02:38, very feeble.
9. January 23, 14:40, slight, E-W dismantled, Mauna Loa instrument dismantled. Felt locally and Pahala, near Puu Ulaula.
10. January 23, 15:28, very feeble, probably same origin as No. 9.
11. January 23, 23:42, feeble, NE rift of Mauna Loa.
12. January 28, 17:23, very feeble, Mauna Loa instrument dismantled, NE rift of Mauna Loa.
13. February 1, 11:31, very feeble.
14. February 2, 19:18, very feeble, NE rift of Mauna Loa.
15. February 3, 01:02, slight, near SW end of Kilauea Crater.
16. February 3, 01:16, slight, under Kilauea Crater.
17. February 3, 01:19, very feeble, Kilauea shake.
18. February 3, 01:27, very feeble.
19. February 3, 01:28, slight, Kilauea Crater.
20. February 3, 03:37, very feeble, NE rift of Mauna Loa.
21. February 5, 21:49, very feeble, near Mokuaweoweo.
22. February 5, 23:32, very feeble.
23. February 8, 02:41, very feeble, SW rift of Mauna Loa.
24. February 22, 09:47, very feeble, near Mokuaweoweo.
25. February 27, 04:49, feeble, under Kilauea Crater.
26. February 29, 04:53, slight, E-W dismantled, underneath observatory.
27. March 3, 12:37, very feeble, E flank of Mauna Loa.
28. March 5, 09:39, slight, felt locally, NE rift of Mauna Loa.
29. March 8, 04:47, very feeble.
30. March 23, 10:36, very feeble, NE rift of Mauna Loa.
31. March 25, 10:45, very feeble.
32. March 25, 20:18, very feeble.
33. March 29, 19:54, slight, dismantled instruments, under southern end of Kilauea Crater.
34. March 29, 20:38, very feeble, same origin as No. 33.
35. March 29, 22:20, slight, probably same origin as No. 33, though initial wave was compressional in No. 35 and dilatational in No. 33.
36. March 29, 22:41, slight, similar to No. 35.
37. March 30, 00:55, very feeble.

TELESEISMS

With the exception of what appeared to be feeble long waves of two teleseisms recorded in the midst of large microseisms on March 6, no teleseisms were recorded during the quarter.

MICROSEISMS

Microseisms were strong on February 12, and March 4, moderate on February 20, March 4, and 5. Throughout the rest of the quarter microseisms were present though slight.

Tilting of the Ground

Normal southwesterly tilt started early in January and continued throughout the quarter. The direction of tilt was really south-southwest as westerly tilt was less than normal and southerly tilt above the average. In fact southerly tilt for the first three months of 1944 exceeded that for similar periods of every year since 1937. If, as seems probable, easterly tilt correlates with increase in internal pressure under Mauna Loa the less than normal westerly tilt indicates a sustained high pressure under that mountain. There were some fluctuations in the direction of tilt at the stations near the rim of Halemaumau.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount of Tilt	Direction of Tilt
January	2	1.14″	N 58° E
	9	0.60″	N
	16	2.30″	S 25° W
	23	0.65″	S 22° W
	30	1.45″	S
February	6	0.33″	S 45° W
	13	0.53″	S 68° E
	20	1.09″	S 27° E
	27	1.74″	S 33° W
March	5	1.27″	S 17° E
	12	3.60″	S 39° W
	19	0.44″	S 34° W
	26	1.46″	S 5° W

Crack Measurements

There was a slight opening of 5 of the cracks around Halemaumau though most of those measured showed no movement. No movement was detected in the cracks at the Devil's Throat and along the Chain of Craters Road. R.H.F.

RADIO TRANSMISSION OF EARTHQUAKE RECORDS

By ROBERT J. STRATTON[1]
Federal Communications Commission
Radio Intelligence Division

Time control for several of the seismographs operated by the Volcano Observatory of the Hawaii National Park is obtained by a phantom circuit on Park telephone lines.[2] The location of outlying seismographs is determined by existing roads and telephone lines. This leaves a vast expanse of Mauna Loa where it is impractical to locate ordinary seismographs. If all the instruments could be made to register at one central point continuously, much travel could be avoided.

The use of radio at once suggests itself as a possible solution. The radio seismographs could be made to record on one shaft and the problem of synchronizing would be solved. Also in the case of a disturbance, records would be immediately available at the Observatory.

Radio links for the remote recording of seismographs were utilized in 1931 by Seizo Haeno.[3] He developed a short-distance, short-time scale instrument based upon the principle of frequency modulation for use in geophysical prospecting. His transmitter was a simple self-excited oscillator in which the capacity in the tank circuit was varied by the displacement of the seismograph mass. His receiver was an equally simple Tuned Radio Frequency receiver tuned off resonance and using galvanometer recording. This system was sufficiently stable for geophysical work since the recording run is normally only for a few minutes. It would not be stable, however, for continuous recording because of frequency drift.

Frequency stability could be gained by using crystal controlled transmitters. Moreover, the frequency of a crystal oscillator may be varied within limits by the use of a variable capacity across the crystal. It is proposed, therefore, that each element of the outlying Hawaiian Volcano Observatory seismographs should be equipped with a low-powered, battery-operated, crystal-controlled transmitter as shown in figure 1. Each transmitter would be far enough separated from the others in frequency so that mutual interference would be avoided. The variable "seismograph" condenser shown in figure 1 would have its rotor plates attached to the movable arm of the seismograph, while the stator plates would be attached to the seismograph frame. Any movement of the arm, however slight, would cause a corresponding change in the frequency of the oscillator. This is, of course, nothing more than frequency modulation of the rest-position carrier.

Several of the Hawaiian Volcano Observatory seismograph stations are within reach of A.C. power lines. The radio transmitters at these stations could be supplied from A.C. power in conventional ways. Some of the Hawaiian Volcano Observatory seismograph stations, both present and proposed, are in remote areas and would necessarily be battery operated. With the proper choice of frequency, tubes, and oscillator design, the use of number 6 dry cells for filament supply and 45 volt B-batteries for plate supply would be economically possible.

The continuously emitted signal would be received with a well-designed Tuned Radio Frequency receiver as shown in figure 2. As shown in the diagram, the amplified radio frequency output of this receiver is fed into a Wheatstone bridge which is

---

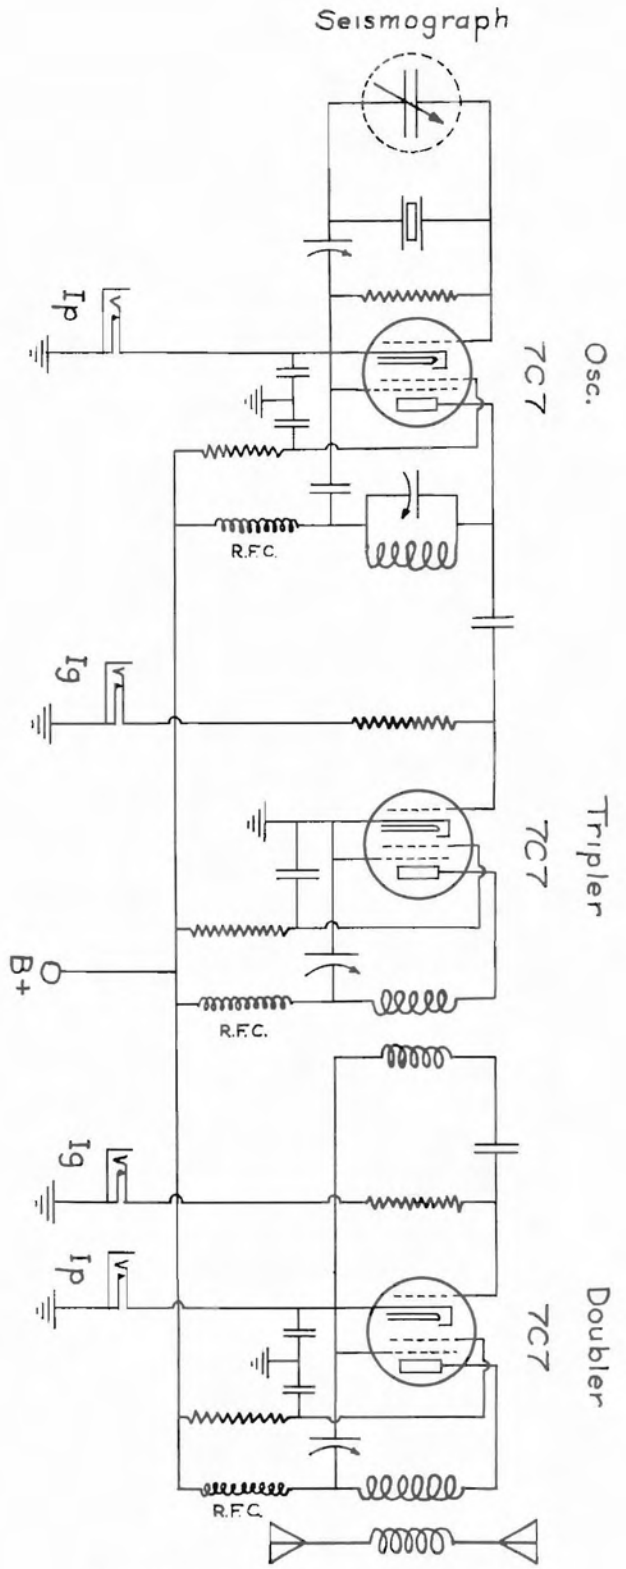

Fig. 1—Transmitter for radio seismograph.

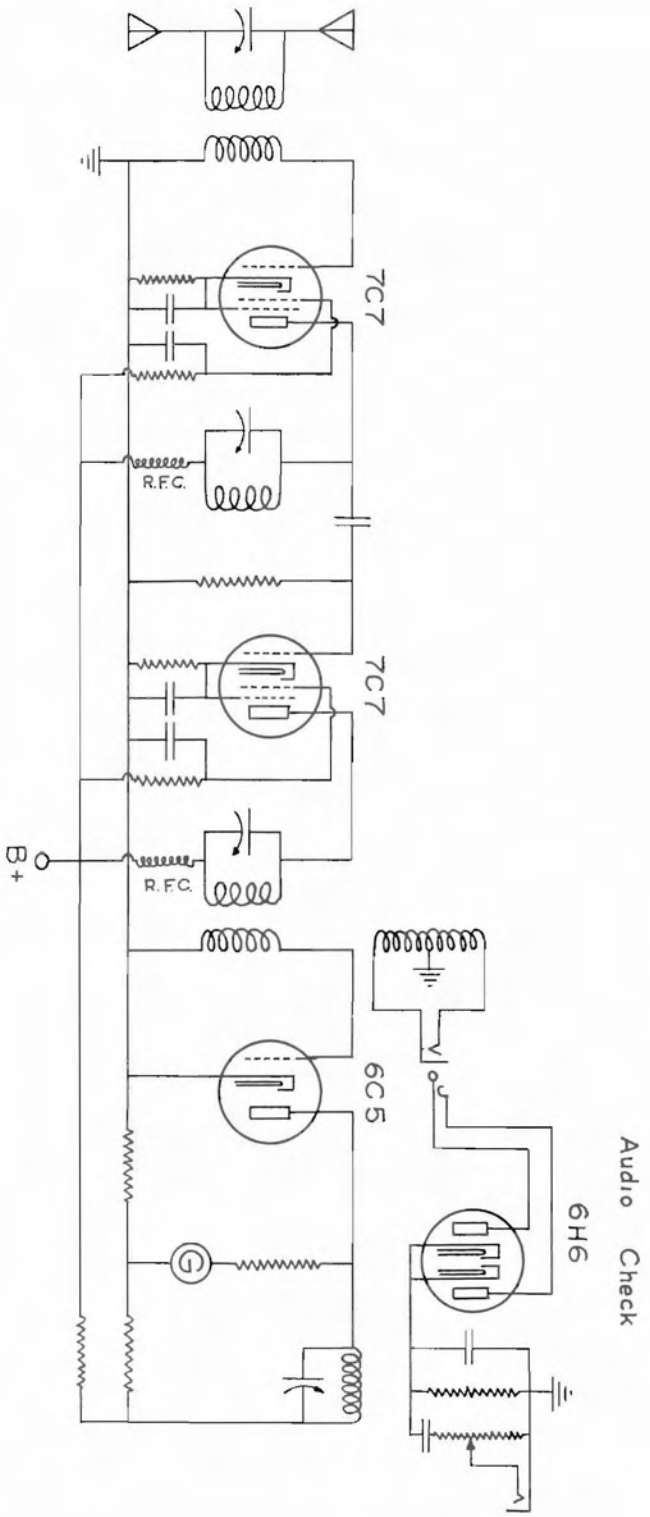

Fig. 2—Receiver for radio seismograph.

balanced at the rest-position carrier frequency. When the seismograph arm is displaced, the frequency changes, the bridge is then unbalanced, and the galvanometer is deflected. For proper operation, of course, the parallel tuned circuit in the bridge must be tuned far enough away from the rest-position frequency so that it presents a linear rising impedance over the modulation range. The actual production of the seismograph record would be by optical recording by a pin-point beam of light, reflected from the galvanometer mirror onto a continuously moving photographic film.

This system, of course, requires a separate receiver and recording chain for each transmitter. All of the receiving and recording equipment at the Observatory would be A.C. operated.

The recording of tilt is much simpler. The proposed plan for this also makes use of the principle of varying the frequency of an oscillator but with a different application. Since the change in tilt is very slight over a considerable period of time, no rapidly variable indicating instrument is necessary. For this purpose, it is proposed to use two crystal oscillators with a difference of frequency of 440 cycles per second. Only one of these oscillators will be equipped with a variable capacity as described in figure 1. The other oscillator remains constant. It then is apparent that, with the arm of the tilt instrument at center position, the two oscillators will beat against each other producing a resultant audio tone of 440 cycles. Any change in the position of the movable arm on the tilt instrument will vary the resultant tone. If the tilt is in one direction, the tone will be raised. If in the other, the tone will be lowered. The Bureau of Standards Station WWV can always be heard in this area on a frequency of either 15 mc., 10 mc., or 5 mc. depending on the time of day. This station transmits a tone standard of 440 cycles which is accurate to 0.000001 cycles per second. With this as a standard any change in the pitch of the beat of the tilt oscillators can be determined as can the direction of the tilt.

The selection of frequencies for all of these transmitters is quite important, both from the point of possible outside interference and of propagation characteristics. The latter point offers no particular difficulty for this location since all of the seismograph locations are within "line of sight" of the Observatory. Therefore, in order to avoid possible interference from extraneous signals, the use of frequencies around 50 to 60 mc. is indicated. Theoretically, no difficulty should be encountered in the use of this band of frequencies, although experiment may prove otherwise. Higher frequencies require the use of more tubes with the corresponding higher battery drain.

Owing to conditions incident to the war, it has not been possible to test the above ideas experimentally.

Hawaiian Volcano Observatory Report for April-June 1944

VOLCANOLOGY

April

Blue fume was observed over Mokuaweoweo on March 30 and again on April 1. The only other surface activity observed at Kilauea and Mauna Loa was the usual steaming. The number of steam vents as well as the amount of steam escaping at Kilauea and Mauna Loa is essentially the same as at the commencement of continuous observations in 1912.

No earthquake strong enough to be felt locally was experienced in April. Eighteen small seismic disturbances were recorded at Kilauea and 44 at Mauna Loa.

There were several small landslides from the walls of Halemaumau.

May

A conspicuous steam cloud that was observed over the lower part of the 1942 lava flow from Mauna Loa shows that the lava was still hot 2 years after it was erupted.

May continued the seismic quiet of the last several months. The Mauna Loa seismograph registered 48 seismic disturbances while the number recorded at Kilauea was 28.

June

The seismic lull that was especially noticeable in April and May continued through June. No perceptible earthquakes were recorded at the Observatory. Twenty-three seismic disturbances were recorded at Kilauea and 44 at Mauna Loa. A majority of the shakes distinct enough to show phases originated on the northeast slope of Mauna Loa at shallow depths. R.H.F.

TELESEISMS

May 23, 04 : 30, slight.
May 25, 02 : 38, moderate. 6600 km. New Ireland.
June 16, 11 : 42, slight.
June 27, 21 : 56, slight.

MICROSEISMS

Microseismic motion was quite uniformly slight throughout the quarter.

TILTING OF THE GROUND

Southerly tilt was more pronounced during the first three months of 1944 than for the corresponding period in the last several years. The total, however, was not unusual as northerly tilt set in on April 1, or over a month earlier than common.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount of Tilt	Direction of Tilt
April	2	0.75″	S 56° W
	9	0.12″	E
	16	0.44″	N 56° W
	23	1.77″	N 16° E
	30	1.31″	S 67° W
May	7	1.36″	N 80° W
	14	0.74″	N 70° E

OUTPUT CHANGES IN KILAUEA STEAM VENTS

By GUNNAR O. FAGERLUND
Naturalist and Chief Ranger
Hawaii National Park

There is some evidence that the volume of steam from vents at the northern end of Kilauea Caldera has decreased in the last 100 years.

In 1823 Ellis[1] reported pools of water there adjacent to and on the lee side of steaming chasms. These condensation pools could exist only with much greater steam volume than there is at present. The pools subsisted during rainless periods. However, the 1790 explosion may have provided an impervious ash layer that helped in pool formation for many years.

Accompanying Kilauea activity in 1886, the steaming at Sulphur Bank fluctuated for a short period. First the steam temperature increased, then the steaming almost ceased, and finally normal temperature and volume resumed.[2] Normally the volume and temperature of the steam change little if any to correlate with Halemaumau activity.

Gordon A. Macdonald[3] states: "The distribution of altered rock and deposits of sulfur and salts, indicates that solfataric activity was once more extensive than now. Some migration of the active vents occurs."

Photographic stations have recently been established for photographing the steaming vents. Photographs taken at ten-year or greater intervals under nearly identical conditions of humidity, air temperature, and wind velocity should show whether or not the steam volume is changing.

The visibility of the vapor varies with different conditions of air temperature, humidity, and wind velocity. Actually the amount of water vapor escaping from any one vent is nearly constant. Figures 1 and 2 show visibility difference under somewhat different air conditions, but by no means do they show the maximum visibility contrast. On warm, sunny days with comparatively low humidity, some vents produce no visible vapor, while on cold damp days the same vents produce conspicuous vapor clouds. Even during a single clear day a marked contrast may be seen between early morning or evening and noon visibility of the vapor. On cold days the vapor density of the steam increases and its increased condensation forms conspicuous fog clouds. An increase in the number of hygroscopic nuclei also causes greater condensation. This fact can be demonstrated by directing tobacco smoke into steam vents where no vapor is visible. This causes a visible cloud to appear instantly. It is by this effect of nuclei that air humidity influences vapor visibility. Wind also affects visibility by dispersing and evaporating the fog.

Though air conditions affect the vapor visibility most markedly, a difference exists too when vapor is viewed in transmitted and in reflected light; this is most manifest when the sun is low. The greater visibility is in transmitted light. There is also a color difference—the vapor appearing bluish in reflected light and trending toward the red end of the spectrum in transmitted light.

The making of reliable photographic records of the vapor volume output from the steaming vents must take into account all the conditions that affect the visibility, or more precisely the photoactinicity, of the vapor. Pictures taken at intervals to show change, if any, in the actual steam volume output must

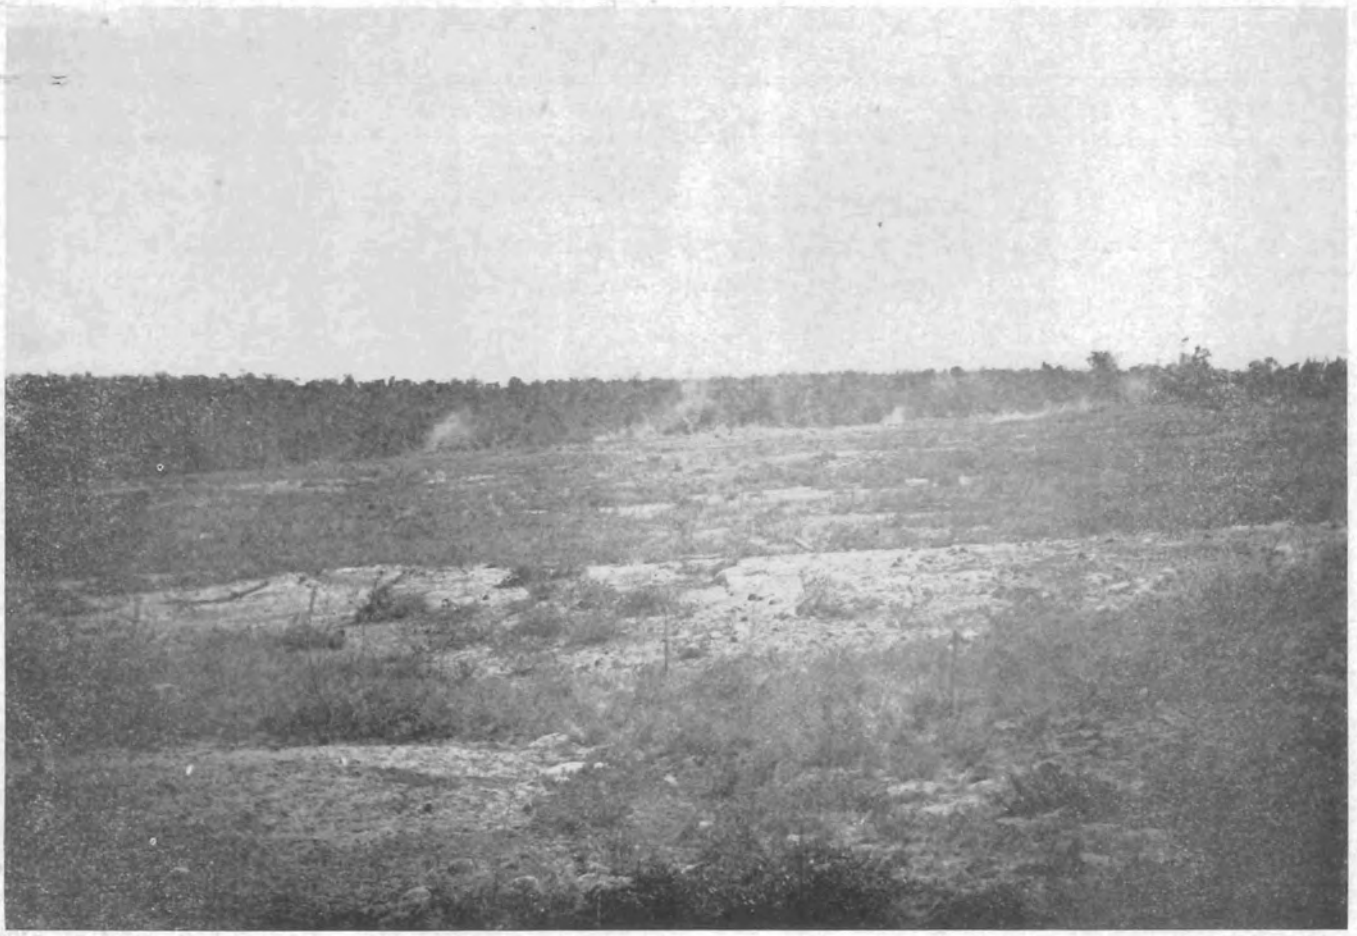

Figure 1.—Vapor issuing from vents west of Sulphur Bank. Photographed on November 19, 1944, with air temperature 62° F., humidity 68%, wind velocity 8 to 10 m.p.h. (Photographic station located on steaming flat 80 feet north of road, on line 12°49′ left from Uwekahuna to Observatory bench marks.)

be taken under nearly identical air and light conditions, with similar color sensitive film, and printed on similar paper. It would be advisable to use similar processing methods.

A factor that will affect the reliability of photographic records, and therefore should be given attention, is the pulsating manner in which the steam issues from the vents. The photographs herein were exposed as near to the instant of maximum output for the existing conditions as could be determined. The effect of the pulsating action becomes less as the distance between the vent and the camera increases. The volume of vapor recorded on a photograph encompassing considerable horizontal and vertical distances, as in the illustrations herein, would be little if at all affected by the pulsating action, except in high wind velocity.

Hawaiian Volcano Observatory Report for July-September 1944

VOLCANOLOGY

July

The seismic quiet of the last several months continued through July. No earthquakes strong enough to be perceptible at the Hawaiian Volcano Observatory were recorded though some shakes were felt at Kapapala 17 miles to the southwest. Thirty-two seismic disturbances were recorded at Kilauea and 58 at Mauna Loa.

August

A conspicuous fume cloud was observed over Mokuaweoweo from Puu Ulaula on August 12. A similar cloud was observed from the rim of Mokuaweoweo during the afternoon and evening of August 14. No glow was detected. By morning of August 15, however, nothing but the usual steaming was noted. On August 31, another conspicuous cloud was observed from the rim of Mokuaweoweo. During the fuming spell of August 12 to 14, two sharp earthquakes were felt at Puu Ulaula. The seismograph indicated that these shakes, like many that have been recorded here during the past year, occurred at very shallow foci along the upper northeast rift of Mauna Loa. Fourteen seismic disturbances were recorded at Kilauea and 56 at Mauna Loa.

September

Unusually heavy steam clouds were observed over Mokuaweoweo during the afternoons of September 11, 12, and 16. Three of the 19 earthquakes recorded at Kilauea were strong

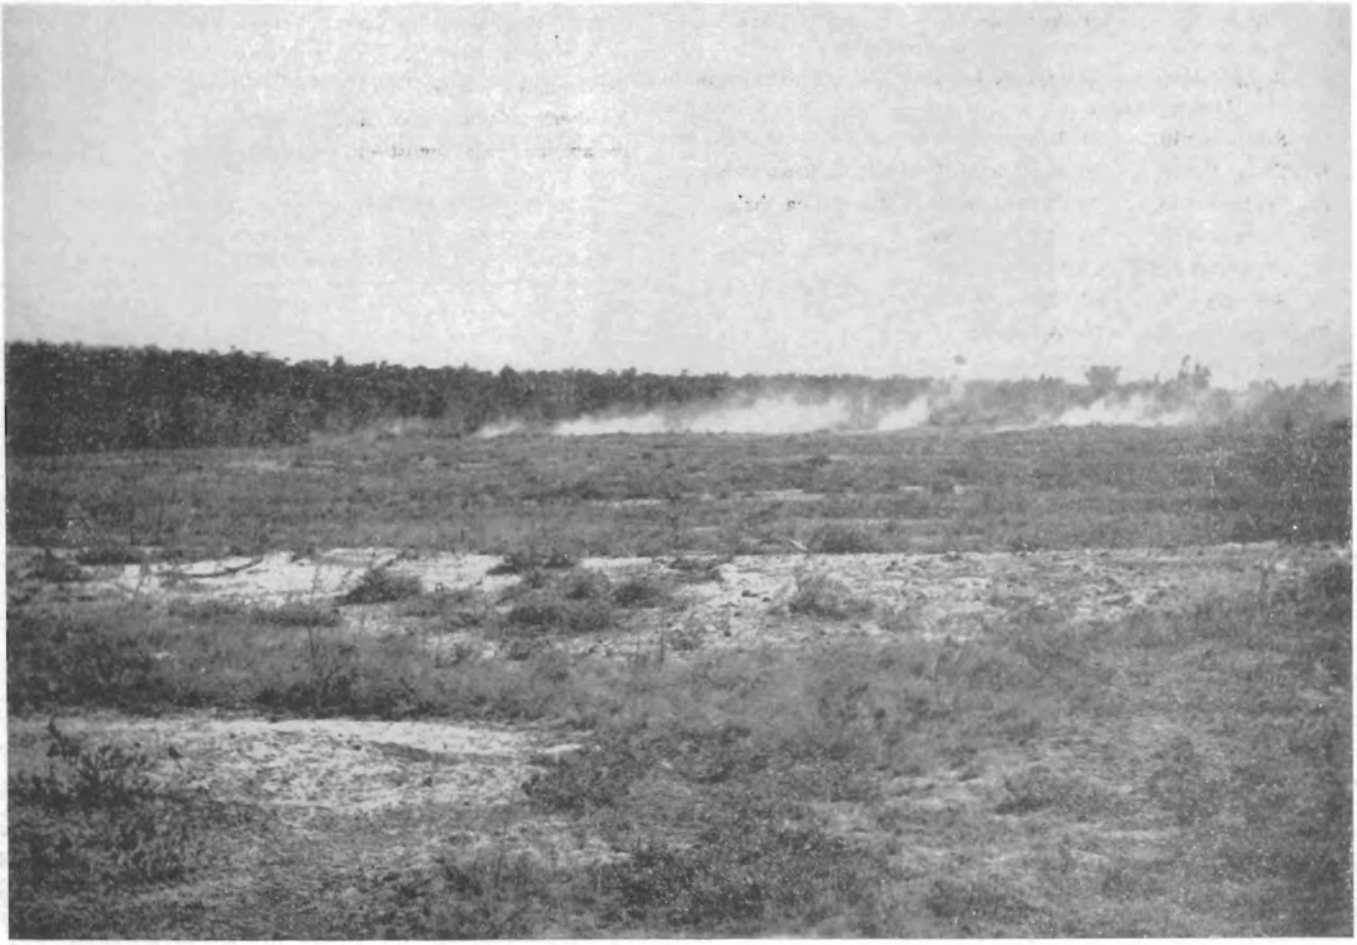

Figure 2.—Vapor issuing from same vents as in Figure 1, showing the higher visibility associated with somewhat lower temperature and higher humidity. Photographed on December 18, 1944, with air temperature 54° F., humidity 81%, wind velocity 10 to 15 m.p.h. (Photographic station the same as for Fig. 1.)

enough to be felt locally. They appear to have originated under the northern end of Kilauea crater. A majority of the 48 shakes recorded at Mauna Loa originated along the northeast rift. R.H.F.

July 19,	00:36, slight.	Off Japan.
July 20,	02:12, slight.	
July 26,	13:41, slight.	Off Aleutians.
August 9,	15:40, slight.	Off British Columbia.
August 18,	00:13, slight.	Japan.
September 3,	09:04, slight.	
September 23,	01:52, slight.	5400 km.

MICROSEISMS

Microseisms were present though slight throughout the quarter.

TILTING OF THE GROUND

Very slight westerly tilt prevailed during July and until August 20, when normal easterly tilt set in and continued through the rest of the quarter. The time of change from west to east tilt in 1944 corresponds to that of 1941, 1942, and 1943 though it is more usual for the change to occur during the spring. Northerly tilt was continuous throughout the quarter though the amount from August 4 to September 30 was less than normal.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount of Tilt	Direction of Tilt
July	2	0.51″	N 15° E
	9	0.62″	N 79° W

THE NOVEMBER-DECEMBER 1944 CRISIS AT KILAUEA

By R. H. FINCH

For over a year and a half the seismographs and tilt records have indicated a fairly high pressure under the Kilauea-Mauna Loa volcano system. In November, 1943, Mauna Loa produced several rather conspicuous fume clouds.[1] In August, 1944, fuming greater than the normal from Mokuaweoweo was observed.

It was not surprising then to find Kilauea showing definite signs of uneasiness starting with an earthquake on November 12 that originated 8 to 10 miles below the southwest rim of Halemaumau. The history of Kilauea indicates that some form of activity might be expected at any time now. In a press release dated September 13, 1943, the following statement was made: "If the present period of volcanic activity is to parallel the probable sequence following the 1790 explosive eruption, lava activity at Kilauea or Mauna Loa, or both, may be expected about the middle of this decade."

It has been over ten years since molten lava was present in Halemaumau. This is the longest period of inactivity in the recorded history of Kilauea. This is not overlooking the thirteen more or less quiet years from 1894 to 1907. During this thirteen-year period molten lava was visible for short intervals on several occasions, and considerable fume was always present. The longest period of total inactivity was the three years from July, 1924, to July, 1927. The interval between the last activity which started on September 6, 1934, and the next previous outbreak was two years and eight months or well above the average of such intervals since molten lava disappeared from Halemaumau in 1924. It is interesting to note that the 1934 outbreak was the most gaseous and lasted the longest of any of the short-lived outbreaks that have occurred since 1924. It might be expected then that a return of activity to Halemaumau will be marked by high pumice producing fountains.

On November 15, 1944, there was another earthquake with about the same epicenter as the one on November 12, but with a much more shallow focus. From November 15 until December 6 there were a few scattered Kilauea shakes with indications of a more or less progressive decrease in depth of foci. Two earthquakes on November 29 that were felt as sharp jolts at Halemaumau and recorded as feeble or slight shakes only at the Observatory twenty-two miles away were obviously of very shallow foci. The fact that the earthquakes occurred as separate shakes, often several days apart, rather than in swarms is what might be expected if molten lava were rising in the feeding conduits under Halemaumau.

At the Observatory, on the northeast rim of Kilauea, the northeast tilt was but little more than normal for this season of the year though rather definitely indicating a pressure increase under Kilauea. Beginning about the 12th of November, however, tilt instruments near Halemaumau showed a pronounced tilt; this indicated that the crater floor was doming appreciably with the maximum rise in the vicinity of the southern edge of Halemaumau. The amount of tilt during the last week in November at the Halemaumau tilt cellars is not known since the index of each instrument went completely off the scale and was stopped by horizontal braces.

[1] FINCH, R. H. ACTIVITY AT MAUNA LOA IN NOVEMBER 1943. Volcano Letter No. 482. October-December, 1943.

The focus of application of the force producing this final spurt of tilting must have been rather high to produce such marked effects near Halemaumau and so comparatively little effect at the Observatory.

The retreat of the lava column also indicates that a high level of the molten magma was reached. By the morning of December 7, both Halemaumau tilt instruments had gone completely off their scales and were resting against their frames. In this case the direction was the opposite of that during November; this indicated a sinking of the crater floor. The rapid sinking of the crater floor occurred on December 6 and 7, but a sharp southerly tilt did not start in at the Observatory until December 21. This southerly tilt continued until December 30 and amounted to 3.6 seconds of arc.

The earthquake pattern accompanying this minor 1944 crisis is rather typical. First one or two rather strong shakes of appreciable depth occurs marking the introduction of lava to the conduits under Halemaumau. (The earthquake of November 12 appears to have been of this type.) Then follow scattered lighter shakes of decreasing depth of foci accompanying the upsurge of molten lava. The spreading apart of walls of fissures and introduction of hot lava and gases reduce the tendency of seismic grating. At times of rapid recession of the lava column and appreciable subsidence of the crater floor, earthquakes are numerous. Twenty-nine earthquakes occurring between 08:30 December 6 and 13:50 December 7 accompanied the suspected 1944 recession.

The uneasiness manifested at Kilauea in the autumn of 1944 was the most conspicuous indication of fairly high internal activity that has been observed since the 1934 outbreak. It should be borne in mind that lava pressure in a volcano conduit can vary through a large range without any lava appearing at the surface. Whether molten magma reaches the surface or not depends upon, among other things, the duration of high pressure and the amount of lava involved in any particular upsurge.

Hawaiian Volcano Observatory Report for October-December 1944

VOLCANOLOGY

October

Mauna Loa and Kilauea were both quiet throughout October, Forty-eight seismic disturbances were recorded at Mauna Loa and 26 at Kilauea. Four shakes were felt at the Observatory and six were felt at Hilo. The number of distinctly Mauna Loa shakes was the smallest for the last several months.

November

For the first time in several months more earthquakes of Kilauea than of Mauna Loa origin were registered. The fact that 36 seismic disturbances were recorded at Mauna Loa and 35 at Kilauea does not show the true relative seismicity because most of the Kilauea shakes were recorded at Mauna Loa and several of the Mauna Loa shakes did not register at Kilauea. Starting with an earthquake on November 12 that was widely felt on the island of Hawaii, Kilauea showed distinct signs of uneasiness. The origin of the shake was 8 to 10 miles below the surface to the southwest of Halemaumau. On November 15, there was another Kilauea shake with about the same epicenter but with more shallow focus. A progressive decrease in depth of foci of earthquake continued until the end of the month. The tilt instruments on the crater floor indicated a distinct doming of the crater floor with the maximum rise in the vicinity of the southwest rim of Halemaumau.

December

The uneasiness of Kilauea continued until December 6. A series of earthquakes that started on this day and tilt indications of subsidence of the crater floor in the vicinity of Halemaumau clearly showed that a return of lava to the fire pit of Kilauea could not be expected.

A strong earthquake on December 27 caused Mauna Loa again to be the main center of interest. This quake as well as four others that followed within 3 days originated about 15 miles below the eastern rim of Mokuaweoweo. There was a slight migration of epicenters in a northeasterly direction in this series of shakes as though they followed along a fault block connecting southwest and northeast branches of the fundamental Hawaiian rift.

The strong earthquake of December 27 started many landslides at Halemaumau. The largest produced a roar that was audible 3 miles away, which was reminiscent of the explosions in 1924. R.H.F.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

82. October 2, 17:27, slight. Deep focus, near Ookala.
83. October 4, 15:22, very feeble.
84. October 6, 14:30, feeble.
85. October 6, 14:40, very feeble. Probably same origin as No. 84.
86. October 7, 14:41, very feeble.
87. October 11, 21:11, feeble. Felt locally, under Mokuaweoweo.
88. October 11, 21:12, feeble. Felt locally. Probably same origin as No. 87.
89. October 17, 13:54, feeble. Felt in Hilo, Mauna Kea.
90. October 17, 14:52, very feeble.
91. October 29, 17:17, feeble. Felt locally and in Hilo, Mauna Kea.
92. October 31, 04:26, feeble. Felt in Hilo.
93. October 31, 04:28, feeble. Felt in Hilo.
94. October 31, 04:32, very feeble.
95. November 5, 01:46, very feeble. Kilauea shake.
96. November 8, 02:16, very feeble.
97. November 8, 02:18, very feeble.
98. November 9, 08:25, very feeble.
99. November 12, 04:56, moderate. Widely felt in southern half island of Hawaii. Eight to 10 miles deep to the SW of Halemaumau. Dismantled seismograph at Hilo and Kona as well as at the Observatory.
100. November 15, 18:19, moderate. Felt locally. About same epicenter as No. 99 but with shallower focus.
101. November 15, 19:33, feeble. Felt locally. Origin at NE rim of Kilauea.
102. November 22, 22:53, slight. Under Kilauea.
103. November 23, 13:43, feeble. SW of Halemaumau.
104. November 23, 21:16, very feeble.
105. November 26, 00:48, very feeble.
106. November 26, 13:02, feeble.
107. November 28, 00:43, feeble.
108. November 29, 09:34, feeble. Felt as a sharp jolt at Halemaumau.
109. November 29, 09:36, slight. Felt as a sharp jolt at Halemaumau.
110. December 2, 00:17, feeble. Under Kilauea.
111. December 6, 07:38, very feeble. Under Kilauea.
112. December 6, 08:08, very feeble. Same as No. 111.
113. December 6, 09:47, feeble. Same as No. 112.

118. December 7, 00:58, very feeble. Same as No. 116.
119. December 7, 02:51, very feeble. Same as No. 116.
120. December 7, 05:15, very feeble.
121. December 7, 07:17, slight. Felt locally. Under Kilauea.
122. December 7, 08:46, very feeble. Accompanied by rumble audible at Halemaumau rim.
123. December 7, 11:18, very feeble.
124. December 7, 11:22, very feeble. Under Kilauea.
125. December 7, 11:39, feeble. Same as No. 124.
126. December 7, 12:50, slight. Same as No. 124.
127. December 9, 12:40, very feeble. Under Kilauea.
128. December 11, 22:01, very feeble.
129. December 15, 16:17, very feeble.
130. December 16, 15:08, very feeble. Kilauea shake.
131. December 16, 23:45, very feeble.
132. December 18, 10:38, very feeble. Kilauea shake.
133. December 21, 00:36, very feeble.
134. December 26, 09:35, very feeble. Probably Mauna Loa origin.
135. December 27, 03:42, strong. Dismantled all seismographs on island of Hawaii. Plainly felt on Oahu. Some objects toppled from shelves at places as widespread as Pepeekeo and Naalehu, stone fences were thrown down in vicinity of Hilea. Origin about 15 miles below eastern edge of Mokuaweoweo.
136. December 27, 04:21, very feeble. Same as No. 135.
137. December 27, 04:27, very feeble.
138. December 27, 05:46, slight. E-W instruments dismantled the same as by No. 135.
139. December 30, 09:21, moderate. Instruments dismantled the same as by No. 135.
140. December 31, 11:10, moderate. Instruments dismantled near Wood Valley. Twelve to 14 miles deep.
141. December 31, 19:53, very feeble.

TELESEISMS

October 5, 07:07, very slight. 4790 km.
November 16, 02:13, near Solomon Islands.
November 23, 16:26, slight.
December 6, 18:16, moderate. 3700 miles, Japan.
December 29, 12:50, slight.
December 29, 13:39, slight.
December 30, 11:47, slight.

MICROSEISMS

Microseismic motion was strong on October 12 and 13, moderate from October 14 to 20, 27 to 30, and on November 23. Throughout the rest of the quarter microseisms were present though slight.

TILTING OF THE GROUND

Northerly tilt was normal to the north in October, above the normal during the first three weeks in November, and about normal to the north until December 21, when a pronounced southerly tilt set in that continued until the end of the month. Easterly tilt was about normal in October and November. From December 6 to 26 there was a slight westerly tilt. A distinct east tilt accompanied the strong Mauna Loa earthquake of December 27, then the seasonal westerly tilt started.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended		Amount	Direction
October	1	1.50″	N 14° E
	8	1.11″	N 40° E
	15	1.03″	S 45° E
	22	1.23″	N 11° E
	29	0.34″	N 45° E
November	5	1.75″	N 34° E
	12	0.72″	N
	19	1.45″	N 55° E

December	3	0.64″	N 22° W
	10	0.44″	N 34° W
	17	0.76″	N 18° W
	24	0.61″	S 11° E
	31	3.02″	S 37° E

CRACK MEASUREMENTS

During October there was no movement of consequence at any of the cracks around Halemaumau nor along the Chain of Craters Road. In November a majority of the cracks around Halemaumau showed an opening accompanying a rather rapid doming of the crater floor, though a few showed a distinct closing as is to be expected during times of such movements. There was considerable movement, both opening and closing, accompanying the rapid subsidence of the crater floor in December.

ON MAGNETIC STUDIES

By GUY C. OMER, JR.

On leave of absence from the Department of Physics

University of Hawaii

While a remarkable amount of data pertaining to the internal status of the volcanoes has been collected by the seismographs of the Hawaiian Volcano Observatory, this is only one of the many possible geophysical methods that could be used. Other geophysical procedures that suggest themselves are magnetic, gravitational, and earth-current programs. The advantages of using several geophysical methods simultaneously are first, that additional data is obtained, since different effects are being measured, and second, that a very valuable cross-check is possible in the interpretation of the collated data.

A rising or falling magma column could be expected to have at least two magnetic effects. One is the local change in the permeability of the earth's crust produced by the presence of the hot magma column and the associated heating of the surrounding rock. The other is a Lenz law local field produced by eddy currents induced in the hot magma column while it is rising or falling. A change in the measured magnetic elements between two observational dates spaced a month or so apart, might well correlate with volcanic activity while the absolute value at any one date might not in itself have much significance.

The first magnetic work at Kilauea was done by J. W. Green[1] of the United States Coast and Geodetic Survey at the suggestion of Dr. T. A. Jaggar. This consisted of many magnetic measurements around Kilauea and Mauna Loa during the winter of 1913. During this time Mauna Loa was quiet and Kilauea was relatively quiet between short periods of visible activity. Many striking magnetic variations were observed, but the time available for this work was too short to allow any definite conclusions.

Magnetic observations have been made upon the volcanoes of Japan. Typical of this would be the work of Y. Kato[2] who compared regional magnetic surveys made before and after volcanic eruptions and found large and regular local changes in the magnetic elements.

It is not possible to make magnetic surveys without special instruments, so a full-fledged magnetic program cannot be immediately started at Hawaiian Volcano Observatory. However, some preliminary work has been done using instruments and data that are available. This preliminary work is of value, however, since it indicates the fruitfulness of the magnetic method and the scope and nature of an enlarged magnetic program that could be begun.

The first of this preliminary work was a crude dip survey of the entire island. The instrument used was a Swedish mining compass, which could be read to 0.2°. However, the greatest

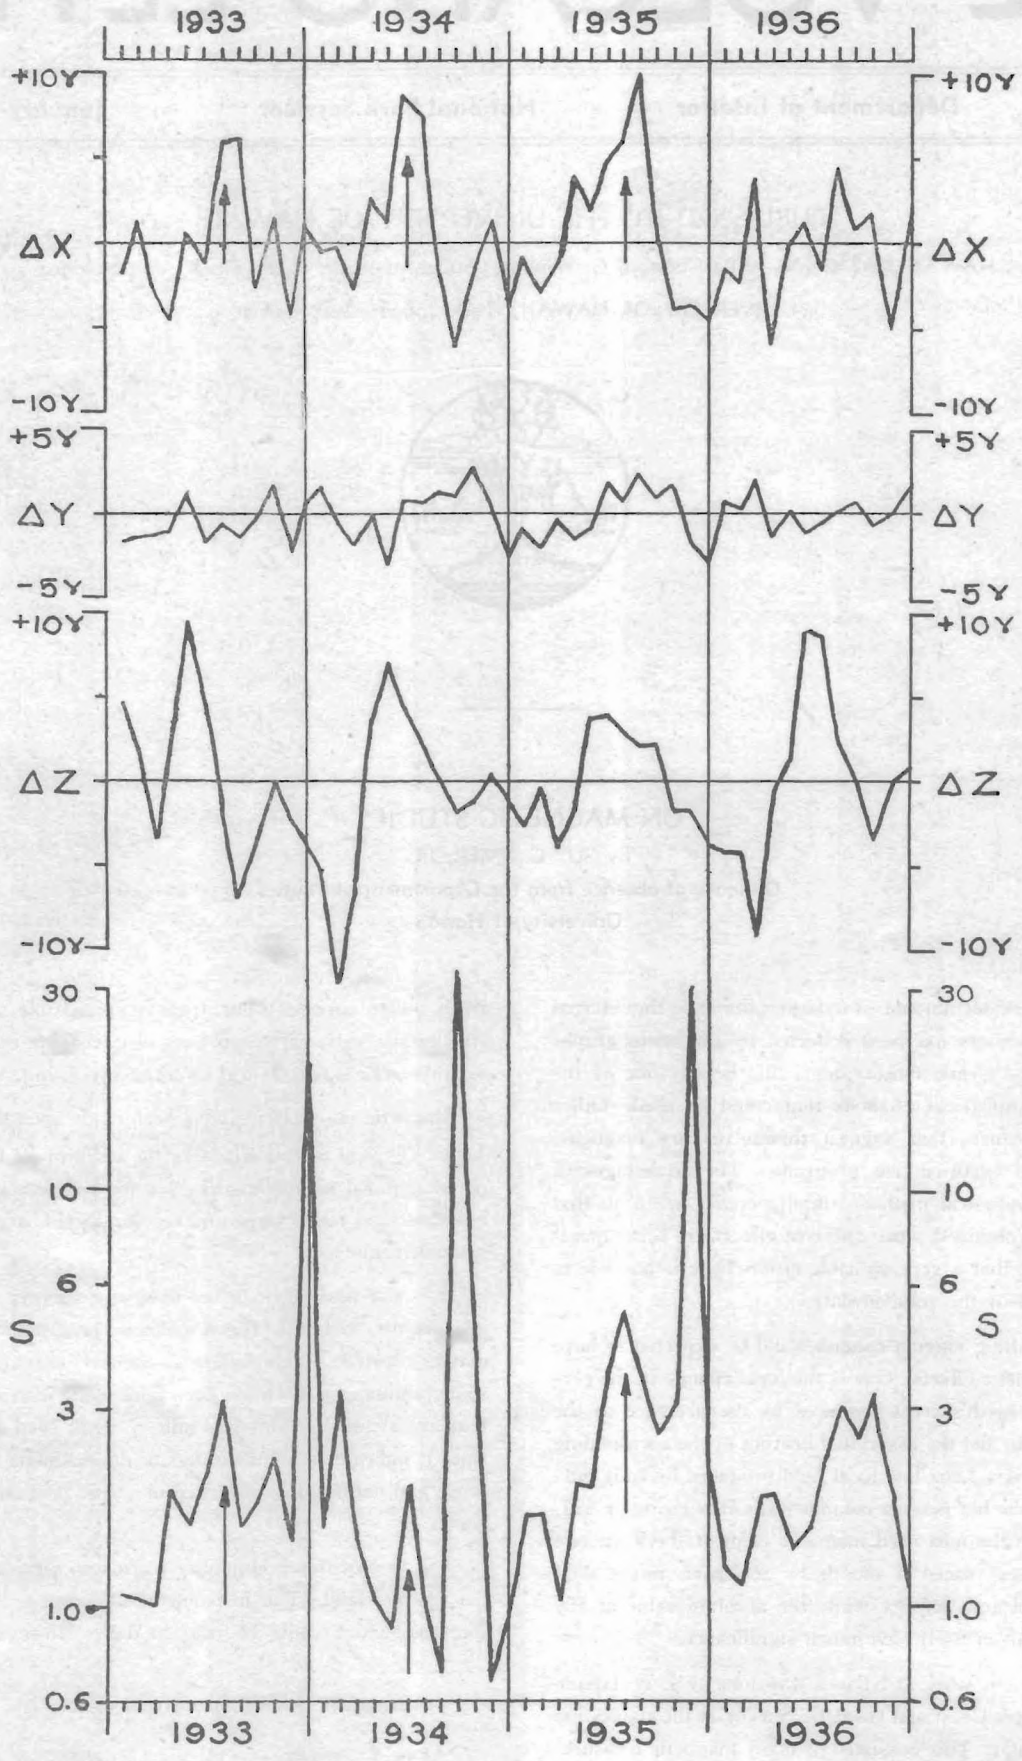

Figure 1.—Magnetic departures at Honolulu and seismicity at the Hawaiian Volcano Observatory. ΔX, ΔY, and ΔZ show the departures from the mean in gammas for the north-south, east-west, and vertical fields, respectively. *S* shows the monthly seismicity.

handicap to this survey was the extreme variation in local magnetic conditions. An attempt was made to correct this by taking an areal average, but the scatter in the data was still too great to allow the construction of a reliable iso-dip map. Nevertheless, a decrease in magnetic dip averaging between one and two degrees between the shore line and the summits of the volcanoes was definitely indicated. This is the effect to be expected if the heating of the rock under the volcano is higher in temperature than that for areas some distance from the summit caldera.

Another available source of magnetic data is the published results of the Honolulu Magnetic Observatory of the United States Coast and Geodetic Survey. While the Magnetic Observatory is about 190 miles away from the volcanoes, it is a highly sensitive station that is in continuous operation. The reduced data[3] for this station from 1933 to 1936 is plotted in Figure 1 against the monthly seismicity at Hawaiian Volcano Observatory.

The earth's magnetic field is continually varying because of a number of causes, most of which are balanced out in the published monthly means through the system of selected averaging. The remaining variations are those of secular change and any peculiar local effect. The secular change is a slow continuous varying of the magnetic field which is world-wide and of unknown cause. The secular change was eliminated from the published data by determining a smooth running mean and plotting the departures from this mean as the upper three curves of Figure 1. This should be the peculiar local effect which might correlate with volcanic activity. The unit used in plotting this magnetic data is the *gamma* which is 10^{-5} gauss. The ΔX curve shows the departures from the mean for the north-south field, the ΔY curve shows the departures from the mean for the east-west field, while the ΔZ curve shows the departures from the mean of the vertical field. This latter data is subject to the greatest instrumental inaccuracy.

Since the magnetic data plotted are monthly averages, the seismicity curve plotted is also for corresponding monthly averages, slightly adjusted in two cases to compensate for distance effects. This period included three eruptions indicated by the momentarily extremely high seismicity. These eruptions are: Mauna Loa in December, 1933; Kilauea in September, 1934; and Mauna Loa in November, 1935.

The most striking coincidence that will be noted in these curves is the high sustained positive departure in the ΔX curve which preceded each of the three eruptions by several months. The three sets of corresponding arrows on the ΔX curve and the seismicity curve indicate the probable time at which magma began to rise in the upper system of the volcano as determined by analyzing the seismic data. This occurs during the marked positive departure. A closer inspection will show the coincidence of most of the maxima and minima of these two curves. The correspondence is not one-to-one since sometimes a maximum will coincide with a maximum, and at other times a maximum will coincide with a minimum. However, a reversal of magnetic polarity is to be expected for rising and for falling magma; but a seismic maximum may occur with both.

On the other hand, there seems to be but a very slight correlation between the ΔY curve, the ΔZ curve and the seismicity. However, it must be remembered that the data plotted is only for four years and three eruptions. No definite conclusions can be drawn upon any seeming correlation over so short an epoch. The United States Coast and Geodetic Survey has just recently furnished us with the Honolulu Magnetic Observatory results from 1905 to 1943, inclusive. This data for thirty-nine years and for many eruptions of Mauna Loa and Kilauea will be handled in the same way as the data of Figure 1. From this much longer epoch the reality or the nonreality of these seeming correlations should be definitely shown.

A third possible bit of preliminary work is to determine the variation in the magnetic declination at certain selected stations around the volcanoes to the accuracy inherent in a good modern transit. This program has just been begun. The stations indicated on the map of Figure 2 have been established. Each station consists of a nonmagnetic bench mark along with a corresponding nonmagnetic azimuth mark, which fix an observing point and a fixed azimuth line. The magnetic bearing of this fixed azimuth line is read on the transit each time that the station is reoccupied. The error in resetting the transit over the bench mark and in reading the magnetic needle should not exceed 0.1° and is certainly not over 0.2° at the most.

Stations A to H inclusive were established at an average date of about February 1, 1945, and were reoccupied at an average date of about March 20, 1945. The variation found in these two readings is:

Station	Variation	
A	0.35° W	
B	0.35° W	
C	0.15° W	
D	0.00°	(Station disturbed)
E	0.15° E	
F	0.25° W	
G	0.05° E	
H	0.10° E	

The variation for some of the stations is much higher than the maximum possible error; hence the variation must be real. If this variation is plotted on the map, it will be found that the vector lines radiate out from a point which very roughly might be guessed to be on the northeast rift of Mauna Loa at about 8,000 feet. These readings coincide with a seeming period of rising magma in Mauna Loa as indicated by a seismic series which came to a climax on April 2, 1945.

No data is given for stations I and J since these were established only recently. Immediate plans are to construct a simple suspended magnet to be read optically with a telescope and scale at a fixed location each day to determine changes in declination to within a minute of arc or better.

Hawaiian Volcano Observatory Report for January-March 1945

VOLCANOLOGY

January

Following the earthquakes of the last of December, 1944, Mauna Loa continued to show signs of uneasiness with shakes on January 6 and 9 that originated near Wood Valley and in the southwestern part of Mauna Loa. Thirty earthquakes were recorded at Kilauea and 22 at Mauna Loa.

February

Several times during the last of January and the first of February distinct fume clouds were observed over Mokuaweoweo.

The tilt record gives evidence of continuing high pressure under the Kilauea-Mauna Loa volcano system. Seasonal southwesterly tilt stopped about the middle of the month and by the last of the month there was a noticeable easterly tilt. A volcanic tilt sufficiently strong to overcome the southwest tilt that is normal for this season of the year is really a positive northeast tilt.

Several landslides from the Halemaumau rim were noticed during the month. A large one on February 11 filled the pit with dust and sent up a cloud with definite outlines well above the Halemaumau rim.

Twelve seismic disturbances were recorded at Kilauea and 22 at Mauna Loa.

March

The tilt records for March show that the uneasy condition of Kilauea mentioned for February continued into March. Northerly tilt, an indication of doming at Kilauea volcano, was strong enough during the first half of the month to overcome the normal southerly tilt and show an actual accumulation to the north. The spell of uneasiness was over about the middle of the month and during the last half of the month there was about the normal accumulation of southerly tilt. An easterly tilt that set in about the middle of February continued until March 6, when the usual westerly tilt was resumed. It continued until the end of the month.

This period of uneasiness coming only two and a half months after the one of November-December, 1944, indicates that the possibility of surface manifestations of volcanic activity at Kilauea within the next year or so are rather good. The easterly tilt and the distribution of earthquakes indicate that Mauna Loa is sharing the uneasiness with Kilauea.

Forty-two seismic disturbances were recorded at Mauna Loa and 37 at Kilauea.

* For definition of local seismicity see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

1. January 4, 12 : 18, very feeble.
2. January 6, 05 : 57, feeble, near Wood Valley. Felt at Kapapala and Pahala.
3. January 9, 18 : 57, slight. Felt at Pahala.
4. January 9, 19 : 08, very feeble.
5. January 11, 18 : 53, very feeble.
6. January 24, 10 : 38, moderate. Widely felt in SE half of the island. 10 to 15 miles below east rim of Kilauea.
7. February 5, 18 : 43, feeble. Felt locally. Probably at NE rift of Mauna Loa.
8. February 17, 04 : 24, very feeble.
9. February 18, 15 : 55, slight. Felt locally; E-W dismantled. Both components dismantled at Mauna Loa. About 9 miles deep near Ohaikea.
10. February 21, 02 : 00, very feeble.
11. February 23, 10 : 53, feeble. Origin about same as No. 9.

12. February 24, 18:43, very feeble. Origin probably same as No. 9.
13. February 26, 06:34, very feeble.
14. March 4, 00:00, moderate. At SW rift of Mauna Loa. Widely felt over island. Stopped clocks in South Kona.
15. March 12, 19:00, moderate. Instruments dismantled. Felt locally. In ocean off the Puna-Kau boundary.
16. March 13, 09:03, very feeble.
17. March 18, 07:54, feeble.
18. March 24, 13:33, feeble.
19. March 26, 10:04, slight. Felt locally.
20. March 26, 10:37, slight. Off coast south of Kilauea. Felt in eastern part of island.
21. March 28, 05:22, very feeble.
22. March 28, 19:58, feeble. At NE rift of Mauna Loa.
23. March 29, 18:32, very feeble.
24. March 30, 05:34, very feeble.
25. March 30, 08:31, very feeble.
26. March 31, 20:02, very feeble. Origin near Puu Keokeo. Felt in South Kona.

TELESEISMS

No teleseisms were recorded during the quarter.

MICROSEISMS

Microseisms were present though slight throughout the quarter.

TILTING OF THE GROUND

The seasonal SW tilt that started in December continued until about the middle of February when a NE tilt set in. The easterly tilt ceased on March 6 though the northerly tilt continued until March 14. During the last half of March the usual seasonal SW tilt prevailed.

Table of Tilt at Observatory on NE Rim of Kilauea

Week Ended	Amount	Direction
January 7	1.21″	S 48° W
14	0.88″	N 17° W
21	0.48″	S
28	0.62″	N 79° W
February 4	1.91″	S 26° W
11	1.46″	S 45° W
18	0.54″	N 63° E
25	0.17″	S 45° W
March 4	1.84″	N 62° E
11	1.47″	N 75° W
18	0.72″	S
25	0.71″	N 58° W

CRACK MEASUREMENTS

In January a majority of the cracks at Halemaumau rim and along the Chain of Craters Road showed a slight opening though a few showed some closing. There was considerable fluctuation in the width of these cracks in February. The net result, however, was a distinct opening in a few cracks and no change in the majority of them. In March a majority of the cracks around Halemaumau showed an opening and none showed a closing. There was no movement at any of the cracks along the Chain of Craters Road.

A FLOOD-DEVELOPED CHASM OVER A BURIED FAULT

By GUNNAR O. FAGERLUND

Naturalist and Chief Ranger, Hawaii National Park

An apparent seismic movement occurred on April 8, 1945, along a concealed fault about eighteen miles southwest of Kilauea near the old belt road. A chasm approximately 325 feet long, 40 feet wide, and 20 to 40 feet deep was formed in the Pahala ash that lies 30 to 50 feet thick upon prehistoric basalt.[1] The northern end of the chasm is about 1,800 feet southwest of the benchmark at 1,856 feet elevation near Kapapala Ranch gate and about 100 feet east of the old belt road.

Figure 1.—General view of the flood-developed chasm. (Photo by G. O. Fagerlund.)

The ash lying above the section of the fault disappeared into a fissure in the underlying prehistoric lava and created the chasm (Fig. 1). Extension of the northern end of the chasm was stopped by a bridging lava flow that withstood undermining. Beyond the southern end of the chasm the ash slumped some. A block 18 feet wide and 150 feet long dropped as much as 2 feet (Fig. 2). This slump block and the topographic sag shown in the background of Figure 2 indicate the continuation of the buried fault. A wider fissure in the basalt probably accounts for the sag in the ash that was laid down upon it at this point. Another slumped section, about twelve feet long and as wide as the chasm, occurs near the southern end of the chasm and breaks its continuity.

Only the west wall of the chasm shows two lava flows, one at zero to two feet and the other at four to ten feet below the surface. Before the breakdown, the edges of these flows probably lay almost directly above the buried fault. The upper flow bridges the northern end of the chasm.

A direct seismic cause of the chasm is precluded by the absence of earthquakes at the time it was formed. However, earthquakes of former years may have fractured or weakened the ash structure.

Extraordinarily heavy rainfall occurred on April 7 and 8 of this year. The total for the storm in the vicinity of Kapapala was about twenty-five inches. The prolonged downpour caused

[1] STEARNS, HAROLD T., AND CLARK, WILLIAM O. GEOLOGY AND WATER RESOURCES OF THE KAU DISTRICT, HAWAII (INCLUDING PARTS OF KILAUEA AND MAUNA LOA VOLCANOES). Plate 1. U. S. Geological Survey Water-Supply Paper 616. 1930.

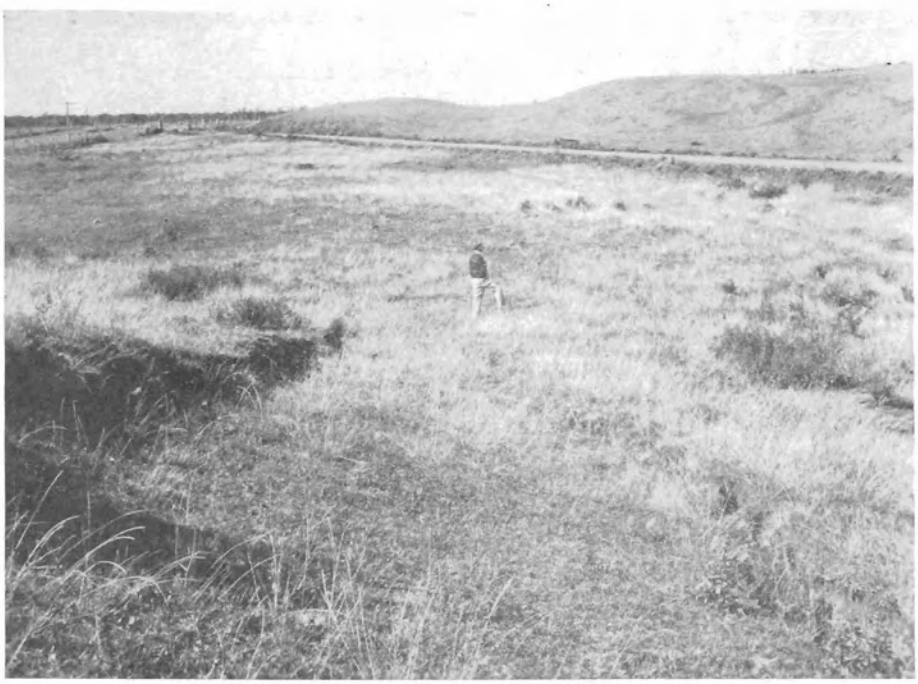

Figure 2.—Slump block near the southern end of the open chasm. The sag in the background shows extension of the buried fault. (Photo by G. O. Fagerlund.)

floods of uncommon magnitude and destructiveness. Sections of highway were washed out and fences were carried away. At Kapapala Ranch, one building was carried away and others were shifted.

Boulder-carrying floodwater moved over the area where the chasm formed. Sustained flooding probably led to seepage through the ash. Seepage may have been promoted at the fault line by earlier seismic movement there and by the edging lava flows above the fault. The seepage undermined the ash from the bottom of the bed upward in the manner of a linear swallet. This accelerating process developed into a waterfall that carried the ash into the fissure in the underlying basalt. The undermining continued until the roof collapsed.

Partial collapse followed lesser undermining near and beyond the southern extremity of the chasm, where the two slump blocks previously mentioned wedged into the ash above the fissure. Because these slumped sections formed on higher ground that was not covered by floodwater, they did not wash away, although a section of equally high ground between them collapsed completely. About twelve feet from the top of this high slumped section the presence of a water line indicates that the floodwater nearly filled the chasm for some time. Thus the length of the chasm was determined by a bridging lava flow at one end and by high ground at the other.

Figure 3 shows boulders on the edge of the chasm. Their presence indicates that the breakdown occurred after the maximum flood had passed. Floodwater, in this instance, produced a physiographic feature, viz., a chasm, of which a superficial inspection could lead one to conclude that it had been caused by seismic movement.

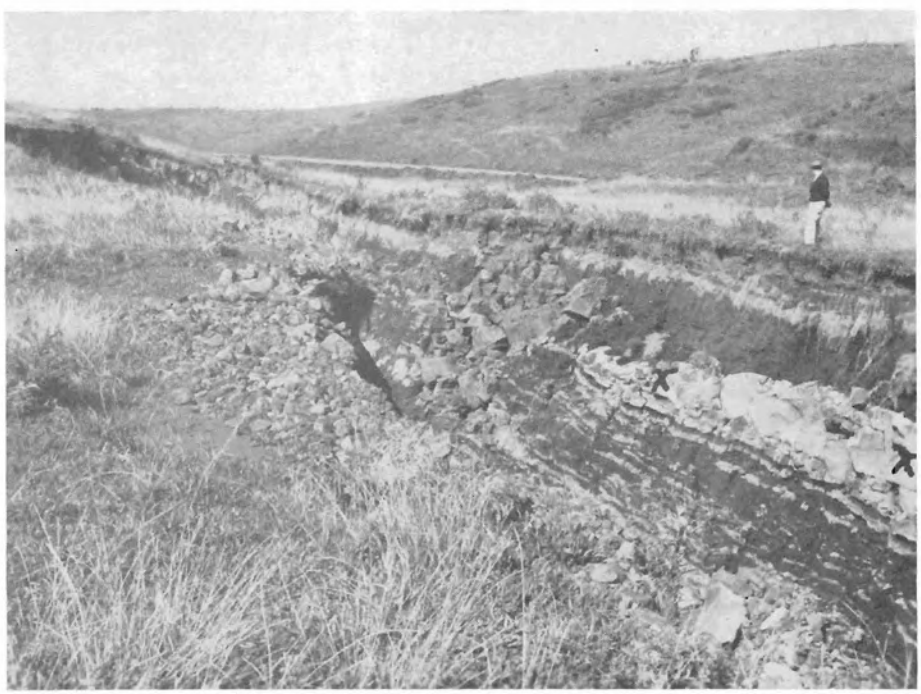

Figure 3.—The west wall of the chasm shows an interbedded lava flow from X to X. Note the fresh boulder deposit on the left rim. (Photo by G. O. Fagerlund.)

Hawaiian Volcano Observatory Report for April-June 1945

VOLCANOLOGY

April

A strong northeast tilt accompanied the torrential rains of April 7 and 8. The north tilt recovered rapidly after the rain stopped, but a slight easterly tilt continued for over a week before there was a recovery to the west. There were no signs of uneasiness at either Kilauea or Mauna Loa, though internal pressure continued high. A total of 54 seismic disturbances was recorded at Kilauea and 32 at Mauna Loa.

Several of the rim cracks at Halemaumau showed distinct openings.

May

An earthquake which occurred at 02:48 (HST) on May 19 is of especial interest. It originated at a depth of 12 to 15 miles below the surface on the east slope of Mauna Loa, about half way between Halemaumau and Mokuaweoweo. It was just strong enough to awaken light sleepers on the island of Hawaii and appears to have been only slightly less intense on Oahu. The shake produced a good record on the U. S. Coast and Geodetic Survey seismograph in Honolulu. Only one component of the horizontal seismograph at the Observatory was dismantled, though both were dismantled at the Mauna Loa station, which is about 3 miles nearer the epicenter. The widespread and rather uniform intensity suggests that the origin may have been at an even greater depth than the indicated 12 to 15 miles. At any rate, the energy of the surface waves was not much greater in the epicentral region than at places 50 miles and more away.

A total of 25 shakes was recorded at Mauna Loa and 19 at Kilauea.

June

Pressure under Kilauea and Mauna Loa changed little during June. Only two earthquakes strong enough to be felt locally were recorded. They originated along the lower southwest Kilauea rift.

Forty-one seismic disturbances were recorded at Mauna Loa and 19 at Kilauea.

45. April 18, 09:04, slight. Kilauea origin.
46. April 20, 16:08, very feeble. East slope of Mauna Loa.
47. April 21, 02:41, very feeble. Mauna Loa origin.
48. April 22, 18:33, very feeble.
49. April 29, 01:59, slight. Felt locally.
50. May 1, 13:33, very feeble.
51. May 19, 01:48, moderate. East-west dismantled. East slope of Mauna Loa. Generally felt on Hawaii and slightly felt on Oahu.
52. May 19, 02:05, very feeble.
53. May 19, 02:18, very feeble.
54. May 19, 03:33, feeble. Felt by a few.
55. May 19, 21:21, slight. Origin on Mauna Loa.
56. May 29, 18:45, slight. East slope of Mauna Loa, 5 miles southwest of Red Hill, 12 to 14 miles deep. Felt locally, at South Kona, and at Hilo.
57. May 30, 01:27, very feeble.
58. May 31, 15:06, slight. Five to 7 miles deep off coast south of Kilauea. Felt locally.
59. June 1, 16:13, very feeble.
60. June 7, 00:26, very feeble.
61. June 8, 04:25, very feeble. Origin in Kona.
62. June 14, 19:46, slight. Near Pahala. Felt locally and at Pahala.
63. June 27, 08:34, feeble. Kilauea shake.
64. June 27, 19:40, very feeble. Mauna Loa shake.
65. June 28, 04:08, feeble. Felt locally.
66. June 29, 16:37, feeble. Upper northeast rift of Mauna Loa.

TELESEISMS

May 19, 04:40, slight. Off northern California.
June 21, 22:58, slight.
June 27, 02:56, slight.
June 29, 19:05, slight.

MICROSEISMS

Microseisms were moderate on June 3 and 4 and unusually small throughout the rest of the quarter.

TILTING OF THE GROUND

Except for a sharp northeast tilt accompanying the unusually heavy rain of April 6 to 8, the southwest tilt that commenced in March continued until May 8. The westerly tilt, however, continued a month longer. The seasonal southwest tilt that started on June 8 continued into July.

CRACK MEASUREMENTS

In April several of the cracks around Halemaumau showed a distinct opening and none showed a closing. One crack along the Chain of Craters road opened slightly. One crack near the southwest rim of Halemaumau opened 16 mm. in May. Most of the other rim cracks also opened considerably. Only slight movement of the cracks around Halemaumau was detected in June.

SUMMIT AND NORTHEAST RIFT ZONE OF MAUNA LOA

By GORDON A. MACDONALD

Associate Geologist, U. S. Geological Survey

The summit and northeast rift zone of Mauna Loa were mapped by the writer in the summer of 1942 as a part of the study of the geology and ground-water resources of the island of Hawaii made by the U. S. Geological Survey in cooperation with the Territory of Hawaii. The mapping of the vents and identifiable historic lava flows is shown in the accompanying figures. It is a pleasure to acknowledge the aid of Harvey Finch during field work in the summit area of Mauna Loa. The National Park Service permitted the use of rest houses on the mountain, and extended many other courtesies. James Y. Nitta prepared figure 2.

The topographic base used in the accompanying figures was prepared several years ago by the topographic branch of the Geological Survey. Boundaries of the historic lava flows to and including the 1926 flow which were shown on earlier topographic maps were re-examined. The delineation by E. G. Wingate and his associates of the 1926 and 1851 lava flows on the upper southwestern slopes of the mountain was found to be excellent, and the boundaries of these flows on the accompanying maps are taken from the topographic map. The flow of 1880 on the southern side of the northeast rift zone also is taken from the topographic map. But the boundaries of the flows of 1880-81 and of 1899 on the north side of the rift zone required extensive revision. In general, the area of these flows as indicated on the topographic map includes only the pahoehoe phase of the flow, the aa phase having been ignored.

Remapping of the flows of 1880-81 and 1899, and original mapping of the lavas of 1935, 1940, and 1942, was done partly on the ground and partly with the aid of aerial photographs. The source of one of the 1935 flows (A, fig. 2) was mapped on the ground by H. T. Stearns and checked with aerial photographs. The area of 1933 lava in Mokuaweoweo was shown on a map by F. M. Bullard and P. H. Baldwin,[1] and the outline of the 1940 lava in Mokuaweoweo is taken from the map by P. E. Schulz,[2] after checking in the field. There follow a few brief notes on volcanic features along the northeast rift zone and in the summit area.

A cone northeast of Puu Ulaula (C, fig. 2) gave vent to lavas rich in large crystals of olivine. It may be the source of similar lavas exposed along the trail below Puu Ulaula. The top of this cone has partly collapsed inward, possibly owing to failure of support on withdrawal of the fluid lava at the end of the eruption.

The cone with a summit altitude of 9,617 feet, and 1.4 miles N. 24° E. of Puu Ulaula (D, fig. 2), may be a source of the lava flow of 1880-81, as suggested by Jaggar.[3] The adjacent cones lie east of the flow boundary, however, and are older than the 1880 lava.

The 1899 flow issued at Pukauahi[4] and also along a fissure a mile farther west-southwest. A small tongue of lava flowed southeastward for about a mile, parallel to the Kau branch of the 1880 flow. The southeastward-flowing branch was mentioned in contemporary accounts. The northeastern branch of the 1899 flow is considerably more extensive than is shown on previous maps.

The lava flow of 1855, which lies to the north of the area shown in figure 2, cannot be traced upslope beyond the point where it is overlapped by a branch of the 1880 flow. Undoubtedly it is largely buried by the flows of 1880 and 1899, and parts of it which are not buried are indistinguishable by ordinary field methods from the many late prehistoric flows. The place of eruption is variously stated as 12,000 feet altitude, and 5 miles from Mokuaweoweo.[5] Judging from these locality descriptions and the position of the known portion of

the flow, it probably was near Pukauahi. One possible source is a cone of unknown date west of Pukauahi (E, fig. 2). Another is a cone just south of the trail at 11,750 feet (F, fig. 2), from which the channel of a lava river leads eastward to the vicinity of Pukauahi. Hot rock is still present at some unknown but probably shallow depth beneath this cone which frequently gives off visible steam clouds when weather conditions are favorable.

Besides the generally recognized vents at higher altitude, during the 1935 eruption a small amount of lava issued from a fissure slightly offset from the alignment of the main fissure along the edge of the flow at 11,550 feet altitude (G, fig. 2). During the eruption of 1942 the principal eruptive fissure crossed North Pit and extended along the western wall of Mokuaweoweo (figure 1), sending cascades of lava into the caldera. The fissure in North Pit was largely buried by the lava flow, but one small cone of spatter and cinder is still visible there. At several places just east of the rim of North Pit, lava issued from concentric fissures as well as from the normal radial fissures of the rift zone.

It would undoubtedly prove worthwhile to continue the mapping of the rift zone of Mauna Loa after each eruption.

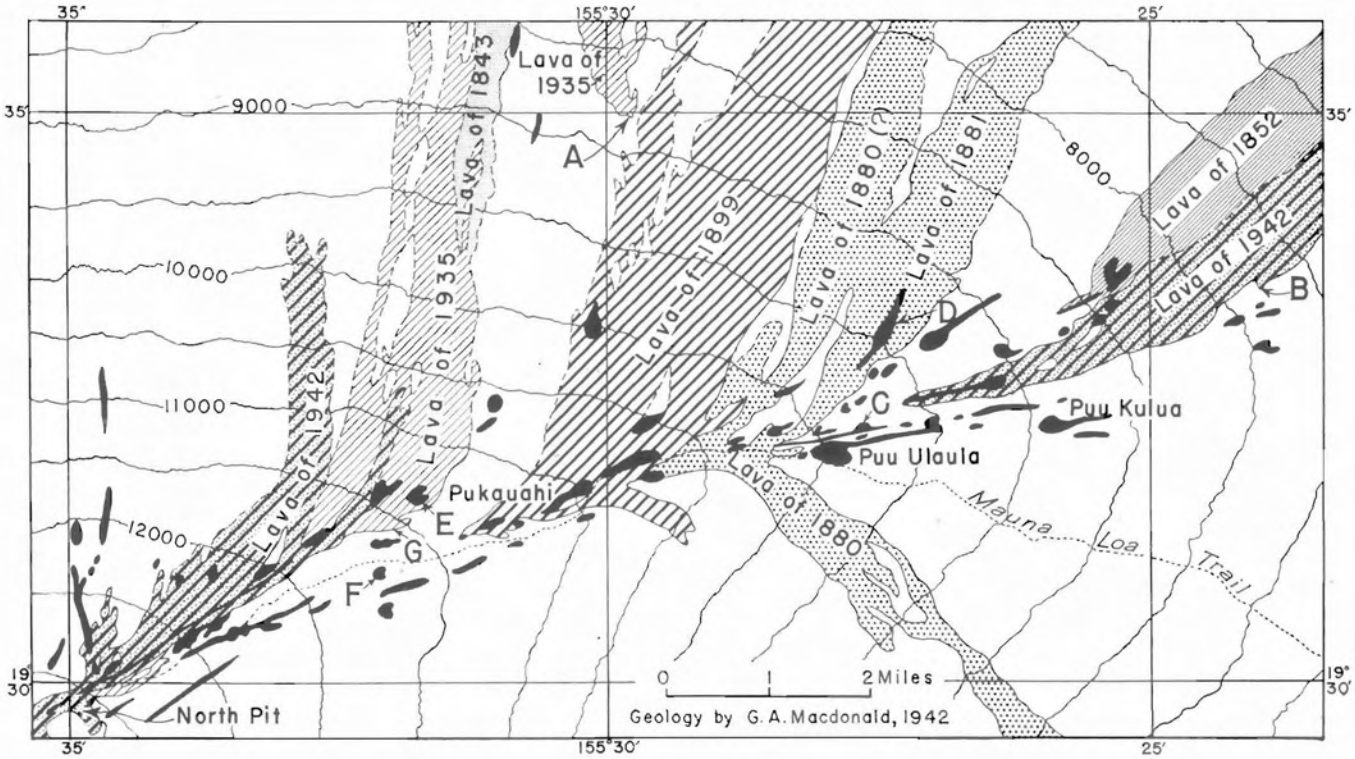

Figure 2.—Map of the upper part of the northeast rift zone of Mauna Loa, showing the location of vents and the areas covered by identifiable historic lava flows. Cinder and spatter cones are shown in solid black.

A NEW BOOK ON PACIFIC VOLCANOES

Volcanoes Declare War: logistics and strategy of Pacific volcano science. By Thomas Augustus Jaggar. 166 pp. Quarto 8 x 11 inches. Copyright 1945. 32 halftone plates, 34 text figures, 5 color plates, 2 cartoons. Paradise of the Pacific, Ltd., Honolulu, T. H. $3.75.

This handsome volume, with colored picture of Paricutin in eruption on the jacket, contains 173 separate reproductions of photographs and drawings, and a text intended for popular reading. The plates have full descriptive titles and are together in the middle of the volume. There is a glossary of technical terms and a list of references.

The table of contents covers Hawaiian volcanoes, south sea outbreaks, East Indian explosions, western Pacific rim, the Aleutian islands, Canada and the Cascade mountains, Mexico, Central America, the Caribbee eruptions, and Chile. This is followed by a review of volcano science, accenting insurance and protection, and specifically giving the author's conclusions based on studies from Pelée in 1902 to Mauna Loa in 1942.

Here are descriptions, engineering experiments, statistics, journals of expeditions, theories, adventures and surveys, insurance, and economic use of power. The author reserves his experiments with earthquakes for a later volume. He insists on the need for core drilling to rock under the oceans.

Hawaiian Volcano Observatory Report for July-September 1945

VOLCANOLOGY

July

Small fume columns were visible from the Observatory in afternoon sunlight over Mokuaweoweo on July 31. About the usual fuming was observed from the rim of Mokuaweoweo from July 23 to 29.

Tilt to the north was slightly greater than normal.

A total of 27 shakes was recorded at Kilauea and 42 at Mauna Loa.

August

Fuming in amounts greater than usual was observed over Mokuaweoweo on several afternoons. Conspicuous north tilt continued during August. This tilt indicates a pressure build-up under Kilauea. There was a conspicuous widening of some of the cracks near the southwest rim of Halemaumau.

Seismicity was low in August with 32 earthquakes recorded at Mauna Loa and only 15 at Kilauea.

September

Landslides from the southwest rim of Halemaumau became unusually conspicuous on September 17 and continued for a week with diminishing frequency. Apparently the largest slide of the series occurred at 16:59 September 17 when a section of the rim about 80 feet long and 6 or 8 feet wide went in. It caused an earthquake sufficiently large to make a conspicuous record on the Observatory seismographs.

Rapid north tilt continued during the first week in September, thereafter the northerly tilt was less than normal.

A total of 25 earthquakes was recorded at Kilauea and 30 at Mauna Loa.

* For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

67. July 1, 07:46, very feeble.
68. July 3, 20:06, very feeble.
69. July 4, 18:08, very feeble. Northeast rift of Mauna Loa.
70. July 6, 06:54, very feeble.
71. July 6, 13:46, very feeble.
72. July 13, 02:15, moderate. East-west dismantled. Four to six miles deep along Puna coast southwest of Kalapana. Widely felt in eastern half of island of Hawaii.
73. July 14, 02:54, very feeble.
74. July 16, 04:15, very feeble.
75. July 25, 03:46, very feeble.
76. July 25, 07:03, very feeble.
77. July 28, 10:50, very feeble.
78. July 30, 05:14, feeble. Kilauea shake. Felt locally.
79. August 2, 07:51, very feeble.
80. August 9, 10:46, slight. Generally felt in southwest part of island. East slope of Mauna Loa above Kapapala.
81. August 15, 15:26, very feeble.
82. August 27, 03:31, feeble.
83. August 30, 06:54, very feeble.
84. September 5, 09:18, feeble. Northeast rift of Mauna Loa north of Red Hill. Felt locally and in Hilo.
85. September 7, 18:51, very feeble.
86. September 8, 15:26, very feeble.
87. September 17, 16:59, feeble. Landslide at Halemaumau at this time.
88. September 19, 05:33, slight. Widely felt over entire island. Between Mauna Loa and Mauna Kea.
89. September 21, 04:47, very feeble. Kilauea origin. Not felt, but rumble heard.
90. September 23, 15:39, feeble. Northeast rift of Mauna Loa.
91. September 29, 21:45, very feeble.
92. September 29, 21:52, very feeble.
93. September 30, 02:05, very feeble.
94. September 30, 18:18, very feeble.
95. September 30, 21:49, very feeble. North end of Kilauea Crater.

TELESEISMS

July 1, 22:24, slight.
July 14, 19:14, slight. In the Marianas.
August 28, 23:52, slight. 5400 km. New Hebrides.
September 1, 13:09, slight.
September 28, 12:08, slight.

MICROSEISMS

Microseisms were moderate from July 12 to 16 inclusive and very small throughout the rest of the quarter.

TILTING OF THE GROUND

Northerly tilt was continuous throughout the quarter though less than usual during the last three weeks of September. There was a slight westerly tilt in July. The east tilt in August and September was less than normal. There was a sharp west tilt on September 19 with a recovery to the east on September 20.

CRACK MEASUREMENTS

The only measured cracks that showed any appreciable opening in July were along the southwest rim of Halemaumau. The movement of the southwest rim cracks continued in July with one crack opening 27 mm. In September there were numerous landslides from the southwest rim. One measuring station was carried away and another made inaccessible.

ON THE DEPTH OF FOCI OF EARTHQUAKES ON THE ISLAND OF HAWAII

By R. H. FINCH

The depth of foci of island of Hawaii earthquakes ranges from near the surface—sometimes distinctly less than one mile—to 25 to 30 miles. Shakes originating near the surface under the summit of Mauna Loa may actually have foci higher than most of the seismographs on the island.

The most active rift on Mauna Loa is aligned NE–SW with a distinct bend where Mokuaweoweo is crossed. Eighteen miles of the surface length of this rift is above 10,000 feet. The most active rift system at Kilauea is roughly parallel to that of Mauna Loa. Since shallow-focus earthquakes along both Mauna Loa and Kilauea rifts may have foci above sea level, the paths of the waves of nearby shakes with such depths may lie wholly in dry rock. With greater distances or greater depths the earthquake waves would traverse layers of rock saturated with ground water. As the velocity of earthquake waves is less in saturated than in dry rock, one could easily be misled into assuming a discontinuity at the ground-water level.

Hawaiian earthquakes originate in three principal types of fault systems: (1) the fundamental rift which determines the location of the Hawaiian islands; (2) comparatively superficial faults within the volcanic structures that have been built up from the ocean floor 15,000 feet below sea level; and (3) within volcanic conduits. The minimum depth of focus that is possible in the first group is, then, about 3 miles below sea level or within the original surface of the ocean floor. Usually, of course, the depth is much greater than the 3-mile lower limit. The range in depth of Group 2 is from the surface to about 5½ miles below the summit of Mauna Loa—this is nearly 14,000 feet above sea level to about 15,000 feet below sea level. If, as would appear to be the case, the NE–SW trending rifts of Mauna Loa and Kilauea represent structural weakness within the volcanic edifices, then they must of necessity terminate at or above the ocean floor. The depth of focus of Group 3 may vary from near the surface to many miles or approximately as deep as those of Group 1. Movement in Group 3 may be produced by rising or falling of the lava column or by temperature changes induced thereby. Activity in any one group may induce activity in any other group though the effect of Group 2 shakes in this respect is probably quite small.

There are some indications that there are at least two branches of the fundamental rift under the island of Hawaii—one under Kohala and Mauna Kea and the other in the vicinity of Hualalai, Mauna Loa, and Kilauea. There is not much evidence that Mauna Kea and Kilauea are located on the same rift. It might be expected that the radius of curvature of the Hawaiian arc would become shorter as the two ends are approached but not enough to put these two volcanoes on the same rift. The distribution of the foci of deeper earthquakes strengthens the idea of the two branches of the fundamental rift.

It would not be surprising to find cases where movement along the fundamental rift was contemporaneous with movement along a superficial rift and with a volcanic eruption. In 1868 there appear to have been concomitant movements along the fundamental rift under Mauna Loa and along the southwest rift of that mountain. Wood[1] has shown that the largest shake of the

[1] WOOD, HARRY A. ON THE EARTHQUAKES OF 1868 IN HAWAII. Bul. Seis. Soc. Amer. Vol. 4, No. 4, Dec. 1914.

series should be classed as of tectonic origin. The tectonic quake or quakes with some aftershocks occurred at a time when the southwest rift was working and a maze of earthquakes resulted. The strongest shake was felt on Kauai or at a distance of about 320 miles. Subsequent studies of other quakes originating in the same general area would lead one to believe that the depth of focus of the 1868 earthquake was over 30 miles.

The present writer is of the opinion that the 1868 shake had its origin along the fundamental rift under the east slope of Mauna Loa or 15 to 20 miles northeast of the then active portion of the southwest rift of Mauna Loa. The opinion is based on later determinations of many foci with depths of 20 to 30 miles in the same general area. Jones[2] shows a grouping of such earthquakes under the east slope of Mauna Loa. Other shakes with similar depths of focus are still being located in this area.

On December 27, 1944, an earthquake strong enough to dismantle all the seismographs on the island of Hawaii occurred about 20 miles below the surface of the eastern slope of Mauna Loa. The epicenter appears to have been a little to the northeast of most of the comparatively deep focus shakes that Jones located in this area. At least 10 or 12 aftershocks accompanied the December 1944 shake. The order of magnitude of the depth of focus is attested by the fact that the shake, while doing but little damage locally, was felt on Oahu and toppled objects from shelves at places as widespread as Naalehu and Pepeekeo on Hawaii.

An earthquake of the same type, which occurred on May 19, 1945, is of special interest in that despite the fact that it dismantled only one component of the Bosch-Omori seismograph, which is some 12 miles from the epicenter, it was felt on Oahu, nearly 200 miles away. The disturbance was just strong enough to awaken light sleepers on the island of Hawaii and but little less intense on Oahu. While both components of the Mauna Loa seismograph, which is about 3 miles nearer the epicenter than the Bosch-Omori, were dismantled, horizontal motion in the epicenter area was but little more than at points 50 or more miles away. There were five or six aftershocks. The epicenter was located to the southeast of the shake of December 27 or a little lower down the east slope of Mauna Loa. General considerations indicate that the depth may have been greater than the indicated 20 miles. Owing to uncertainties in interpretation of seismograms and in travel times, our locations of earthquake foci are at best but approximations.

Hawaiian Volcano Observatory Report for October-December 1945

VOLCANOLOGY

October

Fume columns were observed over Mokuaweoweo on several afternoons during the month. On October 21 observations were made simultaneously at the Observatory and at the rim of Mokuaweoweo. The fuming as observed from the rim was distinctly more than usual.

As in September, northerly tilt was less than usual for this season of the year. Easterly tilt was about normal.

A total of 55 seismic disturbances was recorded at Mauna Loa and 48 at Kilauea.

November

Spells of conspicuous fuming were observed over Mokuaweoweo several times during the month. On November 18 the fume was visible from the Observatory even in morning light until about 8 a.m. Very distinct fume columns were observed from the east rim of Mokuaweoweo several times during the afternoon and evening of November 29.

There was a continued lack of northerly tilt which for this season of the year is equivalent to a slight southerly tilt. Easterly tilt was about normal.

Seismicity was again low with 19 seismic disturbances recorded at Kilauea and 30 at Mauna Loa.

December

Yellow fume was observed over Mokuaweoweo during the late afternoons of December 25 and 26. Some steaming was observed on other days.

Landslides at Halemaumau were frequent during the middle of the month and on the last 3 days. The majority originated at the NW rim.

A total of 31 seismic disturbances was recorded at Kilauea and 37 at Mauna Loa.

There was an accumulation of WSW tilt during the month. Despite the falling off of N tilt in September and the unusually early change to S tilt in November there was an accumulation of 3.6" of northerly tilt during the year. This may be taken as an indication of a slight pressure build up under Kilauea. The accumulation of E tilt during the year amounted to over 6". If, as seems to be the case, there is a correlation between E–W tilt and Mauna Loa activity, then there was a pressure build up under Mauna Loa in 1945.

TELESEISMS

October 29, 00 : 40, slight. Off British Columbia.

November 27, 11 : 50, moderate. Arabian Sea.

December 27, 07 : 14, moderate. Distance 4,000 miles.

MICROSEISMS

Microseisms were conspicuous from October 25 to 29, on November 12, from December 2 to 5, and on December 28. During the rest of the quarter they were very small.

CRACK MEASUREMENTS

A few of the cracks near the Halemaumau rim and along the Chain of Craters Road opened slightly, though a majority that were measured showed no movement. Landslides were frequent from the northwest rim of Halemaumau during the middle and on the last three days of December.

TILTING OF THE GROUND

There was a slight northerly tilt from October 1 to November 9 though less than normal for this season of the year. From November 9 to the end of the year there was a slight southerly tilt. The change to southerly tilt came over a month earlier than usual. The seasonal change to westerly tilt occurred on December 20 or about the usual time. There was a slight accumulation of easterly tilt during the quarter.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

in cooperation with UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter,** a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE VOLCANO LETTER

No. 491 Department of Interior National Park Service January-March 1946

PUBLISHED BY THE UNIVERSITY OF HAWAII

HAWAII NATIONAL PARK: Gunnar O. Fagerlund, Acting Superintendent; R. H. Finch, Volcanologist

UNIVERSITY OF HAWAII: T. A. Jaggar, Geophysicist

THE TIDAL WAVE OF APRIL 1, 1946

By H. A. POWERS
Geologist, Hawaii National Park

Figure 1.—The waterfront, city of Hilo, April 1, 1946. Two thirds of the railroad bridge spanning the Wailuku River can be seen in the right background. One span was lifted from the piers and carried upstream. The railroad station occupied the barren area on the near bank of the river. The station and the tracks which circled the bay have completely disappeared. All the waterfront buildings between the railroad station and the park (marked by the trees in the center) floated into the street and collapsed. With the exception of the reinforced concrete warehouse, all of the waterfront buildings which occupied the foreground were completely demolished and scattered inland and out to sea. HONOLULU STAR-BULLETIN Photo

The Hawaiian Islands suffered their greatest natural disaster of modern times from a tidal wave which reached the islands from the north Pacific early on the morning of April 1, 1946. Over 200 persons are known to have lost their lives or to be missing. The greatest number of casualties is from the island of Hawaii, particularly from the city of Hilo. Property damage was suffered on all the islands and will total many million dollars in loss of homes and personal property. The greatest industrial losses were concentrated in the area around Hilo Bay.

The earthquake which caused the tidal waves apparently had its epicenter in the vicinity of the Aleutian Trough, a region of great ocean depth south of and paralleling roughly the Aleutian Island chain. The earthquake was recorded on all of the horizontal component instruments operated by the Volcano Observatory of the Hawaii National Park. On the Bosch-Omori instrument at the Observatory, the first impulse of the preliminary wave was recorded at approximately 02 06 20 Hawaiian Standard Time, the exact emergence being somewhat obscured by very strong microseismic motion caused by the heavy trade-wind surf which had prevailed for a number of days. The arrival of the secondary wave was recorded approximately at 02 11 10, and of a long wave at 02 14 05, indicating a probable distance from the origin of at least 2,100 miles. Reports from other seismographs indicate that 2,300 miles is more nearly correct. The earthquake was of sufficient intensity to cause continuous disturbance of the seismographs on Hawaii for two hours, though this long duration of disturbance may be due partly to a second quake which appears to be recorded in the coda of the major quake. Seven distinct aftershocks were recorded here. Most of them were registered by impulses lasting less than a minute, but a larger one at 08 44 disturbed the seismograph for about ten minutes. A disturbance of several minutes' duration starting at 06 46 probably is the record of the primary earthquake waves which traveled around the longer arc of the earth.

It is reported that the tide gage in Honolulu Harbor showed the following record of the disturbance:

06 30 Beginning of 7½-inch rise
06 36 Crest of first wave
06 42 Trough of second wave, a drop of 26¼ inches
06 48 Crest of second wave, a rise of about 33¾ inches
06 54 Trough of third wave, a drop of 40½ inches
07 00 Crest of third wave, a rise of about 4 feet

The Hilo tide gage was destroyed. Eyewitness reports indicate that the first wave occurred at Hilo a few minutes after 07 00 and electric clocks in the first damaged area were stopped at 07 06. The Observatory seismogram shows a short electric power stoppage on the suburban line at 07 18 21. Eyewitness testimony indicates that the second wave at Hilo did damage, so it is possible that this short power interruption marks the time of the crest of the second wave in Hilo Harbor at 07 18.

If these time interpretations are correct, the time-lag between arrival of the wave at the two island harbors is exactly 30 minutes. The time of the actual earthquake, taken from seismologic tables, must have been approximately 02 00 Hawaiian time. Thus the fastest wave reached Honolulu in 4 hours and 30 minutes, and Hilo in 5 hours.

The average velocity of the water wave through the open ocean approached 460 miles an hour, but slowed down in the shallow water near the islands to 300 miles an hour. The greatest speed of a wave recorded at the Volcano Observatory was that of a wave on November 10, 1938 which traveled from the Aleutian Islands at an average of 497 miles an hour.

Measurable water waves caused by submarine earthquakes in the Pacific reach Hawaiian shores perhaps as often as once a year. However, most of them cause a water rise of only a few inches and so are not noticed. Since 1800, the wave of April 1, 1946 is the seventh from a distant source to cause damage in the Hawaiian Islands. It was by far the most destructive of the seven. Though the waves of 1837 and 1877 were of greater magnitude, there was less life and property within reach of the waves in this earlier period.

The outstanding tidal waves reaching Hawaii in the nine-

teenth century have been described by a number of writers, and were summarized by T. A. Jaggar in THE VOLCANO LETTER, No. 321, February 19, 1931.

The earliest noted was in May 1819, but no information remains as to the possible source, or the damage done.

Three severe waves were caused by earthquakes off the coast of South America. The first, November 7, 1837, affected all the islands of the Hawaiian group. An unrecorded number of lives were lost, and a number of houses were destroyed. On August 13, 1868 a wave from near Peru reached a height of 15 feet above low water at Hilo and 12 feet deep on windward Maui. The damage caused by another from Chile on May 10, 1877 included loss of five lives at Hilo and the destruction of many dwellings. Water reached into the second business block from the waterfront along Waianuenue Street, which parallels the Wailuku River.

One tidal wave was described from an earthquake off Kamchatka on May 17, 1841, but no damage is described.

The terrific Hawaiian earthquake of April 2, 1868 caused a severe local tidal wave along the south coast of the island of Hawaii, but was not so damaging in other localities. Forty-six persons lost their lives and 108 dwellings in Puna and Kau were destroyed in addition to much other damage. Water in Hilo rose 10 feet. A smaller tidal wave, apparently of local origin, did no great amount of damage on August 27, 1872.

The source of Hawaii's damaging tidal waves of this century has shifted to the north Pacific. The first, on September 7, 1918, came from Kamchatka and caused relatively small damage. One person lost his life and extensive property damage was caused at Hilo and at Kahului, Maui, on February 3, 1923 by a wave from Kamchatka. At Hilo the funneling effect of the bay forced the third and the highest wave up to nearly 20 feet above mean low sea level in the small boat harbor at the mouth of the Wailoa River. A quake off the coast of Japan started a wave on March 2, 1933 which caused some damage along the Kona coast of Hawaii.

Table 1, compiled from seismograms at the Volcano Observatory, summarizes the date, origin, and velocity of tidal waves recorded in Hawaii during the nineteenth century. Since installation of the tide gage at Hilo in 1927, it has been possible to determine travel time of waves with more accuracy.

With the present tremendous increase of American interests in the islands of the Pacific and in Alaska, it is possible that a workable system of tidal wave warning may be placed in oper-

Table 1.—Origin and Rate of Travel of Nineteenth-Century Tidal Waves Determined from Seismograms at the Hawaiian Volcano Observatory

Date	Origin	Distance	Travel Time	Average Speed
		Statute miles		*Miles per minute*
1918, Sept. 7	Kamchatka	3,200 (approx.)	7 hrs. (nearly)	7.6
1922, Nov. 11	Chile	4,900 (approx.)	11 hrs. (nearly)	7.5
*1923, Feb. 3	Kamchatka	3,000	7 hrs. (nearly)	7.2
1923, Apr. 13	Kamchatka	3,200	7¼ hrs.	7.3
1927, Nov. 4	California	2,400	5 hrs. 10 min.	7.7
1927, Dec. 28	Kamchatka	3,310	7 hrs. 35 min.	7.3
1928, June 16	Mexico	3,915	8 hrs. 30 min.	7.7
1929, Mar. 6	Aleutian Islands	2,270	4 hrs. 35 min.	8.2
1931, Oct. 2	Solomon Islands	3,680	8 hrs. 20 min.	7.45
*1933, Mar. 2	Japan	3,950	8 hrs. 25 min.	7.95
1938, Nov. 10	Alaska	2,485	5 hrs.	8.27
*1946, Apr. 1	Aleutian Islands	2,300	5 hrs.	7.7

* Except for waves indicated by an asterisk all listed were of very small size and did no material damage. However, they were originated by earthquakes of considerable magnitude which caused damaging waves near their origin. In fact, the earthquakes of 1929 and 1938 were both recorded on the seismograph as stronger than the recent one of April 1, 1946.

ation. This can be done with proper coordination of existing facilities and service organizations at very nominal expense. A workable plan must include the following important phases:

1. Immediate detection and location of submarine earthquakes in the Pacific area by a network of seismographs.
2. Computation of possible time of arrival of ensuing tidal wave at all American island or coastal installations, and immediate notification of the installations closest to the source of the wave.
3. Observation by outposts nearest to the source of the wave as to arrival time and size of the wave, and sending of immediate reports from these outposts to Central Control.
4. Report from Central Control to all vulnerable outposts and installations based on information obtained from first outpost reports.

Seismographs which would serve to greatest advantage in a system of tidal-wave warning should have two features which are not essential to the instrument in use at present: (1) the instrument must sound an alarm to notify the attendant personnel that a teleseism is being recorded, and (2) the recording method should be such that the record can be removed and prepared for study within a very few minutes.

A net of four such instruments located, perhaps, one at Honolulu and three on the North American mainland would make possible a rapid preliminary determination of the epicenter of any Pacific earthquake. Observers at these stations would make immediate studies of a quake which might be located in a critical area and would be given priority use of long distance telephone facilities to report their data to one of the four stations designated as the Central Control. This control would quickly make the best possible determination of the location of an earthquake, and *if* a tidal wave were indicated as probable, would quickly compute the possible time of arrival of a wave at vulnerable points in and around the Pacific.

Tide observation stations, to be most useful in a system of tidal-wave warning, should satisfy the following conditions: (1) be operated by an installation which can or does maintain 24-hour watch on a two-way communication system, (2) be equipped with recording tide gages which can be read easily at any time, (3) be geographically located in all possible vulnerable places in the Pacific which can satisfy the first condition.

At present, the United States Naval installations, connected by the excellent Navy Communications net, probably offer the best organization and facilities to handle the system of observation stations.

Each of the tidal observation stations would be alerted by a priority message from the previously mentioned Central Control warning of the possibility and direction of a tidal wave and the computed arrival time. The outposts first in the path of the possible wave would be notified first.

Each outpost would make negative or positive statistical reports to the Central Control immediately as it obtained negative or positive information on the appearance of the tidal wave. From these reports, relatively competent information would then be sent to areas more remotely in the path of the wave.

The functioning of such a system need not create mass hysteria, nor need it fall into the position of Aesop's boy who cried, "Wolf!" Rapid routine location of the epicenter by the seismograph net would screen out any public mention of tidal wave in connection with all earthquakes except those which actually were so located as possibly to cause a wave. The immediate collection of reports, both positive and negative, from those outposts earliest in the path of the possible wave, would make available relatively specific warnings to areas more remotely in the path of the wave.

Communities subject to tidal waves could provide an additional simple alarm system which might prevent loss of life by taking advantage of the fact that an abnormally low water precedes by a few minutes the approach of an abnormally high wave. A tide gage could be connected with a loud siren in such a manner that the alarm would be sounded when the tide gage dropped to a point somewhat below low tide mark.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

320 James Campbell Building, Honolulu 48, T. H. Telephone 3834

To the Donors and Members
Hawaiian Volcano Research Association

Your Directors this day meeting in the office of President Thurston, have to report that our Scientific Director T. A. Jaggar and his assistant R. A. Okuda are continuing laboratory work in measuring hardness of metals and minerals; the book on Pacific volcanoes was published and now is on sale on the mainland; a paper on tidal waves, a book manuscript on explosive volcanoes, and another on craters, are in press in New York; and Dr. Jaggar is now working on alleviation of tidal waves.

The disastrous beach flood of April 1 in Hawaii engages our scientists, and the Honolulu and Hilo Chambers of Commerce, and the Government. Our Association has dealt with such cataclysms and was founded to alleviate them. Some alleviation in the future is possible and with financial support our laboratories are suitable to cooperate with others in design of warning instruments.

With this program decided on, need for a larger budget is brought to your attention. We approve raising $5000 for 1946, with costs of tidal wave investigation and the usual volcanology research shared with University and National Park. We hope you will increase your generous support, and the University of Hawaii looks forward to extending this work to a Pacific Ocean Institute, a project that has been taking shape for several years past. Gifts from new donors are welcomed.

Very truly yours,

L. P. Thurston, President
L. W. de Vis-Norton, Secretary and Treasurer

Hawaiian Volcano Observatory Report for January-March 1946

VOLCANOLOGY

January

The year opened with both Kilauea and Mauna Loa inactive.

During heavy rains on January 31 dense steam clouds arose from the Halemaumau floor. Steam was escaping from nearly all cracks in the floor with a velocity of escape sufficient to set up a swishing roar that could be heard a few feet back from the rim.

One large landslide from the northwest notch of Halemaumau was observed at 4:25 P.M. on January 3.

No perceptible earthquakes occurred during the month. A total of 25 seismic disturbances was recorded at Kilauea and 30 at Mauna Loa seismographs.

February

Two earthquakes were felt locally during the month. A good record was obtained of a shake on February 14 which originated along the lower southwest rift of Mauna Loa. It was felt in Pahoehoe, South Kona, as a vertical drop without conspicuous horizontal motion. A total of 51 shakes was recorded at Mauna Loa and 27 at Kilauea.

Normal southwest tilt obtained during the month.

March

No perceptible earthquakes were recorded in March though 44 seismic disturbances were recorded at Kilauea and 51 at Mauna Loa.

There was a slight accumulation of north tilt during the month, abnormal for this season of the year. Westerly tilt was fairly uniform and about normal for March.

A large section of the southwest rim which had been in a precarious position since last September fell in sometime during the month.

R.H.F.

SEISMOLOGY

Earthquake Data, January-March 1946

Week Ended		Minutes of Tremor	Very Feeble	Feeble	Slight	Local Seismicity*	Teleseisms

	24	6	1	0	0	2.00	0
	31	7	5	0	0	4.25	0

* For definition of local seismicity, see Volcano Letter No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

1. January 2, 22:51, very feeble.
2. January 3, 05:52, very feeble.
3. January 3, 09:18, feeble. Kilauea shake.
4. January 4, 02:26, very feeble.
5. January 4, 02:28, very feeble.
6. January 8, 10:40, very feeble. Mauna Loa shake.
7. January 10, 15:13, very feeble.
8. January 15, 09:43, very feeble.
9. January 18, 13:20, very feeble.
10. January 22, 09:21, very feeble.
11. January 26, 21:56, very feeble.
12. January 27, 02:35, very feeble.
13. January 27, 10:46, very feeble.
14. February 4, 12:12, very feeble.
15. February 6, 04:45, slight. East-west dismantled. Near coast below Pahala. Felt at Kau and South Kona.
16. February 6, 17:43, very feeble. Northeast rift of Mauna Loa.
17. February 8, 06:15, slight. Felt locally, and at Pahala and Hilo. Northeast rift of Mauna Loa.
18. February 14, 09:03, slight. Middle southwest rift, Mauna Loa.
19. February 14, 16:02, very feeble.
20. February 16, 15:26, very feeble. Mauna Loa shake.
21. February 17, 02:26, very feeble. Kilauea origin.
22. February 17, 06:27, very feeble. Northeast rift, Mauna Loa.
23. February 23, 22:44, slight. Felt at North Kona and South Kohala.
24. February 26, 09:24, very feeble.
25. March 3, 08:20, very feeble.
26. March 3, 08:38, very feeble.
27. March 5, 09:42, feeble. Near Puu Ulaula, northeast rift of Mauna Loa.
28. March 6, 00:26, very feeble.
29. March 9, 17:12, very feeble.
30. March 12, 07:04, very feeble.
31. March 12, 18:19, very feeble.
32. March 20, 15:06, very feeble.
33. March 27, 18:57, very feeble.
34. March 27, 21:44, very feeble.
35. March 28, 21:36, very feeble.
36. March 29, 01:28, very feeble.
37. March 30, 16:11, very feeble.

TELESEISMS

January 12 10:03, slight.

MICROSEISMS

Microseisms were moderate on January 17-18 and February 27-28 and moderate to strong during March. During the rest of the quarter they were slight.

CRACK MEASUREMENTS

A few of the cracks around the Halemaumau rim opened slightly during the quarter. No movement was detected at the cracks along the Chain of Craters Road.

TILTING OF THE GROUND

Westerly tilt was about normal for the quarter except for an easterly excursion from January 23 to February 5. There was but little tilting in the north-south direction until January 21 when a distinct south tilt set in and continued until March 2. There was a noticeable accumulation of north tilt during March, or opposite to the normal for this season of the year. Such a northerly tilt does not necessarily mean an increase in pressure under Kilauea because the mean temperature for March was nearly 2° F. below that for January and February.

R.H.F.

REANALYZING TILT RECORDS AT THE HAWAIIAN VOLCANO OBSERVATORY

By H. A. POWERS
Geologist, Hawaii National Park

Tilting of the ground under the Hawaiian Volcano Observatory continues to be one of the most critical studies maintained by the Observatory.[1] The war seriously interrupted the expansion of the investigation to include installations of clinometers at critical points on the slopes of Mauna Loa, as well as the periodic triangulation and leveling surveys in the vicinity of Kilauea. However, daily readings have been maintained from the Bosch-Omori seismograph in the old instrument cellar and from the clinometer in the new instrument cellar.

Infallible interpretation of the measurements of ground movement would increase tremendously the possibility of accurate anticipation of volcanic events. In the constant effort to improve the technique of current interpretation of tilt records, the old records are periodically re-examined and subjected to various methods of analysis. Such a re-examination is now in progress at the Observatory and results will be presented from time to time in the VOLCANO LETTER.

The chart showing the general tilt changes at the Observatory from 1913 to 1939 (published as figure 8 in VOLCANO LETTER 467, January-March 1940) is reproduced on pages 4 and 5 as figure 1. The average of daily tilt coordinates from the Bosch-Omori seismograph for each month is determined, then the tilt curve is further smoothed by plotting five-month overlapping means. This plot presents the generalized seasonal tilt pattern and the longer term accumulations of tilt. Pronounced accumulations first to the north and then to the south during the period 1913 to 1925 kept the graph sufficiently open to be fairly clearly studied. The lack of large north-south accumulations in the years since 1925 has produced a maze of overlapping traces which has lost its clarity.

[1] Bibliography on page 2.

Figure 2 (page 6) presents the same type of tilt curve for the years 1940 to 1945 inclusive. It has been drawn separately, but is on the same scale as figure 1, and the months June 1929, January 1931, January 1936, and May 1939 have been added to the curve to fix its correspondence with the curve of figure 1.

Outstanding features of figure 2 are: (1) The relatively long north-east swing from May 1940 to January 1941; (2) the equally long southerly swing from February 1941 to August 1941, but with accumulation to the east; (3) the pronounced easterly swing from September 1941 to January 1942 with the annual loop of 1941 replaced by an acute angle; (4) the accumulation of westerly tilt during the two short annual loops of 1942 and 1943; (5) the almost perfect closure of the annual loop for 1944; and (6) the accumulation of north-east tilt in 1945.

The accumulation of easterly tilt prior to, and the accumulation of westerly tilt subsequent to, the flank eruption of Mauna Loa in the spring of 1942 is quite striking. Equally striking is the absence of any surface activity in Kilauea to accompany the rather large north and south swings. The details of the tilt swings during the last six years will be discussed in a later VOLCANO LETTER; the rest of this discussion will be devoted to a further study of the long-term tilt pattern.

A legible picture of the major tilt trends during the entire period 1913 to 1945 has been regained by sacrificing the presentation of the annual loops and computing one tilt position for each year. These data are further "smoothed" by plotting three-year overlapping means which eliminates part of the detailed annual change, but yields a more legible generalized curve. The coordinates used in the plot do not carry any reference to a particular time of the year.

The graph on the left in figure 3 (page 6) shows the average

tilt position for each year, further smoothed by three-year overlapping means, for the 33 years beginning with 1913. The coincidence of tilt accumulation with major volcanic events, pointed out by the previous writers, is still very apparent in this very simplified graph.

The azimuth of Kilauea collapse, so striking in figure 1, traced by the tilt line for the spring and summer of 1924, appears again as a much longer "direction line" in figure 3. Here the annual accumulation of tilt from 1922 to 1925 makes almost a straight line on the bearing South 20 degrees West. The same azimuth shows up numerous times, both in plots of daily accumulation and in those of monthly accumulation of tilt. It occurs both as a direction of subsidence towards Kilauea, as in 1924, and as a direction of uplift preceding lava appearance in Kilauea. The accumulation of evidence now seems to indicate that the azimuth N 20 E or S 20 W is the line of response to uplift or subsidence in Kilauea for the section of Kilauea rim upon which the old instrument cellar stands. At least the evidence is strong enough to warrant the use of this direction as a starting point in analysis of the accumulated tilt pattern.

Using the direction N 20 E—S 20 W instead of true N-S as a base line, the northerly or southerly accumulations shown by the annual averages have been re-computed, and similarly the easterly or westerly accumulations have been computed at right angles to the new base line, i.e., E 20 S and W 20 N, and the two accumulations plotted in the right hand graphs of figure 3. One line thus is assumed to present average annual accumulations of uplift or subsidence of Kilauea. The other line (pseudo east-west) presents accumulations of tilt at right angles to the dominant Kilauea azimuth, and may well represent, in part at least, uplift or subsidence of Mauna Loa, though the instrument location is too far from Mauna Loa to expect a tilt magnitude comparable to that of Kilauea.

The curve of Kilauea uplift and subsidence shows four main phases: the six-year uplift of 75 seconds of arc from 1914 to 1920, most of which occurred in 1918 and 1919; the five-year subsidence of 83 seconds of arc from 1921 to 1925, most of which occurred in the collapse of 1924; 14 years of interrupted subsidence from 1925 to 1939 amounting to 21.5 seconds of arc; and interrupted uplift to the present time amounting to almost 13.5 seconds of arc at the 1945 average. The first two phases were associated with volcanic events too well known to need repetition; the latter two phases have been associated with a period of extreme volcanic quiet in Kilauea. There is little correlation to be found between the slight peaks of uplift in 1927, 1931, 1936, and 1943 and the short-lived appearances of lava in Halemaumau in 1927, 1929, 1930, 1931, and 1934. The association of no appreciable volcanic activity with no appreciable accumulation of either uplift or subsidence is in itself significant. Further, it is at least suggested by the tilt curve that the bottom of Kilauea subsidence occurred in 1939. The first interruption of the big collapse occupied two years, 1926-1927, and gained 4 seconds of arc in uplift. The second interruption of the collapse again occupied two years, 1930-1931, and gained 2 seconds of arc. The third interruption occupied three years, 1934-1936, and gained 8.7 seconds of arc and the fourth, if it be only an interruption and not the turning point, gained 10.3 seconds of arc in 4 years, 1940-1943, and has continued the uplift after a minor subsidence in only one year, 1944.

The curve presenting accumulation of tilt at right angles to the line of Kilauea uplift and subsidence (the pseudo east-west tilt) shows three main phases: a sharp easterly tilt from 1913 to 1918 of 38.5 seconds of arc; a sharp westerly tilt from 1918 to 1920 of 27 seconds of arc; and a long gradual increase of easterly tilt, with several minor interruptions, from 1920 to 1942 with a total accumulation of 22.25 seconds of arc. At first glance there appears to be excellent correlation between the main peaks of accumulated easterly tilt and major Mauna Loa activity. The easterly peak in 1918 led up to the major flank eruption of 1919 with the westerly subsidence following the lava flow. The easterly peak in 1942 coincided with the flank flow of 1942, and again westerly subsidence followed the flow, though on a much smaller scale. The flank flow of 1926 occurred on a bulge of easterly tilt, but there was no westerly subsidence of magnitude great enough to affect the average for 1927, which actually shows further accumulation of easterly tilt. The summit activity of 1933 occurred with accumulation of easterly tilt, which held static then until the flank flow of 1935. There was westerly subsidence in 1936 after the flow, but 1937 shows further easterly accumulation. The major summit flow of 1940 occurred at the bottom of three years accumulation of westerly tilt. Thus the correlation is far from being "cut and dried," but it does seem apparent that increases and decreases of pressure under Mauna Loa are reflected to a considerable extent in the tilting at the Observatory at right angles to the axis of Kilauea uplift and subsidence.

Jaggar and Finch pointed out a closer correlation between the curve of temperature and the curve of east-west tilt than between the temperature and the north-south tilt. The question of a possible cumulative effect of temperature on average annual accumulation of easterly and westerly tilt will be considered in a forthcoming VOLCANO LETTER.

Two groups of five consecutive years, 1925-1929 and 1932-1936, show very modest accumulation of either easterly or westerly tilt within the span of the group. The seasonal tilt curves of these particular years are being studied in detail in an effort to evaluate quantitatively and qualitatively a "standard" seasonal tilt pattern. If such a pattern can be reasonably established, it will facilitate greatly the week to week evaluation and interpretation of the tilt curves as they are recorded.

SEISMIC SEA WAVE VELOCITIES

In Transactions of the American Geophysical Union, 27 (3) : June 1946, E. C. McKay has supplied considerable statistical material dealing with the seismic sea waves induced by the Aleutian earthquake of April 1, 1946. In VOLCANO LETTER 491, January-March 1946, H. A. Powers discusses effects in Hawaii only. The velocities as given in the McKay table do not always agree with the velocities of waves induced by other disturbances that travel nearly identical paths.

In the following table are shown some of the data for the April 1, 1946, sea waves and for the August 11, 1868, Arica, Peru, shake.[1]

[1] MILNE, JOHN. EARTHQUAKES (London, 1913), p. 182.

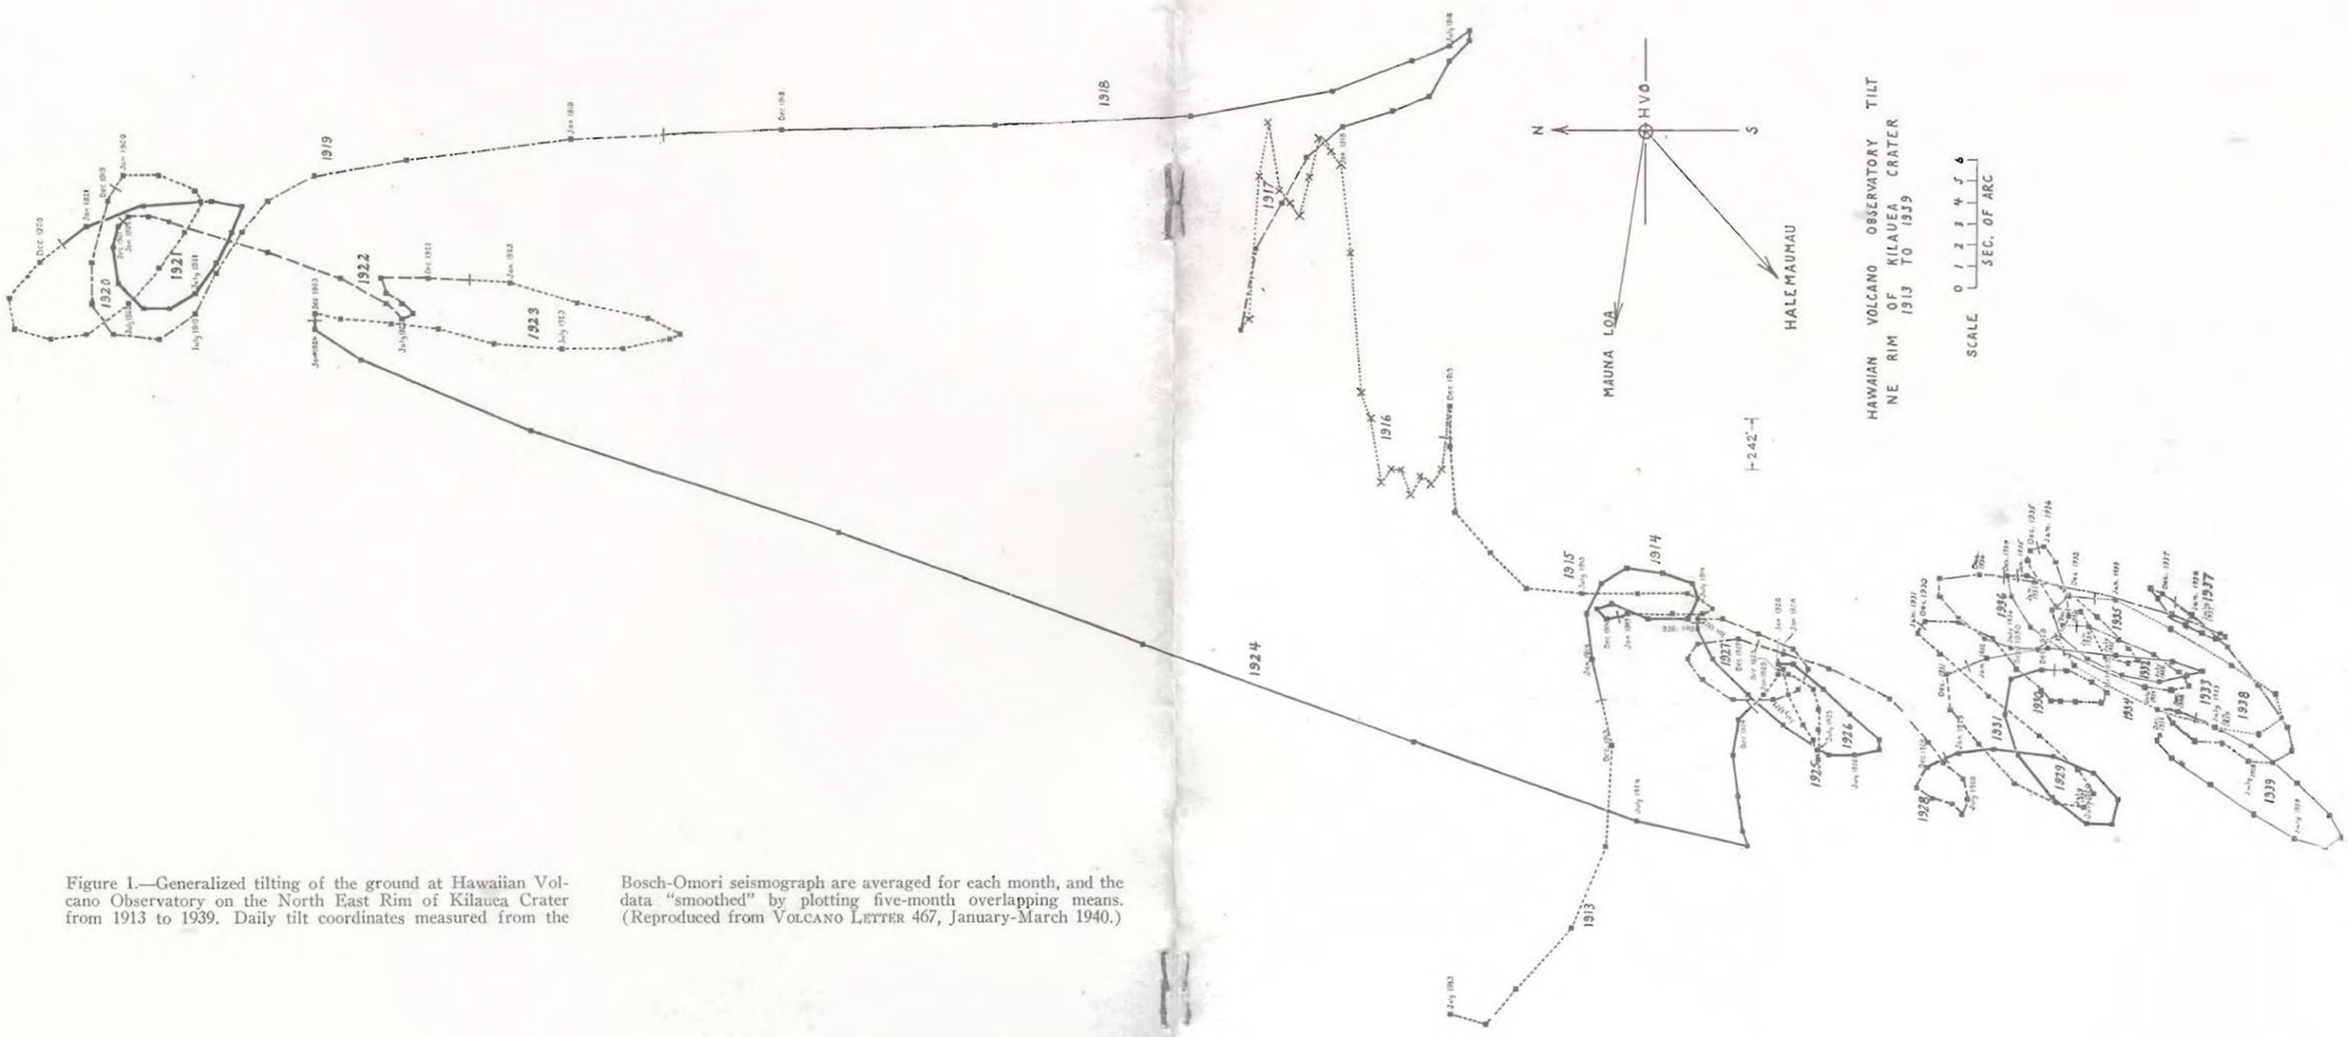

Figure 1.—Generalized tilting of the ground at Hawaiian Volcano Observatory on the North East Rim of Kilauea Crater from 1913 to 1939. Daily tilt coordinates measured from the Bosch-Omori seismograph are averaged for each month, and the data "smoothed" by plotting five-month overlapping means. (Reproduced from VOLCANO LETTER 467, January-March 1940.)

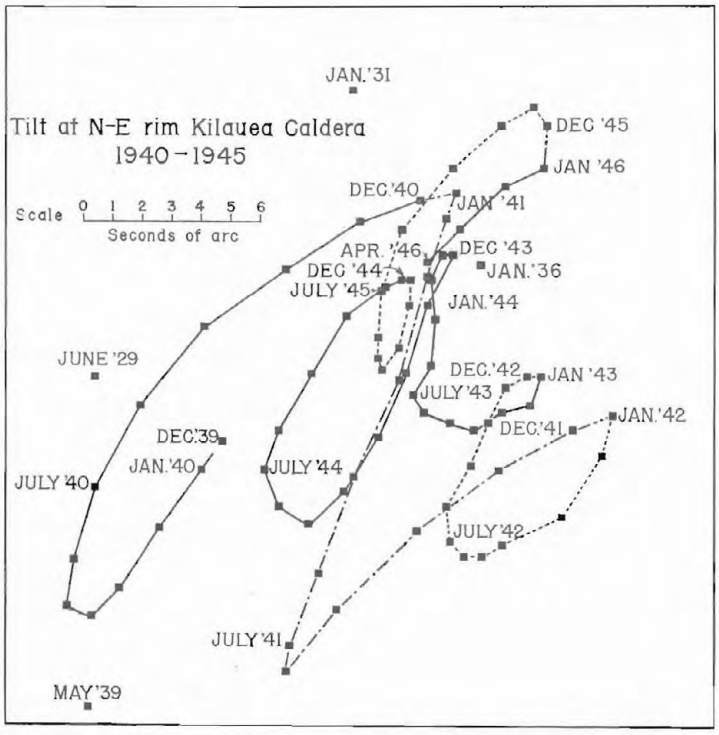

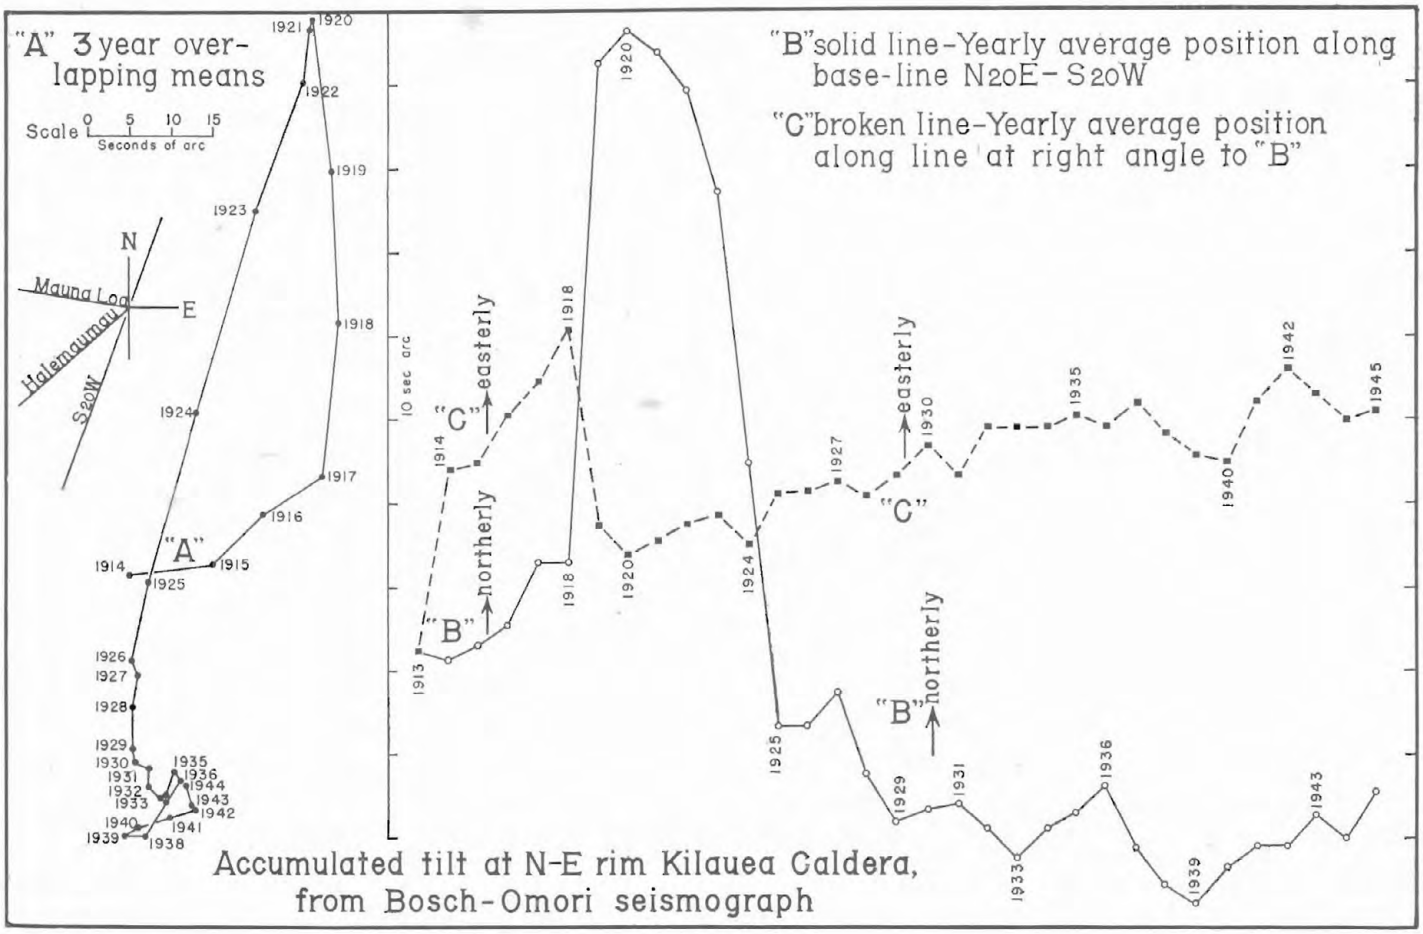

Figure 2.—A continuation of the curve of figure 1 covering the years 1940 to 1945 inclusive.

Figure 3.—"A". Data from figures 1 and 2, further smoothed by computing average coordinates for each year and plotting three-year overlapping means. "B". Accumulated annual average tilt measured on a base line N 20 E—S 20 W, the dominant direction in which the block of rim under the Observatory tilts in response to uplift and subsidence in Kilauea. "C". Accumulated annual average tilt measured at right angles to the base line used in "B," which expresses (at least in part) tilting of the Observatory rim in response to uplift and subsidence in Mauna Loa.

Hawaiian Volcano Observatory Report for April-June 1946

VOLCANOLOGY

April

A fume cloud was observed over Mokuaweoweo on April 30.

The seismographs recorded 49 local disturbances at Kilauea and 47 at Mauna Loa during April.

The tilt curve for the first four months of the year may be taken as indicating a slight build-up of internal pressure under Kilauea.

May

The number of earthquakes recorded during May was 65 at Kilauea and 68 at Mauna Loa. There has been an increase in earthquake frequency during recent months, though neither the number of shakes nor their distribution can be taken as signs of impending activity of Kilauea or Mauna Loa.

June

Mauna Loa had several spells of rather conspicuous fuming during the month. The usual amount of steaming was also observed on several days.

More earthquakes were recorded at Kilauea than at Mauna Loa—64 and 35, respectively.

Tilt records indicate that there has been a slight pressure build-up under both Kilauea and Mauna Loa during the past two years. There is, then, a possibility that either Kilauea or Mauna Loa, may erupt in the next year or two with but few additional premonitory symptoms.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

38. April 8, 08:58, slight. Deep under Mauna Loa. Widely felt.
39. April 9, 10:03, slight. Kilauea shake. Felt locally.
40. April 17, 12:56, very feeble.
41. April 18, 01:46, very feeble.
42. April 21, 07:10, very feeble. Deep under Kilauea.
43. April 21, 22:35, very feeble. Mauna Loa shake.
44. April 22, 10:48, very feeble. Kilauea shake.
45. April 23, 03:37, very feeble. Mauna Loa shake.
46. April 23, 22:24, very feeble. NE rift Mauna Loa.
47. April 25, 18:25, very feeble. Under E slope of Mauna Loa.
48. April 27, 19:11, very feeble.
49. April 30, 04:55, very feeble.
50. May 7, 14:38, very feeble. Mauna Loa shake.
51. May 15, 09:45, very feeble.
52. May 19, 18:36, slight. Felt locally and at Hilo.
53. May 19, 21:35, very feeble.
54. May 23, 08:40, very feeble. Under Mauna Kea.
55. May 30, 17:17, feeble. E slope of Mauna Loa.
56. May 31, 09:09, very feeble.
57. June 5, 02:39, feeble. E slope of Mauna Loa near Ainapo.
58. June 5, 10:02, slight. Felt in Kau. Along coast near Puu Kapukopu.
59. June 5, 16:17, very feeble.
60. June 8, 01:13, very feeble.
61. June 10, 02:56, very feeble.
62. June 10, 17:51, feeble. Felt in Kau.
63. June 20, 13:34, very feeble. Kilauea shake.
64. June 20, 13:38, very feeble. Kilauea shake.
65. June 20, 13:51, feeble. Kilauea shake.
66. June 26, 21:01, very feeble. E slope of Mauna Loa.
67. June 27, 04:38, very feeble. Felt in Kona.
68. June 29, 12:01, very feeble.
69. June 30, 22:02, very feeble.
70. June 30, 03:03, very feeble.

TELESEISMS

April 1, 02:06, strong. South of Unimak Island. Caused a destructive tidal wave.

June 22, 06:50, slight. 4300 km.

June 25, 21:33, slight.

MICROSEISMS

Microseisms were strong during April from the 1st to the 19th inclusive, and on the 26th and 27th. They were light to moderate on other days. During May they were strong on May 6 and light to moderate the rest of the month. Nothing but light to moderate microseisms were recorded in June.

CRACK MEASUREMENTS

There was but little movement at any of the cracks measured near the Halemaumau rim or along the Chain of Craters Road.

TILTING OF THE GROUND

There was a slight and rather uniform tilt to the south during April and May. The seasonal change in direction took place on May 31, and during June there was about the usual northerly tilt. Westerly tilt was slight and rather uniform during the quarter except for slight easterly excursions on May 20 to 29 and June 9 to 14.

R.H.F.

Table of Tilt at Observatory on Northeast Rim of Kilauea

Week Ended	Amount	Direction
April 7	0.60″	W

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

in cooperation with UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter**, a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE PUNA RIFT OF KILAUEA

By R. H. FINCH

Volcanologist, Hawaii National Park

The active rift systems of Mauna Loa and Kilauea are roughly parallel and aligned northeast-southwest. The last few miles of the southwest portion of the Kilauea rift trends about S 15° W while the lower southwest portion of the Mauna Loa rift trends nearly due north and south.

A glance at the map (fig. 1) shows that it is not appropriate to speak of the northeast portion of the Kilauea rift because for the first 8 miles from Halemaumau the general direction is southeast. The direction change is not by means of a sharp angle but rather by a broad sweeping curve. Makaopuhi pit crater marks the beginning of the northeast portion. From this crater the trend is about N 60° E for about 25 miles until it passes under the ocean near Cape Kumakahi. The Puna rift, as the rift in the eastern flank of Kilauea might best be called, is interesting not only for the distinct curve in its upper reaches but also for the numerous lava flows that have originated along it and for the many pit craters.

Lava flows have issued at many places along most of the length of the Puna rift. Some of the flows issued quietly from fissures and did not build up conspicuous spatter or cinder cones, but numerous cinder cones mark the point of origin of other flows that had persistent fountains at their sources. The lava in the flows from this rift came from Kilauea by means of rift tubes—that is, lava tubes that formed in cracks at varying depths below the surface. The entrance to the SW rift tube that fed the 1920 and 1921 flows from Kilauea was only a little over 100 feet below the Halemaumau rim.[1] The entrance to the tube that fed the Puna rift flows at Makaopuhi and Napau Craters in 1922 must have been about 1,000 feet below the rim as the collapse of that year left 900 feet of the Halemaumau wall exposed and no entrance was revealed. It is interesting to note that the Reverend Titus Coan surmised that the lava in the rift tube of 1840 was about 1,000 feet below the surface.[2]

The Puna rift and its attendant tubes is continuous despite the curving upper portion. This was shown in 1840 by the lava first appearing in the curved upper portion 6 miles from the source, then near the middle portion, and finally issuing from a crack 23 miles from Kilauea caldera. The source of the lava in the flows from both the Puna and southwest rifts is in Kilauea. This has been repeatedly shown by the sinking of the lava column in Halemaumau that accompanies drainage through rift tubes. Examples are the flank flows and collapses in 1840, 1868, 1919, 1920, 1921, 1922, 1923, and probably 1924. The vents along both rifts of Kilauea are parasitic. The ascent of lava is confined to the feeding conduits under Halemaumau.

There is considerable evidence that the thickness of Kilauea lavas is comparatively slight. Stone has offered evidence that the depth of Kilauea lavas in the vicinity of Makaopuhi is about 900 feet.[3] There is, in general, a gradual decrease in the thickness of Kilauea lavas with increase in distance from the caldera. Pahala ash, which marks the base of the Kilauea series, is found at the surface with a depth of 3 to 5 feet 2.5 miles southwest of Olaa village and with lesser depths in small kipukas 0.5 and 1.3 miles southwest of Pahoa. The more southwesterly of these kipukas is very near the edge of the Puna rift zone. The Kilauea lavas of the Puna rift poured out onto a terrain that had a very flat slope on the northwest side and a steep slope with fault scarps on the southeast. These scarps are distinct in the vicinity of Hilina Pali and for 16 miles or so to the northeast. Farther on to the northeast there have been sufficient lava flows to mask

[3] STONE, J. B. THE PRODUCTS AND STRUCTURE OF KILAUEA. Bernice P. Bishop Mus. Bul. 33, p. 38. 1926.

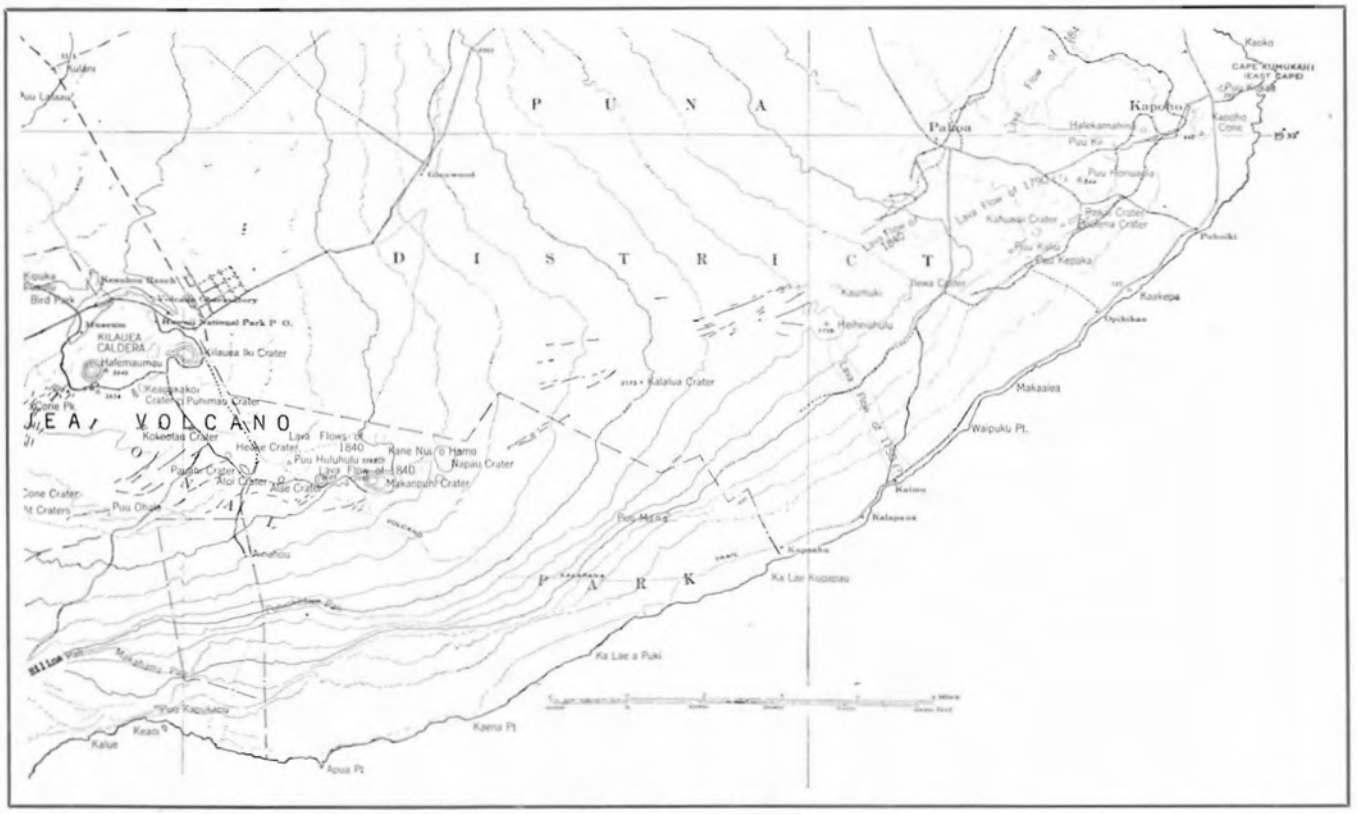

Figure 1.—Map showing the Puna rift of Kilauea and a portion of the southwest rift. Note the numerous intersections of the curved portion of the rift with NE–SW-trending fissures.

any true scarps, but the steep southeast slope indicates that the topography is still dominated by the effects of destructive forces.

Pit craters are formed by engulfment into rift tubes. Counting Keanakakoi and Lua Manu, both of which are within the general breakdown of Kilauea caldera, there are at least 18 pit craters on the Puna rift. None of the pit craters has been a source of real lava flows though lava has appeared in several of them one or more times after they were formed. Pauahi is really two pit craters of appreciable difference in age that happened to form close enough for the younger western one to break down the barrier that for a time separated it from the older eastern pit. Makaopuhi is a doublet. It is likely, though not definitely known, that its two parts formed at different ages. There are at least 14 of the pit craters in the upper portion of the Puna rift and 4 more in the vicinity of Puulena Crater, or 18 miles northeast of Napau Crater. Puulena is counted as two pits though the age difference between the two components is uncertain. Near Iilewa (Ilewa on the map) there is a distinct formation that may be a pit crater with one wall nearly buried. It was not counted to make the total of 18, however. In the southwest rift zone of Kilauea there are but two pit craters with depths of about 220 feet. The deepest one on the Puna rift is Makaopuhi with a depth of 950 feet.

The reason for the concentration of pit craters along the Puna rift is readily apparent. The upper grouping of the craters is due to the intersection of the Puna rift by a series of fissures trending NE–SW roughly parallel to the Hilina Pali breakdown series in their upper reaches and tending to an alignment with the southwest rift system in their lower. Any such intersection, even at a flat angle, would be a favorable location for the development of pit craters.

The four pit craters in the vicinity of Puulena are on the edge of the Puna rift. They are located on what appears to be a buried fault scarp of the Hilina Pali system. The slope of the country in the vicinity of these craters is 400 to 600 feet to the mile with some small ash-covered slopes that are much steeper. The ash appears to be of local origin though whether it buries Pahala ash is not certain. Large explosion blocks, definitely of local origin, are found in the vicinity of Puulena Crater.

It is conceivable that pit craters can develop at almost any place over a rift tube where appreciable stopping takes place. That they should be numerous in the upper portion of the Puna rift and non-existent or rare elsewhere, except for the four near Puulena, points to a systematic local control. A greater gas content of the lava and a resultant greater stopping near the source does not seem adequate to account for the grouping of the pit craters. The 18 pit craters are located at known or suspected places of intersection of the Puna rift by other faults.

Hawaiian Volcano Observatory Report for July-September 1946

VOLCANOLOGY

July

In July, as in June, considerable steaming was observed over Mokuaweoweo. Observations from the rim of Mokuaweoweo on July 23 showed both steam and dark fume escaping.

Forty-four seismic disturbances were recorded at Kilauea. An incomplete record indicates that there were more Mauna Loa than Kilauea shakes.

August

During the month of August, 53 earthquakes were recorded at Kilauea and 46 at Mauna Loa.

The volume of steam escaping from Mokuaweoweo has been more than normal for the last 3 years. Observations from the rim on August 28 and 29 revealed a distinct bluish cast to the fume.

There has been a gradual decrease in the amount of steam escaping at the hot area in the vicinity of Kokoolau Crater.

September

The Kilauea and Mauna Loa seismographs recorded the same number of earthquakes during September—33 each. This is the lowest monthly total recorded during the last 5 months.

A dark, conspicuous fume column was observed over Mokuaweoweo shortly after sunset on September 2. The fume column developed about 2 hours after a perceptible earthquake that originated deep under the east slope of Mauna Loa.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

71. July 3, 03:21, very feeble. Kilauea.
72. July 5, 12:14, very feeble. Mauna Loa, NE slope.
73. July 6, 02:06, very feeble. NE, Mauna Loa.
74. July 9, 13:33, very feeble. Deep Kilauea.
75. July 11, 04:43, very feeble. Mauna Loa, NE slope.
76. July 13, 23:34, feeble. Mauna Loa, E slope.
77. July 15, 10:45, very feeble. Mauna Loa, NE slope.
78. July 20, 11:49, very feeble. Mauna Loa, E slope.
79. July 25, 14:32, feeble. Felt at Pahala.
80. July 27, 05:51, very feeble.
81. July 28, 15:40, feeble. Kilauea.
82. July 29, 15:25, very feeble.
83. July 29, 22:51, very feeble. Mauna Loa, NE slope.
84. August 1, 12:59, feeble. Mauna Loa, NE slope.
85. August 5, 09:30, very feeble. Mauna Loa, NE slope.
86. August 8, 16:28, slight. Mauna Loa, NE slope. Felt at Kilauea.
87. August 20, 10:10, very feeble. Deep. Mauna Loa.
88. August 29, 22:45, feeble. Mauna Loa, NE slope.
89. August 30, 02:43, very feeble. Mauna Loa, SW slope.
90. September 2, 16:39, feeble. Mauna Loa, NE slope. Felt at Kilauea and Kona.
91. September 4, 13:21, slight. Mauna Loa, NE slope. Felt at Kilauea.
92. September 11, 11:59, very feeble. Mauna Loa, NE slope.
93. September 12, 10:25, very feeble. Mauna Loa, E slope.
94. September 15, 01:52, very feeble. Mauna Loa, E slope.
95. September 18, 03:33, very feeble. Shallow Mauna Loa, E slope. Felt at Kapapala.
96. September 19, 19:00, very feeble. Mauna Loa, NE slope.
97. September 20, 22:18, very feeble. Mauna Loa, NE slope.
98. September 23, 19:43, very feeble. Mauna Loa, NE slope.
99. September 24, 03:43, very feeble. Mauna Loa, NE slope.
100. September 24, 11:08, very feeble. Kilauea.
101. September 24, 20:06, very feeble. Mauna Loa, NE slope.
102. September 27, 07:00, very feeble. Mauna Loa, NE slope.
103. September 29, 23:07, very feeble. Mauna Loa, NE slope.

TELESEISMS

July 9, 02:52. Slight.
July 17, 19:50. Slight.
July 17, 21:03. Slight.
August 4, 07:33. West Indian quake.
August 8, 03:10. West Indian aftershock.
September 26, 00:28. Slight.
September 28, 16:40. About 3,750 miles distant.

MICROSEISMS

Microseisms were strong during the first 12 days of July and moderate to light during the rest of the month. August 1st to 3rd had strong microseisms with moderate and light the balance of the month. September microseisms were strong on the 1st and 2nd and again on the 29th and 30th. The rest of the month was light to moderate.

CRACK MEASUREMENTS

There was but little movement at any of the cracks measured around Halemaumau or along the Chain of Craters Road.

TILTING OF THE GROUND

The 3-month period, July-September, showed a total tilt of 4.5 seconds of arc in a direction N 26° E, which is slightly more easting than average for this season of the year.

H. A. Powers.

Table of Tilt at Observatory on Northeast Rim of Kilauea

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

in cooperation with UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter**, a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

REVIEW OF "GEOLOGY AND GROUND-WATER RESOURCES OF THE ISLAND OF HAWAII," H. T. STEARNS AND G. A. MACDONALD

By H. A. POWERS

Seismologist, Hawaii National Park

Geology and Ground-Water Resources of the Island of Hawaii, Bulletin 9 of the Hawaii Division of Hydrography of the U. S. Geological Survey, and the latest of the series describing the geology and ground-water resources of the islands of the Territory of Hawaii, is the only recent publication which presents a compilation of all that is currently known of the geology of the island of Hawaii. As such, it is in a position to become the most widely read source book on Hawaii and her volcanoes. Most sections of the book merit this outstanding position in the literature, notably those parts dealing with the geomorphology of the major volcanic cones, the historic activity of both Mauna Loa and Kilauea, the geology of Mauna Kea, the petrography of Hawaii, and the ground-water resources of the island; other parts fall short of this caliber, notably the section on vocabulary of volcanic terms, the treatment of the "ash problem" of the island, and the correlation of volcanic and erosional history with Pleistocene swings of sea level and the geologic time scale.

A line-by-line study of Bulletin 9 has been made with the thought of enhancing somewhat its value as the outstanding source book on Hawaii. In the presentation of this study, to avoid prohibitive length and at the risk of appearing over-critical, less space can be devoted to favorable comment than to constructive criticism. A few remaining editorial errata, and a very few errors in statement of fact have been picked up. Attention is called to a few misquotations and a few omissions of reference to literature. Caution is indicated in certain passages in which the authors' conclusion on an unsettled question is stated in phrases which suggest that other interpretation is no longer possible.

R. H. Finch, Volcanologist, and G. O. Fagerlund, Naturalist, of Hawaii National Park, have taken an extremely active interest in this review, and significant remarks of praise or criticism are the well-considered summation of much discussion among the three of us.

A few errata and miscellaneous comments which would fit awkwardly in the subsequent paragraphs are listed here.

Plate 3, item 67. *1924* should be *1790.*

Page 7. The use of land for ranch versus forest is poorly presented by figure 3, which appears to be a map showing classification of land for tax purposes. This is partly explained on page 10.

Page 22, line 7 from bottom. The use of *dike* here does not conform to the definition given above for *dike.*

Page 26, Plate 13. The caption 13A refers to plate 13B, plates A and B being reversed.

Page 39, line 8 from bottom. *Figure 47* should be *figure 4.*

Page 48, line 3 from bottom. *Southwestern* should be *southeastern.*

Page 48, bottom line. *60 inches* should be *120 inches.*

Page 51. *Honokane Nui Valley* should be located by the text in Kohala.

Page 70. Wentworth is misquoted in regard to Halai and Puu Hono. He says that their relationship is obscure, but probably with Mauna Loa and not Mauna Kea.

Page 99, line 16. *1928* should be *1930.*

Page 108, line 9. *Aa* should be *ash.*

Page 117, line 13. *500 feet* should be *1500 feet.*

Page 119, line 17 from bottom. *Night* has no significance except to describe a period of a few hours time.

Page 120, line 16. *Water gas* might better be expressed as *water vapor.*

Page 122, last paragraph. Much periodic fuming and occasional glow in the pit characterized the quiet period at the beginning of the century, which has not been the case in the current period of quiet.

Page 127, line 8 from bottom. *Percolating* is not a good word to express the sudden rush of water necessary to create a "flash boiler" explosion.

Page 145. The phrase "It has not been recognized previously as a lava flow," is incorrect, as Sidney Powers states "The Puu Anahulu trachyte represents a flow at least 5 miles in length and over 100 feet in thickness. . . ." on page 269 of his *Notes on Hawaiian Petrology* published in 1920.

Page 198, line 13 from bottom. *Hills* should be *sills.*

Page 209, line 6 from bottom. A breeze which reverses its direction every 12 hours should not be called a *prevailing wind.*

Abstract, Geologic and Guide Maps

A visitor may get an excellent picture of the geology, volcanology, topography, and climate of the area, with a minimum of reading, by careful study of the ABSTRACT, of the geologic map (plate 1), and of the maps of points of interest (plates 2 and 3). The abstract is particularly well written, conveying a maximum of concise information. The point made in the abstract, referring to augite phenocrysts in Mauna Loa lavas, must be based on the paper by Macdonald on petrography (waiting publication as a Professional Paper of the Geological Survey), as no reference to such petrographic detail is made in Bulletin 9. A reader not familiar with the symbolic presentation of information in a geologic cross section should be cautioned not to form his conclusions as to volcanic processes from the map without careful study of the text. For example, the map symbol picturing dikes cannot convey the fact (discussed in the text) that erupting lava may move laterally as well as vertically through a crack extending from the central vent area down one or the other of the rift zones.

Definitions and Descriptions

In a work of this nature, written for the use of persons with professional backgrounds other than geology as well as for geologists, a definition of terms is probably necessary. For the non-geologist a few of the definitions are too brief to be of the greatest vlaue, *i.e.,* the definitions of rock names and *rift zone* on page 13; a few are long enough to be descriptions rather than definitions, *i.e., vent breccia* on page 19. Most of the terms used are concisely defined and well chosen, but a few are not altogether satisfactory and justify further comment.

The specific use of the word *ash,* defined on page 16, describes a fragmental volcanic product of fine size; the use of the word in a formation name, *i.e., Pahala ash* on page 71, describes a deposit essentially consisting of fine material, and the value of the word is not disturbed by the fact that some fragments of size greater than fine may be found in the deposit. In a description of a deposit in which all the ash has been produced by magmatic explosion (vitric ash), the word *ash,* by gentlemen's agreement so to speak, may be used to mean only *vitric ash.* To make the word *ash* carry this additional restriction by definition (page 18, "the terms ash and tuff, if not qualified by descriptive adjectives, refer herein to such lava fountain deposits") is impractical because it prohibits the use of the word in its originally defined sense. The authors have been forced to violate the additional restriction in so many places that a reader will find more clarity if he ignores the statement quoted above from page 18.

The use of the word *caldera* is not clear and precise throughout the text, nor is the definition given on page 14 sufficient to clarify the authors' intended usage. Parts of the discussion on pages 29 to 33 indicate that *caldera* defines the entire area of summit collapse around Mokuaweoweo and Kilauea. However, the statements of dimension indicate that *caldera* is used to denote only the areas known in the literature as the *craters* of Mokuaweoweo and Kilauea. The mere substitution of *caldera* for *crater* seems hardly justified; the introduction of *caldera* to name the entire area of active summit collapse would be very satisfactory, as it tends to emphasize the concept that Kilauea, Halemaumau, Keanakakoi, and Kilauea Iki are *craters* of more or less fugitive existence within the active *caldera* of Kilauea. Such usage would eliminate some of the discussion as to whether certain flows are flank or summit flows (page 82), since most of the troublesome ones definitely are *caldera* flows under the broad definition of *caldera.*

At times there is a tendency in science to "over define" too many terms, leaving no "free-lance" words which can be used, with appropriate adjectives, to convey a precise meaning when needed. The point is illustrated by the restricted definition of *crater* and *pit-crater* (page 16) which literally leaves one with no precise word for Halemaumau, the pit marking the most permanent vent of Kilauea.

The definitions of *aa* and *pahoehoe* are not precise and tend more to description. More precision of definition could have been gained had the authors chosen to limit the application of the terms to congealed lava forms, following Austin E. Jones.[1] Conforming to this limitation, *pahoehoe* is congealed lava with an unbroken surface of quenched glass, and *aa* is lava with a broken surface of spiny, granular, mostly crystallized rock. A flow is called *pahoehoe* or *aa* depending on which type of surface is greatly predominant. The type of surface which will form upon quenching is determined by the nearness of the liquid lava to the crystallization range of most of its constituent minerals. Nearness to crystallization is determined greatly by temperature, and secondarily by the proportion of volatile constituents in an erupted lava. Probably all Hawaiian primitive basaltic lavas are hot enough, when erupted, to quench as pahoehoe if conditions met with after eruption are favorable, *i.e.,* the turbulence of any particular body of liquid must be low enough to permit the quenched skin of glass to remain unbroken and contain the body of liquid until it congeals. If turbulence, due to fountaining or velocity of flow, postpones the formation of a containing skin of glass long enough for loss of temperature and loss of volatile constituents to bring the liquid within the critical crystallization range, quenching can no longer produce a glass skin, *pahoehoe,* but will produce granulated, spiny rubble, *aa.*

The authors' statement on page 20, "They [tumuli or pressure domes] may be formed by collapse as well as by pressure" is not at all clear. The use of *vesicular* rather than *scoriaceous* (page 20) to describe the lava immediately next to the glassy skin of pahoehoe would be more precise, as *scoriaceous* is also used in geology to express the concept of slaggy. The statement on page 20 "No true pillow lava has been found in the island—" should have been modified to anticipate references in the text to the formation of pillow lava at the submarine end of the 1859 Mauna Loa flow (plate 2, item 24, and page 85). In the definition of explosion products on page 16, avalanche material might have been mentioned as an additional source of *accessory ejecta.*

Hawaiian Volcanism in General

The section on MAJOR CONES (page 24) is an excellent, concise discussion of the broad pattern of volcanic development in the Hawaiian Islands based on intensive field study of all the volcanoes of the group. It gives authoritative corroboration to the general concept advanced by Whitman Cross in his paper on the lavas of Hawaii and their relations.[2] The chapters on Mauna Loa and Kilauea contain detailed descriptions of the forms and products of the early stages of development. The chapter on the geology of Mauna Kea is "textbook" description of one of the best type examples of a volcano which has "lived" through almost all stages of Hawaiian volcanism. The chapter on PETROGRAPHY is an excellent presentation of the processes involved and the nature of changes accomplished in the composi-

[1] THE FORMATION OF BASALTIC LAVA FLOWS. Jour. Geol. Vol. 45, No. 8, p. 873. 1937. (Not cited by the authors.)

[2] CROSS, WHITMAN. LAVAS OF HAWAII AND THEIR RELATIONS. U. S. Geol. Survey Professional Paper 88. 1915.

tion and physical characteristics of volcanic products during the development of the entire cycle.

Perhaps a word of caution should be introduced against too complete acceptance of the concept of the Eastern and Western Fundamental Fissures. Though far too incomplete as yet to constitute proof, the gradually accumulating data on the location of deep earthquakes in the islands suggest an echelon arrangement of the deep fractures, rather than separate parallel alignment.

Pleistocene Shorelines, Age of Rocks, and Geologic History

A tabulation is made on page 54 showing all Pleistocene shorelines determined to date in the Hawaiian Islands, and a summary is presented of the evidence for each found on the island of Hawaii. Study of the text shows that some of this evidence is positive, while some is largely inference. The evidence is positive that the coast of Kohala and the northeast coast of Mauna Kea were submerged in the latest 25-foot high stand of the sea. Also positive are the shoreline deposits on Kohala at 250 feet above present sea level and the evidence that the major canyons of Kohala have been drowned and re-trenched at least once since their erosion. Some soil stripping suggests that Kohala may have been submerged to 1,200 feet below present sea level, but the evidence does not compare with that found on Lanai, the type locality. Evidence of the two intermediate negative shifts of sea level is inferred, as is also the hypothesis that the major canyons of Kohala and Ninole were cut on an old surface that antedates Stearns' Lualualei 1,200-foot negative stand of the sea.

Possible stratigraphic relations and geologic age of the five volcanic series are tabulated on page 62. The relationship of the Mauna Kea glacial deposits to the Laupahoehoe volcanic series permits a logical dating of Recent or Late Pleistocene for those volcanic series which are either younger than, or interbedded with, lavas and ash deposits of the Laupahoehoe series. This category includes the surface members of the Hualalai, the Kau, and the Puna volcanic series. Those series known to be older than the base of the Pahala ash are confidently assigned a date of pre-Wisconsin. Without question this category includes the Hawi, Hamakua, Kahuku, and Hilina volcanic series, and the much older Pololu and Ninole volcanic series. There is some question in the case of the Waawaa volcanic series. The field evidence described on page 145 places it at least correlative with the Laupahoehoe series, but the lack of exposure in deep sections precludes any assurance that the Waawaa lavas lie under all of the Pahala ash section.

By definition the Hamakua, Kahuku, and Hilina series lie under the base of the Pahala ash, but another consideration perhaps justifies caution in considering them all of the same age. The surface lava flows of the Kahuku and Hilina series show much less decomposition than those of the Hamakua series. The amount of rock decomposition depends on so many factors other than age that this fact cannot be considered as compelling evidence. Only in the narrow belt of rainfall on the southeast slope of Mauna Loa are Kahuku lavas found in moisture conditions approaching those of the northeast slope of Mauna Kea. In this one area of exposure of Kahuku lavas, the lack of rock decomposition and the absence of stream erosion in their surface at least suggest that the Kahuku volcanic series may be considerably younger than the Hamakua volcanic series of Mauna Kea.

The tentative correlation and age assignment offered for the Pololu and Ninole volcanic series seem to hinge on a comparison of local erosional history with that of Oahu and West Maui. Almost all information on this subject is gained from Kohala. No field work on the Ninole series was done for this report in addition to that upon which the earlier Kau report was based. In the discussion of the great erosional unconformity between the Ninole and the overlying volcanics, the only comment (page 66) on decomposition of the rocks is that "Some of the [lava] beds are partly altered by weathering." This modest statement is hardly what one would expect to find describing the decomposition of porous lava in an area of 120 inches of rainfall which had undergone erosion sufficient to carve the topography attributed to erosion, and is certainly different from the description of decomposition of the Pololu volcanic series. One wishes that more field work had been done in the Ninole area to yield more information about the decomposition, as the possibility that block faulting may have played a great part in the formation of this "old" topography seems still not to be excluded by the present descriptions.

In the discussion of the erosional unconformity between the Pololu series and the Hawi series the authors conclude (page 178) that "a repose period intervened between the eruption of the Pololu and Hawi volcanic series." When one considers the facts—presented in the text—that the Hawi volcanic series is made up of flows numbering in the order of magnitude of only a hundred, widely separated from each other in time, each covering a very small part of the surface, one gets the impression that the general picture of erosion and surface decomposition is equally well explained by a slow dying-out of activity, not requiring a "repose period." However, there is no dearth of evidence of a great deal of decomposition of the Pololu, as well as of the older members of the Hawi, volcanic series.

To find correlation between the erosion history of Kohala and West Maui and Oahu, the rather general statement is made on page 171 that older alluvium in the Kohala valleys "was deposited during several epochs and is separated by erosional unconformities," and the inference is drawn on page 55 that different deposits of older alluvium were graded to different stands of the sea. No outcrops of older alluvium are described, nor localities cited in the text, in which an erosional unconformity was found between two deposits of the older alluvium; nor are there descriptions of any locality in which two terraces in juxtaposition show difference of surface elevation to indicate that they were aggraded to distinctly different base levels. Since this evidence is critical in the interpretation of the erosion history of Kohala, one wishes that more detailed descriptions of localities had been given in the text.

Correlation of erosion history, extending back through Pleistocene time, on island surfaces from Oahu to Kohala, presupposes no differential isostatic movement of the islands. The discussion of the correlation back to the Pliocene would be more complete had the authors introduced the question of possible isostatic movement of Kohala Mountain during the Pleistocene in response to the heavy loading associated with the building of the domes of Mauna Kea, Hualalai, and parts, at least, of Mauna Loa and Kilauea. Some data are introduced by the authors (but not discussed in this connection) which might have a bearing on this question. In discussing the structure of Kohala Mountain (page 180), it is pointed out that "an unusual number of dikes dip northward from 60 to 85 degrees in the northern side of the mountain," which is a greater departure from vertical than is to be expected. Not pointed out in the text, but apparent on plate 1 (the geologic map), is the fact that the dip of the Pololu lava surface on the southwest slope is steeper than it is on the northeast slope; and that the southwest slope, from caldera crest to shore, is shortened in comparison with the northeast slope. It would have been interesting had the possibility been discussed that these two structural facts might be related to actual structural tipping of Kohala Mountain to southward, perhaps in connection with the loading postulated above.

The section of geologic history, which cross-correlates the stratigraphic column, the geologic time scale, and the sequence of Pleistocene changes of sea level, is not as well substantiated in two instances as one would hope for from the material presented in the preceding sections of the text. The main bulk of Kohala, the Pololu volcanic series, is considered (page 56) to

be younger than the bulk of Haleakala on Maui, but is assigned a Pliocene age; whereas Haleakala has been assigned an age of Pliocene or Early Pleistocene in the bulletin on Maui.[3] One would welcome a short discussion of the basis for this change. Field evidence presented in the discussion of Mauna Kea (page 167) shows that a glacial outwash deposit, formed during melting of the summit glacier, is older than the cutting of the present Mauna Kea gulches, which have subsequently been drowned and floored with alluvium aggraded to the latest 25-foot high stand of the sea, and lastly re-trenched to present sea level. Yet, with no explanatory discussion, the time of the melting of the Mauna Kea glacier and the described sequence of erosion history are correlated with the latest eustatic lowering of sea level from plus 5 feet to the present. One would expect the melting of the glacier to be correlated with the rise of sea level leading up to the 25-foot positive stand.

Pyroclastic Deposits

The treatment of the pyroclastic deposits of the island warrants considerable comment. The authors have abandoned Wentworth's separate formation names for the different ash deposits,[4] and have combined some of the formations into a proposed new "Pahala ash." Justification for this enlarged concept of the "Pahala ash" seems to be summed up in the statement from page 72, "Despite the fact that accumulation of the Pahala ash continued over a long period, the lower part, constituting the bulk of the deposit, appears to be essentially contemporaneous all over the island. It can be traced directly across Mauna Loa to Mauna Kea, and from Mauna Kea to Kohala Mountain. The lower part . . . serves as a widespread horizon marker. . . ." In the stratigraphic tabulation on page 62, the lower part of the deposit, considered as the horizon marker, is placed on top of the Hamakua, the Hilina, and the Kahuku volcanic series, and beneath the Laupahoehoe, the Puna, and the Kau volcanic series respectively on Mauna Kea, Kilauea, and Mauna Loa. No type locality of the horizon marker is described, but one can be deduced to be on Mauna Kea at some point along the margin of the oldest flow of the Laupahoehoe volcanic series, in a cut sufficiently deep to expose a considerable section of the upper lavas of the Hamakua volcanic series. The formation name "Pahala ash" is limited to this horizon marker in the stratigraphic column (page 62), and the same limitation apparently is in the minds of the authors in many places in the text (*i.e.*, pages 68 and 103), particularly when the reference is to "Pahala time." However, in every description of the field deposits of "Pahala ash," it is pointed out that the ash sections include pyroclastics ranging in age from "Pahala" time to Recent. The reviewer believes that clarity would have been gained by retaining Wentworth's formation names for the several deposits of ash, and by introducing a new local name for the specific horizon of geologic time during which the authors believe the basal member of many of the ash sections was deposited.

The authors' concept of the origin of the Pahala ash is summarized in the section titled ORIGIN on page 71, and the discussion which governed their conclusions is largely found in the following section on distribution and character of the Pahala ash on Mauna Loa. Mauna Kea is well substantiated as the source of much of the ash, especially on its own slopes. The importance of Kilauea as a source of part of the ash is based on the presence of coarser essential lapilli and accessory lapilli, as well as thickening of the deposits to the lee of Kilauea.

The significance of the thickening of the section as proof is depreciated, perhaps, by several points brought out in the text. An unstated proportion of the extra thickness is made up of fine ash which was moved laterally by the wind (page 75) after its initial deposition from the ash showers. Since this whole area in the lee of Kilauea is dry and wind-swept, several thin blankets from a source more distant than Kilauea might easily have been concentrated into local thicker sections. Additional field work might have been directed at a more quantitative evaluation of this factor.

The described thinning of the ash from the slope of Mauna Kea to the Glenwood locality northeast of Kilauea, and the thickening again southwest of Kilauea, is critically significant only if the Glenwood section contains all of the Mauna Kea ash section. The authors cite the test borings near Mountain View and the shaft at Olaa, which penetrate no great amount of ash, as evidence in the third dimension that the Glenwood deposit does contain the whole of the ash section. The deepest borings logged (page 257) are 160 feet deep and cut through, at the most, eight flows; and the Olaa shaft cuts 220 feet through possibly 10 flows (page 248). Both are in the area inundated by flows from Mauna Loa's northeast rift, where one would expect the greatest number of flows to be interbedded in the ash section; so there is reasonable doubt that the borings and shaft are deep enough to prove the question. The small amount of decomposition of the lava flows lying immediately under the Glenwood deposits, and the elementary development of surface streams in the area (page 218), are two other factors which point toward the probability that these lava flows are correlative with some part of the Laupahoehoe volcanic series and are interbedded in the ash series, rather than correlative with the Hamakua flows older than the basal member of the ash series.

In a different part of the text (page 93), not discussed at all in connection with the problem of origin of the ash, the authors point out the possible existence of ash-producing vents, in a position to windward as favorable as Kilauea, which may have contributed to the apparent greater thickness of the sections to the lee of Kilauea. The statement is "It is probable that Mauna Kea extends 6 to 10 miles southward under the Recent lava flows of Mauna Loa directly athwart the latter's northeast rift. The hypothesis is offered that Mauna Loa Volcano terminates against the buried Mauna Kea dome approximately under the 8,000 foot level on the northeast rift. . . ."

The presence of the accessory lapilli (probably from phreatic explosions) and coarser essential lapilli are qualitatively compelling evidence as to Kilauea's contribution to the ash deposits. More detailed field work directed specifically to this phase of the problem probably would have enabled the authors to make a more quantitative appraisal of the duration and amount of Kilauea's active contribution to these ash deposits. This is particularly desirable in this instance, because the ash relationships are the most tangible evidence available in the problem of correlating the age of Kilauea.

In discussing Hualalai as a contributor to the Pahala ash, the authors obviously refer to the original Pahala ash formation on the southeast Mauna Loa and south Kilauea slopes. Hualalai probably contributed to the ash lying on the lavas mapped on Kahuku in the cliff at Kealakekua Bay which is Pahala ash under the new definition. It also contributed to the ash on the kipukas in the Kainaliu area (page 70), and to the ash interbedded with the flows of the Kau volcanic series in Kona; all correlative with the Laupahoehoe volcanic series, and thus correlative with the upper part of the new Pahala ash.

It is apparent from their discussion of the origin and distribution that the authors consider Mauna Kea the source of much of the ash in the basal "horizon marker," the ash of "Pahala time" in the stratigraphic column. This consideration would suggest that the choice of a name for the horizon should have been made, more appropriately, from some Mauna Kea feature

or locality. Also, the proven diversity of origin of the ash deposits in different areas constitutes an additional strong objection to the abandonment of the several local formation names for the deposits.

On page 75 the authors describe the showers of pumice and Pele's hair produced during historic eruptions from Mauna Loa and conclude "Although such deposits during any one eruption are too small to measure, the 30,000 years of Recent time, [30,000 probably used purely to indicate order of magnitude] with several eruptions each decade, must have produced an accretion of ash measurable in feet in the leeward kipukas." According to the stratigraphic column on page 62 the ash mantle from all of the eruptions of the Lower and Upper Laupahoehoe volcanic series, and from the eruptions of the exposed part of the prehistoric member of the Hualalai volcanic series must be added to the above described showers, and be interbedded with or accumulated in kipukas in the lava flows of the Kau volcanic series. Part of this deposit is described by Wentworth and called the Kona formation, and comparable deposits are exposed on the favorable parts of the eastern flank of Mauna Loa between the rift zones. In the present text, however, the only description is as follows (page 78): "The ash deposits of the prehistoric member of the Kau volcanic series are insignificant in volume. Deposits of pumice a few inches to 2 feet thick lie just leeward of the large cinder cones but they cover too small an area to be shown on plate 1." It is regrettable that the authors did not do additional field work sufficient to present a better picture of these ash deposits associated with the Kau volcanic series which have an important bearing on their study of the Pahala ash; in fact they are the upper part of the Pahala ash as newly defined.

In the section on the ash deposits of the Puna volcanic series (page 106), the authors' use of the word *ash*, not in conformity with their restricted definition on page 18, is most confusing because these Kilauea surface pyroclastic deposits (Wentworth's Keanakakoi formation) include important horizons of pure lithic material as well as horizons of pure vitric material. Careful field recognition of these two types of deposit of different physical origin, and critical separate mapping of their aerial thickness and distribution is essential before the best analysis of Kilauea's possible contribution to the older Pahala ash sections can be made. In the present publication, the authors use Stearns' former distribution map from the Kau report,[5] which has been found to be unsastifactory for a critical analysis of ash distribution by subsequent workers.[6]

Historic Volcanic Activity

Very comprehensive, yet well-summarized, discussions of historic volcanic activity are found in the three chapters on Hualalai, Mauna Loa, and Kilauea. The information presented represents a thoughtful and selective accumulation of essential material from the maze of recorded observations and data derived from lay as well as scientific sources.

Some adverse comments seem justified on the presentation of legendary evidence of activity. The statement (page 78) "Hitchcock reports an eruption in 1780 . . . and one on January 21, 1803, [from Mauna Loa] . . . but cites no authority for these statements" is incorrect. Hitchcock cites as authority for the 1780 activity, the statements of Hawaiians who correlated the time with the time of Captain Cook's ill-fated visit, an event of sufficient interest to the Hawaiians to stand clearly in their memory. He also cites as authority for the flow of January 21, 1803, a report by John Turnbull, who saw the activity from his ship as it left Kealakekua Bay. Eruptions of Mauna Loa in about 1780, 1803, and 1832 thus are all well substantiated, whereas the location of each is not exactly described in the literature. Under the circumstances it seems inadvisable to map one of several possible flows and label it *1832-?* on the geologic map.

The references to Hitchcock (page 112) on Hawaiian legends of Kilauea activity should have been checked against Hitchcock's later book,[7] Fornander's collection, and Ellis' reports, because Hitchcock himself corrects some of the material presented in his earlier short paper. The date A.D. 140 should be about A.D. 450. The idea that the activity of 1420 (not 1620) was violently explosive was Hitchcock's own surmise and not based on legend. The quotation from Ellis suggests that there was a flank flow from a cone on the Puna rift a few miles distant from Kilauea in the time of Liloa (1420 to 1450). "Within a few miles of Kilauea, we passed three or four high and extinct craters. One of them . . . sent forth, in the days of Riroa, . . . most of the lava over which we were travelling." The legendary accounts of activity in the time of Kanipahu (1180-1210) read more like descriptions of an explosive eruption.

Sufficient detailed description of different eruptions is given to bring out material needed in the excellent discussions of typical eruptions of various nature which have taken place, and the summaries of presently known facts about volcanic activity, gained from the studies of Hawaiian activity, are thorough and very clearly presented. Attention perhaps should be called to a few specific passages.

One might possibly gain the impression from the discussion of the 1790 eruption (page 116) that the "Black Ledge" was terrace left by the engulfment of 1790. This is not intended, as the "Black Ledge" marked the high point of the tremendous refilling of the crater between 1790 and the collapse prior to Ellis' visit in 1823, probably associated with the flank eruption of 1823.

The discussions of summit caldera activity compared with flank eruptions would have been a little more complete had the authors enlarged on what appears, from the descriptions, to be a difference between certain flank flows. In one type, illustrated by the Kilauea flows of 1920, 1922, and 1923, and perhaps even by the flows of 1823 and 1840, the flank flow apparently is fed by lateral passage of the lava from a lake in the caldera through shallow rift-zone channels, and no fountaining or building of vent cones is apparent at the point on the rift where the lava re-emerges. In the other type, illustrated by most of the historic Mauna Loa flank flows, and perhaps many of the pre-historic Kilauea flows, the caldera vent appears to be abandoned after a flank vent is opened and the fountaining and vent-cone building takes place on the flank at the point where the flow emerges.

The statement (page 93) that the 1935 lava flow was "bombed . . . in an effort to stop the flow . . ." is inaccurate. Quoting from the VOLCANO LETTER for December 1935, page 4, "The volcanologist recommended bombing the source at elevation 8500 feet on Mauna Loa, to break up the stability of the flow tunnels, and to divert the flowing at the source region." The wording of the text in this section, and the paucity of references, fail to convey to the reader the fact that the plans of the Volcano Observatory for such diversion of flows which threaten vital areas date back before precision bombing was possible.

The authors have made a valuable and competent tabulation of known statistical data on all historical eruptions of both Mauna Loa and Kilauea, and submit the data to searching analysis for possible periodicity of eruption and possible correlation of eruption between the two volcanoes. They conclude that the statistical record shows no periodicity, no correlation with external influences such as sun spots, and no relation between the eruptions of Mauna Loa and Kilauea, in direct opposition to the beliefs of Jaggar and other workers who have used the same statistics to demonstrate possible periodicity and cor-

relations. There are two relevant facts which save a cautious reader from the necessity of "jumping off either deep end." First, the fact that definite volcanic activity need not culminate in a visible surface eruption, so that it is possible that many periods of sub-surface activity have occurred without being known and recorded in the hundred-odd years for which we have eye-witness testimony. Thus the historic record of activity must be considered as incomplete at best. Second, the fact that even the eye-witness record is too short to prove or disprove statistically the existence of periodicity or correlations of the sort being considered.

The authors offer a comprehensive consideration of the evidence bearing on the age of Kilauea and its structural relation to Mauna Loa and conclude that Kilauea started activity as a vent perhaps nearly coincident with the renewal of Mauna Loa activity which produced the Kahuku volcanic series. There seems to be no serious objection to considering the Hilina and the Kahuku volcanic series as the same age. At the same time, there seems to be no compelling evidence to decide for or against the Mauna Loa origin of the lavas of both series. Projections of slopes in cross section can reasonably permit either point of view and seem to favor neither. Also there is no question that Kilauea has contributed to the Pahala ash. Its type of contribution is not associated with "old age" activity, but could have started from the first eruption of the newly opened vent. Further field work may add a good deal more specific information on the questions of how much material, what kinds of material, and in what part of the section are the contributions from Kilauea in the Pahala ash deposit. Until additional information is available, the authors' conclusions are as tenable as any which have been considered, though personally the writer favors Stone's[8] thesis that the Hilina lavas are part of Mauna Loa, and that Kilauea as a vent was "born" during the time of the accumulation of the ash series lying on the Hilina lavas.

Page 2, last paragraph, lines 2 and 6: *for* stopping *read* stoping.

Hawaiian Volcano Observatory Report for October-December 1946

VOLCANOLOGY

October

The number of earthquakes recorded at Kilauea and Mauna Loa was 49 and 59 respectively. The shake at 18:43 on October 29 originated deep under the east slope of Mauna Loa. This shake coupled with those of September 2 and 4 may be taken as a slight indication of uneasiness of Mauna Loa. A greater than normal easterly tilt during October is probably a further indication of such uneasiness. Northerly tilt was normal.

November

Earthquakes of Mauna Loa origin predominated in November. Sixty shakes were recorded on the Mauna Loa seismograph and 54 at Kilauea. There was no tilt in the east-west direction and a slight accumulation of southerly tilt.

Fume over Mokuaweoweo was observed from the Saddle Road during the morning of November 27.

December

During December, as in the past 2 months, more earthquakes originated under Mauna Loa than under Kilauea. Seventy shakes were recorded at Mauna Loa and 54 at Kilauea. The preponderance of Mauna Loa shakes as well as the earthquake pattern are indications of continued uneasiness of Mauna Loa. Tilt records, however, do not show indications of impending activity. There was no accumulation of tilt either east or west in December. The slight southerly tilt that started in November continued in December.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

104. October 8, 16:34, very feeble. Kilauea shake.
105. October 8, 23:56, slight. Felt locally and in Hilo. About 10 miles deep. NE slope of Mauna Loa, 1 mile east of seismograph.
106. October 10, 05:59, very feeble. Felt in Kona and on Maui. Deep under NW coast of Hualalai.
107. October 12, 12:59, very feeble. Kilauea shake.
108. October 14, 03:25, very feeble. Shallow focus near N end of Mokuaweoweo.
109. October 16, 10:09, very feeble.
110. October 16, 23:02, very feeble. Mauna Loa shake.
111. October 18, 01:04, very feeble.
112. October 25, 07:13, very feeble. Mauna Loa, NE rift.
113. October 25, 09:35, very feeble.
114. October 26, 05:52, very feeble.
115. October 27, 00:14, very feeble.
116. October 28, 06:53, very feeble. Mauna Loa, E slope.
117. October 29, 18:43, slight. Mauna Loa, E slope.
118. October 29, 21:00, very feeble.
119. October 29, 23:58, very feeble.
120. November 3, 19:04, very feeble.
121. November 4, 10:03, very feeble. Mauna Loa shake.
122. November 5, 08:37, feeble.
123. November 7, 00:59, very feeble. Mauna Loa shake.
124. November 11, 13:37, very feeble. Kilauea shake.
125. November 12, 13:24, feeble. Kilauea shake.
126. November 13, 05:41, very feeble. Kilauea shake.
127. November 13, 22:10, very feeble. Mauna Loa shake.
128. November 17, 01:14, very feeble. Mauna Loa, E slope.
129. November 20, 02:09, very feeble. Kilauea shake.
130. November 23, 10:15, very feeble. Mauna Loa shake.
131. November 30, 01:54, slight. Deep under E slope of Mauna Loa.
132. December 3, 12:56, feeble.
133. December 5, 11:33, very feeble. Mauna Loa, NE slope.
134. December 11, 13:53, very feeble. Kilauea shake.
135. December 12, 23:28, feeble. Kilauea shake.
136. December 13, 17:10, feeble. 5 to 10 miles under NE slope of Mauna Loa.
137. December 15, 02:36, feeble. Felt locally. Kilauea shake.
138. December 22, 07:02, feeble. Felt in eastern Hawaii. 15 miles deep, S of Hilo.
139. December 22, 11:53, feeble. Felt locally. Deep under Glenwood.
140. December 23, 00:10, very feeble.
141. December 24, 20:09, very feeble.
142. December 27, 12:05, very feeble. Kilauea shake.
143. December 28, 22:24, very feeble. Mauna Loa shake.

TELESEISMS

November 1, 00:50. slight.

November 11, 07:04. Slight.

December 20, 08:58. Moderate. Japan shake.

December 21, 00:17. Slight.

MICROSEISMS

Microseisms were moderate to strong throughout the quarter except on December 31 when they became very strong.

CRACK MEASUREMENTS

A few of the cracks around Halemaumau opened slightly in October. In November and December the cracks were stationary.

TILTING OF THE GROUND

Seasonal southerly tilt set in November 3, or a little earlier than usual. There was less than normal northerly tilt in 1946. Westerly tilt started on December 9, or about the usual time for change from easterly to westerly. There was no accumulation of tilt either east or west in 1946.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

in cooperation with UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter**, a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE VOLCANO LETTER

No. 495 **Department of Interior** **National Park Service** **January-March 1947**

ANNUAL TILT PATTERN AT THE HAWAIIAN VOLCANO OBSERVATORY

By H. A. POWERS

Seismologist, Hawaii National Park

The 22 years following the 1924 "collapse" of the Kilauea lava column have been relatively free of lava activity in Kilauea. Thus the tilt records from the Bosch-Omori seismograph on the northeast rim of Kilauea for this span of years offer a particularly valuable series from which to study the annual tilt pattern which is developed by forces other than visible eruptions.

As a starting point, tilt curves for a "standard" year have been computed (Figure 1, curves A and B, and columns A and B in Table 1). First an average north-south and east-west coordinate value was computed for each calendar month of the years 1925 through 1946 by adding the daily coordinates[1] of each month and dividing by the appropriate number of days. Then an arithmetic average was computed for all Januarys, Februarys, etc. The plotting of these average monthly coordinates was then compared in detail with the plotting of the actual monthly coordinates for each year in the series. Several of the actual annual "loops" departed radically from the computed average "loop" both in shape and dimension. In most of these, the departure was of a nature to be expected from volcanic events known to have occurred. A second computation of averages was made, using only the 7 years which showed the most symmetrical annual loop. This computation yielded an average loop which is remarkably comparable to the loop representing the average of all 22 years. Apparently the most radical deviations canceled themselves out in the larger average. The coordinates used to express the "standard" year were then derived by "smoothing" the 22-year averages in the direction of the values obtained in the selected 7-year average. The tilt loops for the years 1931 and 1944 most closely approach the "standard" loop. Admittedly this standard loop is not real, and perhaps never would be duplicated in nature, but it does give a quantitative picture of trends which are very real in the actual annual loops.

As the first step in the attempt to analyze the "standard" loop, the plotted curves of actual daily tilt were carefully searched for indications of dominant directions of tilt. Periods of time were chosen in which tilt continued for several consecutive days on the same azimuth. The most common direction in which tilt accumulated is N 45 E or S 45 W, associated in many instances with decided changes in air temperature. This direction also seems to have a significant structural expression, in that the Waldron Ledge segment of the rim of Kilauea Crater (the block upon which the tilt has been measured) strikes in general N 45 W, and is bounded to some extent by radial fault cracks trending N 45 E. This direction has been adopted in this study to express the direction of yielding to superficial causes of tilt. The direction N 20 E or S 20 W, which was discussed in VOLCANO LETTER No. 492, 1946, is used to express the direction of yielding to deep-seated forces affecting the Kilauea dome-structure. The most remarkable appearance of this Kilauea azimuth was in the extreme tilt to the southwest at the time of the collapse of the lava column and the explosive eruption in 1924. It has not appeared frequently in the daily tilt since 1924, but it does show up as a major direction in smoothed curves of daily and monthly tilt. These facts of occurrence are compatible with the concept that it is a direction of yielding to deeply acting forces, and that movements along it would be often interrupted by superficial movements of shorter duration. A third direction of facile movement, almost due east and west, appears occasionally. The swings of this azimuth, though rather infrequent, are of important amplitude and occur in many instances prior to a Mauna Loa eruption.

Other azimuths of tilt can be selected from the daily records, particularly from the smoothed curves. Some or all of them may have a significance which is being overlooked, but

[1] The daily coordinates refer to an arbitrary zero point, and state, in millimeters, the lateral migration of the writing pens of the instrument induced by tilting of the pendulum support. The constants are such that 10 mm. of lateral movement is induced by 1.21 seconds of tilt. Increase of ordinate and abcissa numbers indicate, respectively, north and east tilt.

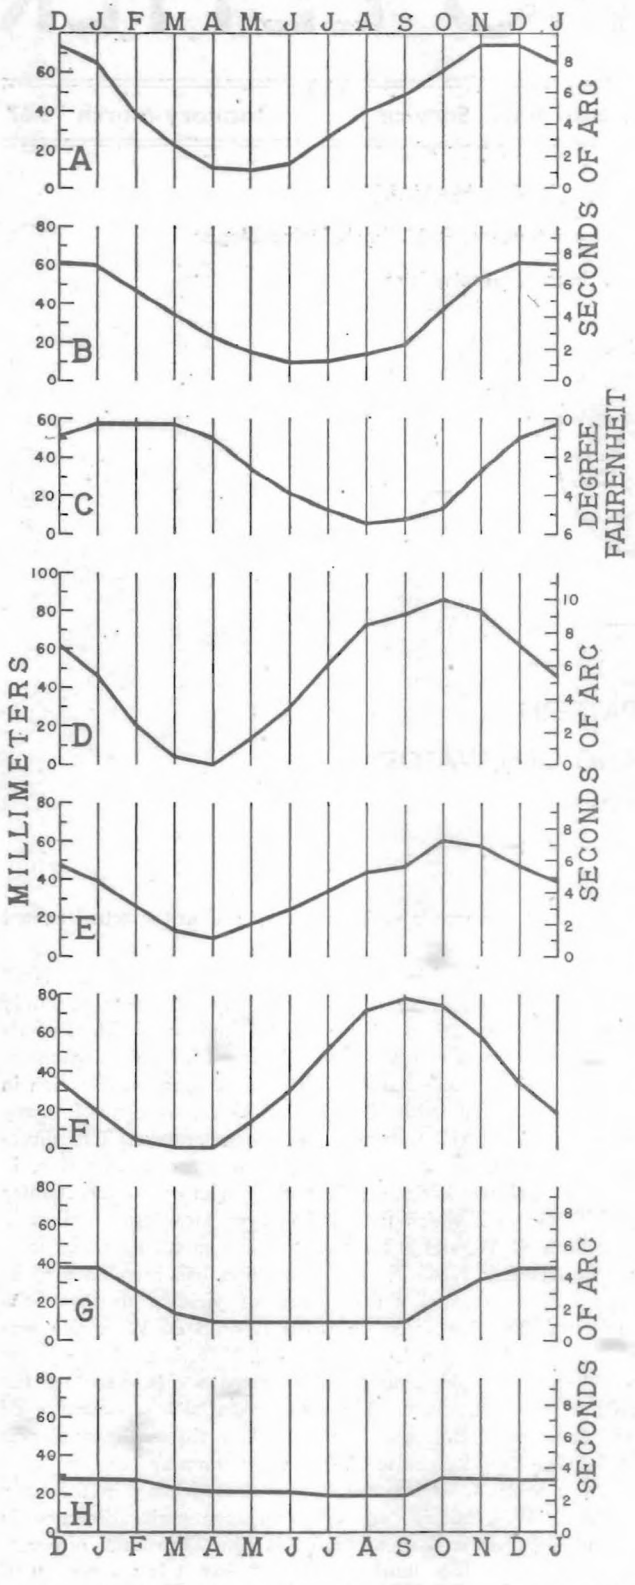

Figure 1.—*A* and *B*, respectively, N–S and E–W components of the "standard" annual tilt loop, computed from 22 years of tilt recorded by the Bosch-Omori seismograph on the northeast rim of Kilauea. North and east are up on the graph, and south and west are down. *C*, changes in mean monthly air temperature (slightly modified) on scale comparable to that of *A* and *B*. Lower temperature is up on the graph, equivalent to north or east tilt. *D* and *E*, respectively, residual N–S and E–W tilt obtained by subtracting curve *C* equally from curves *A* and *B*. *F*, postulated curve of effect of cumulative angular pull of sun. North pull is up on the graph. Scale is proportional to curve *D*. *G* and *H*, respectively, Kilauea and Mauna Loa azimuth residuals of tilt, computed from residuals remaining after subtracting *F* from *D* and *E* in proportions appropriate to tilting on direction N 20 – S 20 W. Upward pressure under the domes is up on the graphs.

this study to date seems to indicate that they are resultants of simultaneous movement on two or even three of the first-mentioned directions. Attention in this study will therefore be concentrated on the three directions postulated above: the N 45 E superficial block movement, the N 20 E Kilauea deep movement, and the east–west Mauna Loa deep movement.

Previous work[2, 3] has shown the influence of temperature change on tilt for periods of time ranging from one day, or of several consecutive days, to a year, in which increases in temperature compared with south and west tilt. A curve (not inverted) showing mean monthly range of air temperature at the Observatory was compared with the curves showing the N–S and E–W components of the "standard" tilt loop. A suggestion of similarity was observed if the temperature change was assumed to have either a three- or four-month lag in its effect on the tilt with increase in temperature correlating with north and east tilt. Study of actual annual loops versus their corresponding temperature curves showed a great lack of correspondence. It also posed the question of why the great lag in temperature effect "on the average," in the face of measured responses of daily tilt to daily temperature with at most a few hours' lag. Accordingly the mean monthly temperature curve was inverted so that decrease of temperature was associated with north and east tilt as originally advocated. Curves showing mean monthly maximum and mean monthly minimum temperature range were also introduced. It was obvious that perfect correlation of any one of the temperature curves with the tilt curves was not possible. However, studies of the daily curves show beyond a doubt that tilt is affected by temperature changes, and by presence or absence of strong insolation. Several consecutive cold cloudy days are associated with the greatest amounts of pure northeast tilt; warm cloudy days, with lesser amounts of northeast tilt; while days with extremely low minima but high insolation may show no northeast tilt at all. For the present analysis of the "standard" tilt loop, a curve intended to express a quantitative approximation of the monthly weather change which affects tilt was constructed by modifying the curve of monthly minima so as to give some weight to the factor of insolation (Figure 1, curve C). The changes of temperature are assumed to cause tilt of the superficial block in the direction N 45 E – S 45 W. The values from the temperature curve were subtracted from the values of the NS and EW components of the "standard" loop, and the residual values thus obtained give curves (Figure 1, curves D and E, and Table 1, columns D and E) which, surprisingly enough, suggest the possible tilt effect of another seasonal force, *i.e.*, the cumulated north–south component of the sun's gravitational pull.

H. O. Wood[4] outlines a theory of the possible influence of forced nutation strains on the rise and fall of lava in Kilauea. He says "These nutations (forced solar and lunar) are produced by the integration of this effect of inclined attraction upon each and every particle in the earth. If the earth were strictly rigid in the mathematical sense this action would produce only nutation and precession. But the earth is only quasi-rigid and, therefore, in addition to the tilting tendency, a tendency to the reconstitution, or readjustment, of the internal configuration of the earth particles may be expected." He evaluated the proportional influence of solar nutation and lunar nutation. and built up a time curve of strain which exhibits semi-annual maxima and minima at time of solstice and equinox, and fortnightly arches of smaller magnitude reflecting lunar influence.

* Columns A and B. Coordinates of the "standard" tilt loop, stating change from preceding month, expressed in millimeters as measured on the Bosch-Omori seismograph. Negative coordinates represent south and west tilt. 10 mm. is equivalent to a tilt of 1.21 seconds of arc.

† Column C. Fractional part of tilt attributed to changes in mean monthly air temperature. 10 mm. postulated to be equivalent to a change of 1° F. Warmer temperatures postulated to cause south and west tilt. Total range of tilt on northeast–southwest direction is 8.7 seconds.

‡ Columns D and E. Residuals obtained by algebraically subtracting column C from A and B.

§ Column F. Fractional part of tilt attributed to cumulative warping of the equatorial bulge by seasonal changes in the angle of the sun's pull. Total tilt on direction N 20 E – S 20 equals 10.6 seconds.

‖ Columns G and H. Residual tilt not accounted for by columns C and F, divided onto "Kilauea" and "Mauna Loa" azimuths, respectively. This tilt may possibly represent a seasonally recurring "squeeze up" of lava pressure, followed by collapse, under the two volcanic domes, possibly associated with the kneading effect postulated in curve *F*.

Jaggar and Finch[5] suggest the possibility that the semi-annual solar tidal maxima and minima may warp the excess of mass of the earth's crust at the equator and in the Hawaiian ridge.

If Wood's strain is applied as a directional force on the equatorial bulge, and the application of the force is considered as cumulative in effect, the maximum accelerations would appear at solstice, but the points of flexure would occur at equinox. If the cumulative application of these strains actually caused a bulging to the north in summer and to the south in winter, the probable curve of bulge would be skewed somewhat in its shape from a pure sine curve. In the northern hemisphere, the north bulge might possibly show a lag because the yielding to the force would have to be a positive bulging against the elastic strength of the crust and against gravity; whereas, after the flexure from northward to southward application of the strain (at fall equinox), elastic rebound and gravity would be coupled in the same sense with the application of strain which might allow the greatest acceleration of the southing curve to appear rapidly after the point of flexure.

Curve F in Figure 1 is a crude concept of the possible cumulative north–south angular pull of the sun, skewed in accord with the discussion above. The amplitude of the curve was arbitrarily chosen to be of the same order of magnitude as that of the residual N–S tilt pictured in curve D. While the curve is not a precise mathematical computation, sufficient scientific honesty was employed in its construction to satisfy the writer that the resemblance between curves D and F is not solely due to "wishful thinking."

The residuals obtained by subtracting curve F from curves D and E are the algebraic sum of (1) the cumulative errors introduced in the analysis to this point, (2) any rhythmic tilt factors which may possibly exist but have not been considered, and (3) the average of any tilt effect caused by strictly volcanic pressure fluctuations during the period studied. These residuals have been computed to two curves, G and H, showing the residual tilt changes on the direction N 20 E to S 20 W (Kilauea) and the direction due E to W (Mauna Loa), respectively. These curves show pressure increase in the winter season and pressure decrease in the summer, which may be entirely coincidental, but also may fit with the observed fact that Hawaiian volcanic eruptions show a tendency to begin more frequently in winter than in summer.

As an approach toward a testing of the possible reality of these hypotheses, the curves of monthly tilt for the years 1930 to 1946 inclusive have been adjusted, factoring out the postulated tilt effect of the accumulated sun strain and the postulated effect of monthly changes of temperature. In the first step, monthly tilt, assumed to be caused by accumulated sun strain, was algebraically subtracted from the actual monthly tilt curves, in proper proportion from the north–south and the east–west curve to express the assumption that this tilt is effective on the Kilauea or N 20 E – S 20 W azimuth. From the residuals thus obtained, monthly tilt, assumed to be caused by the recorded changes in mean air temperature from month to month during this period, was algebraically subtracted in proper proportion to express the assumption that this tilt is superficial and affects the N 45 E – S 45 W azimuth. No attempt was here made to give a quantitative correction for changes in insolation. The residuals were then factored into tilt changes on the Kilauea azimuth (N 20 E) and the Mauna Loa azimuth (E–W).

The monthly residuals obtained from these computations are arranged in Table 2, *A* and *B*. It is apparent in the tabula-

[5] Jaggar, T. A., and Finch, R. H., *Op. cit.*

Table 2.—Monthly Residuals on Kilauea and Mauna Loa Azimuths

	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.

Neutral residuals between plus 0.5 sec. and minus 0.5 sec.	9	7	6	11	6	10	12	9	12	8	7	9
Negative residuals (W tilt) greater than 0.6 sec.	5	2	2	2	3	2	2	4	4	8	8	7

tion for the Kilauea azimuth residuals, and less so for Mauna Loa, that there is remaining an annual curve which has not been factored out. On the Kilauea azimuth, a majority of the months show pressure increase tilt in October, November, and December, and a pressure decrease tilt in February and March. On the Mauna Loa azimuth, a majority of the months show pressure increase in October, but there are no outstanding months of pressure decrease. In view of this evidence, it is assumed that curves G and H (the residuals from the breakdown of the "standard" loop) may represent a third annually recurring tilt pattern. These curves were accordingly factored out from the actual monthly record and the residuals obtained are again grouped in Table 3, *A* and *B*. Approximately half of the residuals now show a neutral change of tilt, slightly more than one fourth show pressure increase, and one fourth show pressure decrease. This distribution might be expected from a random group of numbers. However, the plot of the 204 residuals in their respective order in the 17-year record shows pressure trend groupings. Of the 117 months on the Kilauea azimuth which show an appreciable tilt residual, only 31 occur as zigzag months, *i.e.*, isolated months flanked by residuals of opposite sign, and the rest occur in groups of 2 to 7 consecutive months with the same pressure sign. On the Mauna Loa azimuth, of 98 months, only 25 occur as zigzag months. This grouping in patterns suggests that the residuals may represent real tilt fluctuations caused by changes of volcanic pressure, and not merely accidental random values produced by the manipulation of a set of numbers.

SUMMARY

A "standard" annual tilt loop is derived from study of the tilt of a block of the northeast rim of Kilauea Crater recorded on the Bosch-Omori seismograph during the years 1924 to 1946, inclusive. From patterns of tilt developed during short periods of several days' duration, the hypothesis is advanced that the recorded tilting of this block is the resultant of tilting from three principal causes: (1) a superficial tilting in a northeast–southwest direction stimulated by surface forces, chiefly changes in air temperature and insolation; (2) a deep-seated tilting in the direction N 20 E – S 20 W, stimulated by changes of pressure under the dome of Kilauea; and (3) a deep-seated tilting in the direction approximately east–west, stimulated by changes of pressure under the dome of Mauna Loa.

The quantitative effect of seasonal changes of temperature is estimated to be a 12 second of arc tilt to the northeast for each drop of 1° F. in the mean monthly air temperature, and vice versa. The average annual effect is postulated to be a tilt to the southwest of about 8 seconds from April to September, and a northeast recovery of equivalent amount from October to February.

The hypothesis is advanced that two cyclical forces of annual period also affect the tilt. The first is postulated to be an annual swelling and deflation due to the cumulative effect of the angular pull of the sun on the equatorial bulge and the Hawaiian ridge. The effect of this cause is postulated to be a tilt in the direction N 20 E (at the site of the Bosch-Omori seismograph) of approximately 10.5 seconds of arc from April to September, and a recovery of equal amount and opposite direction from October to March. The second is postulated to be an annual swelling of about 5 seconds of arc in the direction N 20 E during October, November, and December, offset by an equivalent subsidence to the S 20 W in February, March, and April. A similar swelling to the east of less than 1 second of arc occurs in October, with the recovery spread over several spring and summer months. The thought is tentatively advanced that this short tilt loop expresses an actual annual "squeeze up" of lava pressure within the two volcanic domes which is an aftermath of the kneading of the equatorial bulge by the annual change in angular pull of the sun. Some slight support to this thought is offered by the fact that more eruptions of both Mauna Loa and Kilauea in historic time have started during the winter months than during the rest of the year.

The 204-month tilt record from the Bosch-Omori seismograph for the years 1930 to 1946 inclusive, has been adjusted by algebraically subtracting the postulated temperature effect and the three postulated deep-seated tilt effects. The residual tilt curves express the algebraic sum of (1) errors in the hypotheses and (2) true tilt due to increase and decrease of volcanic pressure. The fact that the residual curves show patterns of increase and decrease of pressure of several months' duration encourages the thought that the latter outweighs the former. A critical analysis of these residual monthly curves will be reported in a future VOLCANO LETTER.

Hawaiian Volcano Observatory Report for January–March 1947

VOLCANOLOGY

January

The year opened with both Kilauea and Mauna Loa inactive. Unusually heavy steaming from Mokuaweoweo was observed from January 19–22 inclusive. On January 21 the steam ascended as distinct columns a few hundred feet above the rim of Mokuaweoweo.

Tilt to the southwest was in about the usual amount for January. Tilt records indicate a slight decrease in pressure under Kilauea during 1946.

Sixty-three earthquakes were recorded on the Mauna Loa seismograph and 55 at Kilauea.

February

The number of earthquakes recorded during February, 35 at Kilauea and 42 at Mauna Loa, was the lowest since last September. Earthquakes originating from the southwestern part of Mauna Loa were more numerous than in the preceding several months.

There was a distinct accumulation of southerly tilt and a slight easterly tilt during the month. Such a southerly tilt is normal for February. The slight easterly tilt, instead of the normal westerly, may indicate an increase of pressure under Mauna Loa.

March

There was an increase in seismicity for the month because of an increase both in the total number of earthquakes and in the number of perceptible shakes. Fifty-three earthquakes were recorded at Kilauea and 62 at Mauna Loa.

The southwest tilt usual for this season of the year ceased about the last of February and was not resumed in March. The lack of southwest tilt may be explained partially by the fact that the mean temperature for March was lower than that for February.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

1. January 2, 04:16, very feeble. Kilauea shake.
2. January 9, 07:16, very feeble. Mauna Loa shake.
3. January 11, 02:52, very feeble. Mauna Loa.
4. January 13, 01:43, very feeble. Mauna Loa.
5. January 15, 09:47, slight. NE rift Mauna Loa.
6. January 16, 14:03, very feeble. Mauna Loa.
7. January 19, 07:42, very feeble.
8. January 22, 22:46, feeble. Kilauea.
9. January 25, 18:16, very feeble.
10. January 26, 17:34, very feeble. Kilauea.
11. January 28, 16:22, very feeble. Near Mokuaweoweo.
12. January 29, 20:46, very feeble. Mauna Loa.
13. February 5, 22:53, slight. Kilauea.
14. February 11, 05:15, very feeble. W slope Mauna Loa.
15. February 13, 02:37, very feeble. Kilauea.
16. February 13, 09:44, very feeble. Mauna Loa.
17. February 17, 02:39, very feeble. Kilauea.
18. February 19, 15:19, very feeble. Felt in Kona.
19. February 21, 18:06, very feeble. Mauna Loa.
20. February 26, 18:54, feeble. NE rift Mauna Loa. Felt generally in eastern Hawaii.
21. March 5, 23:08, very feeble. Kilauea.
22. March 8, 21:40, very feeble.
23. March 8, 23:03, very feeble.
24. March 13, 03:52, feeble. Felt locally.
25. March 15, 16:14, feeble. Kilauea. Felt locally.
26. March 19, 23:06, moderate. Widely felt on island of Hawaii. Deep under Mauna Loa. Mauna Loa instruments dismantled.
27. March 20, 11:41, very feeble.
28. March 21, 17:37, feeble. Keahole Point, Kona.
29. March 22, 14:29, very feeble.
30. March 28, 09:57, feeble.
31. March 28, 09:59, very feeble.
32. March 28, 11:56, slight. Mauna Loa.
33. March 29, 20:11, slight. NE slope Mauna Loa. Felt locally and at Hilo.
34. March 30, 15:50, very feeble.
35. March 31, 00:37, very feeble. NE slope Mauna Loa.

TELESEISMS

January 24, 06:17, slight.
January 25, 23:50, slight.
February 25, 21:25, slight.

MICROSEISMS

Microseisms were moderate to strong throughout the quarter except for light spells on January 16; February 16, 21–23; and March 2–5, 27–31.

CRACK MEASUREMENTS

Cracks that were measured around Halemaumau and along the Chain of Craters Road showed practically no movement.

TILTING OF THE GROUND

Normal southwesterly tilt obtained until February 25. From this date until the end of the quarter there was no tilt accumulation.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
in cooperation with UNIVERSITY OF HAWAII

The Hawaiian Volcano Research Association was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The University of Hawaii cooperates in maintaining a research laboratory at Hawaii National Park. The Association and the University supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The Volcano Letter, a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE VOLCANO LETTER

KILAUEA IN 1790 AND 1823

By R. H. FINCH

Volcanologist, Hawaii National Park

The object of this paper is to review the accounts dealing with the activity of Kilauea in 1790 and the lava flow of 1823 and to discuss probable events between these years.

There are several versions of the 1790 explosive eruptions of Kilauea based largely on accounts given by Ellis[1] and Dibble.[2] Accounts and interpretations by various authors were reveiwed by T. A. Jaggar[3] in 1921. Facts of the 1924 explosive eruption make it possible to give a different interpretation to some of the details.

The explosive eruption of 1790 was an important event in Hawaiian history as it occasioned the destruction of a portion of the army of Keoua, a chief of Hawaii, that was engaged in a civil war. The army had come to the volcano by the trail through Olaa from Hilo and had camped at the northern end of the crater. Hitchcock[4] assumed that the army passed to the south of Kilauea crater on the upper Puna-Kau trail across the Kau Desert. In view of the fact that the army camped for 3 nights and 2 days at Kilauea, the trail by the northern rim of the crater where water was available seems a more logical route. Bloxam[5] in 1825 was shown the place to the north of Kilauea Iki where some of Keoua's troops had encamped. The distribution of the 1790 ash also indicates that the northern route was the one used. An explosion took place shortly after the arrival of the army at Kilauea, and other explosions occurred during the next 2 days. On the third day the army continued on its way in three different companies. Shortly after getting under way a more violent explosion occurred and totally destroyed the middle company of about 80 people. The probable position of the middle company was at an elevation of about 3,800 feet on the Kapapala-Uwekahuna trail near the outer rim of Kilauea. The greatest thickness of the 1790 ash is found on the west-southwest inner rim of Kilauea crater and as the thickness diminishes rapidly both to the northwest and to the southeast, it appears that the greater thickness here is due to one or more directed blasts. The middle section of the army may have been passing at the time of a directed blast.

All native accounts agree that incandescent material was present in the explosion clouds. Some have interpreted the native accounts as indicating that spouting columns of molten lava were present. The absence of pumice and the relatively few bombs in the explosion debris make this idea improbable. The incandescence of an appreciable amount of material thrown out and numerous lightning flashes could account for all the glow reported. Many of the night explosions in 1924 produced a brilliant glow, and the sand and dust of some explosions was hot enough to scorch vegetation 1,800 feet from the Halemaumau rim. The deaths in the middle section of Keoua's army can easily be accounted for by hot sand and dust. The amount and distribution of the 1790 ash indicate that the explosions of that

year were larger than in 1924. It may be assumed then, that in some of the larger explosions in 1790 the ash was still hot at a distance of 1½ miles from the explosion vent. The 1½ miles is a possible distance of the middle company. A temperature below the charring point of dry grass, about 400° F., could easily cause death and yet show no signs of severe burns.

The 1790 explosions were essentially phreatic in that they were produced by ground water gaining access to the conduit from which molten lava had recently withdrawn. The molten lava that was present as evidenced by cored bombs was not essential to the mechanics of the explosions. The bombs found in the ash may have been produced from a trapped pocket of lava that was left behind in the retreat of the lava column.

The 1790 ash represents the topmost layer, except for a small amount of 1924 ash, of the rather coarse material of the ash deposits around Kilauea. The greatest depth on the rim is 45 inches at the west-southwest. On the southwest rim it is about 12 inches thick. To the east of Cone Peaks, 9 inches of the 1790 ash are still in place. The time required to produce the widespread erosional unconformity that is found between the upper layer of coarse material and the next layer under it definitely indicates that the two topmost layers are not the product of one explosive period.

There had been one, perhaps two, lava flows in eastern Puna previous to the 1790 explosions. It is reasonable to suppose that the 1790 eruptions followed a collapse in the crater accompanying an eastern Puna lava flow. Ellis (p. 214) tells of a lava flow in the Malama district of eastern Puna about 30 years prior to his visit, or about 1790. On page 218 he tells of a lava flow in about the same area, which occurred in the time of Taraiopu. Fornander[6] shows that Taraiopu is another name for Kalaniopuu, who died about 1782. It is doubtful if these two accounts refer to the same flow. The description of the Kalaniopuu flow fits well the southern portion of what Macdonald[7] has called the lava flow of 1793 [1790]. The Macdonald map shows two flows essentially parallel and two separate fissure sources. The separate fissures are merely a further indication and not a proof that there were two flows. Thrum in the Fornander collection[8] lists a great eruption of Kilauea in 1783. As Hawaiian dates at this time were not exact, one wonders if the older of these eastern Puna flows was the great eruption of 1783.

The condition of Kilauea following 1790 is not known. On January 11, 1794, (Hitchcock, p. 161) Vancouver passed to the south of Kilauea and reported columns of smoke arising. This may have been due to short-lived activity such as has occurred several times since 1924 or it may have been due to a dust cloud in the Kau Desert. Menzies, on February 12, 1794, (Hitchcock, p. 72) reported an eruption from Kilauea in terms suggesting that he had merely encountered a dust cloud from the Kau Desert.

Sometime in the period between 1790 and 1823—the year of a great collapse in Kilauea and a lava flow from the southwest rift—a considerable quantity of pumice was deposited over the upper Kau Desert. The pumice is 44 inches thick near the southwest rim of Kilauea and can be found in place 1½ miles from the rim. It probably came from a vent near the southern end of Kilauea while trade winds were blowing. It may well be that Kilauea showed but little or no activity for several years following 1790 and that the pumice eruption occurred about the time that continuous activity commenced.

The sinking of the lava column in 1823 left a relatively flat floor about 1,000 feet below Uwekahuna.[9] The flat floor indicated the drainage of a lava lake involving nearly all of Kilauea crater. The drainage must have been through a crack leading to the southwest rift system that was about 700 to 800 feet below the Kilauea rim on that side. Widespread activity prior to the 1823 lava flow and collapse is evidenced by the presence of several spatter cones on the black ledge as shown by a sketch in Ellis, page 176. The black ledge which represented the level reached by molten lava prior to the 1823 flow resulted from contact cooling with the crater walls. The flatness of the floor after the collapse of 1823 is a good indication that the crates had been filled with molten lava and that the fill must have been made in a short time.

The infilling of the crater prior to the collapse in 1832 affords a clue as to the possible time involved in the infilling prior to 1823. The volume of the infilling prior to the 1823 collapse is not known, but it must have exceeded the amount engulfed in 1823 plus the volume of the black ledge. The 1790 explosive episode must have left a pit or some portion of the crater with a depth much greater than the 1,000 feet below Uwekahuna found by Ellis. Such a pit may have been partially filled by short-lived activities prior to the commencement of continuous activity. As there is no way of estimating the volume of such a pit it will be ignored in what follows. A crude approximation of the volume of the pre-1823 infilling may be had by taking the amount engulfed in 1823, 19,052,000,000 cu. ft. (Volcano Letter 470 and 471), and adding an estimate for the volume of the black ledge, 120,000,000 cu. ft., thus obtaining a total of 19,172,000,000 cu. ft. The fill in Kilauea crater between 1825 and 1832 was estimated to have been 23,850,000,000 cu. ft. (Volcano Letter 471) or at a rate of 3,400,000,000 cu. ft. a year. Applying this rate to the 19,172,000,000 cu. ft., we obtain 5.6 years as the time required to make the pre-1823 fill. Now the fill may have been considerably greater than the amount given above but the rate of fill may have been greater than that between 1825 and 1832, so that an estimate of 6 or 7 years as the time required to complete the fill prior to the 1823 collapse seems reasonable. This would seem to indicate the possibility that Kilauea was rather quiet or inactive for about 25 years after the 1790 explosions.

Hawaiian Volcano Observatory Report for April–June 1947

VOLCANOLOGY

April

The numbers of earthquakes recorded at Kilauea and Mauna Loa during April, 41 and 49 respectively, were less than in March. Six earthquakes, two of which were felt at Kapapala, were recorded in an interval of 1 hour and 40 minutes on the morning of April 12. The shakes originated at three different places and thus have but little volcanic significance. The majority of the earthquakes recorded in April appear to have originated under the eastern half of Manua Loa.

May

The total number of shakes recorded in May, as in the past 8 months, was greater at Mauna Loa than at Kilauea, or 54 and 43 respectively. During the latter part of the month there was a slight increase in the number of shakes originating under Kilauea.

Seasonal westerly tilt continued throughout the month. There was no tilt in the north-south direction.

June

The numbers of earthquakes recorded during the month were: Mauna Loa, 48, and Kilauea, 45. Earthquake No. 79, which occurred at 05:04 on June 19, had unusually long periods for all phases. This long period was also shown on the Mauna Loa and Hilo seismographs. The quake had a shallow focus under Kilauea.

A conspicuous fume cloud was observed over Mauna Loa about sundown on June 11.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours and 30 minutes slower than Greenwich until June 8 then 10 hours slower. The number preceding each earthquake is the serial number of the quake for the current year.

36. April 2, 23:57, very feeble.
37. April 8, 05:10, very feeble.
38. April 10, 05:57, very feeble. Mauna Loa shake.

65. May 9, 06:07, very feeble.
66. May 9, 17:10, very feeble.
67. May 11, 05:09, very feeble.
68. May 15, 21:18, very feeble.
69. May 17, 09:38, very feeble. Kilauea.
70. May 21, 09:44, feeble. SW rift Kilauea.
71. May 27, 03:31, very feeble. Kilauea.
72. May 27, 17:09, very feeble.
73. May 29, 17:12, very feeble. Kilauea.
74. May 31, 03:05, very feeble. Kilauea.
75. May 31, 17:37, very feeble.
76. June 1, 05:48, very feeble. Mauna Loa.
77. June 9, 14:53, very feeble.
78. June 14, 23:00, moderate. Felt locally and as far as Papaikou. Moderate depth under Kilauea. Mauna Loa instrument dismantled.
79. June 19, 05:24, moderate. EW dismantled. Felt locally. Shallow under Kilauea.
80. June 19, 05:36, very feeble.
81. June 21, 11:01, very feeble. Mauna Loa.
82. June 26, 14:23, slight. Felt locally, Naalehu, and Hilo. 15 miles under E slope Mauna Loa.

TELESEISMS

April 10, 05:43, slight. Southern California.

April 13, 21:14, slight. Japan.

MICROSEISMS

Microseisms were strong from April 6th to the 9th and light to moderate during the rest of the month. They were moderate during the entire month of May. In June they were light to moderate from the 1st to the 11th and then moderate for the rest of the month.

CRACK MEASUREMENTS

A few of the cracks around Halemaumau opened slightly in April. No appreciable movement of any of the cracks measured was detected in May and June.

TILTING OF THE GROUND

Seasonal southerly tilt ceased during the latter part of March and there was a very slight accumulation of northerly tilt during the quarter. Westerly tilt continued throughout the quarter.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The **University of Hawaii** cooperates in maintaining a research laboratory at Hawaii National Park. The **Association** and the **University** supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The **Volcano Letter**, a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE INACTIVE PERIODS OF KILAUEA

By R. H. FINCH

Volcanologist, Hawaii National Park

Continuous activity of Kilauea ceased with the withdrawal of the lava column preceding the explosive eruption in May, 1924. Since then there have been seven periods of short-lived activity. The last activity was on October 9, 1934. The present period of inactivity—practically 13 years—is the longest on record. The 13-year period from 1894 to 1907 has sometimes been compared with the present. The 1894–1907 period, however, is not comparable as in those years there was much fuming and occasional glow in Halemaumau. Meager data indicate that there may have been a similar period of inactivity following the 1790 explosions.

Discrepancies in the estimates of the percentage of the time that Kilauea has been inactive since the written record began in 1823, are to be expected. Some of the discrepancies may be accounted for by differences in the definition of activity and others may be due to differences in the interpretation of the records. For the 47 years prior to the establishment of the Hawaiian Volcano Observatory in 1912, the history of Kilauea is quite faithfully given in the record books of the Volcano House, the hotel on the northeast rim of the crater. Some of the indications of lack of activity even after the hotel was established in 1865 may be due more to a lack of observations than to actual inactivity. A study of the hotel record books shows that some periods of slight activity between spells of spectacular activity have erroneously been classed as inactive.

Any period in which magmatic effervescence is indicated as at or near the surface is classed as active in this discussion. To be conservative, for periods with considerable fuming and incomplete observations (as in 1849–1851 and 1894–1907), the duration of inactivity as given in Table 1 is greater than if the above definition were strictly followed. An open vent which is fuming in appreciable volume with lava occasionally visible had best be classed as active. Periods in which high-level internal activity without fuming is indicated, as in November–December, 1944,[1] are thus not classed as active.

A list of the known inactive periods of Kilauea from 1823 to May, 1924, inclusive, is shown in Table 1.

Table 1.—Dates and Duration of Inactive Periods at Kilauea

Year	Duration	Remarks	Year	Duration	Remarks
	Months			*Months*	
1848	1	See note *A* below	1897	7	
1849	6	See note *B*. May be less	1898	11	
1850	6	May be less	1899	10	
1851	6	May be less	1900	9	
1852	1		1901	8	
1868	1		1902	5	See note *C*
1871	2		1903	7	
1879	1		1904	9	
1886	1		1905	2	
1891	1		1906	5	
1894	1	Fuming nearly continuous 1894–1907	1907	3	
1895	8		1913	1	
1896	6		1922	1	

Note *A*. Stearns and Macdonald[1] show questioned inactive periods in 1823, 1832, and 1840. The writer's interpretation of the records makes activity continuous in these years.

Note *B*. A plug dome formed at the Halemaumau vent in 1848. Mr. Coan correctly explained its formation as being due to the "compound action of upheaving forces from beneath and of eruptions from the openings forming successive layers upon its external surface."[2] Unusually viscous lava that issued from cracks in the plug was of comparatively small volume though sufficient to give a more or less smooth outline. The dome was over 300 feet high and about 2,000 feet in diameter. The continuance of the dome through 1849, 1850, and 1851 indicates that the lava column was high during these years; otherwise the dome would have collapsed. In the spring of 1852 there was a pit in the top of the dome. This was about 100 feet in diameter with a boiling pool of lava about 100 feet below the rim. The dome gradually disappeared by engulfment. A similar elevation of the epimagma took place prior to 1846. In the earlier 1840's elevation, the area involved was much greater than in 1848. Also there was a greater volume of less viscous molten lava.

Note *C*. On February 14, 1902, it was found that there was a recent lava fill in the bottom of Halemaumau, but the activity was not observed despite a rather close watch from the hotel.

[1] STEARNS, HAROLD T. and MACDONALD, GORDON A. GEOLOGY AND GROUND-WATER RESOURCES OF THE ISLAND OF HAWAII. Hawaii Div. of Hydrography, Bul. 9. 1946.

[2] DANA, JAMES D. CHARACTERISTICS OF VOLCANOES. (New York 1891), p. 80.

Since the explosive eruption in 1924, there have been seven periods of activity at Kilauea. Prior to the commencement of the present 13-year period of inactivity in 1934, the longest period of inactivity since 1924 was the three years from July, 1924, to July, 1927. The dates and duration by days of the active periods since May, 1924, are shown in Table 2. If the duration of inactivity by months were used, as in Table 1, for the 23 plus years of this period most of the entries would be 12, or 11 and a fraction.

Table 2.—Eruptions at Kilauea Since May, 1924

Date	Duration
	Days
July 1924	12
July 1927	14
February 1929	2
July 1929	4
November–December 1930	18
December 1931–January 1932	13
September–October 1934	33

The total in the above table is 96 days. This means that Kilauea has been active but a little over 1.1 per cent of the time since May, 1924.

During the 124 years and 9 months ended September 30, 1947, Kilauea has been active about 73 per cent of the time. For the 123 years ended 1945—the period used by Stearns and Macdonald, p. 112—the writer finds that Kilauea was active about 75 per cent of the time. The Stearns and Macdonald computation makes the figure about 67 per cent. This means that they classed as inactive about 110 months which the writer called active. The statement that Kilauea was active almost continuously from 1823 to May, 1924, is correct. Computations show that Kilauea was active about 90 per cent of the time during this period.

The behavior of Kilauea before and after the 1924 explosions indicates that an explosive eruption marks a turning point in the behavior of Kilauea. During the 16 years preceding the 1924 explosions, Kilauea was active over 98 per cent of the time. During the first 16 years following the explosions, activity totaled 1.7 per cent.

In VOLCANO LETTER 496, p. 2, the writer has given some calculations to indicate that Kilauea may have become continuously active about 1816 to 1818 or 26 to 28 years after the 1790 explosions. An estimate of 25 to 30 years would probably be better than 26 to 28 as 1790 might well be given 1790± and 1816 to 1818 is derived by calculations based on assumptions. If the behavior of Kilauea after 1924 is to be similar to the behavior following 1790—analogy and suggested periodicity in the occurrence of steam blasts make this seem a possibility—then some year from 1947 onward should be the equivalent of 1816±. It should be borne in mind that there is always the possibility of another period of short-lived activity before a resumption of continuous activity.

Hawaiian Volcano Observatory Report for July–September 1947

VOLCANOLOGY

July

July, 1947, was the quietest month seismically since September, 1946. The number of earthquakes recorded at Mauna Loa and Kilauea, respectively, were 29 and 14. Many of the shakes appear to have originated along the northeast rift of Mauna Loa with shallow foci. For the year ended June 30 there was a slight accumulation of southwest tilt which may be taken as indicating a slight pressure decrease under Kilauea.

August

In August, for the first time in several months, more earthquakes were recorded at Kilauea than at Mauna Loa, or 40 and 39, respectively. A conspicuous fume cloud was observed over Mokuaweoweo on August 5. From the rim it appeared dense and bluish. Ordinary steam clouds from Mokuaweoweo were observed several times during the month.

September

During September more earthquakes of Mauna Loa than of Kilauea origin were recorded, or 33 and 20, respectively. Two earthquakes that indicate deep-seated uneasiness along the fundamental rift under Hawaii occurred during the month. The first was at 05:50 on September 21 with a depth of from 20–25 miles and the second at 04:05, September 30 with a depth of 8–10 miles.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number of the quake for the current year.

83. July 7, 05:59, very feeble.
84. July 14, 11:52, feeble. Kilauea shake.
85. July 15, 12:25, very feeble. Mauna Loa.
86. July 17, 15:17, very feeble.
87. July 21, 06:18, feeble. Mauna Loa.
88. July 23, 01:52, feeble. Kilauea.
89. July 23, 10:25, feeble. SW rift Mauna Loa.
90. July 26, 16:57, very feeble. NE rift Mauna Loa.
91. July 28, 15:40, very feeble.
92. July 30, 17:15, very feeble. Kilauea.
93. August 7, 05:04, very feeble. NE rift Mauna Loa.
94. August 7, 20:36 slight. Felt locally, and at Naalehu and Hilo. E slope Mauna Loa.
95. August 10, 02:16, very feeble. NE rift Mauna Loa.
96. August 11, 12:52, very feeble.
97. August 12, 07:42, very feeble. Mauna Loa.
98. August 15, 18:46, very feeble. Mauna Loa.
99. August 18, 09:52, moderate. E–W seismograph dismantled. Felt locally and at Naalehu. Deep under Kilauea.
100. August 18, 10:01, feeble. Kilauea.
101. August 18, 14:11, feeble. Mauna Loa.
102. August 19, 01:22, very feeble.
103. August 19, 06:44, slight. Felt locally and at Naalehu. Mauna Loa.
104. August 24, 02:35, very feeble. Kilauea.
105. August 28, 15:15, very feeble. Mauna Loa.
106. August 29, 21:49, very feeble. Mauna Loa.
107. August 30, 15:21, very feeble.
108. September 1, 01:33, very feeble.
109. September 2, 05:17, very feeble. Kilauea.
110. September 4, 17:49, very feeble.
111. September 6, 17:28, feeble. Kilauea.
112. September 6, 17:45, very feeble. Kilauea.
113. September 12, 04:29, feeble. Kilauea.
114. September 21, 05:50, slight. Widely felt on this island and by a few on Maui. About 20–25 miles deep below Humuula.
115. September 22, 07:41, very feeble.
116. September 30, 04:04, moderate. Generally felt from South Kona to Hilo. Instruments dismantled. 6–8 miles deep east of Kilauea.
117. September 30, 04:09, slight.

TELESEISMS

July 24, 02:24, slight. New Hebrides.
August 17, 20:23, slight.
September 23, 04:10, slight. Off North California coast.
September 26, 06:14, slight.

MICROSEISMS

Microseisms were moderate on July 8, 9, and 10 and on the last three days of September. During the rest of the quarter they were light.

CRACK MEASUREMENTS

Some of the cracks around Halemaumau opened slightly, though the majority showed but little or no movement.

TILTING OF THE GROUND

Northerly tilt was quite uniform throughout the quarter except for a strong spurt during the last week in August and a sharp southerly tilt September 8–13. Tilting in the east–west direction was about stationary until July 25 when a rather uniform east tilt set in to continue through September.

REVIEW OF "ORIGIN AND DEVELOPMENT OF CRATERS" BY T. A. JAGGAR

By R. H. FINCH
Volcanologist, Hawaii National Park

In the *Origin and Development of Craters,* Dr. T. A. Jaggar sets forth many of his ideas gained from a lifetime study of volcanoes. The book is memoir No. 21 of the Geological Society of America and contains 508 pages, 14 text figures, and 87 plates. The price at New York is $6.00.

Dana, in his *Characteristics of Volcanoes,*[1] generalized from Hawaiian volcanoes. Jaggar's memoir is modeled on Dana's book. It would be well for all readers of *Origin and Development of Craters* to peruse carefully the abstract and introduction. This will help in an understanding of the author's aims and prepare the reader for Part 1, which is largely the hitherto unpublished material in the record books of the Hawaiian Volcano Observatory from the second week of April, 1912, to the last of June, 1913. This section gives an excellent picture of the features and behavior of a lava lake as well as the initiation and development of observational methods. The strictly diary part probably is too detailed for most readers and might well have been included as an appendix. This comment might also apply to the diary of Part 3, Kilauea Steam Blast Eruption, 1924. The manner of treatment makes reading of the book rather difficult for all but those especially interested. It is not, however, intended as a popular book on Kilauea and Mauna Loa.

On page 267 occurs the statement: [The author] "makes no apology for introducing anywhere, if it is relevant, a geological discussion." Interpretation and definition are thus mingled with description. If there is any defect in this treatment it is largely overcome by a good index and an excellent table of contents. The table of contents merits attention as it permits those who lack time to read the book page by page to read by topics. The table of contents will also be especially helpful in using the memoir as a reference.

Part 2 gives a more or less chronological account of the activity of Kilauea and Mauna Loa from 1909 to 1935 and a condensation of 26 years of Hawaiian volcano observations and experiments. The author states that "The year 1909 is a good year to begin with because until 1913 the lava was intensely active but receding." The purely historical account of Hawaiian volcanoes given by Hitchcock[2] and Brigham[3] stops with 1908 and June, 1909, respectively. The year 1909 is thus an especially appropriate year with which to begin this part.

In the subtitle for Part 2—"The Cross of Hawaii"—the belief that Kilauea may be older than Mauna Loa is kept alive, though on page 90 there is the statement that geological mapping may demonstrate that Mauna Loa is older than Kilauea.

Mingled with the history in Part 2 are many geological discussions and the results of experiments. In 1912 a temperature of 1000° C. was found 2 feet below

[3] BRIGHAM, W. T. THE VOLCANOES OF KILAUEA AND MAUNA LOA. Bernice P. Bishop Mus. Mem. Vol. 2, No. 4, Honolulu, 1909.

the surface. The so-called "floating islands" were found to be but some of the epimagma, or the somewhat stiff upper portion of the lava column that normally forms the basin in which the lava lakes are located. The depth of the lava lake—40 to 50 feet—was determined both by experiment and direct observation.

On page 125 there is a discussion under the title, "Sympathy of Kilauea with Mauna Loa," wherein it is stated that there was an increase in output of a Kilauea flow attending the 1919 eruption of Mauna Loa. Collapses in Halemaumau following eruptions of Mauna Loa in 1914 and in 1916 offered definite suggestions of sympathy between the two volcanoes. There are indications of a similar collapse at Halemaumau in 1855 following an eruption of Mauna Loa in that year. These suggestions of sympathy led to the successful forecast of a collapse in Halemaumau in 1919 (p. 34).

The case for comparing the amphitheater breaches in the slag heap, Mauna Iki (p. 143), and large amphitheaters is not too good. The Mauna Iki slag heap was built up in days and the interior was composed of hot pasty material while the large amphitheater embayments occur in structures that were centuries in forming. Mohokea is cited as one such breach. Stearns and Macdonald[4] maintain that Mohokea was produced by erosion. Powers,[5] however, points out that block faulting may have played an important part in the formation of the Mohokea embayment.

The behavior of the upper end of the Kilauea lava column is quite fully treated in Part 4, Sketch Maps and Profiles of Halemaumau, 1917–1934. This method of treatment of necessity duplicates some of the history given in Part 2. Before detailed discussions of the maps and profiles are taken up there are seven pages of general statements. In reading this Part one wishes that the pertinent plates had been included as text figures instead of in an envelope containing 14 loose plates on the inside back cover. As printed, most are already of a size suitable for use as text figures.

Part 5 is a short summary of the histories of Kilauea and Mauna Loa. An excellent feature of this Part is a list of discussions bearing on crater history that appeared in the *Bulletin of the Hawaiian Volcano Observatory*. This is a helpful contribution as the *Bulletin* was never indexed. The table (p. 327) outlining Hawaiian activities is not intended as a complete listing of active years but rather to show lava culminations and lowerings. The propriety of giving probable times and amounts of lowering in such a table for the years 1800 and 1810, for which there are no records, is questioned. The dates and amounts of lowering are taken from the hypothetical portion of Plate 86.

On page 329 the author, as do Stearns and Macdonald,[6] favors a position south of the summit crater of Mauna Loa as the locus of the 1832 flow. The reviewer feels that the 1832 eruption was at the summit with a possible short flow from the northeast rim.

The idea that the north and south flanks of Mauna Loa at Humuula and Kahuku lands may be thought of as breaking down, undermined by lava flows, is given on page 333. Aside from the ancient breakdown to form the Kahuku Pali near the south point of Hawaii, there are no surface indications of such a process. If, as seems to be the case, the rise of lava at Mauna Loa is confined to the feeding conduits under Mokuaweoweo we would not expect much undermining by outflow at the places in question.

Part 6, Principles of Crater Evolution, commences with 10 pages of general statements of some of the broader aspects of volcanism. The subtitle for this part, "Earth, the Offspring of the Sun," emphasizes solar derivation. The next 40 pages treat of the work of 17 authors dealing with classification and ideas of volcanic processes. Direct quotations from many authors and comments on the work of all are given. There is evidence of a gradual increase in knowledge of volcanic processes. "Crater Physics and Chemistry" are treated in the last 20 pages of this Part. The importance of combustible gases in volcanic processes is emphasized. The three types of magma: hypomagma (profound and gas charged, rising from the earth's interior—the lava column in the depths), pyromagma, (the frothy fluid in lakes and flows), and epimagma (the stiff or pasty upper portion of the lava column) are discussed more fully here than elsewhere in the book.

Part 7, Summary and Conclusions, is a stimulating résumé with thought-provoking speculations on several subjects. The author's idea of ignisepta, "igneous partitions in earth mantle profound to the core" or "giant rift belts full of magma, leading down to the centrosphere," merits careful consideration.

The 73 plates of photographs deal mainly with Kilauea and Mauna Loa though a few are included dealing with the history of the Hawaiian Volcano Observatory. It is an excellent collection of photographs and, with the more extensive legends than usual, gives a quite comprehensive view of volcanic processes and products as exemplified by Kilauea and Mauna Loa.

The memoir is an outstanding contribution to the literature on volcanoes and will maintain this position for years to come.

Hawaiian Volcano Observatory Report for October–December 1947

VOLCANOLOGY

October

October was quiet seismically at Kilauea with but 11 earthquakes recorded. This is the smallest number recorded at Kilauea for many months. The Mauna Loa seismograph recorded a more usual number, or 30. The majority of the Mauna Loa shakes were very small with origins along the northeast rift. The strongest earthquake of the month occurred at 02:13, October 31. It dismantled the Mauna Loa and Kona seismographs. The indicated origin of the quake was at a depth of 12–15 miles below the southern end of Mokuaweoweo. There was about the usual northerly tilt during the month. The slight westerly tilt was opposite in direction to the normal for October. Tilting of the ground gave no indication of impending activity.

November

November, like October, was quiet seismically with but 18 earthquakes recorded on the Kilauea and Mauna Loa seismographs. This is the smallest number recorded at Mauna Loa for several years. The distinct earthquake of October 31 may have occasioned movement along the rift that extends from Mokuaweoweo to Kealakekua Bay. The Kona seismograph recorded two shakes from this rift on November 18 and 19. The rift was active in 1877 producing a small lava flow in Kealakekua Bay. On November 25 there were two periods of continuous tremor each lasting over 3 minutes. The tremor was more like that which accompanies an outbreak of Mauna Loa than individual earthquakes. The origin of the tremor was at Kilauea.

On November 15, following a 4-inch rainfall, heavy steam clouds developed in Halemaumau.

December

December was the third consecutive month with but few earthquakes of Kilauea origin. The Kilauea seismographs recorded but 16 shakes while the Mauna Loa instrument recorded 43. Five of the shakes were perceptible. One of these originated deep under Kilauea and four had shallow origins under various portions of Mauna Loa. The preponderance of Mauna Loa shakes, together with a distinct easterly tilt during the month, may be taken as signs of slight uneasiness under Mauna Loa. History and the scattered earthquakes give some indications that the next eruption of Mauna Loa will be at the summit. There was a slight accumulation of southeast tilt during 1947.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the Hawaii National Park. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

118. October 3, 09:21, very feeble.
119. October 17, 00:27, slight. Generally felt on eastern part of island. Near Kapapala.
120. October 23, 09:42, very feeble.
121. October 24, 18:02, very feeble. Felt at Naalehu.
122. October 28, 22:00, very feeble.
123. October 30, 15:07, very feeble.
124. October 31, 02:13, moderate. E–W dismantled. Widely felt eastern half of island. Clocks stopped in South Kona. Origin under summit of Mauna Loa.
125. November 8, 15:53, feeble. Mauna Loa shake.
126. November 8, 16:15, very feeble. Mauna Loa.
127. November 13, 21:01, very feeble. Mauna Loa.
128. November 15, 01:43, very feeble.
129. November 16, 03:55, very feeble. Kilauea shake.
130. November 23, 01:17, very feeble. Mauna Loa.
131. November 25, 08:43, very feeble.
132. November 25, 11:31, very feeble. Kilauea.
133. December 9, 21:14, feeble.
134. December 12, 12:50, very feeble.
135. December 14, 10:10, moderate. Felt locally and at Hilo. E–W dismantled. 20 miles under Kilauea.
136. December 17, 00:01, very feeble. Felt at Kapapala. East slope of Mauna Loa.
137. December 18, 09:01, very feeble. Mauna Loa.
138. December 19, 23:07, feeble. East slope of Mauna Loa.
139. December 20, 05:18, slight. Felt eastern half of island. Near summit of Mauna Loa.
140. December 22. 02:55, feeble. East slope of Mauna Loa.
141. December 24, 06:38, slight. Felt locally, and at Hilo and Naalehu. East slope of Mauna Loa near Ainapo.
142. December 29, 16:28, very feeble.

TELESEISMS

October 15, 16:18, slight. Near Fairbanks, Alaska.

November 1, 05:12, slight. Peru.

November 3, 14:20, slight.

November 20, 18:14, slight. Mexico.

November 21, 22:26, slight.

MICROSEISMS

Microseisms were moderate to strong October 25–31 and December 11–21 and light on other days.

CRACK MEASUREMENTS

Some of the cracks near the southwest rim of Halemaumau opened slightly; other measured cracks were essentially stationary.

TILTING OF THE GROUND

The seasonal northerly tilt that continued until November was less than usual. There was a slight southerly tilt from November 7 until December 20, then a slight northerly tilt until the end of the year. There was a slight westerly tilt during the first week in October. On October 7 a distinct easterly tilt commenced that continued until December 16. During the last half of December there was a slight accumulation of westerly tilt.

TRANSFER OF THE HAWAIIAN VOLCANO OBSERVATORY

On December 28, 1947, by order of the Secretary of the Interior, the Hawaiian Volcano Observatory was transferred to the United States Geological Survey. The Observatory will continue measurement and observation of volcanic behavior, and, in addition, will serve as a training station in the Geological Survey's program of volcanic studies in the Pacific and elsewhere.

It is anticipated that with the expanded program and with growing fundamental interest in study of volcanoes, a period of renewed growth and accomplishment is indicated for the 40-year-old Hawaiian Volcano Observatory.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with UNIVERSITY OF HAWAII

The Hawaiian Volcano Research Association was founded in 1911 for record of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Government, Department of the Interior, National Park Service.

The University of Hawaii cooperates in maintaining a research laboratory at Hawaii National Park. **The Association** and the **University** supplement the work of the government with research associates, instrumental plants and special investigation. Dr. T. A. Jaggar is their geophysicist resident in the National Park.

The Volcano Letter, a quarterly record of Hawaiian volcano laboratories and published by the University of Hawaii, is issued by authority of the Department of the Interior and supplied to a restricted membership and exchange list of the above establishments.

THE VOLCANO LETTER

No. 499 **U. S. Geological Survey** **January—March, 1948**

UNIVERSITY OF HAWAII: T. A. Jaggar, Geophysicist

THE ACTIVE PERIODS OF MAUNA LOA

By R. H. FINCH

Volcanologist, U. S. Geological Survey

This note is intended as a companion one to the discussion of the inactive periods of Kilauea in VOLCANO LETTER No. 497. A similar study of the activity of Mauna Loa, owing to the small percentage of the time it has been active in its recorded history, is simplified if the active periods are used.

Dr. T. A. Jaggar[1,2] and Stearns and Macdonald[3] have made rather comprehensive statistical studies of Mauna Loa outbreaks. There can be but minor differences in the estimates of the small percentage of the time that Mauna Loa has been active. Differences have arisen as to whether some eruptions are to be classed as summit or flank. For example, Jaggar and the writer class the 1832 outbreak as a summit eruption while Stearns and Macdonald class it as a flank eruption. The 1851 outbreak is classed as a flank eruption by Jaggar, though by most definitions it is best classed as summit activity.

A summit eruption is one that takes place in or near the caldera and does not produce a lava flow originating in a rift outside the caldera area. A flank eruption is one that occurs on a rift outside the caldera. The records indicate that all flank eruptions start with short-lived activity at or near the summit. The duration of this preliminary activity varies from a few hours to 2 or 3 days. Such activity at the summit indicates that the ascent of lava from the depths is confined to the feeding conduits under Mokuaweoweo, the caldera of Mauna Loa. The longest dimension of the general breakdown that constitutes the caldera is more than 5 miles northeast-southwest and is roughly parallel to the southwest portion of the main rift of Mauna Loa. The southwestern limits of the caldera are not well defined, as the area has been covered by numerous lava flows some of which continued down the mountain for several miles. It is not surprising, then, that an outbreak may be placed in the caldera by one observer and on the southwest rift by another.

A list of the known eruptions of Mauna Loa and the probable duration of each is shown in Table 1.

The first eruption of Mauna Loa for which there is a definite date started on June 20, 1832. The table shows that during the 115 years and 9 months from this date to the present (March 31, 1948), Mauna Loa has been active 2,718 days, or 6.4 per cent of the time. It is interesting to note that the average duration of the 33 eruptions, starting with that of 1832, is 82 days. This large number is due mainly to four long-continuing eruptions, viz.: 1855-56, 480 days; 1859, 300 days; 1873-74, 560 days; and 1880-81, 275 days.

The first reported eruption of Mauna Loa, which is based on tradition, occurred about 1780. The exact date is not known but reports from different sources place the date definitely about 1780. The Turnbull report of activity in 1803 is quite definite and was probably a summit eruption[4]. The next reported eruption was in 1832. There may have been two or more eruptions between 1780 and 1832 instead of the one that was reported. A review of the records of the 1832 eruption rather definitely makes it a summit one, though there may have been one or more short lava flows from the caldera area. Stearns thought that a recent but un-

dated lava flow from an elevation of about 8,000 feet on the southwest rift above Waiohinu occurred in 1832[5]. Aside from the freshness of the flow there is little to justify such a belief. An old map of the Hawaiian government survey shows a short flow from the east rim of Mokuaweoweo dated 1832. There is no such recent flow at the place indicated on the map. A mile or so to the north and to the southwest there are flows fresh enough to have occurred in 1832. The Goodrich[6] account of the 1832 outbreak states that it lasted from 2 or 3 weeks and that lava flowed from several vents about the summit. The records of later eruptions show that when a flank eruption starts, activity at the summit ceases. The belief that activity in 1832 was confined to the summit seems justified.

In studying the record books of the Volcano House, the hotel on the northeast rim of Kilauea, two different accounts of a summit eruption in 1871 were found. This eruption is not given in the list compiled by Hitchcock and subsequent writers. The first entry in the record book under the date of August 9, 1871, reads, "A great fire to be seen in the Mono Loa Crater." On August 28, the second entry reads, "Faint light at night from the outbreak on Mauna Loa." A search was then made to see if Macdonald[7] had found any reference to this outbreak. The Macdonald bibliography shows that Titus Coan had reported the outbreak in the *American Journal of Science* in 1871. Coan reported that Mauna Loa had been active for weeks prior to August 22, 1871. The record book of the Volcano House indicates that the eruption lasted about a month as there was no activity in Mokuaweoweo early in September, 1871. It seems safe to give a value of 30 days for the duration of activity in 1871.

In accordance with the definition of activity given in the discussion of the inactive periods of Kilauea in VOLCANO LETTER No. 497, the summit eruption of 1887-88 has been included in the table though no molten lava was observed. The intermittent fuming and steaming spell of November, 1943 (VOLCANO LETTER No. 482) has not been included in the list because of the very short duration, the small volume of fume involved, and the fact that it was intermittent.

There is the possibility that occasionally a short-lived summit eruption has escaped notice owing to the remoteness of the summit of Mauna Loa and the fact that it is often obscured by clouds. In 1873, Green[8] noted no glow over the summit of Mauna Loa during three clear nights prior to his ascent of the mountain on June 6, but when the crater rim was reached, a light smoke could be seen drifting away and great fountains were playing. There was insufficient fume to reveal the activity at a distance either by day or night. A characteristic tremor that is recorded on the seismographs

[8] GREEN, W. L. VESTIGES OF THE MOLTEN GLOBE. Honolulu, 1887. P. 167.

during Mauna Loa eruptions indicates that an outbreak can now be detected whether the mountain is visible or not.

It has often been stated that a summit eruption is usually followed by a flank eruption in about two years. Computations made from the preceding graph (Fig. 1) indicate that this relationship holds for only about 56 per cent of the time. The 1832-43 relationship has not been used in these computations as the interval between the two outbreaks was 10½ years. Activity may have been more continuous in 1870-77 than indicated in Figure 1, where seven different summit eruptions are plotted. The 56 per cent was derived by calling this group four instead of seven. The last eight summit eruptions have been followed by flank eruptions 75 per cent of the time with an average interval of 18 months. A summit eruption is thus a factor that may be considered in forecasting flank eruptions.

Hawaiian Volcano Observatory Report for January—March, 1948

VOLCANOLOGY

January

The Mauna Loa seismograph recorded 29 earthquakes during January and 26 were recorded at the Kilauea seismograph. Of the five perceptible shakes felt during the month four originated under Mauna Loa and one under Kilauea.

Landslides from the walls of Halemaumau were especially frequent from January 15 to 18, inclusive.

February

Eight more earthquakes were recorded at Mauna Loa than at Kilauea, or 28 and 20, respectively. Three perceptible shakes originated under the southwest slope of Mauna Loa and one under Kilauea Crater.

The seasonal change in direction of tilt from northeast to southwest occurred about the middle of December. There was a normal accumulation of southerly tilt during February while westerly tilt was distinctly less than normal.

March

Forty earthquakes were recorded during the month. Thirteen more shakes were recorded at Mauna Loa than at Kilauea. The strongest earthquake of the month occurred at 16:18 March 19. It originated deep under Kilauea and was generally felt over the eastern part of the island of Hawaii.

There was a slight accumulation of easterly tilt since the middle of February. As westerly tilt is usual for this season of the year, the easterly tilt gives some indication of a pressure increase under Mauna Loa. The rapid southerly tilt that started at the beginning of the year continued throughout the month.

* For definition of local seismicity, see VOLCANO LETTER No. 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

1. January 3, 06:04, feeble. Felt locally. Under Mokuaweoweo.
2. January 8, 16:15, slight. Felt locally. East slope Mauna Loa.
3. January 10, 17:11, slight. Felt locally. East slope Mauna Loa.
4. January 11, 1:50, very feeble.
5. January 15, 6:16, slight. Felt locally and at Hilo. NE slope Mauna Loa.
6. January 17, 9:50, feeble. Near Hilina Pali.
7. January 18, 12:10, very feeble.
8. January 23, 15:04, very feeble.
9. January 26, 23:02, slight. Felt from Naalehu to Hilo. NE rift Mauna Loa.
10. January 29, 8:55, very feeble.
11. January 31, 10:32, very feeble.
12. February 1, 11:58, feeble. Felt at Naalehu. SW slope Mauna Loa.
13. February 2, 1:12, very feeble.
14. February 2, 22:31, very feeble.
15. February 6, 13:44, very feeble.
16. February 6, 16:17, very feeble.
17. February 7, 8:59, very feeble.
18. February 7, 18:04, very feeble. SW slope Mauna Loa.
19. February 8, 3:56, slight. Kilauea.
20. February 8, 4:18, very feeble. Kilauea.
21. February 8, 7:07, very feeble. Kilauea.
22. February 10, 10:40, very feeble. Mauna Loa.
23. February 12, 4:14, slight. SW slope Mauna Loa.
24. February 20, 9:30, slight. Felt locally. Kilauea.
25. February 20, 9:37, feeble. Kilauea.
26. February 26, 0:52, very feeble. Mauna Loa.
27. February 27, 21:20, very feeble.
28. March 2, 10:05, very feeble. Mauna Loa.
29. March 2, 17:07, very feeble.
30. March 5, 2:43, very feeble. Mauna Loa.
31. March 9, 8:30, very feeble. Mauna Loa.
32. March 9, 15:46, slight. Felt from Hilo to Kona. Off coast north of Hualalai.
33. March 16, 3:43, very feeble.
34. March 19, 16:18, moderate. E–W dismantled. Felt from Hilo to Naalehu. Deep under Kilauea.
35. March 19, 23:09, very feeble. Felt at Naalehu.
36. March 26, 6:08, feeble. Mauna Loa.
37. March 27, 1:03, very feeble.
38. March 27, 11:44, very feeble.
39. March 30, 0:53, very feeble.
40. March 31, 8:41, very feeble. Mauna Loa.
41. March 31, 16:44, very feeble.

TELESEISMS

January 13, 16:55, slight. 1200 km. north of Easter Island.
January 24, 8:20, slight. Philippines.
January 27, 2:06, slight.
February 29, 15:30, slight. New Guinea.

MICROSEISMS

Microseisms were moderate to strong January 23–31 and February 8–10 and moderate March 26–31. They were present though slight on other days.

CRACK MEASUREMENTS

Despite many slides from the walls of Halemaumau during the middle of January all cracks that were measured showed but little or no movement during the quarter.

TILTING OF THE GROUND

The southerly tilt that was continuous throughout the quarter was slightly greater than usual. There was about the usual accumulation of westerly tilt until February 20. From this date until March 31 there was an accumulation of one second of arc of easterly tilt. As there is normally a westerly tilt during this season of the year one second of easterly tilt may actually be greater than the figure indicates. Past records suggest that an easterly tilt is an indication of increase of pressure under Mauna Loa.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter,** a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE TELESEISM ANNUNCIATOR AT THE HAWAIIAN VOLCANO OBSERVATORY

By BURTON J. LOUCKS

Instrument Maker, U. S. Geological Survey

The Hawaiian Volcano Observatory has issued warnings of the possibility of a tsunami or tidal wave on several occasions. The warnings were based on the seismograms of distant earthquakes and were made only when the fact that a strong shake had occurred was discovered during routine attention to the seismographs. The disastrous tidal wave of April 1, 1946,[1, 2] brought forcibly to mind the need for immediate discovery of the recording of potential tsunami-producing earthquakes regardless of the time of occurrence.

The April 1, 1946, earthquake started recording on the Observatory seismographs at 2:06 A.M. but it was not noted until the record was changed at 7:30 A.M., over half an hour after the waves reached Hilo. If the record had been seen earlier, a warning of the possibility of a tidal wave would have been issued. Experience had taught that the amplitude and distance to origin were such as to indicate the possibility of a tidal wave.[3]

In cooperation with the Hilo Chamber of Commerce, an earthquake annunciator was set up in the seismograph vault of the Hawaiian Volcano Observatory on December 16, 1946. The installation is intended to be only a stopgap to function until the U. S. Coast and Geodetic Survey station at Barbers Point, Oahu, is in operation.

[3] FINCH, R. H. ON THE PREDICTION OF TIDAL WAVES. Proc. 2nd Pacific Science Congress, Australia, 1923. P. 1368.

The instrument consists of a horizontal seismograph pendulum with a boom and magnifying lever (Fig. 1). Whenever a quake of appreciable amplitude occurs, the long arm of the lever makes alternate contact with two pools of mercury (Fig. 2) and closes an electrical circuit. In this circuit (Fig. 3) is a buzzer that is audible in the Observatory building and a relay that closes another circuit with buzzers located in the residences of two members of the Observatory staff. One component of the Hawaiian-type seismograph is used. The heavy mass is a 3-foot section of 8-inch steel pipe filled with sand. The pipe is bolted into a framework of steel 2 by ½ inches with about 3 inches projecting out at the back, both top and bottom. These projections are slotted and 1½-inch pieces of No. 20 music wire with retainers on the ends are inserted in the slots and corresponding ones in the adjustable back plate to suspend the heavy mass as a horizontal pendulum. An aluminum boom is secured to the pipe framework and projects forward about 4 feet from the hinge line. The forward end of the boom is coupled to the magnifying lever by a thin piece of brass with cups that fit over phonograph needles in the end of the boom and of the short arm of the lever. A piece of steel wire which projects downward about ½ inch from the end of the long arm of the magnifying lever makes contact with the mercury when the pendulum oscillates or becomes displaced by tilt. Two brass rods project up from the lever support on either side of the end of the boom to act as buffers in case of strong local shakes. The buffers are wired into the electrical circuit. If a strong local earthquake dis-

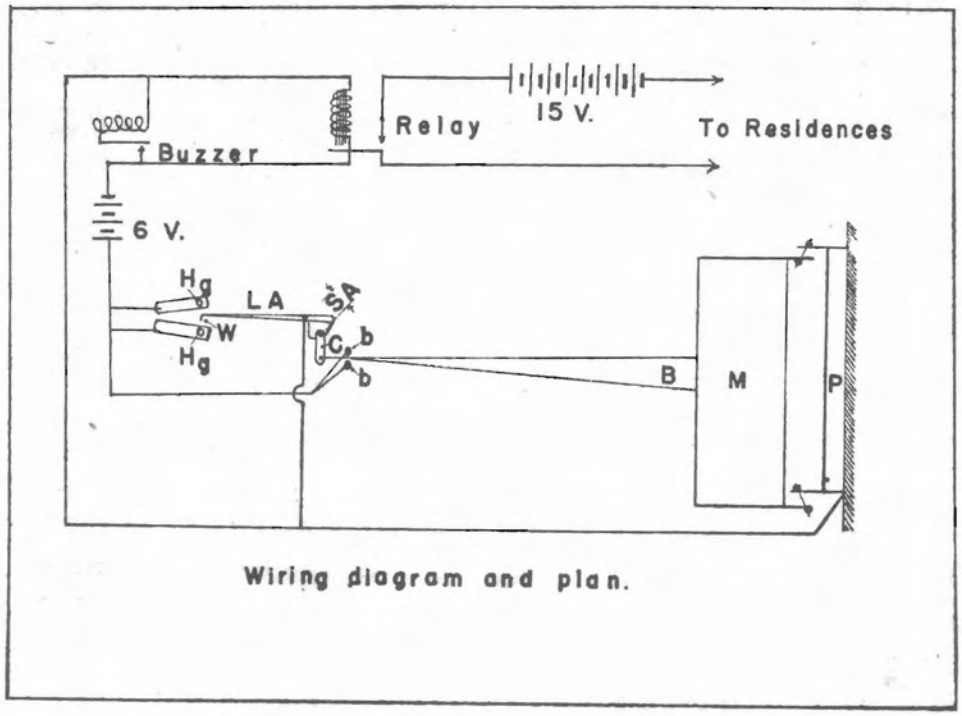

Figure 3. Wiring diagram and plan of the teleseism annunciator. Letters correspond to those in Figure 2.

mantles the instrument by throwing off the coupling mentioned above, it will still continue to function as an annunciator by means of the buffer contacts, though with diminished sensitivity.

The pools of mercury are in steel bars mounted on a piece of insulating material and are 1⅝ inches apart. When first set up they were only ¾ of an inch apart. Tilt due to daily temperature changes was so great that it was found necessary to increase the distance.

When the instrument was first installed, it was operated with a period of 12 seconds. To reduce the trouble due to tilt, the period was reduced to 7 seconds. The pendulum is undamped.

The instrument has been quite satisfactory and has announced several local earthquakes as well as a few teleseisms. It gave a good warning signal for the teleseism of May 14, 1948, which caused the tidal wave warning system in the Territory to be put into operation. This earthquake was the only one announced which was deemed to have sufficient amplitude and proper distance to justify a warning of the possibility of a tidal wave.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR APRIL-JUNE, 1948

VOLCANOLOGY

April

Forty-two earthquakes were recorded in April. Thirty-eight of the quakes were recorded on the Mauna Loa seismograph and 14 at Kilauea. The felt earthquakes which occurred at 00:25 April 26 originated near the north end of the Kilauea caldera. The facts that the shake was slight to moderate at the Observatory and was recorded as a tremor only on the Mauna Loa seismograph 10 miles away, indicate a very shallow focus.

The strong southerly tilt that set in about the first of the year continued until the last of April.

May

The earthquakes which occurred in May had widely scattered origins, as in the past several months. Twenty-eight quakes were recorded during the month, the majority of which originated under various portions of Mauna Loa. Twenty-five of the shakes were recorded on the Mauna Loa seismograph and 11 at Kilauea.

The accumulation of seasonal westerly tilt during the first 5 months of the year was the smallest for several years, and the records indicate that this may be taken as a suggestion of a slight pressure build up under Mauna Loa. The unusually sharp southerly tilt which began the first of the year ceased early in May.

A conspicuous steam cloud was observed over Mokuaweoweo at sunset on May 16 and on several other days during the month. Such observations are rather common at this season of the year.

June

Thirty local earthquakes were recorded in June. Of this number 28 were recorded on the Mauna Loa seismograph and 18 at Kilauea.

There was no accumulation of tilt during the month. The lack of westerly tilt rather than a positive easterly tilt is the only indication of a pressure build up under Mauna Loa.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

42. April 5, 11:23, very feeble.
43. April 6, 0:25, slight. Felt locally. Shallow under northern end of Kilauea caldera.
44. April 6, 19:53, very feeble.
45. April 6, 22:12, very feeble.
46. April 14, 9:01, very feeble.
47. April 15, 3:37, very feeble. Kilauea.
48. April 24, 10:05, slight. Felt locally and at Hilo. East slope of Mauna Loa.
49. April 24, 23:59, feeble. Felt locally. Mauna Loa.
50. April 28, 20:53, very feeble.
51. April 30, 0:51, very feeble. Mauna Loa.
52. May 20, 20:04, very feeble. Under Mokuaweoweo.
53. May 22, 11:34, slight. Deep under Hualalai.
54. May 24, 23:16, slight. Felt locally. N.E. rift of Mauna Loa.
55. May 26, 0:39, feeble.
56. May 29, 16:29, very feeble. Under Mokuaweoweo.
57. May 29, 18:45, very feeble.
58. June 1, 7:34, feeble. Felt at Ainahou.
59. June 2, 21:13, very feeble.
60. June 3, 8:58, very feeble.
61. June 5, 12:08, very feeble.
62. June 6, 10:17, feeble. Kilauea.
63. June 18, 6:05, very feeble.
64. June 19, 17:06, slight, Felt locally, East slope of Mauna Loa.
65. June 24, 17:49, feeble.
66. June 25, 10:18, feeble. Kilauea.
67. June 25, 13:05, feeble. Felt locally. Mauna Loa.
68. June 26, 1:42, slight. Under Oahu; felt at Hilo.
69. June 28, 10:51, very feeble.

TELESEISMS

May 14, 12:40, moderate. Aleutians.
May 17, 7:57, slight. South of Alaska peninsula.
June 17, 3:04, slight.
June 29, 0:36, slight.

MICROSEISMS

Microseisms were moderate on April 9, 10, 24, and 25 and slight on other days.

CRACK MEASUREMENTS

A few of the cracks that were measured in the vicinity of Halemaumau rim showed slight openings.

TILTING OF THE GROUND

Seasonal southerly tilt, which was stronger than usual during the first 4 months of the year, continued until May 4, when a slight northerly tilt began. The seasonal change from westerly to easterly tilt occurred on June 9.

UNIVERSITY OF HAWAII: T. A. Jaggar, Geophysicist

THE NEW LOCATION OF THE HAWAIIAN VOLCANO OBSERVATORY

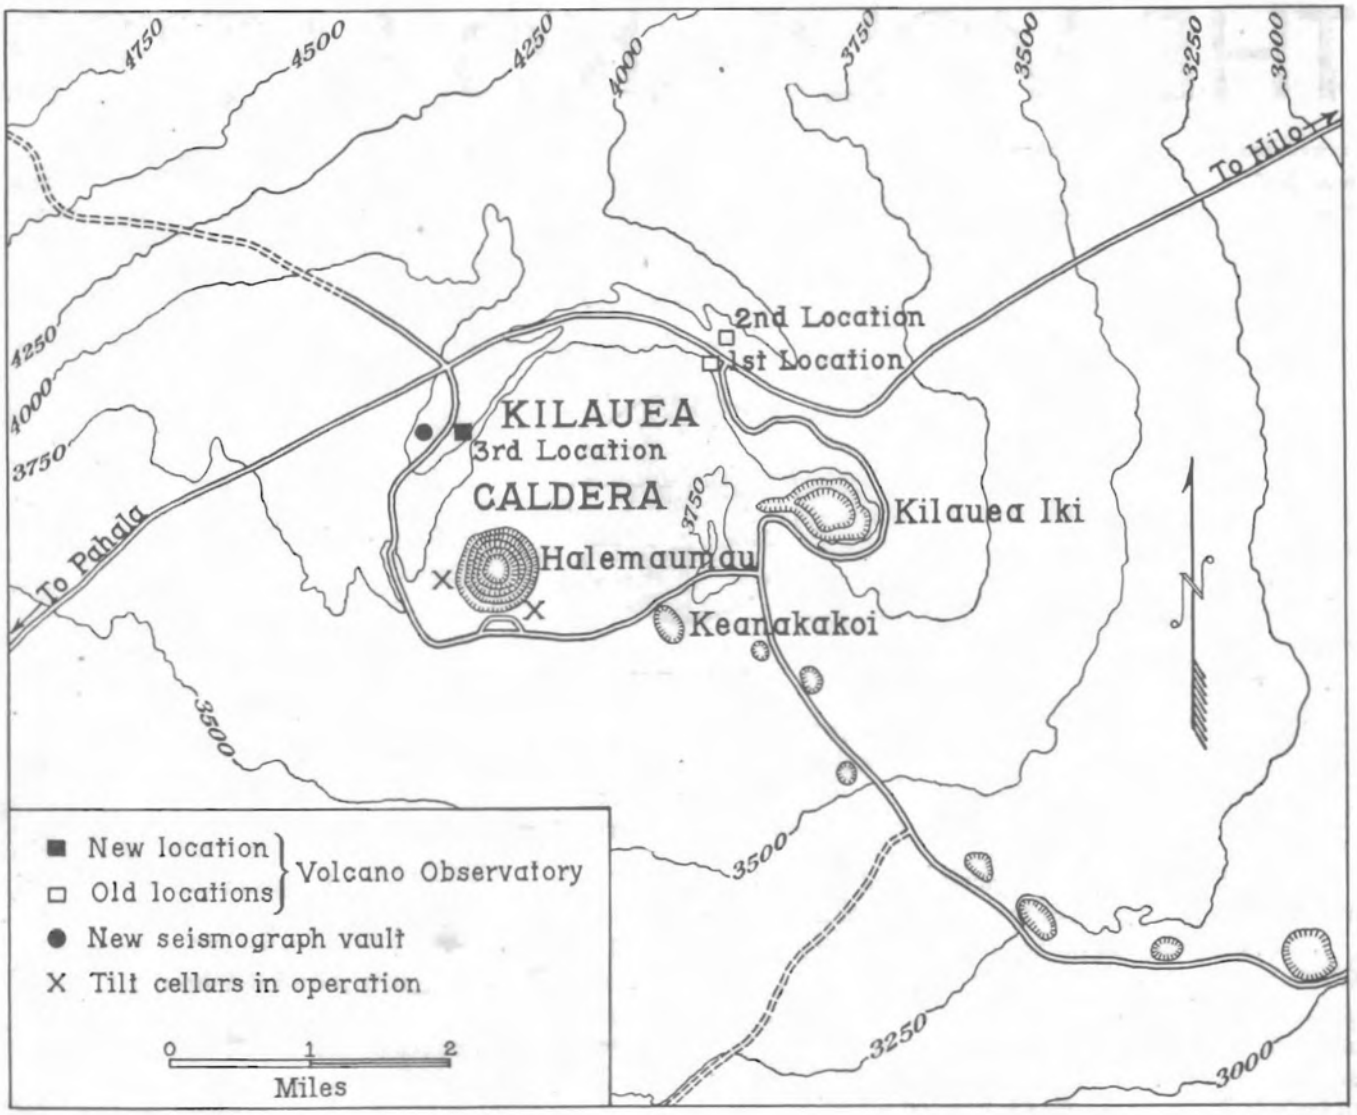
By RUY H. FINCH

Volcanologist, U. S. Geological Survey

One of the results of the transfer of the Hawaiian Volcano Observatory from the National Park Service to the U. S. Geological Survey is the establishing of the Observatory in a new location. It is being moved to the old National Park Museum and Lecture Hall buildings at Uwekahuna Bluff on the western rim of Kilauea Caldera (see figure). The buildings have been remodeled to include offices, shops, and laboratories.

The Observatory was located on the northeast rim of the Caldera from the time it was established in 1912 until 1941, when it was moved 600 feet back from the rim into the newly constructed Observatory and Naturalist Building. The vertical seismograph and a tilt meter were placed in a cellar under this building. The Bosch-Omori seismograph, the principal instrument of the Whitney Laboratory of Seismology, was left in its old location[1] under a concrete slab and 18 inches of soil.

Both the first and second locations of the Observatory were on badly fissured basalt with numerous steam cracks. Because the concrete floor was built over steam cracks, the temperature of the cellar at the original location is about 95° F. the year around. For similar reasons the cellar of the second location has a constant temperature of about 85° F. The mean annual air temperature of the area is about 61° F. A commercial highway passes about 200 feet from each cellar, and the records are marred by the frequent passing of heavy trucks.



[1] Volcano Letter 475, 1942.

Tilt records have been taken from the Bosch-Omori seismograph since 1913. The instrument has been operated since 1919 with a period of about 7.7 and a magnification of about 115. It is proposed to operate this seismograph in its present location for another year before removal to the new cellar near Uwekahuna (see figure). This will afford an opportunity to correlate tilt records of the two locations, one on the northeast rim and the other on the northwest.

The Bosch-Omori seismograph tilt records do not correlate well with those obtained from a special tilt pendulum under the Observatory–Naturalist Building. When the numerous fissures of the area are considered, this is not surprising. Despite the nearly constant temperature of the second cellar, the tilt records obtained here were marred by the large tilt produced by diurnal temperature changes in the superstructure. The tilt data measured at the original location of the Observatory are real as they have been checked by leveling.[2]

The new location of the Observatory is at an elevation of 4,075 feet a short distance southerly from the highest point on Kilauea Mountain. It is 1 mile northwest from the center of Halemaumau just off the Crater Rim Road. The site affords a good view of Kilauea Caldera, the southwest rift, and part of the Puna rift as well as

[2] JAGGAR, T. A., and FINCH, R. H. TILT RECORDS FOR THIRTEEN YEARS AT THE HAWAIIAN VOLCANO OBSERVATORY. Bull. Seis. Soc. Amer. Vol. 19, No. 1, 1929. See also leveling data in T. A. Jaggar, Memoir 21, Geol. Soc. Amer., pp. 208–214, 1947.

Map showing the positions of the successive locations of the Hawaiian Volcano Observatory, the new seismograph vault, and the tilt cellars now in operation.

Mauna Loa. This was the first site selected by Dr. T. A. Jaggar for the Observatory in 1912 but was given up on account of the scarcity of water and its relative inaccessibility at that time.

A new seismograph cellar has been constructed 1,250 feet nearly due west of the Uwekahuna Bench Mark. The new cellar is 1⅛ miles from the center of Halemaumau, about 1 mile closer than the old cellar. It is 450 feet from the Crater Rim Road and about 2,000 feet from the around-the-island highway. The cellar is 12 x 20 feet with an entrance way 5 x 8 feet to serve as an air lock and processing room. The roof is a reinforced concrete slab covered with about 18 inches of volcanic ash. The foundation of the cellar is within massive basalt which lies under 20 inches of ash. There is only one visible fissure between the cellar and the Caldera rim. During the week ended September 16 a thermograph trace made in the cellar showed a drop of less than 1½° F. This record, which was obtained during a dry spell, showed a diurnal variation of about ½° F. The maximum was reached about 6:00 p.m.

The first instrument installed was a portable tilt meter oriented to measure east–west tilt. For the first 2 weeks values obtained seemed to be due largely to cellar floor and instrumental adjustments.

Two tilt meters and the vertical seismograph will shortly be installed in the new cellar. In about a year the Bosch-Omori seismograph will be moved over, and later on it is planned to install a higher-magnification instrument.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY–SEPTEMBER, 1948

VOLCANOLOGY

July

Forty-one earthquakes were recorded during July. Thirty-seven of the shakes were recorded at Mauna Loa and 19 at Kilauea. Six of the seven earthquakes recorded on July 30 were perceptible. They originated at a depth of about 6 miles to the east of Kilauea Caldera. These quakes furnish the most conspicuous signs of uneasiness under Kilauea that have been noted during the last 3 years.

Seasonal northerly tilt during July was slightly greater than usual.

August

Only 27 earthquakes were recorded during August. Eleven of the shakes were recorded at Kilauea and 23 at Mauna Loa. The uneasiness at Kilauea which was quite distinct on July 30 did not continue. The only perceptible quake recorded during August (at 03:04, August 3) had a shallow origin under the northeast rift of Mauna Loa.

There was no accumulation of tilt in the east–west direction during the month. The north–south tilt curve shows an accumulation of northerly tilt greater than in 1946 or 1947. This may be taken as an indication of a slight pressure build up under Kilauea.

September

The majority of the 30 earthquakes recorded during September originated under Mauna Loa. Twenty-one of the shakes were recorded at Kilauea and 26 at Mauna Loa. The strongest of these shakes occurred at 8:20 a.m., September 13. It originated at a depth of 20–25 miles below the surface between Hilo and Mauna Kea.

The north–northeast tilt during the month of September was about normal for this season of the year.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

70. July 3, 18:14, very feeble, Mauna Loa.
71. July 12, 0:29, very feeble. Felt at Naalehu.
72. July 17, 6:11, very feeble. Felt at Naalehu.
73. July 19, 10:08, very feeble. Kilauea.
74. July 24, 13:19, feeble. Felt locally and at Hilo. Mauna Loa.
75. July 30, 2:28, moderate. Awakened some people. East of Kilauea Caldera.
76. July 30, 2:31, moderate. Same location as No. 75.
77. July 30, 2:44, slight. Same location as No. 75.
78. July 30, 12:28, feeble. Same location as No. 75.
79. July 30, 16:46, slight. Same location as No. 75.
80. July 30, 16:56, slight. Same location as No. 75.
81. August 1, 8:59, very feeble.
82. August 3, 3:04, moderate. Felt locally and at Hilo. NE rift of Mauna Loa.
83. August 4, 15:59, very feeble. Kilauea.
84. August 6, 14:23, very feeble. NE rift of Mauna Loa.
85. August 8, 5:14, very feeble. Felt locally. Mauna Loa.
86. August 10, 6:38, very feeble. Mauna Loa.
87. August 29, 17:48, very feeble. Mauna Loa.
88. August 29, 17:49, very feeble.
89. September 3, 20:31, very feeble.
90. September 4, 7:36, very feeble. Near Mokuaweoweo.
91. September 5, 8:01, feeble. Felt locally and at Hilo. NE rift of Mauna Loa.
92. September 5, 8:52, very feeble. Mauna Loa.
93. September 7, 11:05, feeble. Felt locally. Mauna Loa.
94. September 13, 8:20, moderate. Generally felt on east half of island. 20–25 miles deep, SE of Mauna Kea.
95. September 15, 9:45, slight. Near Mokuaweoweo.
96. September 18, 22:23, very feeble. Mauna Loa.
97. September 19, 14:51, very feeble. Mauna Loa.
98. September 21, 18:44, feeble. Mauna Loa.
99. September 28, 3:53, very feeble. Mauna Loa.

TELESEISMS

July 14, 12:48, slight. Near New Guinea.
July 15, 1:12, slight. Off coast of Mexico.
July 15, 20:30, slight.
July 22, 10:22, slight. Off west coast of Vancouver Island.
July 22, 11:10, slight.
September 8, 5:17, slight. Near Tonga.

MICROSEISMS

Microseisms were moderate during the latter half of September and slight on other days.

CRACK MEASUREMENTS

The cracks measured in the vicinity of Halemaumau rim were either stationary or opened only slightly.

TILTING OF THE GROUND

Easterly tilt was unusually slight but nearly continuous throughout the quarter. Northerly tilt was continuous and a little greater than in the past two years.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter,** a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

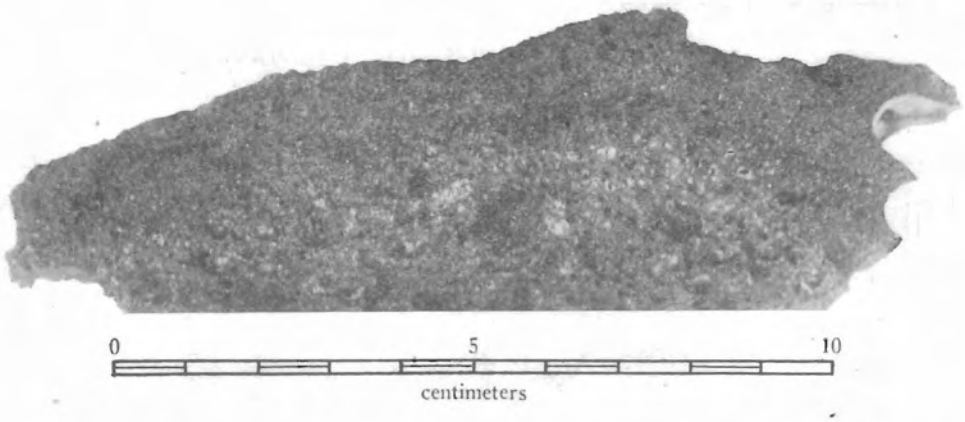
FLOW-PUMICE ON HAWAIIAN BASALTS

By R. H. FINCH, HOWARD A. POWERS, and GORDON A. MACDONALD

U. S. Geological Survey

Mauna Loa is a large, elongate shield volcano, built of lava flows of primitive olivine basalt to an altitude exceeding 13,600 feet above sea level and 30,000 feet above the ocean floor. Most eruptions take place from fissures in two rift zones which meet in a summit caldera. All known eruptions have started in the summit region. In some, activity is confined to the summit; in others, after brief summit action, the main eruption breaks through fissures in the flank of the mountain. In historic time, Mauna Loa has not established and maintained a lake of fluid lava comparable to the lake which has been typical of much of the historic activity of Kilauea.



Cones of pyroclastic material have been built around Mauna Loa vents where lava fountaining has persisted for more than a few hours. Most cones contain much pumice. In addition, a skin of pumice is found on thin, short flows adjacent to eruptive fissures both in the summit area and along the rift zones. The material has previously been observed[1] and studied[2] but without regard to the process of formation.

The flow pumice, as much as an inch in thickness, is composed of basaltic glass, drawn out into thin vesicle walls, which are brown in color. Most of the vesicles are small, and only slightly elongated in the direction of flow of the lava. A few much larger elongated cavities are scattered through the pumice skin. A cube of the flow-pumice chosen to contain the least possible number of larger gas cavities has a gross density of about 0.6; the density of the glass is about 2.7. Thus, the porosity of the pumice due to gas inflation is about 75 percent. The pumice grades abruptly into a layer of vesicular black glass in which the vesicle walls are thicker and the vesicles are larger and less numerous. The layer of black glass grades into the grossly vesicular, partly crystallized rock which forms the bulk of each flow layer of lava. In this inner part, the gas cavities are so large that gross density determination is impractical; but by inspection, the gross porosity of the interior is of the same order of magnitude as that of the surface pumice.

Several details of the field occurrence of the pumice aid in interpreting the process of its formation. At the margin of many of the pumice-covered flows, the last ooze of liquid which formed the toe of the flow was quenched at its exposed surface into vesicular black glass rather than into true brown pumice. Elsewhere, the pumice-covered crust had cracked in places, allowing interior fluid to ooze upward through the cracks. Surface quenching of this residual liquid also produced the vesicular black glass rather than brown pumice. It is apparent in the field that the emplacement of these pumice-covered flows was completed in but a few minutes. During this short time, the liquid of the interior

Specimen of pumice-surfaced lava collected from the 1942 summit flow of Mauna Loa. The pumice is brown, nearly ½ inch in thickness, and grades abruptly into black vesicular glass. Photo by V. R. Bender, National Park Service.

part of the flow, insulated by the skin of pumice, lost enough of its dissolved volatile component but retained enough heat so that oozes of it which reached the air were quenched as black glass. In many other places, only small patches of the pumice-surfaced flows remain exposed because they have been buried by gushes of less gas-rich lava extruded later in the same eruption. These later gushes have congealed with the more common skin of black glass.

Pumice-covered pahoehoe from the 1942 summit activity is exposed throughout an area of about a quarter of a square mile; in an equally large area it is now buried. Lava flows extruded from nearly 4 miles of open fissure during less than 10 hours of eruption cover a total area of 3⅓ square miles. Flows distant from the fissure have an aa surface; the flows near the fissure have a pahoehoe surface. The pumice-surfaced pahoehoe is restricted to gushes of lava which traveled less than a quarter of a mile from their vents. The main flow of 1942 issued from a fissure in the northeast rift zone at an altitude below 9,400 feet, and began about 24 hours after the summit activity had ceased. There is very little pumice-surfaced pahoehoe at this lower fissure, though pumice is plentiful in the pyroclastic cone which was built around the persistent lava fountains. Abundant pumice-surfaced lava is associated with some of the older flank fissure vents, but the pumice was clearly formed only on the earliest gushes of lava.

These occurrences of pumice contribute some data on the time and manner of escape of volatiles from basaltic magma in the Hawaiian volcanoes. Separation of some volatiles from the liquid must have taken place during its rise in the feeding dikes, because fountaining at the vents indicates bursting of gas bubbles, and many larger gas bubbles have left cavities in the pumice formed both at the fountains and on the pahoehoe flows. However, the formation of pumice among the pyroclastic products and as a skin on lava flows indicates that the liquid reached the surface with sufficient volatiles in solution to inflate it to four times in subsurface volume. The fact that pumice does not form on lava surfaces more than a few hundred yards in distance and a few minutes in time away from the point of emission suggests that the release of volatiles involved is nearly explosive in its rapidity and occurs as soon as the magma appears at the surface. Inherently, the great bulk of the congealed products of eruption can give evidence only of the fact that volatile constituents were present and did escape; evidence of the time and manner of this escape is found only in the small amount of material which was quenched as fountain product and as the surface phase of short flows very near the vents.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR OCTOBER–DECEMBER, 1948

VOLCANOLOGY

October

Forty-nine seismic disturbances were recorded at Mauna Loa and 44 at Kilauea. Nearly all of the 76 individual earthquakes were very weak. The majority originated either under Kilauea Caldera or along the northeast rift of Mauna Loa.

North–northeast tilting of the ground on the northeast rim of Kilauea continued at a rate normal for this season of the year.

Moderate amounts of sulphurous fume were observed in the summit crater of Mauna Loa on October 5 and 6.

November

Fifty-two seismic disturbances were recorded during the month. Though the numbers recorded at Kilauea and Mauna Loa were 44 and 38 respectively, the majority of the more distinct shakes originated under Mauna Loa.

The rapid easterly tilt that marked the first half of the month ceased on November 14, and there was no accumulation of tilt in the east–west direction during the last half. There was no accumulation of north–south tilt in November.

December

There was no visible activity at any Hawaiian volcano during 1948. Tilt and earthquake data indicate that there was also a lack of any appreciable subterranean activity.

Seventy-five local earthquakes were recorded during December. Seventy-two of these were recorded at Mauna Loa and 61 at Kilauea. A majority of the earthquakes were weak and originated on the northeast rift of Mauna Loa.

The seasonal change from easterly to westerly tilt occurred on December 2, and there was a slight accumulation of westerly tilt during the month. Seasonal northerly tilt continued until December 27, when normal southerly tilt set in. There was a slight accumulation of easterly tilt during 1948.

TELESEISMS

October 5, 11:15, slight. Near northern Iran.
December 3, 14:32, slight. Off west coast of Mexico.
December 4, 14:01, slight. Southern California.
December 30, 14:00, slight.

MICROSEISMS

Microseisms were strong October 18–25 and November 1–12 and moderate during the rest of the quarter.

CRACK MEASUREMENTS

A few of the cracks near the Halemaumau rim showed a slight opening, though a majority of the cracks that were measured showed no appreciable movement.

TILTING OF THE GROUND

There was a rapid accumulation of easterly tilt from October 27 to November 14. The seasonal change to westerly tilt occurred on December 2. During the year of 1948 there was an accumulation of easterly tilt. Normal northerly tilt continued to December 27, when seasonal southerly tilt set in. Northerly and southerly tilt were about equal in 1948.

THE MAUNA LOA ERUPTION OF JANUARY, 1949

By GORDON A. MACDONALD and RUY H. FINCH

U. S. Geological Survey

HISTORY OF THE ERUPTION

Mauna Loa resumed eruptive activity on January 6, 1949, after a period of quiescence of 6 years and 8 months. The eruption, which was confined to the summit caldera, Mokuaweoweo, and to the uppermost part of the southwest rift zone, is to be classed as a summit eruption. Following the flank eruption of 1942 on the northeast rift, it thus continues the alternation of summit and flank eruptions which has existed since 1926.

At 4:15 p.m. on January 6 a dull rumbling was heard at the Hawaiian Volcano Observatory, apparently originating at the summit of Mauna Loa, 20 miles away. From the Observatory, the summit was hidden by a heavy cloud layer along the southeastern slope of the mountain; but from Hilo to Mountain View, on the eastern slope, the view of the summit was unobstructed. At about 4:00 p.m. B. F. Moomaw of the National Park Service saw, from the highway a short distance southeast of Olaa, a puff of fume rising from the summit. At about 3:45 or 3:50 p.m. Mrs. Walter Eklund observed fume at the summit of the mountain, from the highway in southern Kau. The registration of continuous tremor on the Bosch-Omori seismograph at Kilauea began at 3:47 p.m., indicating the movement of magma in the conduit at that time.

The precise time of beginning of the eruption thus is uncertain. It seems probable that some harmonic tremor may have preceded arrival of the magma at the surface, and therefore the probable time of beginning of surface lava activity may be placed between 3:50 and 4:15 p.m. The arrival of lava at the surface may have been preceded by an increase in the amount of fume being liberated at the summit of the mountain.

The heavy rumbling sounds, audible 20 miles away, indicate that some of the early bursts of gas liberation were of explosive violence. There is no known previous instance of such sounds, originating in summit activity of Mauna Loa, being audible at Kilauea. The audibility may have been partly the result of reflection from a high cloud layer which extended above the summit of Mauna Loa at the time. The strength of the early bursts is further indicated by the finding of pumice at 11,000 feet altitude on the northeastern flank of the mountain, 7 miles from the nearest lava fountains, and of Pele's hair at Kulani Camp, 20 miles east of the fountains.

The lava broke out along a fissure which extended south-southwesterly across the floor of Mokuaweoweo caldera from a point north of its center, up over the boundary cliff of the caldera, and about 1.7 miles down the southwestern flank of the mountain. The distribution of glow, as seen from the Volcano Observatory, indicated that lava fountaining was nearly, if not completely, continuous along this crack, a distance of about 3 miles. On the morning of January 7, D. H. Hubbard of the National Park Service observed the activity from the air and reported that two fountain areas were still active on the southwest rift. However, by the morning of January 9 aviators reported only fume along the fissures outside the caldera, except for very weak intermittent fountaining and short flows at one point. As is usual with summit eruptions of Mauna Loa, activity outside the caldera lasted only a relatively few hours. Within 24 hours it was largely over, and within 72 hours activity was entirely confined within the caldera.

The short-lived fountains, on the upper part of the southwest rift outside the crater, gave vent to a copious outpouring of lava during the first few hours of the eruption. This lava formed several short flows in addition to one long flow which moved rapidly westward just north of, and partly overlying, the lava flow of 1851. (See figure 1.) In its first 24 hours, this flow advanced about 6 miles. It was short-lived, however; with the dying of fountain activity outside the caldera the supply of lava was cut off, and by January 8 the flow appeared to be essentially dead. The lower end of the flow reached an altitude of about 8,500 feet, 6.5 miles from its source.

On the afternoon of January 7, lava fountain activity within the caldera itself had become restricted to two short lengths of the fissure. North of the 1940 cinder cone, near the middle of Mokuaweoweo, a nearly continuous line of fountains half a mile long played to an average height of about 50 feet with occasional bursts up to about 150 feet. As nearly as could be ascertained, these fountains were situated on or close to a zone of fuming fissures which had been observed by Macdonald and Powers in October 1948 (VOLCANO LETTER 502). From these fountains a small lava stream moved westward, forming a pond of lava between them and the western caldera wall; another larger flow was moving eastward.

The other active portion of the fissure was situated at and close to the base of the southwestern wall of the caldera. There a small fountain played intermittently from the fissure directly at the base of the wall, with occasional spurts from the fissure part way up the wall; a much larger and steadier fountain played a short distance out from the wall on the caldera floor. The larger fountain shot constantly to heights of 150 to 200 feet, with occasional bursts as high as 300 feet. The fountains at the southwestern edge of the caldera sent a flow northward into the caldera west of the 1940 cone joining the flow from the more northerly group of fountains, and another flow eastward. The flow to the east divided, sending one branch in the direction of South Pit and another northeastward along the base of the caldera wall. The latter branch joined the flow from the northern fountain-chain, leaving the 1940 cinder cone and part of its surrounding lava shield protruding as an island in the

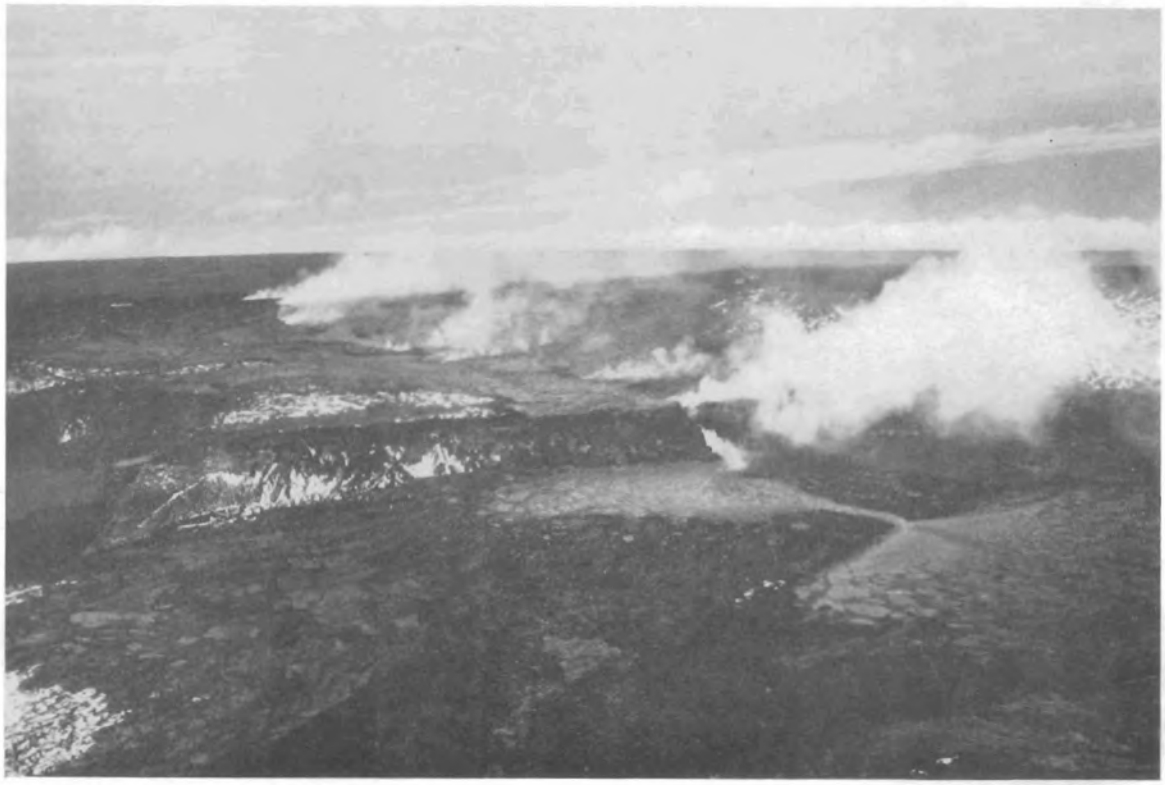

PLATE 1. Eruptive fissure extending up over the southwestern wall of Mokuaweoweo caldera and on down the southwest rift zone of Mauna Loa, on the morning of January 7, 1949. Large lava fountains are playing from the fissure at the base of the caldera wall, and smaller ones can be seen in the background along the southwest rift. In the foreground, new lava is pouring onto the caldera floor, and to the left into South Pit. OFFICIAL PHOTOGRAPH, U. S. NAVY.

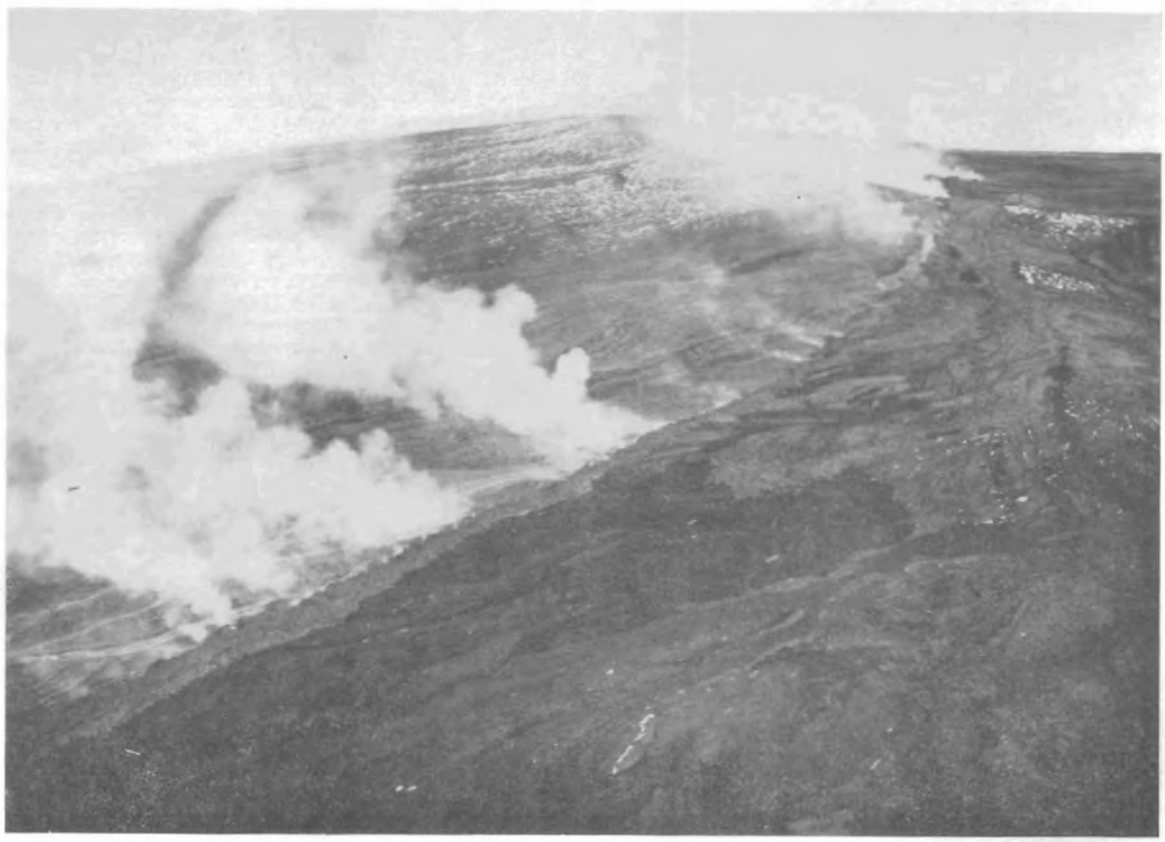

PLATE 2. Spatter rampart and small lava fountains along the fuming fissure on the upper part of the southwest rift zone on the morning of January 7, 1949. The upper part of the western lava flow is visible just left of the fissure. Mokuaweoweo caldera and the summit of Mauna Loa are in the background. OFFICIAL PHOTOGRAPH, U. S. NAVY.

new lava. The eruptive fissure split the 1940 cone and the cone was fuming strongly. During the earliest hours of the eruption a small amount of lava spilled from the fissure at the base of the cone, but by the morning of January 7 these flows were dead and had been partly buried by lava from the northern and southwestern fountains. By the afternoon of January 7 more than two-thirds of the caldera floor had been flooded with new lava, largely pahoehoe.

The fountain-chain near the center of Mokuaweoweo was as short-lived as the fountaining outside the caldera. At 2:00 p.m. on January 9 a Navy pilot reported that the fountains in the middle of the caldera had entirely stopped although the spatter rampart built by them was still fuming strongly. At that time, and for the next several days, reports from planes flying over the mountain indicated that the fountains at the base of the southwest wall were continuous but were varying greatly in the strength of their activity. Lava from them continued to pour both into the caldera and into South Pit. Fountain activity was building a cinder cone against the caldera wall.

For a week or more the southwestern fountains appear to have remained of small, although variable, size. After that, however, they greatly increased in height, ultimately becoming what may have been the highest fountains yet observed on Mauna Loa. On January 19, a United Airlines pilot reported two large fountains, 400 to 500 feet high. On January 21, Frank Hjort and James Orr of the National Park Service reported two fountains, one shooting from the fissure in the lower part of the caldera wall, and the other on the caldera floor about 100 feet from the wall. The fountains were building a compound cinder and pumice cone. The wall-fountain was the smaller of the two. The larger fountain they estimated to be 300 to 500 feet high. On January 23, Orr and D. H. Hubbard estimated the height of the large fountain to be well over 500 feet with some of the higher bursts possibly reaching more than 800 feet. These very high fountains, together with strong shifting winds, resulted in wide distribution of Pele's hair over the southern part of the island, from Napoopoo on the western coast, 21 miles from the summit of Mauna Loa, to the Kau Desert and Kilauea caldera, an equal distance southeast of the summit. The high fountains produced an exceptionally large amount of pumice. The accumulation of this pyroclastic pumice around the vent built up a pumice cone which was banked against the caldera wall and eventually overtopped it, projecting approximately 100 feet above the old rim of the caldera at that point, and resting partly on the outer slope of the mountain. (See figure 2.) West of the cone a blanket of pumice covers an area about a mile long and half a mile wide and attains a depth of as much as 20 feet near the base of the cone.

Hjort and Orr report that on the night of January 21 the two fountains were inclined somewhat toward the east and that most of the ejecta fell into a pool of lava at the eastern, breached side of the cone. Thence the lava moved eastward in a pahoehoe river about 75 feet wide, spreading into aa flows about half a mile from the vent. During the afternoon and evening there was no evidence of lava moving into South Pit. At 3:00 a.m. on January 22 there occurred a moderate earthquake, which apparently broke the rim of the pool at the east base of the cone and allowed two new flows of aa to pour into South Pit. At that time most of the early floods of pahoehoe on the caldera floor had been buried by later flows of aa. The South Lunate Platform, which in 1914 formed a conspicuous crescentic bench at the southern end of the caldera, had been almost wholly buried by new flows. Its north-facing escarpment, now totally obliterated, had been progressively lessened in height by infilling of the inner pit of the caldera in 1933 and 1940.

On January 23, Orr reports, the fountains were pulsating, the wall-fountain with a period of about 3 seconds and the larger fountain with a period of about 1 second. The temperature of the wall-fountain appeared to be a little higher than that of the larger fountain.

The lava fountaining was accompanied by the liberation of huge volumes of fume, smelling strongly of sulfur dioxide. On January 26 the pale brown fume cloud could be seen extending at least 30 miles southwest of the summit of the mountain. On February 1 and 2 sulfurous fume was noticed by residents from North Kona to Waimea, 40 miles north of the summit of the mountain.

The lava pouring into South Pit gradually filled it to the point of overflow. On January 25 Ercell Hart of the Hawaiian School of Aeronautics reported that the lava fill had reached the level of the low southeastern rim of the pit; late on the same day the pit overflowed. The lava stream moved southeasterly, and by the evening of the 26th it had attained a length of about 2 miles from South Pit, or 3 miles from its source at the fountains. On the morning of January 27 the flow was moving in three branches, and by the evening of that day the longest of these had reached a point about 3.2 miles from South Pit. Thereafter the speed of advance of the flow greatly decreased, and on the evening of January 28 transit angles from the Volcano Observatory indicated that it had advanced only about 0.2 mile in the preceding 24 hours. By the evening of January 31 the flow-front had reached a distance of about 4 miles from South Pit, but after that day it advanced very little.

On January 29 or 30 a new branch of the flow broke out near South Pit, and this new branch appears to have robbed the older one of its supply of lava. The new stream advanced downslope just east of the older one and partly overlapping it. It moved more slowly than the earlier flow and eventually attained a length of only 2 miles from South Pit. On the morning of February 7 it was still advancing very slowly. Its advance probably ended on February 8, two days after the cessation of lava fountaining at the vent. On February 7 a small amount of movement was still visible in the older flow also. This continuation of movement of the flows after the end of lava extrusion at the vent probably resulted from draining of the still-fluid lava from the feeding tubes in the flows on the upper slopes of the mountain.

During the night of February 4 the fountain activity at the southwestern edge of the caldera was still moderately strong, producing a pronounced glow on the rising fume column. By mid-morning on February 5, however, fountain activity had become very weak and irregular, only occasional small bursts of liquid lava spray being visible in the cone. Lava was moving underground through a tube almost to the wall of South Pit. There it issued in a small amphitheatral depression in slightly older 1949 aa, flowed as a pahoehoe stream to the edge of South Pit, cascaded down the wall, and spread slowly over the floor of the pit as a sluggish aa flow. The speed of movement of the liquid lava in the cascade was estimated to be generally about 10 miles an hour, reaching about 15 to 20 miles an hour in a short steep portion of the descent. On the floor of South Pit the aa flow was spreading at a rate of only a few feet an hour. About 2:00 p.m. a sudden increase in lava liberation greatly augmented the volume of the cascade and caused a brief rapid spreading of aa tongues in South Pit. Within half an hour the voluminous burst of lava was over, and by 5:00 p.m. there was no further evidence of movement of lava down the cascade into South Pit. The flows on the caldera floor also appeared to be lifeless except for many small secondary fumaroles. On the morning of February 6 the cinder cone at the southwestern edge of the caldera was visited; no further signs of activity could be detected, other than slight glow in the fountain pits and voluminous liberation of SO_2-rich fume. Even on its outer slopes, the cone was still red-hot only a few inches beneath the surface. The lava-pool and flow-channel east of the cone had been completely drained, and collapse had exposed the end of the empty lava-tube leading toward South Pit. Thus this phase of the eruption came to an end on the afternoon of February 5, having lasted just 30 days.

From February 6 to the date of writing (March 22) fume frequently has been visible at the mountain top. On several nights observers at scattered points on the southern part of the island have also reported a distinct glow at the summit. This glow may have resulted from brief weak resumptions of lava fountaining or quiet outwelling of lava, or possibly from slumping of portions of the hot cinder cone or of the cascade into South Pit, exposing glowing material. However, at no time when observers were actually present at the summit or flying over it in planes could any glow or lava movement be seen.

THE CONE

During the early hours of the eruption the "curtain of fire" which issued along the upper part of the southwest rift zone outside of the caldera built a long row of spatter ramparts and small spatter cones. These ranged up to about 20 feet in height, but were mostly less than 5 feet. A similar spatter rampart was built by the fountain-chain in the central part of the caldera.

The true cone building was restricted to the big, long-lived fountains at the southwestern edge of the caldera. The cone built there is one of the largest on Mauna Loa, rivaling in size that of the 1940 eruption. The big cone is built on a broad lava shield which overlies the former South Lunate Platform. The cone itself is compound. An outer cone, breached on the eastern side, consists largely of fine cinder and pumice and rests partly on the outer slope of the mountain and partly on the caldera floor and against the boundary cliff. (See figure 2.) The top of the outer cone is about 100 feet above the former rim

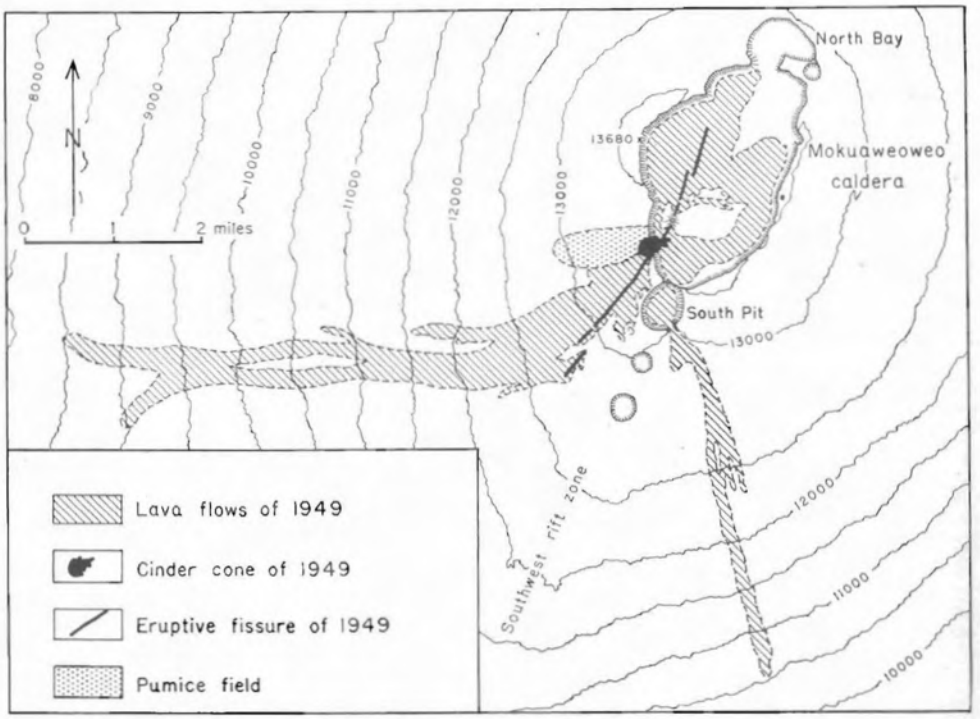

FIGURE 1. Map showing the approximate location of the 1949 lava flows and vents on Mauna Loa.

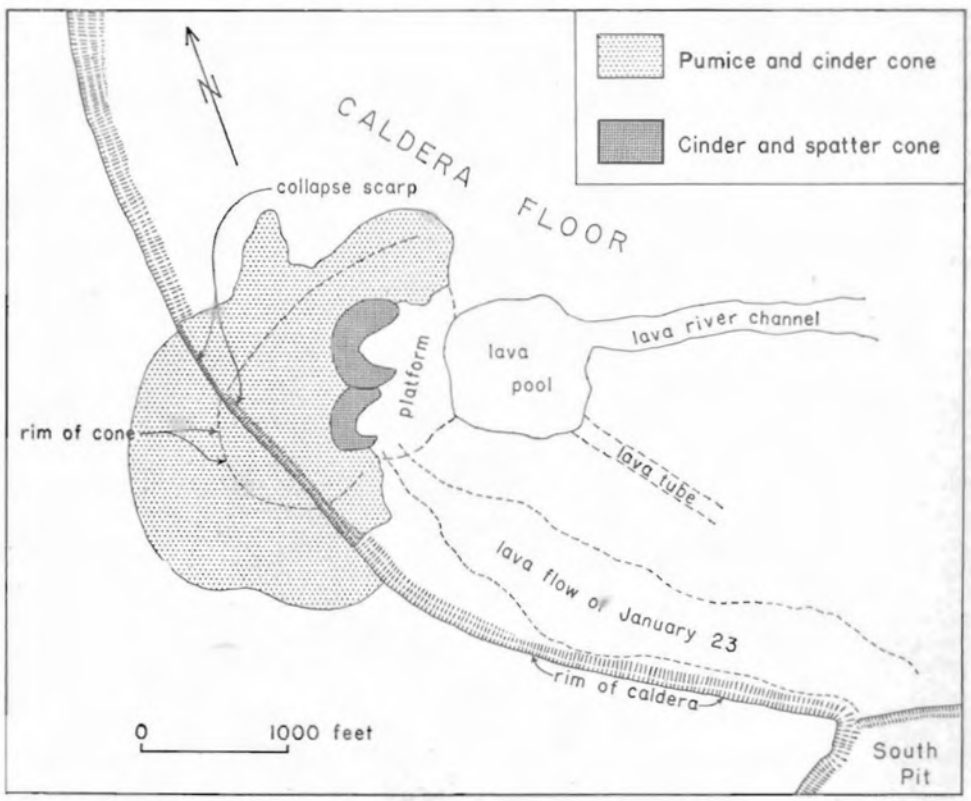

FIGURE 2. Sketch map of the cone area of the 1949 eruption.

of the caldera wall and 250 feet above the lava shield at its base. Its maximum diameter is about 1,500 feet. At the eastern edge of the large cone, and partly enclosed within it, is a small double cone of coarse cinder and spatter, built around the final sites of the two lava fountains. Each crater of the small cone also is breached on the eastern side. The inner cone probably was built during the stage of reduced gas pressure and lower fountains which directly preceded the end of the eruption. This decrease in gas content of the lava in the declining stage also resulted in the deposition of a few rather dense black "pancake" and ribbon bombs on the surface of the pale brown pumice on the southern slope of the outer cone.

The thick accumulation of ejecta against the boundary cliff of the caldera appears to have caused the northeastward migration of the smaller of the two cone-building lava fountains. On January 23, when the cone was visited by Orr and Hubbard, the fountain was situated directly against the caldera wall. By the end of the eruption, however, it had moved outward to the southernmost of the two small cinder and spatter cones, about 150 feet northeast of the base of the wall.

Lava escaping from the cone formed a pool on the lava shield just east of the cone, then drained eastward through an open lava river channel, and southeastward through tubes toward South Pit. At the end of the eruption the lava pool was drained

and its walls collapsed, exposing the mouth of a large lava tube, about 35 feet high, leading toward South Pit. (See figure 2.) The large cinder and pumice cone also partly collapsed, producing a northeast-facing scarp 10 to 15 feet high across the top of the cone. The position of the scarp was governed by the underlying caldera wall. Slumping also produced minor scarps on the outer slope of the cone.

THE LAVAS

The early lava flows in Mokuaweoweo caldera were almost entirely pahoehoe, but as the eruption progressed these were largely covered by later flows of aa. The depth of the fill in Mokuaweoweo is difficult to estimate, but probably averages about 20 feet.

The lavas erupted along the upper part of the southwest rift are pahoehoe near the vents, but as the flows moved downslope they gradually changed to aa. The average thickness of the aa in the lower part of the flow is probably about 10 to 12 feet. Near the vents the pahoehoe flows are very thin, averaging from 2 to 3 feet thick. The flows near the vents were very rich in gas and produced typical shelly pahoehoe with many open tubes and blisters covered by a crust only a few inches thick. The surface of much of this pahoehoe is a thin shell of brown pumice, similar to that formed on many pahoehoe flows in the summit region of Mauna Loa. (See VOLCANO LETTER 502.) Downslope the pahoehoe becomes denser and less shelly.

The lava spilling into South Pit was partly pahoehoe and partly aa. In cascading over the cliff which separated South Pit from Mokuaweoweo some of the pahoehoe changed into aa, probably because of the intense stirring of the liquid and loss of gas. Many exotic blocks which tumbled down from the older lava flows exposed in the walls of the pit are recognizable in the aa. The depth of the fill in South Pit is about 50 feet. At the low gap in the rim of the pit, at its southeastern side, pahoehoe issued from beneath the aa. An arcuate ridge of aa, 10 to 15 feet high, marks the underlying buried wall of the pit. This ridge appears to have been pushed up by the pahoehoe which issued from beneath it.

Just southeast of South Pit the lava is pahoehoe, much denser and more massive than that of the earlier flow from the upper end of the southwest rift. The surface of the flow near South Pit is largely a very rough "shark-skin" type; over the major tubes it shows an accumulation of sublimated sulfur and some white sulfo-salts. On the surface of the pahoehoe near the zone where it issued from beneath the aa there was formed a series of minute, tensional fault scarps, up to 8 inches high, facing down-flow. On the faces of some of these scarps there is found a moderately good development of dendritic lava. Downslope the pahoehoe gives place to aa, and most of the southern flow is aa, averaging 10 to 15 feet thick.

The approximate area and volume of the 1949 lava and of each of its principal divisions are shown in table 1. The figures are not of great accuracy, and indicate only an order of magnitude. The total volume of the lava, 71 million cubic yards, is somewhat less than the volume of the lava of the 1940 and 1942 eruptions, each of which approximated 100 million cubic yards.

TABLE 1. AREA AND VOLUME OF 1949 LAVA

DIVISION OF THE FLOW	AREA (SQ. MILES)	VOLUME (CU. YARDS)
Mokuaweoweo	1.9	40,000,000
South Pit	0.2	8,000,000
Western flow	3.1	16,000,000
Southern flow	0.6	7,000,000
Total	5.8	71,000,000

Temperature measurements with an optical pyrometer were made on the glowing interior portion of a thick aa flow in South Pit on the afternoon of February 5. The glowing portion of the flow was well exposed in a large crack. Three observations were made, all yielding readings close to 760° C. This temperature is believed accurate within 50°. The flow was essentially motionless, but was still creeping a little.

Geiger counter observations were made by D. C. Cox on the hot lava in and close to South Pit on the afternoon of February 5. The number of clicks in the earphones ranged from 38 to 45 per minute. This is of the same order of magnitude as results obtained on the nearby lavas of prehistoric age and only slightly higher than those obtained by Mrs. B. J. Loucks on lavas of Kilauea volcano ranging in date from 1921 to prehistoric. The results are of the order of magnitude to be expected from cosmic radiation, and may have been caused by that alone. Dental X-ray films were mounted on a rock monument at the summit rest-house, 1.5 miles from the lava fountains, and exposed to

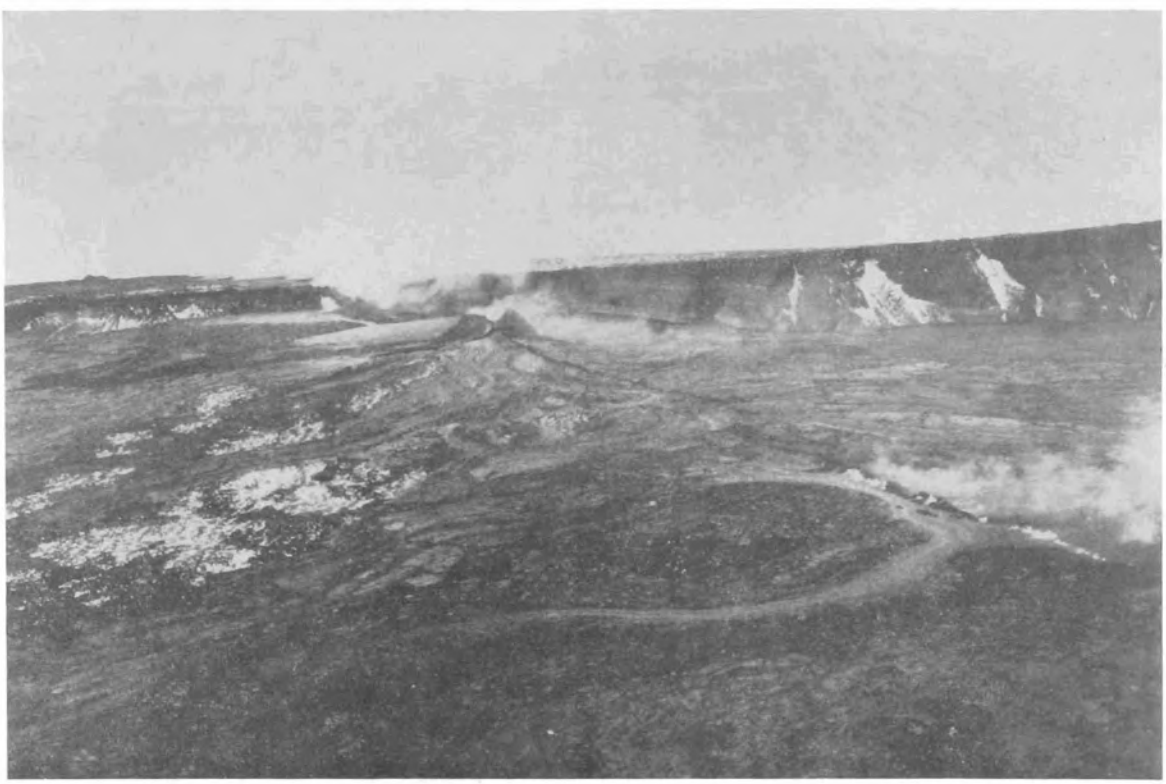

PLATE 3. Mokuaweoweo caldera, looking southwestward on the morning of January 7, 1949. In the right foreground is the northern fountain-chain and the lava flow leading eastward from it. In the middle distance the fissure can be seen cutting through the 1940 cinder cone, which is fuming strongly. OFFICIAL PHOTOGRAPH, U. S. NAVY.

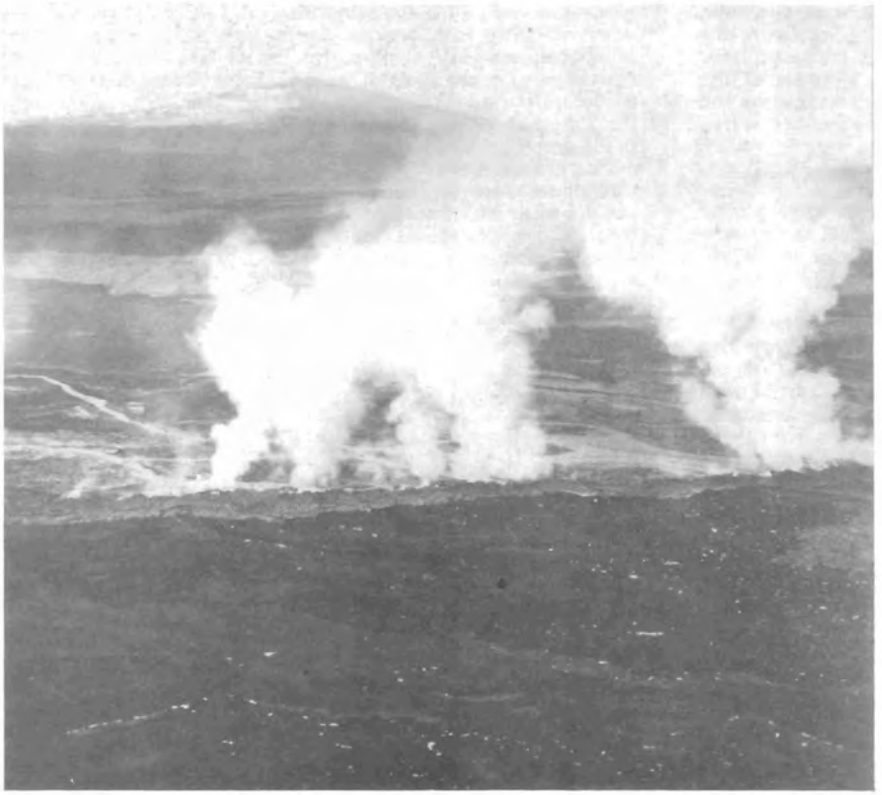

PLATE 4. Lava fountains and upper end of the western flow along the upper part of the southwest rift zone on the morning of January 7, 1949. The spatter rampart and the main lava rivers of the flow are clearly visible. Hualalai volcano is in the background. OFFICIAL PHOTOGRAPH, U. S. NAVY.

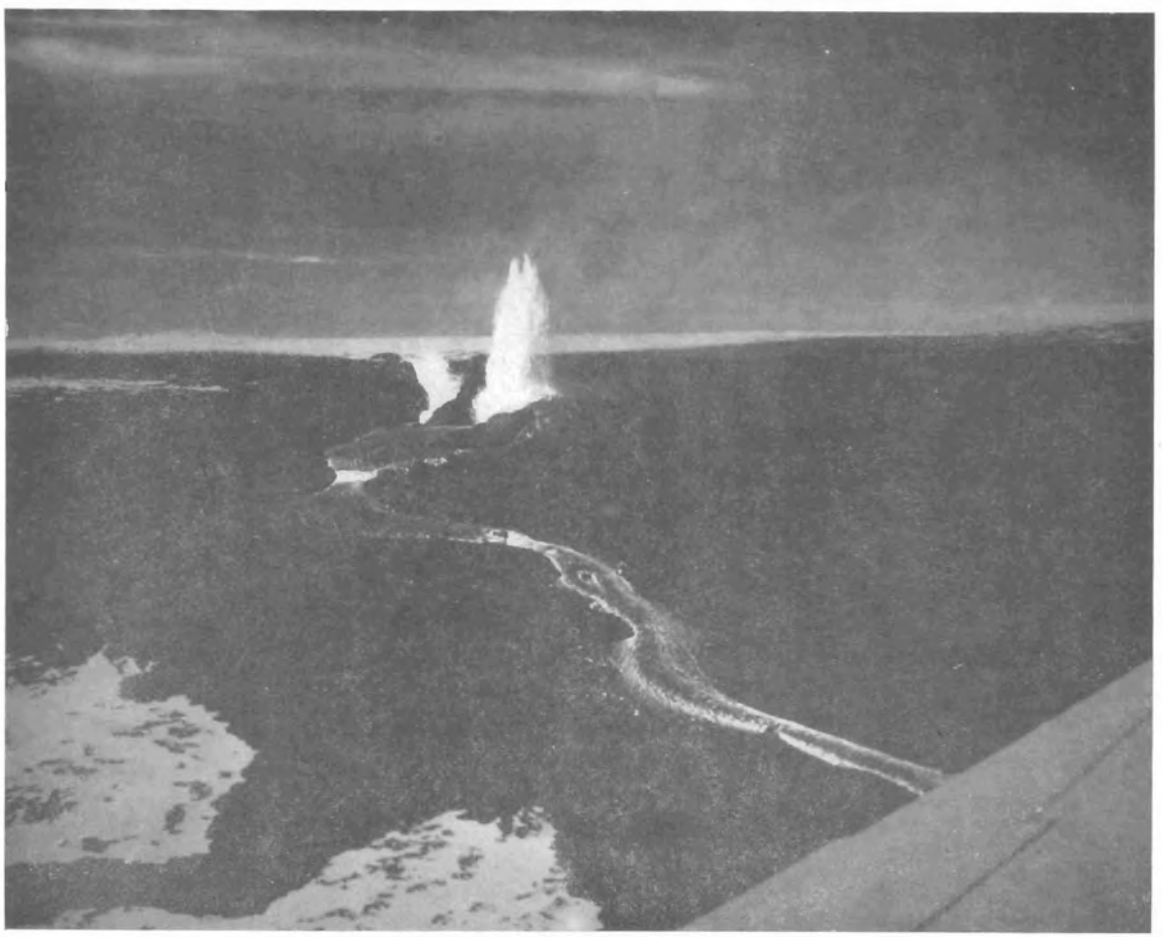

PLATE 5. Lava fountains and flow at the southwestern edge of Mokuaweoweo caldera on the evening of January 19, 1949. The smaller fountain on the left is the wall fountain. The larger fountain is about 500 feet high. PHOTOGRAPH BY K. OTAKI, ACE PORTRAIT STUDIO.

radiation from the fountains for a period of 12 days, from January 24 to February 5. These films showed practically no fogging. Samples of the early lava from Mokuaweoweo and pumice from the fountains were tested for radioactivity by Dr. Harvey White of the University of California, but no radioactivity was found.

PETROGRAPHY

The 1949 lava is a basalt containing approximately 3 per cent olivine. The rock of the more massive central portions of the southern flow, both aa and pahoehoe, is essentially crystalline, containing only a small amount of glass. It consists largely of labradorite and pigeonite (optic angle very small), with less abundant iron ore, olivine, and dark brown, interstitial glass. A roughly stellate arrangement of the feldspar microlites is present in some thin sections. A few of the olivine grains have the dimensions of phenocrysts, with lengths up to 2 mm., but the texture is seriate rather than truly porphyritic.

The rock of the upper portions of the western flow contains a larger proportion of glass, but is otherwise similar to that of the southern flow. The glass of the pumice from the fountains has a refractive index of 1.597 (± .003).

EARTHQUAKES AND GROUND TILT ASSOCIATED WITH THE ERUPTION

No distinct earthquake pattern preceded the 1949 outbreak of Mauna Loa. However, the number of earthquakes recorded in December on the Mauna Loa seismograph, at an altitude of 6,600 feet about 13 miles from the northern end of Mokuaweoweo, greatly exceeded those recorded in any of the preceding 5 months. (See table 2.)

TABLE 2. EARTHQUAKES RECORDED ON MAUNA LOA SEISMOGRAPH DURING 1948

MONTH	NUMBER OF EARTHQUAKES
December	72
November	38
October	47
September	26
August	23
July	37

Most of the quakes during December were tremors with shallow foci. Although a few of them originated under Mokuaweoweo, most of those whose origins were determined originated under the east slope of Mauna Loa or on the northeast rift. The strongest earthquake immediately preceding the eruption occurred on December 13. Its origin was at a shallow focus under the northeast rift about 2 miles from Mokuaweoweo.

Of the approximately 60 earthquakes recorded on the Mauna Loa seismograph in January 1949, 16 occurred on January 6, the day the eruption started. The number of shakes accompanying the outbreak of this summit eruption was less than during flank eruptions. This is to be expected because of the shorter distance of fissuring. During flank eruptions fissuring extends across the summit and also occurs far down the flank, whereas in summit eruptions it is restricted to the summit region. One of the strongest shakes during the eruption occurred at 3:59 p.m. on January 6 at about the time of commencement of surface activity. Its origin appears to have been at a depth of about 5 miles, approximately 2 miles northeast of Mokuaweoweo. If, as seems probable, this quake occurred at the time the fissure across Mokuaweoweo and a little way down the southwest rift was opened, the initial movement must have been at the northeastern end of the fissure.

Continuous harmonic tremor commenced on the Bosch-Omori seismograph at the northern rim of Kilauea caldera, 21 miles from the scene of eruption, at 3:47 p.m. on January 6 and ceased to be apparent at 3:00 a.m. on January 7.

During the year 1948 there was an accumulation of easterly ground-tilt at the northern rim of Kilauea caldera. The eastward tilting was especially strong during the first half of November. Records of several eruptions of Mauna Loa seem to indicate that easterly tilt is an evidence of increase of pressure under that mountain. Despite the easterly tilt and the fact that the average interval between Mauna Loa eruptions (about 4 years) had already been exceeded by more than 2 years, the earthquake pattern did not seem positive enough to justify a prediction of impending activity.

ACKNOWLEDGMENTS

We wish to express our thanks to all those many persons who have contributed information or otherwise aided in the study of the eruption. Deserving of special mention are: Superintendent Frank R. Oberhansley and Chief Ranger Frank A. Hjort of Hawaii National Park, who greatly aided us by the loan of riding horses and packing equipment up the mountain; Ranger James B. Orr, who kindly permitted the use of his field notes on the eruption; Naturalist Douglass H. Hubbard and Ranger V. R. Bender, who contributed ground and air observations; Pilot Ercell Hart, of the Hawaiian School of Aeronautics, who made repeated reports on the progress of the eruption; Harry M. Blickhahn, editor of the Hilo Tribune-Herald, who promptly passed on to the Volcano Observatory the information which came to him; Doak C. Cox, geologist for the Hawaiian Sugar Planters' Association Experiment Station, who operated the Geiger counter at the summit of the mountain; and Dr. Harvey E. White of the University of California Physics Department, who made radioactive determinations on several lava specimens.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JANUARY–MARCH, 1949

VOLCANOLOGY

January

An eruption of Mauna Loa started on January 6 and continued through the rest of the month. History and a lack of a definite earthquake pattern had led members of the Observatory staff to believe that the next eruption would be at the summit. There was but little positive data upon which to forecast an impending eruption, however. A strong easterly tilt of seven seconds of arc near the northern end of Kilauea Caldera in November 1948 was but little greater than similar tilts in 1946 and 1947. Such a tilt could be taken only as a suggestion and not as a good indication of a pressure increase under Mauna Loa that might lead to surface activity. The November tilt and the distinct blue fumes observed in Mokuaweoweo during October 1948 do give some indications that lava was rising in Mauna Loa 3 months prior to its appearance at the surface.

Sixty-seven earthquakes were recorded during the month. Fifty-eight shakes were recorded at Kilauea and 51 at Mauna Loa. The Mauna Loa total is incomplete because the seismograph was dismantled by earthquakes on two occasions. The records of at least eight shakes were lost.

Strong southerly tilt continued throughout the month. Easterly tilt continued until January 16 and then westerly tilt a little stronger than normal set in.

February

The Mouna Loa eruption, except for fuming, came to an end on February 5.

Sixty-four earthquakes were recorded during the month. Of these 47 were recorded at Kilauea and 52 at Mauna Loa.

Strong southerly tilt was continuous in February except for distinct northerly tilt accompanying the strong earthquake on February 26. Normal easterly tilt continued throughout the month.

March

Fuming from Mokuaweoweo was continuous throughout the month.

Thirty-one earthquakes were recorded in March. Thirty of the shakes were recorded on the Mauna Loa seismograph and 16 at Kilauea.

Northerly tilt set in March 6 and continued through the end of the month. Westerly tilt was about normal for March.

CRACK MEASUREMENTS

A few of the cracks near the east rim of Halemaumau opened slightly. The other cracks that were measured showed no appreciable movement.

SEISMOLOGY

* For definition of local seismicity, see Volcano Letter 371.

The data of the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

1. January 4, 20:20, very feeble.
2. January 6, 15:59, moderate. Near Mokuaweoweo.
3. January 7, 03:10, very feeble.
4. January 8, 00:49, moderate. 10–15 miles deep under Alae Crater area.
5. January 15, 00:40, moderate. 20–25 miles deep above Wood Valley.
6. January 15, 11:16, slight. Under ocean west of Kohala.
7. January 16, 14:30, slight. 9 miles deep. Kau Desert near Kilauea.
8. January 20, 14:27, very feeble. Deep. 10 miles southwest of Waimea.
9. January 20, 18:09, feeble. Northeast rift Mauna Loa.
10. January 26, 13:06, feeble. Deep. 10 miles southwest of Waimea.
11. January 26, 11:45, very feeble. Deep under east slope of Mauna Loa.
12. January 26, 23:57, moderate. 5 miles deep near Ohaikea.
13. January 27, 00:04, slight. 6 miles deep, east slope of Mauna Loa.
14. January 27, 00:16, very feeble.
15. January 28, 15:50, moderate, E-W dismantled. 5 miles deep, east slope of Mauna Loa.
16. January 28, 19:45, moderate, E-W dismantled. 8 miles deep, east slope of Mauna Loa.
17. January 29, 03:29, very feeble. East slope, Mauna Loa.
18. February 4, 22:16, very feeble.
19. February 7, 18:08, very feeble. Mauna Loa.
20. February 17, 07:33, very feeble.
21. February 19, 01:13, feeble.
22. February 19, 04:34, very feeble.
23. February 19, 12:04, very feeble.
24. February 19, 14:47, very feeble.
25. February 19, 17:06, very feeble. Kilauea.
26. February 20, 08:45, very feeble. Mauna Loa.
27. February 20, 09:32, very feeble. Mauna Loa.
28. February 20, 09:46, very feeble.
29. February 20, 21:16, feeble. Kilauea.
30. February 21, 16:22, very feeble.
31. February 22, 04:48, feeble. Kilauea.
32. February 23, 23:55, very feeble.
33. February 24, 01:02, very feeble.
34. February 26, 13:20, very feeble. Felt at Kapapala.
35. February 26, 13:54, strong. Instruments dismantled. Strongly felt from Hilo to Naalehu. Shallow focus, northeast rift Mauna Loa at 7,000 feet.
36. February 27, 05:13, very feeble.
37. February 27, 10:28, slight. South slope, Kilauea.
38. February 27, 13:45, feeble. Felt at Pahala.
39. February 27, 17:18, feeble. East slope, Mauna Loa.
40. February 28, 16:58, very feeble. Northeast rift Mauna Loa.
41. March 2, 14:20, very feeble.
42. March 11, 09:31, very feeble.
43. March 23, 11:35, very feeble. Kilauea.
44. March 29, 10:58, very feeble.

TELESEISMS

February 14, 08:30, slight.
March 24, 11:11, moderate. Off north California coast.

MICROSEISMS

Microseisms were strong from January 5–7 and from February 28 to March 1. On other days they were weak to moderate.

TILTING OF THE GROUND

There was a rapid easterly tilt from January 1 to 10 when seasonal westerly tilt set in and continued until March 24. There was a slight easterly swing from March 25 to 28, then a recovery to the west. With the exception of a sharp northerly tilt accompanying the strong earthquake of February 26, southerly tilt was continuous from January 1 to March 6. From March 7 to 31 there was a slight accumulation of northerly tilt.

Table of Tilt at Observatory on Northeast Rim of Kilauea

Week Ended		Amount	Direction

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter,** a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

ACTIVITY OF MAUNA LOA DURING APRIL, MAY, AND JUNE, 1949

By GORDON A. MACDONALD and RUY H. FINCH

The 1949 eruption of Mauna Loa commenced on January 6, and the major activity continued until February 5. This activity consisted of outpouring of lava flows on the caldera floor and down the western and southern flanks of the volcano from vents near the summit, and building of a large cinder and pumice cone at the southwestern margin of the caldera. The activity and cone have been described in VOLCANO LETTER 503.

Following the end of lava fountaining on February 5, fume rising from Mokuaweoweo was visible almost constantly during the remainder of February and March. It was obvious that the magma column must be standing at a very high level in the conduit. On several different nights a distinct glow was reported at the summit of the mountain. Thus, at 2 a.m. on February 19, Charles Hoeppel of the U. S. Coast and Geodetic Survey observed a strong reddish reflection on the fume column. However, at no time when observers were able to see into the caldera was there any sign of lava fountaining or flow. At the time, there was some doubt whether the observed glow was the result of weak resumptions of lava extrusion, or of slumping of surficial parts of the cinder cone or lava cascades, revealing hot glowing material beneath. In view of later developments, there is now little question that the glow resulted from brief quiet outwellings of lava.

The following table lists the dates on which fume or glow was reported and the place from which the observation was made. During many days the summit of the mountain was cloud-covered and invisible to persons at low altitudes. On some days when it was visible, winds at the summit may have been strong enough to dissipate small amounts of fume and make it undetectable from a distance.

OBSERVATIONS ON ACTIVITY OF MAUNA LOA FROM FEBRUARY 7 TO APRIL 7, 1949.

DATE	LOCATION OF OBSERVER	TYPE OF ACTIVITY
Feb. 15	Summit	Weak fume but no glow
17	Kilauea	Weak fume
18	Pahala and Naalehu	Weak glow and fume
19	Near Pahala	Two conspicuous puffs of fume in early morning
19	Planes over summit	Fume but no glow
21	Kilauea	Thin fume during morning
21	Kulani Camp	Glow in evening
22–27	Kilauea	No fume visible
28	Kilauea	Light fume
Mar. 1	Kilauea	Light fume during day
1	Naalehu	Distinct glow in evening
16	Kilauea	Strong fume column in evening
18	Kilauea	Strong fume column in evening
19	Kilauea	Weak fume
20–21	Kilauea	Strong fume in evening
22–23	Kilauea	Weak fume
28	Humuula	Pulsating fume cloud in morning
28	Kilauea	Glow in evening
April 1–6	Kilauea	Conspicuous fume

During late March or early April the quiet outflow of lava became essentially continuous, and was observed at close range by staff members of Hawaii National Park. The account of the activity on April 7 to 9 and May 5 to 7 is based largely on the excellent reports of Ranger James B. Orr, and the writers wish to thank Mr. Orr for making the reports available. The results of the activity were examined on the ground by Macdonald, in company with Orr, on the second and third of June, after lava extrusion again had ceased.

The precise date when lava extrusion again became fairly continuous is uncertain. On March 28 the fume column rising from Mokuaweoweo was unusually conspicuous, and on the evening of that day the glow was intense. On April 1, harmonic tremor was recorded for

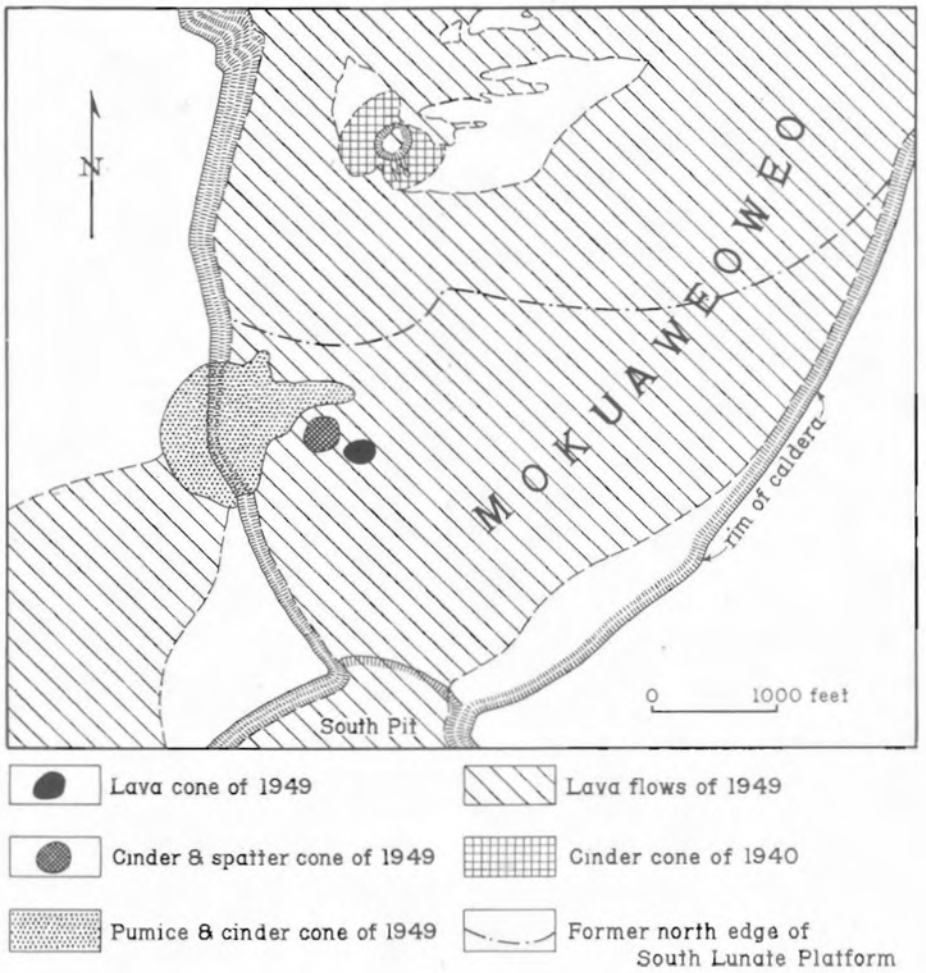

FIGURE 1. Sketch map of the southern portion of Mokuaweoweo caldera on June 3, 1949, after the end of lava extrusion.

a few minutes on both the Mauna Loa seismograph and the Bosch-Omori seismograph at Kilauea. Orr's observations at the summit on April 7 indicate that at that time lava extrusion must already have been in progress for several days. It appears probable, therefore, that fairly continuous lava extrusion was resumed sometime between March 28 and April 1.

The activity of April and May was confined entirely to the vent area on the floor of Mokuaweoweo caldera close to its southwestern wall. The large-scale lava fountaining of late January had built up a big cone of fine cinder and pumice resting against the caldera wall and on the outer slope of the mountain. (See figure 2, VOLCANO LETTER 503.) Within the breached crater of this large cone, diminished fountain activity in early February had built a smaller double cone of coarse cinder and spatter.

On April 8 the small cinder and spatter cone was rhythmically emitting voluminous puffs of fume, but no lava. About 250 feet east of the fuming cinder cone a small lava cone had been built, about 80 feet high and 150 feet across at the base, with a crater 40 feet in diameter containing a small, surging pond of molten lava. The lava composing the cone was notably denser than the highly vesicular lavas which had characterized the earlier phases of the eruption. The lava pond in the crater heaved slowly up and down, the depth from the rim to the pond surface ranging from a few inches to 15 feet during the few hours it was under observation. However, no overflow of lava occurred while Orr was there, from April 7 to 9, although the cone obviously had been built up by repeated overflows previous to April 7 and continued to grow by additional overflows later. From the vent area liquid lava moved through tubes beneath the surface, emerging about a mile east–northeast of the cones to feed two sluggishly advancing flows of aa. Another small sluggish aa flow was moving southeastward into South Pit.

On May 5 the height of the lava cone had increased to about 95 feet, as measured from its southeastern base. The lavas composing it were still relatively dense, and the pond of molten lava was still present in its crater. The cinder and spatter cone was the principal source of fume and had liberated some short flows of lava which partly veneered its flanks. Some of this lava was dense, but some was highly vesicular and shelly. A small pahoehoe flow was spreading near the base of the lava cone; another larger flow moved through tubes, issuing about a mile northeast of the cone to form a moderately active pahoehoe flow.

The activity at the cones on May 7 showed a distinctly cyclic pattern, the cycles being repeated at approximately 3½-hour intervals. Successive cycles were essentially identical, except for minor variations in the duration of the parts of the cycle. The cycle commenced with a loud hissing and roaring within the cinder and spatter cone, accompanied by copious liberation of pale brown to white fume. This lasted for 5 minutes, and was followed by rapid outpouring of gas-rich pahoehoe accompanied by a little fume. The lava effusion lasted about 45 minutes, the rapidity of extrusion gradually decreasing until all flows ceased. Within about 5 minutes after the lava ceased to flow, the hissing and roaring within the cone started again. At the summit of the cone the escaping gas tilted large slabs of partly cooled pahoehoe, lifting some of them a foot or two, then dropping them back into place. This relatively violent escape of gas continued for about 10 minutes. Immediately afterward the lava cone, which had been quiescent with its crater empty, started to fume copiously, and shortly thereafter fluid lava entered the bottom of the crater from an opening on its west–southwest side. Within 10 minutes the crater was completely filled. With the entrance of lava into the crater fuming was greatly diminished, and by the time the crater was filled fuming had practically ceased. The fluid lava bulged up above the crater rim as a broad flat dome a foot or two high, then the confining crust ruptured and the lava poured down the flanks of the cone. The crust of the bulge of lava at the summit of the cone was continually broken up, forming large irregular plates of still flexible pahoehoe which coasted down the flows on the flank of the cone, crumpling and twisting as they encountered obstacles. This phase of overflow from the lava cone continued with varying intensity for about an hour. Then the lava in the crater drained away, accompanied by liberation of large volumes of fume at the lava cone and by the renewal of the hissing and roaring in the cinder and spatter cone. This was followed by a period of quiet lasting about an hour, after which the entire cycle was repeated.

The date of final cessation of the lava extrusion is uncertain. Flows still were moving actively on the caldera floor east of the vent on May 19, when the summit was visited by H. Whitten. When Orr and Macdonald reached the summit on June 2 there was no sign of movement in any of the flows, although a weak glow still was visible on the cinder cone. The cone still was fuming copiously on June 2, but by the afternoon of June 3 the fume was very light and consisted almost entirely of steam. During the remainder of June no glow, and only weak fuming, were reported. Lava extrusion ended sometime between May 20 and June 2, probably about the end of May. The eruption appears to be over, although it is still possible that another resumption of activity may occur.

On June 3 both the cinder cone and the lava cone were climbed and examined in detail. The cinder cone was an irregular dome, about 80 feet high, with no sign of a crater. It was largely veneered with very late flows of frothy pahoehoe. (See plate 1.) The lava cone was about 110 feet high, with a crater some 30 feet across and 50 feet deep. (See plate 2.) The late lavas, erupted at the lava cone after Orr's visit on May 5, were shelly gas-rich pahoehoe, in contrast to the denser, partly degassed lavas which built most of the cone.

It is estimated that the volume of lava extruded in the late phase of the eruption after February 5 was about 4 million cubic yards, bringing the total volume for the eruption to about 75 million cubic yards. The late lavas were restricted to the southern end of Mokuaweoweo caldera, and completed the burial of the northward-facing scarp of the South Lunate Platform, which had already been partly buried by the lavas of 1933 and 1940. Only at its western end is there still visible a topographic expression of the scarp, mantled by cascades of the 1949 lavas. (See figure 1.)

It has already been pointed out that the pahoehoe lava which formed most of the lava cone was strikingly dense, as compared to the highly vesicular and shelly pahoehoe which characterized the earlier lavas of the eruption in the area close to the vents. It resembled much more closely the pahoehoe which forms in long flows which have traveled through tubes many miles from the vents. In the case of the 1949 lava, the denseness resulted from loss of gas before the lava reached the surface. The change from gas-rich to gas-poor lava as the eruption progressed might have been explained by assuming a gas-enriched "head" on the magma column which was released during the early stages of the eruption and gradually exhausted as activity continued. This explanation might be acceptable if the change in gas content had been entirely unidirectional. But it was not. The latest lavas of the eruption, instead of being as dense as or even denser than those which built the bulk of the lava cone, were again frothy and gas-rich like the earliest lavas. The change was from gas-rich to gas-poor, and then back again to gas-rich lavas.

A possible explanation of the changes in density of the erupted lavas is suggested by the time relationships of the density types to the character of the rest of the activity. The dense lavas which built most of the lava cone, and also were erupted in early May or late April at the cinder and spatter cone, were erupted following a period of nearly 2 months duration during which there was very little surface outflow of lava, but nearly continuous liberation of large volumes of fume. Possibly during this period the upper part of the magma column stood undisturbed at levels high enough to permit vesiculation, and for a period long enough for a large proportion of the gas bubbles to escape, supplying the gas for the fume cloud. However, at levels

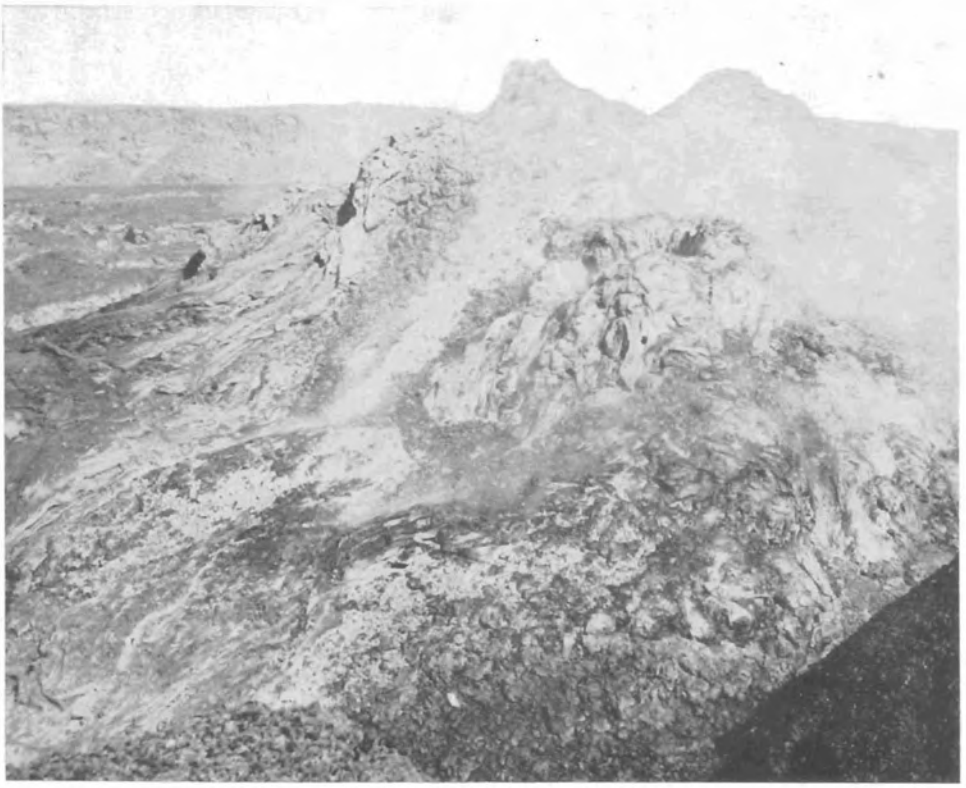

PLATE 1. The small cinder and spatter cone, largely veneered with thin lava flows, seen from the northern rim of the pumice cone, June 3, 1949. PHOTOGRAPH BY G. A. MACDONALD.

below the depth at which appreciable vesiculation could occur the magma lost only the small proportion of gas which was dissipated upward by diffusion. Convection probably would not be very effective in the narrow feeding fissure which led the lava to the surface. When lava extrusion was resumed after the 2-month period of quiet, the first erupted, upper part of the magma body was gas-poor and produced dense lavas. But as time went on the upper, partly degassed portion of the magma was exhausted, and lavas reaching the surface were again as rich in gas, or nearly so, as had been the earliest lavas of the eruption.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR APRIL–JUNE, 1949

VOLCANOLOGY

April

About the end of March, quiet lava extrusion became fairly continuous in Mokuaweoweo, and continued through April. The activity is described in the foregoing article. Fume rising from Mokuaweoweo was visible from the Volcano Observatory on many occasions during April.

Thirty-two earthquakes were recorded in April. Sixteen of these were recorded at Kilauea and 23 at Mauna Loa.

There was a small accumulation of northwesterly tilt during April, possibly indicating a slight increase of pressure under Kilauea and a decrease under Mauna Loa.

May

Quiet lava effusion in Mokuaweoweo continued through most of May. It came to an end sometime between May 20 and June 2, probably about May 30.

Forty-three earthquakes were recorded during May. Of these 31 were recorded at Kilauea and 38 on Mauna Loa. In addition, about 225 tremors of Mauna Loa origin were recorded on the Mauna Loa seismograph on May 20 and 21. These resembled the records produced by small explosions, rather than by ordinary small earthquakes. Many of them were recorded also at Kilauea, and some on the Hilo and Kona seismographs.

Three earthquakes were felt locally during May. The strongest occurred at 5:02 a.m. on May 2. It originated in Kona, where some objects were shaken from shelves, and the seismograph at Kealakekua was broken. As in October and November, 1947, several of the larger shakes originated under the west slope of Mauna Loa, inland from Kealakekua Bay.

There was an accumulation of south tilt, and a little east tilt during May. The latter is normal for this time of year.

June

Both Mauna Loa and Kilauea remained quiet throughout June. A total of 32 earthquakes were recorded, 28 of them at Kilauea, and 27 of them on Mauna Loa. Of these, a moderate earthquake originated at a shallow depth on the northeast rift zone of Mauna Loa on June 8, and two feeble earthquakes at a depth of about 10 miles under the southern slope of Mauna Loa, near Punaluu Kahawai, on June 25.

A small accumulation of southerly tilt occurred during June, probably indicating either a slight decrease of pressure under Kilauea or a slight increase under the northeast rift of Mauna Loa. Almost no net change in tilt in an east–west direction was recorded during the month.

The average interval between summit eruptions of Mauna Loa and following flank eruptions during the past century has been 20 months. On this basis, assuming the 1949 summit eruption to have ended about the end of May, a flank eruption of Mauna Loa might be expected about the end of January, 1951. However, it is important to realize that the average interval means little. Sometimes a summit eruption of Mauna Loa is followed by another summit eruption, not by a flank outbreak. Even when a summit eruption has been followed by a flank eruption, the interval between them has ranged from 6 to 38 months. Prediction of Mauna Loa eruption entirely on the basis of historic precedent is highly uncertain, and thus far there is little else on which to base a forecast of the next eruption.

* For definition of local seismicity, see Volcano Letter 371.

The data for the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

45. April 4, 02:59, very feeble.
46. April 7, 09:55, very feeble. Mauna Loa.
47. April 8, 16:30, very feeble. Mauna Loa.
48. April 11, 18:40, moderate, both components dismantled at Mauna Loa. Kaoiki fault. Felt at Naalehu.
49. May 2, 05:02, strong, Kona seismograph broken. West slope of Mauna Loa. Intensity about 4 on Rossi-Forrel and modified Mercalli scales. Felt in Hilo, strongly at Puu Ulaula, and generally from Holualoa to Naalehu. Many sleepers wakened, some rushed out doors. Some objects thrown from shelves in the area from Honaunau to Kealakekua.
50. May 2, 12:55, feeble. Mauna Loa. Felt at Kapapala.
51. May 7, 23:26, strong, both components dismantled at Mauna Loa. Focus at about 12 miles depth beneath Mokuaweoweo. Felt at Holualoa, Kealakekua, Naalehu.
52. May 9, 03:26, very feeble.
53. May 9, 17:02, very feeble.
54. May 14, 10:54, very feeble.
55. May 21, 01:06, feeble. West slope of Mauna Loa. Felt at Holualoa.
56. May 21, 02:25, feeble. West slope Mauna Loa.
57. May 21, 08:38, feeble.
58. May 21, 10:01, feeble.
59. May 23, 10:24, moderate, both components dismantled at Mauna Loa. South slope Mauna Loa near Kapapala. Felt at Kilauea and Hookena, strongly at Pahala.
60. May 25, 15:10, very feeble.
61. May 26, 14:44, very feeble.
62. May 28, 17:30, feeble. West slope Mauna Loa. Felt at Holualoa.
63. May 29, 01:04, feeble. Kaoiki fault near Ainapo.
64. May 30, 04:18, feeble.
65. June 3, 04:05, very feeble.
66. June 8, 14:12, moderate, both components dismantled at Mauna Loa. Northeast rift of Mauna Loa, shallow.
67. June 9, 18:07, very feeble.
68. June 11, 05:41, very feeble. Northeast rift of Mauna Loa.
69. June 11, 08:05, very feeble.
70. June 17, 05:49, very feeble.
71. June 19, 05:05, very feeble. Mauna Loa.
72. June 19, 12:53, very feeble. Mauna Loa, northeast rift.
73. June 23, 15:34, feeble.
74. June 25, 15:45, feeble. Focus at about 10 miles depth under south slope of Mauna Loa near Punaluu Kahawai.
75. June 25, 19:27, slight. Location same as number 74.
76. June 26, 08:43, very feeble.
77. June 27, 01:57, feeble. Mauna Loa.
78. June 28, 04:53, very feeble. Mauna Loa.
79. June 30, 07:03, very feeble. Kilauea northeast rift, shallow.

TELESEISMS

April 13, 10:03, slight. Between Olympia and Tacoma, Washington.

April 29, 15:36, slight. South coast of Mindanao, Philippine Islands.

May 2, 20:05, slight. Kurile Islands.

MICROSEISMS

Microseisms were slight from April 1 to 9, moderate on April 10 and 11, slight from April 12 to 19, moderate from April 20 to 28, and slight from April 29 to June 30.

CRACK MEASUREMENTS

Most of the cracks measured showed no appreciable movement. However, the crack at the observation area at the east rim of Halemaumau opened 2 millimeters at its northern end during the interval from March 31 to June 30. During the interval since August 31, 1948, it has opened 12 millimeters. The amount of opening decreased southward, reaching essentially zero at the southern end of the crack.

TILTING OF THE GROUND

From April 1 to 22 there was very little tilting of the ground surface in a north–south azimuth. From April 22 to May 4 there was a slight northerly tilting, from May 4 to 29 a distinct southerly tilting, from May 29 to 31 a small northerly tilting, and from May 31 to June 30 a small accumulation of southerly tilting. In the east–west azimuth, there was a small accumulation of westerly tilt between April 1 and 29, a nearly equal accumulation of easterly tilt between April 29 and May 27, and a slight accumulation of westerly tilt from May 27 to June 30. The net westerly tilting is normal for this quarter of the year, although the tilting during June is normally slightly to the east instead of slightly westward. The accumulation of southerly tilt during May and June is abnormal, tilting during these two months generally being distinctly northward.

Table of Tilt at Observatory on Northeast Rim of Kilauea

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE VOLCANO LETTER

No. 505 **U. S. Geological Survey** **July–September, 1949**

PUBLISHED BY THE UNIVERSITY OF HAWAII

REPORT ON PRELIMINARY WORK FOR RADIATION SURVEY

By RUTH C. LOUCKS

INTRODUCTION

In August, 1948, a series of experiments was initiated to determine to what extent available materials could be used to make a survey of radiation from volcanic sources. At that time available materials consisted of X-ray film and a small spectrograph. Later a Geiger type survey meter was made available to the Hawaiian Volcano Observatory.

X-RAY FILM

Since X-ray film registers radiation both longer and shorter than the X-ray range, it appeared to be a possible medium for recording any short-wave radiation that might be present. No X-rays are expected because of their nature, but ultraviolet radiation and gamma radiation may be recorded on X-ray film. Dental pack film was selected for this work because of the ease of handling.

The first series of films, exposed for 10 weeks at Red Hill (10,000 feet) and the rim of Mokuaweoweo, showed heavy fogging of unshielded films and no fogging of slightly shielded films. By accident two films were exposed back to back. The front one was fogged, while the one which was shielded by the two lead foil backing sheets was unfogged. The fact that even masking tape, with which the films were taped to rocks, produced a shadow on the films indicated that the radiation recorded was of relatively long wavelength. Temperature changes from below freezing to above 70° F. apparently did no damage. One film was left for a year deep in a crevice in the roofed cave near the rim of North Bay known as Hotel de Jaggar. It showed slight darkening, possibly due to the small amount of radioactivity in Hawaiian lavas. Film exposed to Hawaiian lava for 12 weeks showed no darkening, but the longer exposure of a year may have recorded the slight amount of radioactivity present (Piggot: Amer. Jour. Sci., 5th Ser., 22(127) : 1931).

The second series was tested at the Kilauea region to determine whether the film pack was actually light tight (for visible light) and whether any of the darkening could be attributed to cosmic rays. The film tested for light tightness was unfogged. Cosmic rays produced no measurable darkening on any of the films tested. The only darkening was due to radioactive lead in the masses of the tiltmeter in the Uwekahuna vault. The radioactivity of the lead was later checked with the Geiger counter. The exposure of 5 weeks produced slight darkening on the film at a distance of 12 to 15 feet from the radioactive lead. This darkening served as a check of the sensitivity of the film to gamma radiation.

The third series of tests was made at Red Hill using unshielded film and film shielded by aluminum foil and various thicknesses of lead. Film was placed in four slots of a lead-covered box. One film was uncovered, one covered by 0.11 mm. of aluminum foil, one by 3.5 mm. of lead, and one by laminations so arranged that one third was uncovered, one third covered by 1.75 mm. of lead, and one third by 3.5 mm. of lead. These were exposed nearly 6 months. The unshielded film was darkened, while the film shielded by aluminum foil and the lead was undarkened. Thus it appears that the darkening encountered was due to ultraviolet radiation and may be eliminated by encasing the film in aluminum foil. The writer wishes to acknowledge the assistance given by the dispensary of Kilauea Military Camp in developing all X-ray films.

SPECTROGRAPH

The spectrograph (Gaertner, Model L 250-W) was checked and calibrated in the laboratory by Harvey E. White of the University of California Physics Department, during a visit to the Volcano Observatory. This is a low-dispersion instrument mounted so as to be used with a tripod in the field. It appeared that an easy way to record the exact object, toward which the spectrograph slit was pointed, would be by the use of a small camera mounted on the tripod with the spectrograph. D. C. Cox donated a camera for this purpose.

GEIGER COUNTER

A Geiger-Mueller counter (El-Tronics, Inc., Survey Meter SGM-18A) was received by the Observatory early in 1949. A few tests were made to determine what might be expected in the way of background radiation (cosmic rays).

1949 ERUPTION

Two series of X-ray films were exposed at the summit of Mauna Loa during the 1949 eruption. Both were exposed near the rest house, about 1 mile or more from the nearest activity. Twice during January, 1949, film was taped to the stone monument in front of the rest house and exposed for periods ranging from 17 hours to 17 days. Since the films were unshielded, there was no noticeable darkening other than that which might be expected from ultraviolet light. At that distance one could not expect to record gamma radiation.

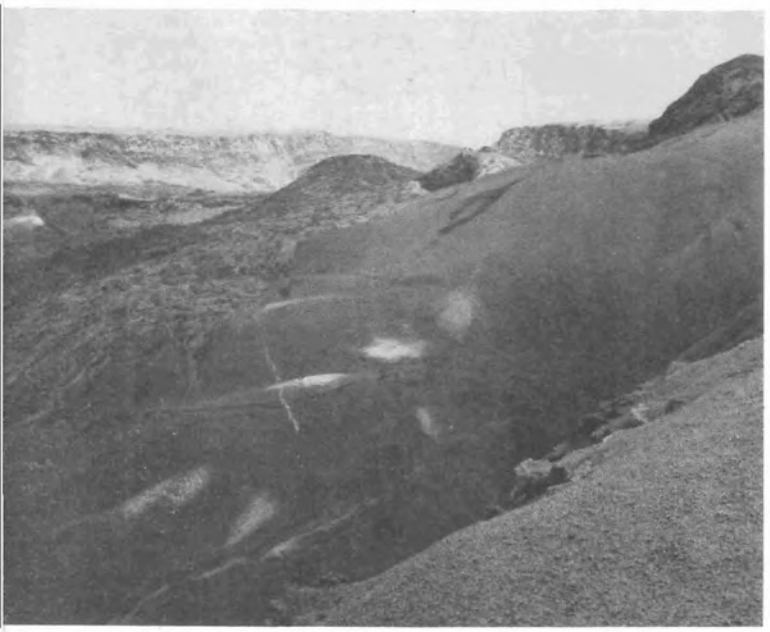
G. A. Macdonald and D. C. Cox took the Geiger counter to the summit of Mauna Loa and made some observations. Their readings were no higher on new lava than on the old lava. However, when they attempted to make readings in a hot crack, they got no reading because the counter does not register correctly above 125° F.

The field conditions were such that it seemed best not to take the spectrograph to the summit.

CONCLUSIONS

It appears that none of the work done during the 1949 eruption constitutes a conclusive test of radiation associated with volcanic activity, particularly the possible presence of short-lived radioactive substances in the gases liberated in the big lava fountains. The films exposed were too far from activity to be significant, and the Geiger counter readings were not complete enough to be conclusive. However, the work done so far serves to point out what should be done to make such tests valid. The year's work shows that among the three recording devices the radiation spectrum from cosmic rays down through the visible range is covered.

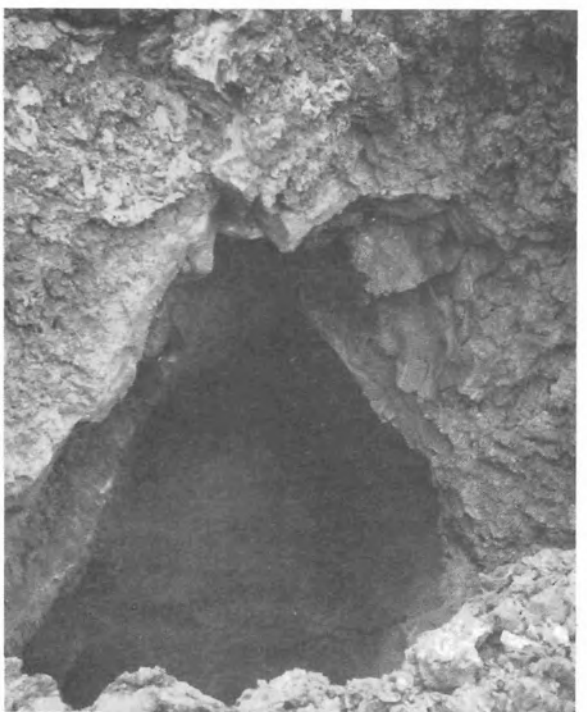
THE HOLLOW CINDER CONE OF THE 1949 ERUPTION OF MAUNA LOA



By GORDON A. MACDONALD

The small cinder and spatter cone, which developed within the breached crater of the larger cinder and pumice cone during the late stages of the 1949 eruption of Mauna Loa, has been described in previous issues of the VOLCANO LETTER. Previous to mid-April the cone had consisted entirely of coarse cinder and spatter. Between April 9 and May 6 the cone started to erupt short thin lava flows, which by early June had almost entirely covered its slopes, hiding the cinder core.

Mokuaweoweo caldera was again visited by the writer on July 26, in company with Ranger J. B. Orr of Hawaii National Park, and Tad Nichols, photographer. It was then found that the cinder and spatter cone had partly caved in, revealing a large cavity in its center. The hole formed by the collapse was on the northeastern side of the cone, and its walls clearly displayed a cross section of the cone. At the surface was the veneer of lava, averaging 6 to 8 feet thick, and consisting of a complex of many thin pahoehoe flows lying parallel to the surface of the buried cinder cone. Many of the flows showed cross sections of filled or partly filled pahoehoe tubes. Beneath the lava veneer the cone consisted of coarse cinder and spatter, largely welded together, and crudely bedded. The fragments ranged up to about 2 feet in length, although most were less than 1 foot. Most were irregular, although some were fairly regular Hawaiian type ("cow-dung") bombs.



By far the most interesting feature of the cone was the open chamber at its center. The chamber was roughly the shape of an artillery projectile, about 25 feet across, with nearly vertical walls which arched inward to a point at the top. The opening was about 40 feet high, but had been higher, as the visible floor was formed of loose rubble which resulted from the collapse of the cone. The walls of the chamber were lined with a layer of pahoehoe 2 to 4 feet thick, in which the flow-lines and flow-planes were disposed parallel to the walls of the chamber and nearly vertical. At the apex of the chamber the pahoehoe lining was continued upward as a 3-foot dike which led to the two small spatter conelets at the summit of the cone.

Apparently the lava rose into the cone, making room for itself by removing the material which in earlier stages formed the core of the cone. There is no evidence whether the removal was by stoping or by redissolving the hot cinder, or both. At the end of the eruption the magma column withdrew, leaving the center of the cone empty, but the walls of the cavity veneered with a thin layer of lava.

LEFT

PLATE 1. View of the cone area of the 1949 eruption, from the top of the caldera wall to the north. In the foreground and on the right can be seen the big pumice cone built on and against the caldera rim during early stages of the eruption. The fissures are the result of partial collapse of the cone, and the white areas are the result of alteration and deposition by escaping gases. In the middle distance can be seen the hollow cinder and spatter cone, and to its left the lava cone. PHOTO BY G. A. MACDONALD.

RIGHT

PLATE 2. The open chamber in the center of the small cinder and spatter cone. The chamber is lined with a thin layer of pahoehoe lava, and on the right the nearly vertical flow-banding in the pahoehoe lining is clearly visible. At the top a flow-banded dike leads upward through the cinder. The chamber is approximately 20 feet across. PHOTO BY G. A. MACDONALD.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY–SEPTEMBER, 1949

VOLCANOLOGY

July

Since the end of lava extrusion about the end of May, Mauna Loa has remained quiet. Mokuaweoweo was visited on July 26. No signs of lava activity could be detected although the new cone built during the early months of 1949 was still hot and fuming weakly and a faint pall of bluish fume hung over the crater of the 1940 cone. The small cinder and spatter cone within the crater of the larger cinder and pumice cone of the 1949 eruption had partly collapsed, and the center of the cone was seen to be occupied by an open chamber lined with a thin layer of pahoehoe.

Forty-six local earthquakes were recorded on the seismographs of the Volcano Observatory during the month of July. Of these, 31 were recorded at Kilauea and 34 at the seismograph on the eastern slope of Mauna Loa. (The total is not the same as the sum of those recorded at each of the stations, because many earthquakes were recorded at both stations.) On July 5 a moderately strong earthquake occurred at a depth of 10 to 15 miles on the east rift zone of Kilauea volcano, in the vicinity of Kapoho. At 8:52 p.m. on July 29 a strong shallow earthquake occurred on the northeast rift of Mauna Loa near the summit of the mountain. This earthquake, which dismantled both components of the Mauna Loa seismograph, was felt strongly at Kapapala and much less strongly by many persons in the area from Kilauea crater to Hilo.

On July 23, at 12:35 a.m., the Bosch-Omori seismograph recorded the long waves of a heavy earthquake with its origin near the New Hebrides Islands.

During the month of July the tiltmeter at the northeastern edge of Kilauea caldera accumulated a small amount of northerly tilt of the ground surface, but there was little change in tilt in the east–west direction. There is generally weak but pronounced easterly tilting and moderately strong northerly tilting at this season of the year. Hence the absence of appreciable easterly tilting and less than normal northerly tilting probably result from a slight decrease in pressure beneath Mauna Loa and Kilauea.

August

Mauna Loa and Kilauea remained quiet during August, although light fume was observed at the summit of Mauna Loa late on the afternoon of August 30.

Forty-seven local earthquakes were recorded on the seismographs during the month of August. Of these, 33 were recorded at Kilauea and 44 at the station on the eastern slope of Mauna Loa. A moderately strong earthquake which was felt in the area east of Kilauea crater at 2:26 p.m. on August 30 had its origin at a depth of 20 to 25 miles, about 8 miles south-southeast of Apua Point. An earthquake, which originated at a depth of about 30 miles under the southwest rift of Mauna Loa at 7:22 p.m. on August 31, was felt weakly in Kona.

On August 5 the seismographs recorded the great earthquake which caused tremendous damage and several thousand deaths in the region around Ambato, in Ecuador. On August 21 they recorded the great earthquake in British Columbia. This earthquake was of considerably greater magnitude than that of August 5 in Ecuador, and the smaller amount of damage must be attributed to its occurrence in an unpopulated area. It was so violent that it dismantled the seismographs, of comparatively low sensitivity, at the Volcano Observatory, 3,000 miles from its origin. It probably is the strongest distant earthquake thus far recorded at the Volcano Observatory. Aftershocks of the British Columbia earthquake were recorded until August 23.

During August the tiltmeter at the northeastern edge of Kilauea caldera recorded moderately strong northerly tilting of the ground, which is normal for this season of the year. There was almost no tilting in the east–west direction. Because there is normally an easterly tilting during this season, the lack of tilt in the east–west direction probably indicates a decrease of volcanic pressure under Mauna Loa.

September

The Hawaiian volcanoes remained quiet during September. The morning of September 6 marked the anniversary of the beginning of the last eruption of Kilauea. The 15 years since that eruption constitute the longest quiet period in historic record. The 13 years from 1894 to 1907 saw little lava activity, but fuming was almost continuous, and glow in Halemaumau was frequent, and one brief period of lava extrusion in Halemaumau appears to have occurred in 1902 (see VOLCANO LETTER 497, 1947). There is no indication that the end of the quiet period is near. Neither ground tilting nor earthquakes appear to indicate activity of Kilauea or Mauna Loa in the close future.

Forty-seven local earthquakes were recorded on the seismographs of the Hawaiian Volcano Observatory during September. Of these, 40 were recorded at Kilauea and 41 at the Mauna Loa station. On September 1 a sharp earthquake was felt strongly from Kapapala to Naalehu, and weakly in Kona and from Hawaii National Park to Hilo. It originated 3 to 4 miles northeast of the Kapapala Ranch headquarters, on the Kaoiki fault zone. A smaller earthquake, less generally felt, originated a little farther northeast on the same zone of faulting on September 14. An earthquake felt by a few persons in South Kona on September 16 had its origin near the coast about 5 miles south of Hookena, possibly on the Kiholo Pali fault.

On September 27, the seismographs recorded a distant earthquake which occurred in or near southern Alaska.

During the month of September the tiltmeter at the northeastern edge of Kilauea caldera recorded a slight easterly and a moderate northerly tilting of the ground surface which is normal for this season of the year.

G. A. MACDONALD

The data for the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

80. July 5, 00:44, moderate. East rift of Kilauea near Kapoho, about 12 miles deep. Not reported as felt.
81. July 5, 17:13, very feeble.
82. July 8, 12:42, very feeble.
83. July 19, 09:55, very feeble.
84. July 28, 17:36, very feeble.
85. July 29, 20:52, moderate. Both components of Mauna Loa instrument dismantled. Felt strongly at Kapapala, weakly from Hawaii National Park to Hilo. Focus about 6 miles deep about 3 miles ENE of Mokuaweoweo.
86. August 5, 14:49, very feeble.
87. August 8, 18:35, very feeble. On west flank of Mauna Loa near Kaunene, 12 to 15 miles deep.
88. August 12, 19:05, very feeble. Southeast slope of Mauna Loa between Ainapo and Ohaikea, shallow.
89. August 16, 02:20, very feeble. Southeast slope of Mauna Loa about 7 miles northwest of Pahala.
90. August 16, 16:23, very feeble. About 2 miles south of Poliokeawe Pali, south of Kilauea caldera.
91. August 19, 07:15, very feeble. About 10 miles deep, near the shore northwest of Huehue Ranch.
92. August 19, 19:24, very feeble. Northeast rift of Mauna Loa at about 7,500 feet.
93. August 21, 18:49, feeble. Felt by a few persons in Volcano district. Offshore, southeast of Kilauea caldera.

94. August 24, 06:03, very feeble.
95. August 24, 14:18, very feeble.
96. August 30, 14:27, slight. Beneath ocean, about 8 miles SSE of Apua Point, 20 to 25 miles deep. Felt in Volcano district.
97. August 31, 19:23, very feeble. Felt at Holualoa. Under southwest rift of Mauna Loa, about 30 miles deep.
98. Sept. 1, 12:53, moderate. Both components of Mauna Loa instrument dismantled. Felt strongly from Kapapala to Naalehu, weakly from Volcano district to Hilo and in Kona from Pahoehoe to Holualoa. Origin on Kaoiki fault, about 3 to 4 miles northeast of Kapapala Ranch headquarters.
99. Sept. 2, 02:31, very feeble.
100. Sept. 12, 03:46, very feeble.
101. Sept. 14, 16:47, feeble. About 6 miles deep, on Kaoiki fault about 3 miles west of Uwekahuna. Felt in Hilo.
102. Sept. 16, 14:08, very feeble. Felt in South Kona. Origin near coast, about 5 miles south of Hookena.
103. Sept. 18, 20:38, very feeble.
104. Sept. 22, 01:31, very feeble. Under southwest edge of Kilauea caldera, about 8 miles deep.
105. Sept. 23, 21:08, very feeble.
106. Sept. 26, 08:27, very feeble.
107. Sept. 28, 12:13, very feeble.

TELESEISMS

July 23, 00:35, slight. New Hebrides Islands; provisional epicenter.

August 5, 14:43, moderate. Central Ecuador, centering around Ambato.

August 21, 18:09, very large. Both components of Bosch–Omori seismograph at Kilauea, and the north–south component of the Mauna Loa seismograph were dismantled. Queen Charlotte Islands, off coast of British Columbia. Caused 2-foot tidal wave at Ketchikan, Alaska.

August 23, 10:38, slight. Probably an aftershock of the British Columbia earthquake.

Sept. 27, 05:38, slight. Origin probably near Juneau, in southern Alaska.

MICROSEISMS

Microseisms were slight from July 1 to 10, moderate from July 11 to 22, slight from July 23 to 29, moderate from July 30 to August 6, slight from August 7 to 20, moderate from August 21 to 27, slight from August 28 to September 1, moderate from September 2 to 10, strong from the afternoon of September 10 through September 14, and moderate for the remainder of the month of September.

CRACK MEASUREMENTS

Most of the cracks measured showed no appreciable movement. However, the crack at the observation area on the east rim of Halemaumau continued to open slightly. During the interval from June 30 to September 30, stations near the northern end of this crack showed opening of 2 to 3.5 millimeters, and stations near the southern end showed opening of about 0.5 millimeter.

TILTING OF THE GROUND

There was a net northerly tilting of the ground surface of 3.5 seconds of arc at the northeastern rim of Kilauea caldera between July 1 and August 21. Minor reversals to southerly tilt occurred during the periods July 9 to 12, 25 to 30, and August 9 to 10. There was slight southerly tilting from August 21 to 23, slight northerly tilting from August 23 to September 17, and slight southerly tilting from September 17 to October 1. The net change from July 1 to October 1 was a northerly tilt of 3.4 seconds of arc. In the east–west azimuth, there was an accumulation of 0.5 second of easterly tilt from July 1 to July 5. From July 5 to September 1 there were minor oscillations from easterly to westerly tilt, but no net accumulation of either. From September 1 to 4 there was a sharp westerly tilting, followed by a moderate easterly tilting during the remainder of the month. The net accumulation of easterly tilt from July 1 to October 1 was 0.9 second of arc.

Oct.	1	0.8″	N 76° E

TEMPERATURE MEASUREMENTS

Weekly measurements of the temperature at the steam well at Sulfur Bank were resumed on September 10. The following uniform procedure has been adopted. The ½-inch plug at the top of the casing of the more easterly of the two drill-holes is removed, and the well is allowed to blow freely for 10 minutes. A maximum thermometer is then completely inserted into the aperture and allowed to remain 5 minutes. To date, the measured temperature has been uniformly 206° F.

Measurements at steaming cracks at Sulfur Bank have ranged from 203° to 208°, probably because of non-uniform exposure. Changes in the amount and direction of the wind appear particularly effective in altering the measured temperature.

PUBLISHED BY THE UNIVERSITY OF HAWAII

BOMBING TO DIVERT LAVA FLOWS

By RUY H. FINCH and GORDON A. MACDONALD

Probably the first attempt to alter the course of a lava flow by artificial means occurred during the 1669 eruption of Etna volcano. The flow was advancing toward the city of Catania and seemed likely to destroy it. In an attempt to save the city, several dozen men covered themselves with wet cowhides for protection against the heat and dug a channel through the wall of hot lava at one edge of the flow. The operation was initially successful. A stream of lava escaped through the gap thus created and moved away at a high angle to the direction of the original flow, partly relieving the pressure on the stream moving toward Catania. Unfortunately, however, the new flow moved toward the town of Paterno, and some 500 irate citizens of that town descended upon the men of Catania and drove them away from the newly dug lava channel. Left unattended, the gap in the flow wall soon clogged up with cooled lava, and the main branch of the flow continued toward Catania, partly destroying it (Rittmann, 1929, pp. 95–96). This early attempt, although it ended in failure, demonstrated the possibility of diverting part or all of a lava flow to a new course by artificially breaking down the confining wall of the flow.

Digging away of the edge of the flow, by hand or by machine, is a difficult and possibly dangerous procedure. It is easier and quicker to blast away the lava by means of explosives. The late Lorrin A. Thurston suggested orally in the early 1920's that in the case of pahoehoe lava flows descending gentle slopes, high explosives might be thrust out over the flow on long poles and dropped through windows in the feeding tube near the flow source, shattering the tube, forcing the lava to spread out again near the source, and removing the supply of lava from the advancing lower end of the flow (Thurston, 1929). Similar methods had been under discussion for several years by members of the staff of the Hawaiian Volcano Observatory. Thurston's suggestion was accepted and advocated by Jaggar (1931), and during the Mauna Loa eruption of 1935 Jaggar introduced the method of emplacing the explosive by dropping military bombs from airplanes (Jaggar, 1936). This is generally the most practical way of transporting and emplacing the explosive. In some instances shells from nearby big guns might be more effective because of the greater accuracy with which they can be directed; but for the most part potential diversion sites are too inaccessible to be conveniently or quickly reached by artillery.

There are three principal ways in which bombing can bring about diversion of the fluid lava, thereby robbing the older flow below the point of diversion of its supply of lava and causing stagnation of the lower end of the flow. These are: (1) bombing of the natural levees along the open lava river of an aa flow or a young pahoehoe flow in which tubes have not yet formed; (2) bombing of the main feeding channel of a mature pahoehoe flow in which tubes have become well developed; and (3) bombing of the walls of the cinder cone at the source of the flow.

In well-established lava flows on little-dissected terrane the liquid lava of the main feeding channels commonly is confined within tubes or between natural levees and is at a level several feet higher than that of the land surface adjacent to the flow. Where the lava river is still open and confined between levees, breaking down of the levee therefore will allow the liquid lava to escape to one side and form a new flow, robbing the old flow of part or all of its supply of liquid lava. If topographic conditions are favorable, the new flow may move off at a high angle to the direction of the older flow, and reach some entirely different destination. More commonly, however, because the older flow was guided by

the direction of steepest slope or pre-existing topographic depressions, the new flow follows the same direction and moves downslope along the edge of the older one. If it does so, it may eventually reach the same place at which the older flow terminated. However, the advance of the lava as a whole is greatly delayed, because the diverted flow may take days, or even weeks, to reach the point attained previously by the older flow. When the second flow has reached the danger point, it also can be bombed, thus still further delaying the advance of the lava front.

A long stretch of the flow, or several separate points on the flow, may be suitable for bombing. If so, in general it appears advisable to select the lowest suitable site for bombing first. If it then becomes necessary to bomb the flow again at a later date the higher sites are still available. On the other hand, if the higher sites are bombed first the new lava streams advancing along the edges of the older one may so alter conditions that the lower sites are no longer suitable. In general, it appears desirable to wait as long as is safely possible before bombing the flow. Every day which bombing is delayed brings the eruption that much closer to an end, and, in general, sees the rate of extravasation diminished. Premature bombing may result in the process having to be repeated, whereas a single bombing might have sufficed had it been delayed a little longer. Care must be taken, however, to allow a sufficient margin of time to cover the possibility of periods of bad weather with low visibility (when bombing is impossible) and rapid forward spurts of the flow.

The practicability of breaking down the levee of an open lava stream by aerial bombing was demonstrated during the 1942 eruption of Mauna Loa (Finch, 1942, p. 4). Disruption of the levee by bombs resulted in at least one new lava stream which poured out through the break in the wall. Topography was not favorable to direct the new flow away from the course of the older one, and consequently it flowed along the edge of the older one for a short distance and then rejoined it. Even such a brief diversion may have some effect in retarding the advance of the front of the major flow, owing to the rapid cooling of the channel of the main flow below the point of diversion, and consequent chilling of the next lava to enter it, with the accompanying tendency to clog the channel.

The method of bombing the main tubes of a pahoehoe flow was tried during the 1935 eruption of Mauna Loa (Jaggar, 1936). Bombs dropped on the roof of the tube may break in the roof and cause the tube to become clogged with solid fragments. Or bombs dropped into the liquid lava within the tubes through the roof or through windows in the roof may cause sufficiently violent stirring of the liquid to transform it from pahoehoe to aa, with increase in viscosity or even local congelation. If it is not swept away with the current, this mass may cause a plugging of the tube. If in either way the tube becomes clogged, the result is an overflow of liquid lava from the tube at the point of clogging and a partial or total removal of the supply of liquid from the tube farther downslope. The lava which overflows at the break forms new tongues which advance downslope on top of, or alongside of, the older flow. If the eruption continues long enough these tongues may develop new major tubes, and may in time reach or pass the terminus of the older flow, but the advance of the lava as a whole will have been delayed and the end of the eruption will be that much closer. It may be possible to repeat the bombing if necessary.

The cinder and spatter cones formed at the source of lava flows commonly contain pools of lava which are held at levels several feet above the surrounding land surface. Likewise, the liquid surface of a mature lava flow issuing from the cone is generally several feet above the adjacent terrane. Breaking down of the cone walls, either naturally or induced by bombing, therefore will allow the liquid in the cone to escape over the surrounding ground, robbing the established lava flow of part or all of its supply of new lava. Many of the cones on the rifts of Mauna Loa have a form especially favorable for bombing. They are built by rows of lava fountains spurting from fissures, and are long and narrow, with relatively thin walls which probably would be quite easy to break down by bombing. Bombing of the walls of the source cone has been suggested (Finch, 1942, p. 6; Macdonald, 1943, p. 255), but has not yet been tried. However, during the 1942 eruption of Mauna Loa there occurred a natural breakdown of the cone walls liberating floods of pahoehoe. A new flow advanced seaward parallel to the older channel. A day later, forward movement at the front of the older flow had practically ceased.

Successful diversion of lava flows by bombing depends upon a combination of several favorable circumstances, including: a lava river flowing in a channel or lava held in the source cone at a level higher than the adjacent land surface; narrow levees, thin cone walls, or thinly roofed tubes which can be broken open by bombs; and favorable topography. The first two conditions are commonly present during eruptions of basaltic lava, but favorable topography is not so general. On the slopes of volcanoes which have been appreciably dissected by erosion, flows may be confined within valleys and diversion may be difficult or impossible. Even under those conditions, however, it may be possible to delay greatly the advance of the flow front by repeated bombing and spreading of the lava in the upper reaches of the valley. On the undissected or little-dissected slopes of young volcanoes, where erosion has not yet cut valleys, bombing to divert the flow is both possible and practical.

It must be pointed out that successful diversion is only possible where the flow has continued long enough to establish well-defined channels, or build at least moderate-sized cones. Probably little can be done with the voluminous bursts which occur during the early hours of Mauna Loa eruptions when the flows are spreading rapidly in several directions and moving through many shifting and anastomosing channels. Fortunately, these early floods are generally high on the mountain where they constitute no danger. Likewise, it must be realized that time is required to prepare the planes and load the bombs, as well as to select the targets and put the plan into operation. Therefore, diversion by bombing may not be possible in time to avert catastrophe where the flow is advancing rapidly down steep slopes, or where the point of outbreak of the flow is too close to the area it is desired to save. It is difficult to place any definite limit on the distance of the vent from the endangered area within which time is insufficient to permit bombing to divert the flow. This depends on the fluidity of the particular lava stream, on the slope, and on the general character of the terrane. For average Hawaiian eruptions, with average slope conditions, it may be about 7 miles. Where the distance is less than that, or where slopes are steep and flow of the lava rapid, only lava barriers such as those suggested by Jaggar (1945) can furnish protection.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR OCTOBER–DECEMBER, 1949

VOLCANOLOGY

October

A total of 39 earthquakes was recorded in October. Of this total 31 were recorded at Kilauea and 37 at the Mauna Loa station. Two of these earthquakes, whose origins were determined, originated under Mokuaweoweo. The stronger of these two shakes was felt at Pahala at 07:55, October 22. Four shakes occurred in less than 15 minutes during the evening of October 26. Three of the shakes were plainly felt at the Kapapala ranch house. They originated along the Kaoiki fault near Kapapala.

The accumulation of northeasterly tilt at the northern end of Kilauea caldera during October was in about the usual amount for this season of the year.

November

An unusual feature of this month was a swarm of earthquakes under Mauna Kea. Sixteen shakes occurred between 09:46 and 20:31 on November 4. A few of the stronger shakes were felt by hunters who were at an elevation of 10,000 feet on Mauna Kea, and they were perceptible at scattered points on the island. An earthquake which occurred at 07:58, November 28, was felt over most of the island. It originated under the east slope of Mauna Loa near Mokuaweoweo at a depth of 20 miles and was strong enough to dismantle seismographs at Hilo, Kilauea caldera rim, and on the east slope of Mauna Loa.

There was about the usual accumulation of northeasterly tilt during the month.

A land slide from the walls of Halemaumau at 14:21, November 24, produced a large brown dust cloud.

December

A distinct feature of the month was the recording of 262 earthquakes on the Mauna Loa seismograph on December 28. Four of the shakes were registered as very feeble and the rest were small tremors. About 80 of the shakes were recorded on the Bosch-Omori seismograph under the Volcano House and 47 on the Kona instrument at Kealakekua. In at least two instances 3 distinct tremors were recorded in 30 seconds. Shortly before the shaking ceased, or at 23:02, continuous tremor started and lasted for 18 minutes.

The frequency of the tremor and the rather uniform small amplitude suggest an intrusion at moderate depth under the northeast rift of Mauna Loa at about 12,000 feet or above.

In addition to the swarm of earthquakes on December 28, 42 shakes were recorded during the month. Of this total 39 were recorded on the Mauna Loa instrument and 25 at Kilauea. Two of the earthquakes were strong enough to be perceptible and both originated under Kilauea. The first occurred at 03:06, December 11. It originated deep under Kilauea and was recorded on seismographs on Oahu. The second occurred at 15:09 also on December 11. It originated at a shallow depth under the northern end of Kilauea caldera and was accompanied by a distinct roar.

R. H. FINCH.

SEISMOLOGY

Earthquake Data, October–December, 1949

(Based on Bosch-Omori seismograph on rim of Kilauea caldera.)

* For definition of local seismicity, see Volcano Letter 371.

The data for the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

108. Oct. 2, 01:28, very feeble. South edge Kilauea caldera.
109. Oct. 3, 08:44, very feeble. 4-5 miles deep on Hilina-Paliokeawe fault 8 miles southeast of Volcano House.
110. Oct. 3, 16:57, very feeble.
111. Oct. 22, 03:51, very feeble. East slope Mauna Loa.
112. Oct. 22, 07:55, very feeble. Felt Pahala. South end Mokuaweoweo.
113. Oct. 23, 10:14, very feeble. East slope Mauna Loa.
114. Oct. 26, 17:58, feeble. Felt at Kapapala.
115. Oct. 26, 18:12, very feeble. Felt at Kapapala.
116. Oct. 27, 03:56, very feeble.
117. Oct. 30, 10:56, very feeble.
118. Nov. 4, 10:37, very feeble.
119. Nov. 4, 10:52, very feeble.

120. Nov. 4, 11:44, very feeble.
121. Nov. 4, 12:00, very feeble. 118 to 121 probably same location as 122.
122. Nov. 4, 12:12, feeble. Felt by hunters at 10,000 feet on Mauna Kea. At a depth of 20 miles under summit of Mauna Kea.
123. Nov. 4, 13:02, feeble. Same as 122.
124. Nov. 4, 14:10, feeble. Same location as 122.
125. Nov. 5, 18:45, very feeble. Under east slope of Mauna Kea.
126. Nov. 23, 02:49, very feeble. Mauna Loa.
127. Nov. 25, 07:58, moderate. Instruments dismantled. Felt locally and from North Kona to Hilo. 20 miles under east slope of Mauna Loa near Mokuaweoweo.
128. Dec. 11, 03:06, feeble. Felt locally. Deep under Kilauea.
129. Dec. 11, 15:08, slight. Felt locally and accompanied by roar. Under north end of Kilauea caldera.
130. Dec. 12, 18:56, feeble. Kilauea.
131. Dec. 16, 07:35, very feeble.

TELESEISMS

Oct. 19, 11:11, slight. Solomon Islands.
Nov. 9, 13:32, slight. North of Easter Island.
Nov. 19, 22:29, slight. Gulf of California.
Nov. 21, 15:02, slight. Kermadec Islands.
Nov. 26, 22:52, slight. Tonga.
Dec. 16, 21:46, slight.
Dec. 16, 22:16, slight.
Dec. 17, 05:58, slight. Near southern tip of South America.
Dec. 25, 20:45, slight.

MICROSEISMS

Microseisms were slight October 26-28 and November 17-21 inclusive, strong from November 12-14, and moderate on other days.

CRACK MEASUREMENTS

The northern end of the crack at the observation area on the east rim of Halemaumau opened 2 millimeters during the 3 months ending December 31. All other cracks that were measured showed little or no movement.

TILTING OF THE GROUND

There was an accumulation of north tilt amounting to 3.3 seconds of arc between October 1 and November 21. The seasonal change to southerly tilt occurred earlier than common, and from November 22 to December 31 there was an accumulation of 2.2 seconds of south tilt. The 4.8 seconds of east tilt between October 1 and December 31 was about the usual for this season of the year.

Table of Tilt at Seismograph Vault on Northeast Rim of Kilauea Caldera

Week Ended		Amount	Direction
Oct.	8	0.7″	N 9° E
	15	2.1″	N 47° E
	22	0.3″	N 26° E
	29	0.7″	N
Nov.	5	0.4″	S 34° W
	12	1.1″	N 26° E
	19	1.5″	N 76° E
	26	0.6″	S 54° W
Dec.	3	1.0″	N 70° E
	10	1.1″	S 12° E
	17	1.3″	S 73° E
	24	1.5″	S 39° W
	31	0.6″	N 53° E

TEMPERATURE MEASUREMENTS

There was a positive decrease in the temperature of the steam well at Sulfur Bank. The decrease amounted to 2° F.—from 206° F. on October 1 to 204° on November 30. The temperature in December appeared to be nearly constant at 204° F. A vent in the Sulfur Bank showed a similar drop from 205° F. on October 1 to 203° F. on December 28. The decrease does not show a good correlation with heavy rainfall and perhaps is a regular seasonal change.

The highest temperature found in the Kokoolau steaming area on November 4, 1949, was 190° F., or a little less than was common for several years after it was noted that trees were being killed there in 1938.

At the Aloi crater steaming area the highest temperature found on November 4 was 194° F.

THERMAL WATER ON KILAUEA VOLCANO

By RUY H. FINCH and GORDON A. MACDONALD

The numerous steam vents within Kilauea caldera are well known. For the most part the steam contains no other gases and appears to represent merely ground water of meteoric origin which has been heated to, or slightly above, the boiling point by contact with bodies of hot rock. At Sulphur Bank and at the nearly buried solfataric area east-southeast of Halemaumau the steam is mixed with a small proportion of sulfur gases and carbon dioxide of magmatic origin, but even there the majority of the steam probably is derived by heating of ground water.

In addition to the steam vents at Kilauea caldera, there are four known occurrences of warm water on Kilauea volcano. It has been reported in a crack near Waiwelawela Point, 12 miles east of Pahala (Stearns and Clark, 1930, p. 190), but no record of the temperature of the water at that locality is known. The warm water undoubtedly results from heating of basal ground water by contact with hot intrusive rock along the southwest rift zone of Kilauea.

The other three occurrences of warm water are all in eastern Puna, on or near the east rift zone of Kilauea. One of these is the well-known "Warm Spring" near the northern base of Puu Kukae, about 0.8 mile east-northeast of Kapoho. The water is basal ground water. It forms a pool in a crack at the foot of the small fault scarp which marks the southern edge of a small graben, or block of rock which has sunk down between two faults. Brigham (1868, p. 374) reported that in 1864 this pool (called by him the "Blue Grotto") had a temperature of 90° F. At present the temperature is only a little above the average air temperature. Measurements on January 11, 1950, gave a water temperature of 84° F. and an air temperature of 79°.

Another pool of warm water is situated half a mile northwest of that just described and within the same graben. The water is in a crack at the back of a shallow cave, the entrance of which is at the base of a low northward-facing fault scarp about 750 feet south of the higher fault scarp that marks the northern edge of the graben. The locality is about 0.6 mile north of the highway junction at Kapoho and 0.2 mile east of the Kapoho-Koae road. At one time the water was bottled for sale under the trade-mark "Volcano Water." The temperature of the water is only a little above that of the air outside the cave. On January 11, 1950, the water temperature was 83° F., and the temperature of the air in the cave was 77°.

The third occurrence of warm water is at Pohoiki, about 3 miles south of Kapoho. There basal springs issue just above sea level from a cobble beach at the head of a small bay. The springs are within the zone of splash from the ocean waves and are distinctly brackish. On January 11 the water temperature was 91° F., and the air temperature 77°.

No other warm waters are known on the island of Hawaii, although steam issues from vents in the caldera of Mauna Loa and on both rift zones. The amount of warm water, at first glance, seems surprisingly small in view of the large amount of volcanic heat undoubtedly still present beneath the surface. However, because of the high permeability of the rocks, as Stearns and Clark (1930, p. 190) have pointed out, most juvenile and meteoric hot waters probably become diluted and cooled at the basal water table and do not reach the surface.

ORIGIN OF PUEHU CINDER CONE, KAU

By GORDON A. MACDONALD and RUY H. FINCH

Puehu cinder cone is a small but prominent cone situated just south of the main highway from Kilauea caldera to Honuapo, about 0.4 mile southwest of the junction with the road to Punaluu. It lies on the southern slope of Mauna Loa about 1.2 miles west of the boundary between the surface lavas of Mauna Loa and Kilauea and is surrounded and partly buried by aa lavas of Mauna Loa. The cone is being excavated to supply cinders for use on roads. Before the mining of cinders began, the cone was about 50 feet high above the lavas on its downhill side, and its exposed base was about 200 feet above sea level. At present a large pit on the southeastern side of the cone exposes cinder for a depth of about 100 feet and has not yet reached the base of the cone.

Stearns and Macdonald (1946, pl. 1) classified the cone as a littoral cone of the Kau volcanic series, formed by steam explosions where lavas of Mauna Loa entered the sea. The better exposures which have resulted from recent excavation indicate that interpretation to be erroneous.

Puehu cone clearly is a cone formed at a primary lava vent. The ejecta exposed in the new cuts are typical of primary cinder cones built at vents. They are moderately to highly vesicular, or even pumiceous, cinder and spatter. Moreover, several thin layers of lava are interbedded with the cinder, some of them obviously rootless flows formed by the aggregation of heavy showers of fluid spatter on the flanks of the cone. Some of these flows still show welded spatter on their surfaces. Lava extends all the way to the summit of the cone, 25 feet higher than the surface of the adjacent aa flow on the uphill side of the cone. On the northeastern side of the cone there is exposed a 15-foot thick section of thin-bedded pahoehoe, the beds ranging from 1 to 6 inches thick and averaging 2 to 3 inches. The rock is olivine basalt with sparingly to moderately abundant phenocrysts of olivine up to about 4 mm. long; much of it is highly vesicular. Such very thin-bedded, highly vesicular pahoehoe typically is found in close proximity to primary vents. Neither it nor the rootless flows would be expected to form on a littoral cone where relatively viscous aa lava enters the sea, nor have they been observed on known littoral cones.

Besides the presence of the aforementioned features typical of cones formed at primary vents, there is a complete absence of the features typical of littoral cones. The angular grains of relatively dense glass, which are characteristic of littoral cone deposits (Macdonald, 1949, p. 72), could not be found. Neither are there present any of the angular blocks of relatively dense lava which are common on the slopes of Puu Hou, the littoral cone formed by the Mauna Loa flow of 1868, and the older littoral cones farther west.

The lower slopes of Puehu cone in the new excavations are covered by as much as 15 feet of yellow Pahala ash, with one intercalated lava flow. The cinder layers in the cone were partly truncated by erosion before deposition of the ash. The Pahala ash is absent from most of the top of the cone, but 2 to 3 feet of ash are preserved in local pockets. Most of the ash appears to have been eroded off the upper slopes of the cone. The ash overlying the lower slopes appears to be the result of primary deposition, and there is no evidence that the thickness of the ash layer resting on the lower slopes of the cone was appreciably increased by secondary deposition of ash eroded from the top of the cone.

The presence of 15 feet of Pahala ash overlying the lower slopes of the cone indicates that the cone is somewhat older than previously was believed. Obviously, it must already have been in existence during the period of deposition of the Pahala ash, and therefore it is older than the rocks of the Kau volcanic series, which are younger than the Pahala ash. However, the Pahala ash has a thickness of 55 feet on Puu Enuhe, only 2.5 miles northwest of Puehu cone (Stearns and Clark, 1930, p. 66). Consequently, it is probable that only part of the total thickness of the Pahala ash overlies the Puehu cone and that the cone is of late Pahala age.

Puehu cone is situated about 12 miles east of the southwest rift zone of Mauna Loa and even farther from any other known vents of Mauna Loa. It lines up with no known Mauna Loa rifts. In contrast, it is only about 3.5 miles from the closest visible vent on the southwest rift zone of Kilauea volcano and lies directly in line with that rift. The cone itself is somewhat elongated in a direction parallel to the Kilauea rift, possibly because the vent fissure had that trend. Although it cannot be definitely proved, it appears highly probable that the cone was formed by eruption from the southwest rift of Kilauea and that it belongs to Kilauea rather than to Mauna Loa.

It is concluded that Puehu cone is a primary cinder cone formed by eruption at a lava vent during late Pahala time, and that it probably belongs in the Hilina volcanic series of Kilauea volcano and is correlative with the upper part of that series exposed in Hilina Pali. If this interpretation is correct, the southwest rift zone of Kilauea must have been in existence at least by late Hilina time, thus strengthening the conclusion of Stearns

and Macdonald (1946, pp. 135–136) that the Hilina volcanic series was derived from Kilauea, as opposed to the belief of Stone (1926, pp. 38, 49–50) and Powers (1946, p. 6) that the Hilina lavas are part of Mauna Loa.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JANUARY–MARCH, 1950

VOLCANOLOGY

January

The year opened with both Kilauea and Mauna Loa inactive save for the usual steam vents and solfataras.

Only 24 earthquakes were recorded during the month. This is the smallest monthly total since October, 1948. Twenty-two of the shakes were recorded on the Mauna Loa seismograph and 17 at Kilauea.

There was an accumulation of 7.8 seconds of arc tilt to the south-southwest during January. This is a little more than usual for this season of the year.

The fact that the lava fill in Halemaumau is still hot was shown by pronounced steaming following heavy rains on January 10.

February

A total of 29 earthquakes was recorded during February. Of this number, 26 were recorded on the Mauna Loa seismograph and 21 at Kilauea.

Dust clouds were especially conspicuous in the Kau Desert on February 12.

A landslide of appreciable magnitude from the walls of Halemaumau was observed at 09: 50 on February 13.

March

Northerly tilt during March indicates that there was a distinct pressure build-up at Kilauea. This increase of pressure was strong enough to overcome the southerly tilt usual for March and to show a positive northerly tilt of 6 seconds of arc. This is the strongest northerly tilt recorded here for several years.

The distribution of the earthquakes recorded during March also indicates a slight uneasiness under Kilauea volcano. Of the 37 shakes recorded during the month, 35 were registered on the Kilauea seismograph and 16 on the Mauna Loa instrument. Most of the earthquakes of Kilauea origin had shallow foci.

Mokuaweoweo was visited by G. A. Macdonald and J. B. Orr on March 28 to 30. No activity was observed other than the mild solfataras, and no changes were noted since the last visit in October, 1949, other than minor collapses in the small cones built during the 1949 eruption. Solfataras are located in the crater of the 1940 cone, on its northern slope, and on the caldera floor north of it. The gas liberated is largely steam, but contains a little sulfur dioxide and in places a small amount of sulfur is being deposited. The 1949 cones are still hot at many places, a little steam is being given off, but no sulfurous gas was detected. Pale yellow stalactites, probably of sulfates, are forming in the hollow 1949 cone. Collapse of the walls of the crater of the 1949 lava cone has reduced the depth of the crater to about 15 feet.

R. H. FINCH

CRACK MEASUREMENTS

None of the cracks that are regularly measured showed an appreciable movement during the 3 months ended March 31.

TILTING OF THE GROUND

Strong southerly tilt set in shortly after the beginning of the year and continued until February 9. The accumulation for the period amounted to 11 seconds of arc. From February 9 to March 5 there was no accumulation of tilt in the N-S direction. Strong northerly tilt commenced on March 6, or about 1 month earlier than usual. The northerly tilt from March 6 to 31 amounted to 6 seconds of arc.

Table of Tilt at Seismograph Vault on Northeast Rim of Kilauea Caldera

Week Beginning		Amount	Direction
January	1	1.4″	S 41° E
	8	2.0″	S 10° E
	15	2.2″	S 52° W
	22	2.0″	S 10° W

* For definition of local seismicity, see Volcano Letter 373.

The data for the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

1. Jan. 13, 11: 54, very feeble. Inland from Kealakekua Bay.
2. Jan. 20, 19: 31, very feeble. Mauna Loa.
3. Jan. 21, 04: 40, very feeble. Near summit of Mauna Loa.
4. Jan. 25, 16: 26, feeble. Felt at 29 Miles and Hilo.
5. Feb. 12, 06: 09, slight. Felt locally and at Naalehu. Near Makaopuhi.
6. Feb. 13, 11: 59, slight. Felt locally and at Hilo. Eight miles deep under east slope of Mauna Loa.
7. Feb. 15, 16: 52, very feeble. Mauna Loa.
8. Feb. 19, 08: 00, very feeble.
9. Feb. 26, 14: 01, very feeble. Kilauea.
10. Feb. 28, 04: 26, very feeble. Mauna Loa.
11. Mar. 1. 08: 00, feeble. Southwest of Hilo.
12. Mar. 7, 21: 47, very feeble. Mauna Loa.
13. Mar. 11, 19: 59, very feeble. Kilauea.
14. Mar. 17, 02: 35, slight. Shallow; under Kilauea.

15. Mar. 17, 04 : 05, very feeble.
16. Mar. 24, 14 : 14, slight. Shallow ; under Kilauea.
17. Mar. 25, 05 : 43, strong. Widely felt on island of Hawaii. Seismographs dismantled. 15-20 miles deep under 5,000-foot contour, east slope of Mauna Loa.
18. Mar. 28, 10 : 57, very feeble. Mauna Loa.
19. Mar. 31, 03 : 43, very feeble. Kilauea.

TELESEISMS

Jan. 9, 17 : 30, slight. Off south coast of Mexico.
Feb. 28, 00 : 30. North coast of Hokkaido.

MICROSEISMS

Microseisms were moderate during the first 2 weeks of January and the last few days of March and slight on other days.

TEMPERATURE MEASUREMENTS

The temperature of the steam well at the Sulfur Bank was 206° F. in October, 1949, then dropped to 204° F. in November. The 204° F. temperature continued until the latter part of March, when a temperature of 202° F. was measured.

MAGNETIC OBSERVATIONS

H. R. Joesting and J. H. Swartz of the Geophysics Branch of the Geological Survey, and R. E. Wilcox of the Volcano Investigations Unit, spent the first 3 weeks of February at the Observatory setting up procedures to be followed in a program of magnetic observations and calibrating instruments and instructing Observatory personnel in their use. The instruments to be used are two Askania-type magnetometers built by Wolfson of Toronto. A series of permanent observation stations is being established on Kilauea and the lower slopes of Mauna Loa, and periodic readings will be taken to determine the variation in the vertical component of the earth's magnetic field, particularly the changes in differences between the various stations.

The magnetic permeability of rocks is decreased by an increase of temperature, and above a certain temperature (known as the Curie point) they become entirely non-magnetic. Thus a body of hot magma rising beneath the surface of the volcano should be non-magnetic, and the rocks around and above it should become less and less magnetic as they are heated up. It is hoped that this reduction in strength of magnetism may be detectable at the surface, and that the effect may appear long enough before the magma reaches the surface to be useful in predicting eruptions.

During February and early March, 29 stations were established around and in Kilauea caldera, along the Chain of Craters road and the upper part of the Hilina Pali road, and along the road to the Mauna Loa seismograph. At each station concrete blocks were built on which to set up the tripod of the magnetometer. It is planned to occupy each of the stations at least once a month, and oftener if possible.

On March 27 to 30 a series of dip-needle measurements was made on Mauna Loa by G. A. Macdonald of the Observatory staff and J. B. Orr of Hawaii National Park as part of the general study by the Observatory of earth magnetism in the vicinity of the volcanoes. The measurements were made along the trail from Kilauea to the summit of Mauna Loa, part way around the summit caldera, and across the floor. Preliminary analysis of the results shows that in general the strength of the magnetic attraction was less along the rift zones than elsewhere on the mountain. It is to be expected that these zones would be hotter than the rest of the mountain and have a smaller magnetic attraction.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:
R. H. Finch, Volcanologist, Director
G. A. Macdonald, Geologist
C. K. Wentworth, Geologist, part-time
B. J. Loucks, Instrument maker
Ruth B. Loucks, Assistant

University of Hawaii:
T. A. Jaggar, Geophysicist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE JUNE 1950 ERUPTION OF MAUNA LOA

By R. H. FINCH and GORDON A. MACDONALD*

Part I

NARRATIVE OF THE ERUPTION

INTRODUCTION

Following the end of the 1949 summit eruption of Mauna Loa, magma pressure remained high, and the molten lava continued to stand high in the conduit. A moderate release of fume continued in the summit caldera throughout the rest of 1949 and the spring of 1950. A normal accumulation of eastward ground tilting was recorded at the Volcano Observatory during the fall of 1949, but during the spring of 1950 westward tilting was markedly less than usual, apparently indicating a tumescence of the mountain. On the basis of past history, it was expected that the summit eruption would be followed by a flank eruption, probably within 2 years; the apparent high position of the magma column suggested that the interval might well be shorter. During May many earthquakes originated at Mauna Loa and pointed to a distinct uneasiness of the volcano. These culminated on May 29 with a strong earthquake originating on the southwest rift near the summit. In a bulletin released by the Observatory, published in newspapers on May 30, Finch called attention to the unrest of the southwest rift of Mauna Loa and stated that if the eruption came soon it would take place there. The expected eruption came on the evening of June 1, 1950.

ACKNOWLEDGMENTS

Many people gave valuable aid during the eruption by contributing information on the activity. It is impossible to list all by name, but to all of them we extend our sincere thanks. Some persons should receive special mention. Colonel L. W. Bryan, island commander of the Hawaii National Guard and island forester of the Territorial Board of Agriculture and Forestry, was exceedingly active in making observations from the air and deserves much credit for his work in keeping track of the flows and warning of danger from them during the first days of the eruption. His unsurpassed knowledge of the terrain was of very great aid. William Stearns and Donald Campbell of Murray Aircraft Agricultural Service contributed many excellent observations from the air. Sergeant Wilmot Vredenburg of the Hawaii Police Department passed on much information on the activity of the Ohia Lodge flow near the highway. Ernest Martin, manager of Kahuku Ranch, contributed information on the lava flows in the Kau District from personal observations and from those of his cowboys. Mrs. Myrtle Hansen of Naalehu was exceedingly helpful in relaying information from various sources in the Naalehu and Waiohinu area as well as in contributing her own observations on the lava flows and earthquakes.

Harry Blickhahn, editor of the *Hilo Tribune-Herald,* and Vern Hinkley, managing editor of the *Honolulu Star-Bulletin,* also were very helpful in passing on information and photographs as they received them.

Pilots of Army and Navy planes made observations from the air, and several of these, as well as observations by commercial pilots, were relayed by the staff of the Civil Aeronautics Authority at Hilo.

Members of the staff of Hawaii National Park contributed many valuable observations on the flows and vent activity. F. A. Hjort, chief ranger, and V. R. Bender, ranger, made aerial observations on the morning of June 2 and observations on the ground at the lower line of vents on June 3 and 4. F. R. Oberhansley, superintendent, I. J. Castro, assistant superintendent, and Herbert Quick, superintendent of construction and maintenance, observed the vent activity from the air on June 3.

* Director and Geologist, respectively, Hawaiian Volcano Observatory, U. S. Geological Survey, Hawaii National Park.

FIGURE 1. Map of the island of Hawaii, showing the approximate positions of the lava flows of June, 1950 (solid black). Numbers in circles indicate the flows referred to in the text: 1. Flow from the initial outbreak above 11,000 feet altitude; 2. Punaluu flow; 3. Hookena flow; 4. Magoon Ranch flow; 5. Ohia Lodge flow; 6. Kahuku flow. Older historic flows are stippled. Most of the flows originate along the two major rift zones.

D. H. Hubbard, naturalist, made observations from the sea and from the ground at the northern side of the Hookena flow on June 2 and 3.

D. C. Cox, geologist for the Hawaiian Sugar Planters' Association, cooperated with the Volcano Observatory staff in making observations on the lava flows and the vent activity and furnished the Observatory with a complete set of his field notes.

Several members of the U. S. Geological Survey not attached to the Observatory staff also cooperated in the investigation and were of great aid in the collection of data in the field. They include C. K. Wentworth, geologist for the Honolulu Board of Water Supply and part-time geologist for the Observatory; D. A. Davis, district geologist; M. H. Carson, district engineer; G. D. Robinson, assistant chief of the General Geology Branch; and Arnold Mason, geologist with the Pacific Geological Surveys Section. H. R. Joesting and J. R. Swartz of the Geophysics Branch carried on magnetometer observations during the eruption.

NARRATIVE

On the evening of June 1, 1950, Mauna Loa volcano erupted from its southwest rift. Glow was first seen from the Volcano House at Kilauea at about 9:25 P.M., but harmonic tremor started registering on the seismograph at 9:04 and it is probable that the eruption actually started then or very shortly afterward. About 9:10 Mr. and Mrs. Alfred Hansen, in Naalehu, heard a deep rumbling from the direction of the top of the mountain.

The first outbreak was high on the rift. At first two narrow illuminated columns of fume were visible, but these rapidly expanded down the mountain slope. A fissure 2.5 miles long opened from about 12,600 to 11,250 feet altitude, the upper end being close to the small pit crater Lua Hou and the lower end near Sulphur Cone. From this fissure poured great volumes of fume rising in a relatively narrow column about 2 miles into the air then spreading laterally to form a mushroom-shaped cloud brightly illuminated by the glare of the incandescent lava beneath. A flood of fluid gas-rich

lava poured from the fissure and down the mountainside, most of it going westward toward the Kona District. Many short flows were formed, and one long flow (flow 1, Fig. 1) extended downslope about 5 miles to an altitude of about 9,000 feet. Robert Duncan of Pahala reported hearing the roar of the lava fountains about 15.5 miles away, at the junction of the Kapapala Ranch road with the highway.

The outbreak at the upper source lasted only a few hours. By 12:30 A.M. on June 2, the glow at the upper source was distinctly less, and by 1:30 A.M. it was feeble. At that time the activity at the upper source had diminished greatly and may already have been finished.

At 10:15 P.M. on June 1, observers at the Volcano Observatory and along the Kau-Volcano highway noticed a small puff of fume rising from a point on the rift at about 8,250 feet altitude approximately 8 miles southwest of the lower end of the glowing fume column at the upper source. At 10:23 bright glow appeared on the fume cloud, indicating that fluid lava had reached the surface. The illuminated fume column rapidly spread as the length of the erupting fissure increased. Margaret Finch, watching from the Volcano Observatory, observed the glow expanding up the mountain, indicating that the fissure opened upslope. The glow from this lower source continued to increase rapidly until 10:45, when it was obscured by clouds. Lava fountain activity was very strong. At 11:40 Finch and Macdonald could hear the roar of the lower fountains distinctly at the point where the highway crosses the western branch of the 1907 lava flow, nearly 15 miles from the site of the eruption.

Early on the morning of June 2 the activity was observed from the air by Frank Hjort. He reported lava fountaining from a line of fissures about 7 miles long extending from about 10,500 down to 8,000 feet altitude. Between the main line of fissuring and the shorter westerly line a broad pond of molten lava had accumulated. Floods of very fluid lava were pouring westward toward Kona, in a series of anastomosing streams. Lava from the principal fissure was pouring over the shorter westerly fissure, partly drowning it. Sulfur dioxide fumes were very strong. About noon Ross Bender flew over the source area. He reported two principal lines of lava fountains playing along fissures at approximately 10,000 and 8,500 feet altitude. The source at 10,000 feet was largely obscured by fume, but no lava movement was observed there or in the flows originating there. From the source at 8,500 feet great floods of lava were pouring westward. At the time of his first observations lava fountains were playing from several isolated stretches of the fissure below 9,000 feet, but while he watched the activity increased and fountains developed along the intervening portions of the fissure, making the curtain of fountains essentially continuous. Some of the fountains he estimated to be about 300 feet high.

A similar condition was reported on the afternoon of June 3, when Frank Oberhansley, I. J. Castro, and Herbert Quick flew over the scene of activity. The lava fountains formed an almost continuous "curtain of fire," averaging 150 to 200 feet high, with some of the bursts reaching 300 feet or even more.

The line of fissures forming the lower source was not continuous. Over a stretch of about 2.5 miles, between 8,950 feet and 9,750 feet altitude, there appears to have been no lava liberation. Between 9,750 and 10,500 feet altitude there was a line of active fountains 1.6 miles long. Below 8,950 feet altitude there was a series of nearly aligned fissures, en echelon and commonly slightly overlapping.

During the first few hours of the eruption two very rapid flows were poured out from the vent area centering at 10,000 feet altitude. One of these (flow 2, Fig. 1) advanced south-southeastward in the general direction of Punaluu. By daybreak on June 2 it had passed the ranch road a short distance west of Punaluu Kahawai. On the morning of June 2 it was examined from the air by L. W. Bryan. At that time it had reached an altitude of about 5,500 feet, approximately 10 miles from its source, but its advance appeared to be essentially over.

The other flow (flow 3, Fig. 1) from the 10,000-foot source moved rapidly westward into the Kona District. At 12:20 it was less than a mile above the highway, and Ruth Macdonald reported that the roar and explosions caused by the lava advancing through the forest were clearly audible and the glare from hot lava and burning vegetation was strong. The flow crossed the highway at about 12:30, destroying Hookena Post Office, several houses, and a filling station. There was a light but steady fall of fine black ash and some Pele's hair mixed with rain. The flow reached the sea, 0.8 mile below the highway, at about 1:05 A.M. on June 2, having covered its 15-mile course down the mountainside at an average rate of 5.8 miles an hour. Where the hot lava entered the sea, a great billowing column of steam arose. However, observers reported no apparent increase in the amount of ash in the air. This first flow to reach the ocean is termed hereafter the Hookena flow.

By daylight lava movement in the Hookena flow had greatly diminished. By 11:00 A.M. it had practically ceased, and very little steam was rising where the flow entered the ocean.

Early on the morning of June 2 another flow branched off from the Hookena flow. The new flow (flow 4, Fig. 1) diverged southward from the older one, and at about 5:00 A.M. it crossed the highway at the Magoon Ranch house, 1.2 miles south of the earlier flow. The ranch house was destroyed, as also were two or three other

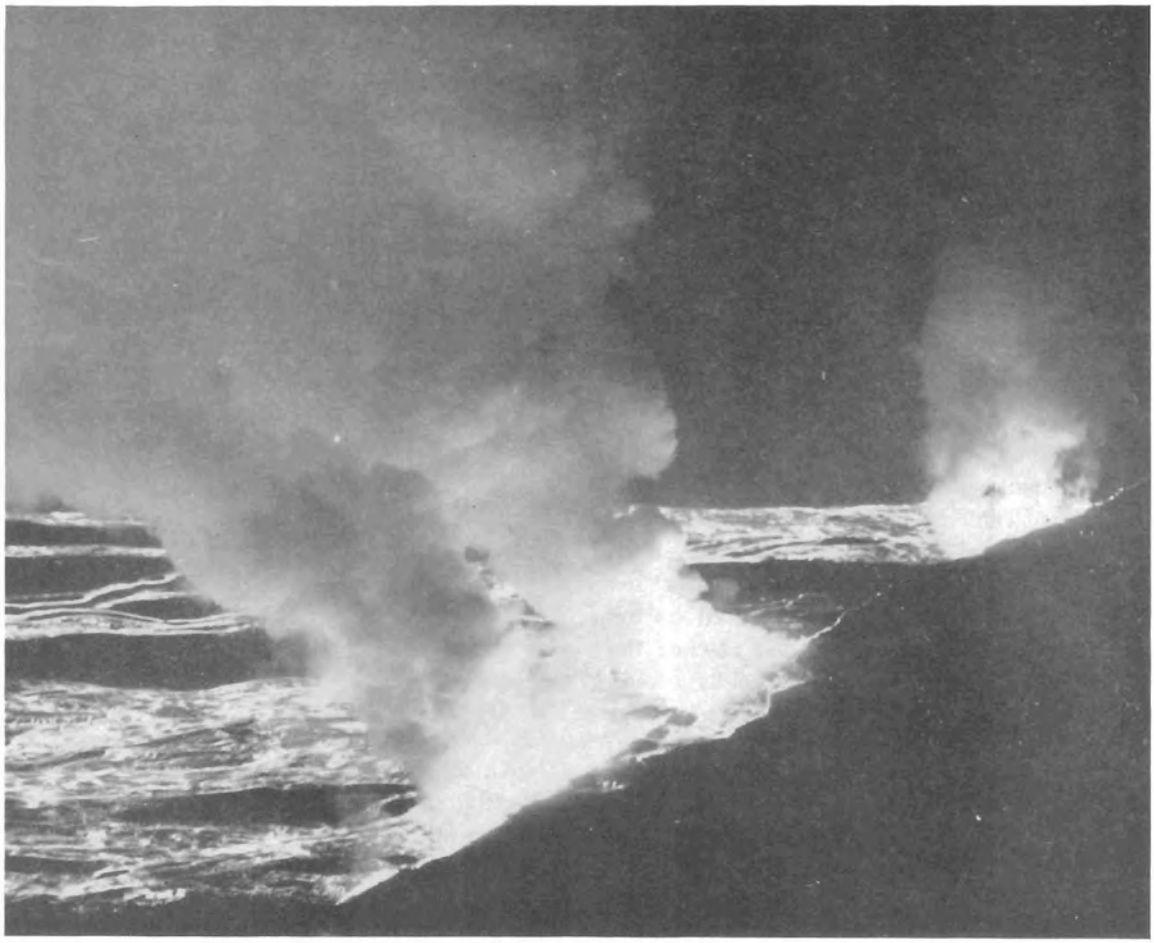

PLATE 1. Floods of lava and clouds of fume issuing from the eruptive fissure at 3:00 A.M. on June 2, 1950. The lava is flowing westward toward Kona. PHOTO BY HONOLULU STAR-BULLETIN.

houses. The flow was aa in character. Along the highway just south of the main ranch house, the advance of the lava was checked by a loose stone wall, about 3 feet high. The lava eventually piled up enough to spill over the wall, but it does not appear to have seriously damaged the wall, and for a distance of about 250 feet it spread only 15 to 20 feet beyond the wall. Farther north the flow continued unchecked on down the mountainside. It entered the sea at 12:04 P.M., destroying another house and part of a coconut grove.

For about an hour and a half before it reached the ocean, the advance of the flow was observed by Macdonald and B. J. Loucks. By that time the lava had lost its initial great fluidity and was creeping ahead at a rate of only about 750 feet an hour. The flow was descending a steep slope half a mile inland and spreading out as a broad fan over the flat sparsely vegetated terrane near the coast. As the edge of the flow engulfed the few large trees there were minor explosions, with flashes of flame. Occasionally similar roars and flashes came from the central part of the flow, probably from tree trunks buried in the flow. Many tree trunks were carried down with the flow from farther upslope. Some of these rode along on the flow surface or projected upward from it, flaming like torches.

At 11:30 A.M. the volume of lava in the flow suddenly increased, and a new flood of lava moved out over the older still-moving flow on the steep slope below the highway. At the base of the slope the new aa front spread out fanwise over the older lava, flowing at about twice the speed of the earlier front, which itself was still advancing. At 12:04 the first front entered the ocean, and a huge column of steam arose in great billows with a cork-screw motion rotating counterclockwise. No sign of ash being thrown up where the flow entered the sea could be seen. At 12:10 the second gush of lava reached the sea. The steam column increased, but there was no evidence of any strong explosive action or any appreciable amount of ash being thrown up. In the meantime the constant light fall of fine black ash, with some Pele's hair, continued as it had all morning.

By the afternoon of June 3 movement in the Magoon Ranch flow appeared to have largely or wholly ceased although the column of steam rising where the flow entered the ocean appeared strong.

Another flow appears to have started late on the night

of June 1, advancing westward south of the Magoon Ranch flow. Because it later destroyed the Ohia Lodge, this flow (flow 5, Fig. 1) may be called the Ohia Lodge flow. The earlier flows started at the erupting fissure at about 10,000 feet altitude, but the Ohia Lodge flow originated at the lower line of fissures between 8,000 and 9,000 feet altitude. At 12:20 P.M. on June 2, Macdonald and Loucks were with a police detail and a small group of refugees at Ohia Lodge waiting developments from this new flow which was known to be advancing through the forest a short distance above the road. Because of the large amount of smoke and fume, combined with a low cloud cover, visibility was very poor and the exact location of the flow front was unknown. About 12:30 a patroling National Guard plane flew over at very low altitude and dropped two Mae West life jackets to which were attached warnings to leave immediately for the southward. These instructions were carried out.

At approximately 2:00 P.M. the Ohia Lodge flow reached the highway about a quarter of a mile south of Ohia Lodge and 4 miles south of the Magoon Ranch flow. At about 3:30 P.M. it entered the ocean just north of Heku Point, having taken an hour and a half to cover the 1.3 miles from the road to the sea. Again a great billowing cloud of steam arose with a counterclockwise rotational movement, but again there was no sign of violent explosion or of the formation of any appreciable amount of ash where the lava entered the sea.

By 5:00 P.M. a line of steaming water, marking the sub-sea course of the flow, extended out to sea for about half a mile from the point where the Ohia Lodge flow entered the ocean. Close to the shore and directly over the submerged flow, the water was boiling, and a semicircular area of hot turbulent water extended for a mile offshore. Many fish were killed and were seen drifting or were washed up on the shore during succeeding days. The prevailing currents drifted the area of hot water southward. Off Milolii, 5 miles south of the flow, many charred logs were seen floating in the water. These were the remains of tree trunks carried down on the top of the flows and dumped into the sea.

At 4:00 P.M. the Ohia Lodge flow was about 750 feet wide and 10 feet thick at the highway. Its outer edges were slowly moving fields of aa, creeping along at a rate of only a few feet an hour. Near its center there appeared to be a narrow, more rapidly moving, lava river, but visibility was very poor and the edge of the flow was still too hot to climb. The flow was still spreading a little laterally. Occasionally trees were pushed over at the edge of the flow. Others burst into flame while they were still standing as the heat from the lava dried out the foliage and raised it to kindling point. Minor explosions were heard from time to time as trees were engulfed in hot lava and the water in their tissues suddenly transformed into steam.

The odor of hydrocarbon gas, probably largely methane, was strong, and the flow smelled much like a leaking gas stove. Yellow flames were common along the edges and top of the flow, issuing from the lava, and there were also many blue flames resembling the flame of a well-adjusted gas burner. These gases undoubtedly were derived from the destructive distillation of the vegetation buried and engulfed by the lava. Many flames burned at cracks in the old lava—commonly 10 to 15 feet and rarely as much as 50 feet or even more from the edge of the new flow. Some of these flames were quite steady, but many went out periodically at the surface only to re-ignite within the crack and burst out again at the surface with a loud "whoomp"! Some of these gas ignitions were explosively violent, throwing rock fragments several feet.

Along the edge of the flow the vegetation was partly broken, leaves were partly blown off trees, and leaves of ti plants were shredded and broken off. Most of the breaking appeared to have been by blasts from the direction of the flow. These were probably in part marginal explosions caused by ignition of hydrocarbon gases, but some of the damage was observed to be caused by the small but strong whirlwinds which formed over the flow and moved across it.

At 6:00 P.M. it was possible to climb the edge of the flow and go out onto it about 150 feet. Beyond that point the gas and heat were unbearable. From the vantage point on the top of the flow, the central lava river could be seen clearly. It was about 25 feet wide. At highway level it was flowing at an estimated rate of 15 miles per hour, but about half a mile upslope from the highway there was a broad double lava cascade on a steeper slope where the speed was estimated to be 25 miles an hour. Temperature measurements on the river ranged from 880° to 900° C. A spectacular feature of the lava river was the many large blocks which it carried along. The blocks were as much as 20 feet high and 30 feet long, although most of them were much smaller. Most were largely incandescent, though a few were largely dark. Occasionally large blocks became wedged sideways in the channel, causing local overflows. The blocks appeared to have been dragged along by a lower, less rapidly moving and probably more viscous stratum in the river. Some could be seen to be moving distinctly less rapidly than the surficial part of the river around them.

Condensation of water in the steam cloud which rose where the lava entered the sea caused a continuous rain beneath the cloud. That the rain was caused largely by the cloud is shown by the fact that just south of the edge of the cloud there was no rain and the night was

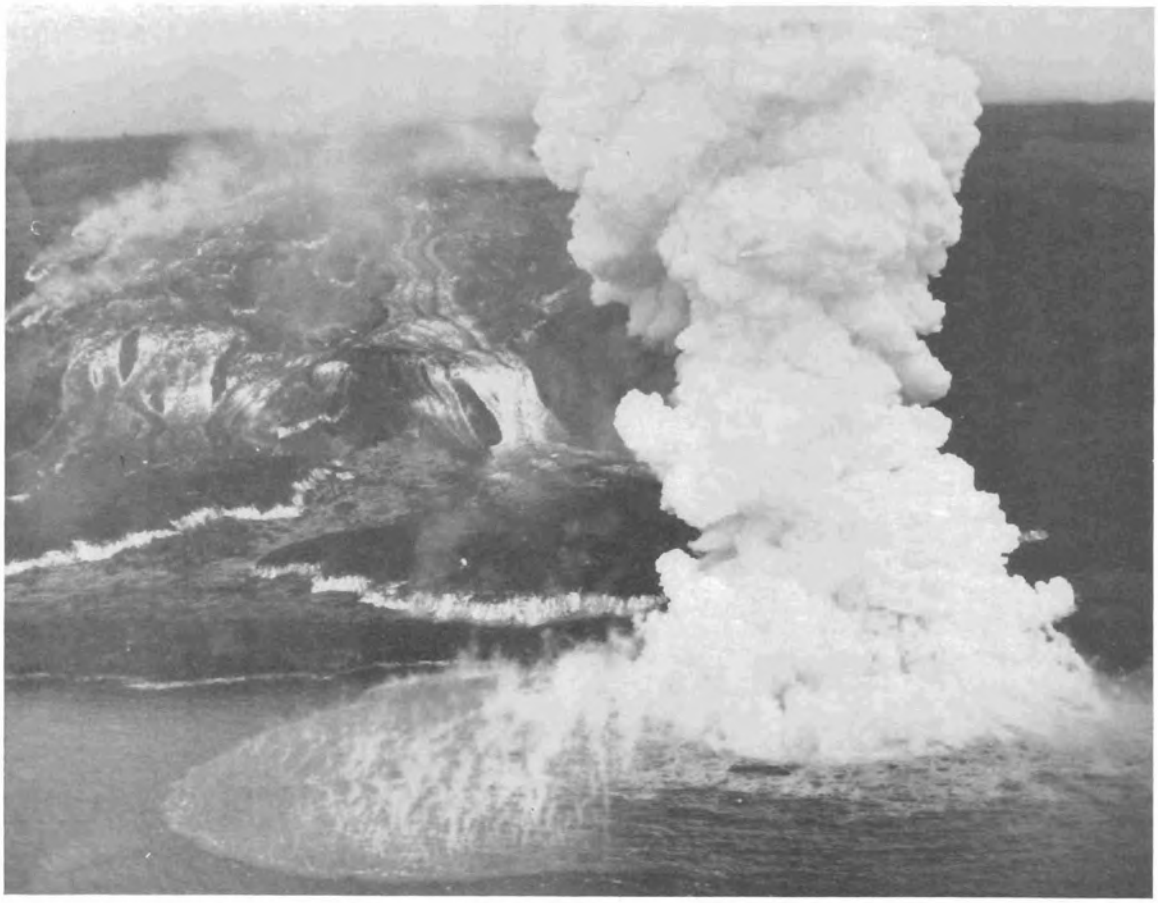

PLATE 4. Ohia Lodge flow pouring into the ocean at about 4:00 P.M., June 2, 1950. In the foreground a high column of steam is rising where the southernmost tongue reaches the ocean. Boiling and steaming water is visible off shore. In the background the flow is descending the mountainside, with smoke rising from the burning forest. Two large, brightly glowing fronts of aa are visible near the left side of the picture. OFFICIAL PHOTOGRAPH, AIR NATIONAL GUARD, 199 FIGHTER SQUADRON.

fairly clear. There was enough salt in the rain beneath the steam cloud to cause the drops to sting the face and eyes and to form a peculiar thin glaze on cars. This glaze was very difficult to remove, even by washing.

At 12:20 A.M. on June 3, Macdonald and Loucks started down the southern side of the flow from the highway. About half a mile from the ocean the flow reached the top of a steep slope formed by a buried fault scarp. There it divided into three branches. At a point just above the steepening of slope the speed of the lava in the river was estimated to be about 15 miles an hour, but as it cascaded down the buried scarp the lava reached a speed estimated at 25 to 30 miles an hour. Temperatures on the cascade were as high as 930° C. On the flatter ground below the scarp the flow slowed and spread out to form a broad fan about three quarters of a mile wide. The central lava river was the most active, and the steam column caused by it was the largest. The river appeared as a bright orange-red streak with long dark streaks paralleling the edge of the river. The southern river was moving less rapidly, and its surface was largely covered with dark blocks between which could be seen red glow.

There was a light but continuous fall of black ash of sand and silt sizes. Some of this ash may have been formed by steam explosions where the lava entered the sea, but much of it appeared to be fine debris picked up from the flow by the numerous small whirlwinds which swept over its surface.

Just above the big cascade blue or greenish-blue flames were common in the slow-moving margin of the flow, and yellow flames even more common. Dancing pale blue flames, resembling will-o-the-wisps, occasionally were seen for a few moments over the main lava river, as much as 35 to 50 feet above the river, and isolated from it by clear air. Some of these appeared to be nearly formless, but others looked like fire-balls.

The Ohia Lodge flow below the highway was examined on the morning of June 3 by D. C. Cox, D. A. Davis, and C. K. Wentworth. At 10:30 A.M. the condition was much like that of the previous night. At 10:35 a sudden increase in the volume of lava in the flow was observed. The speed of the lava in the big cascade between the highway and the shore increased notably, and a sheet of more rapidly moving lava appeared to override the older, less-rapidly flowing sheet.

By 11:15 the surge had decreased and the speed of flow lessened again. Davis estimated the speed in the cascade to be about 20 miles an hour during the peak of the surge and 5 to 6 miles an hour as the surge abated. During the surge the lava fan at the foot of the cascade had built up appreciably. At 11:30, after the surge had ceased, the surface of the central part of the fan was seen to be subsiding as the fluid lava underneath drained away, leaving higher ridges around its edges. The observers on the landward side of the fan could see no lava spilling from the outer edge of the fan into the sea, hence the drainage must have been through hidden subterranean passages. The drainage into the sea was accompanied by an increase in the size of the steam column, some minor explosions along the shore, and pushing up of small lava ridges from the water just offshore.

From 1:00 P.M. June 3 until 7:00 A.M. June 4, the Ohia Lodge flow about 2,000 feet inland from the road was observed by Wentworth, Davis, and Cox. Two streams of lava descended a steep slope in a cascade about half a mile long and reunited to form a single stream before reaching the road. At the foot of the cascade the flow was about 1,000 feet wide. Just north of this main flow another tongue of lava was advancing slowly seaward, burning trees and knocking them over. Optical pyrometer measurements made by Davis and Cox on the surface of the lava river indicated temperatures ranging from 850° to 980° C. About 2:00 P.M. the volume and velocity of the main flow commenced to increase. This surge reached its maximum about 2:30, after which the volume again decreased. Wentworth estimated the volume of actively moving lava in the flow during the surge to be five to ten times as great as that before and after the surge. Similar surges were observed in both channels of the flow at intervals of 65 to 85 minutes during the rest of the afternoon and night. Davis estimated the speed of flow in the main rivers to range from 5 to 20 miles an hour, and angular measurements by Wentworth and Cox during a surge at 11:25 P.M. demonstrated speeds of 7.8 to 8 miles an hour. The front of each surge advanced down the lava river channel, as an aa front 10 to 25 feet high, with loud clinking and crunching sounds. During the larger surges new lava spread from the river over much of the surface of the flow and, directly preceding and during some of the surges, there appeared to be a definite, though small, heating up and inflation of the stationary aa fields at the edge of the flow.

During the afternoon of June 4 the Ohia Lodge flow was watched by Arnold Mason of the U. S. Geological Survey. Conditions remained much as on the preceding day. Several surges of lava were observed, the last three at approximately 5:30, 6:00, and 6:30 P.M. When Finch and Cox arrived at 6:30 P.M. they found that at the road level the flow had been considerably widened by a new tongue which had come down parallel to the older one on its northern side, destroying Ohia Lodge. A sluggish lava river in the new tongue was feeding a slow-moving aa front just below the road. The entire flow at road level was about a quarter of a mile wide. Another tongue still farther north was advancing slowly through the forest about half a mile above the road. Its presence was revealed by occasional glimpses of glowing lava and by a bright glow from burning vegetation.

Davis returned to the Ohia Lodge flow above the road about noon on June 5. The width of the flow had increased to approximately 1,500 feet, and the active channels were entirely in the northern part of the flow. The lava was moving much more slowly than on the two preceding days, and the surges were smaller and of shorter duration. The maximum speeds in the lava rivers were estimated at 4 to 5 miles an hour. The new tongue north of the main flow was still advancing. Cox and Macdonald returned to the flow at 2:00 P.M. and went out onto the flow about 250 feet. The southern edge of the flow was still hot, but essentially motionless. The northern edge, beyond the river, was moving slowly. The flow as a whole had increased in thickness to an average of 20 to 25 feet. On the flat near the coast the flow had spread about 750 feet farther south than on June 3. The coastline had been transformed from a shallow embayment to a slight promontory.

Late in the evening of June 2, or early on June 3, another flow (flow 6, Fig. 1) started from the vent area at 8,300 feet altitude and moved southward down the mountain slope toward the main buildings of the Kahuku Ranch. This has been named the Kahuku flow. The upper portion of the flow was narrow, from 0.1 to 0.15 mile wide. On June 3 the flow was very active, with a narrow bright red lava river in the middle of a dark streak of aa. On June 4 the flow was still very active but was spreading out to form a front nearly half a mile broad at about 7,200 feet altitude, 3½ miles from its source. The lava river was reported to be on the order of 100 feet wide. On June 5 Don Campbell, from aerial observations, reported that the Kahuku flow was still advancing but appeared to have slowed. On the morning of June 6, James Beatty reported that the front had reached an altitude of about 6,500 feet. Movement continued through June 6 and the early hours of June 7, bringing the lower end of the flow to approximately 6,300 feet altitude, 5.8 miles from its source. On the afternoon of June 7 the lower portion of the flow appeared dead, but there was still some movement in the flow near the vents. By the morning of June 8 the flow was completely dead.

Frank Hjort and Ross Bender reached the vent area

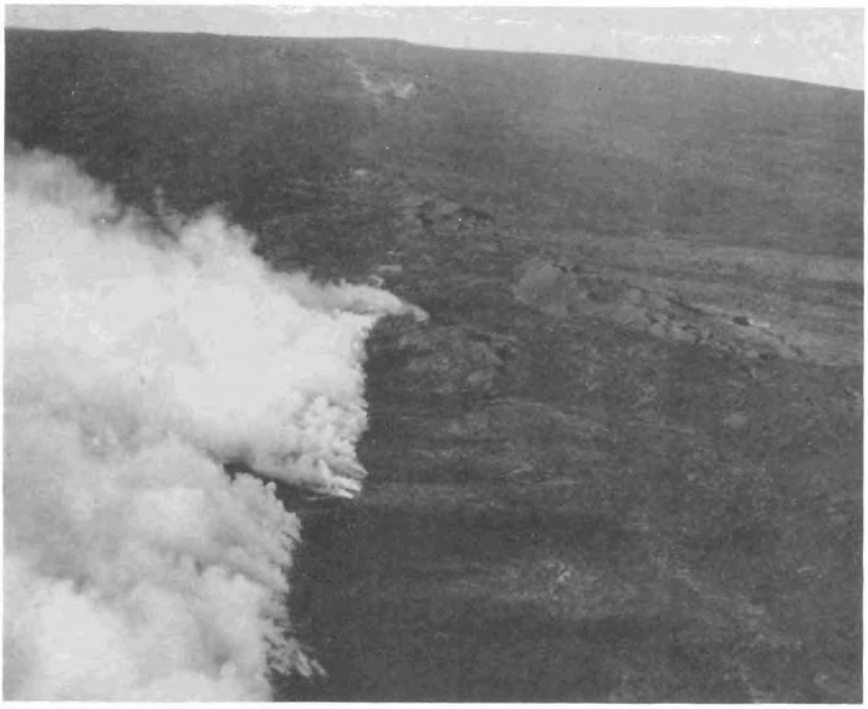

PLATE 5. Heavy fume clouds rising from the rift between 9,000 and 10,000 feet altitude, June 9, 1950. The heads of the Punaluu and Hookena flows are visible in the middle distance, and behind them fainter fume rises in the vicinity of Sulphur Cone. PHOTO BY WERNER STOY, CAMERA HAWAII.

on the afternoon of June 3 and camped at 8,700 feet altitude near the upper end of the lower line of vents. The fissure near 10,000 feet altitude was fountaining sporadically, but most of the activity was concentrated along the lower fissures below 8,900 feet altitude. From 4:30 to 8:00 P.M. activity on the lower fissures was continuous but varied rhythmically in intensity and character. Approximately once an hour an upsurge of activity commenced near the upper end of the fissure and migrated down along the fissure. Each revival of activity commenced at a large spatter cone at about 8,800 feet altitude with a loud roaring noise much like the exhaust from a steam boiler. This rush of gas was followed by a spray of lava droplets and red-hot cinder. The roaring release of gas migrated downhill along the rift, at some places giving rise to noises like thunder or heavy artillery. As the gas release ceased, the fountain activity and amount of lava liberation increased progressively along the rift until it was essentially continuous along the 2 miles of fissure which was in view. The fountains were lower than earlier in the eruption, playing to heights of about 50 feet. This activity gradually abated, and there was a lull of 20 minutes to a half-hour duration before the violent gas release started again at the upper end of the fissure and the cycle was repeated.

Most of the liberated lava was pouring westward toward Kona and feeding the Ohia Lodge flow. A front of hot lava 0.7 mile long had accumulated on the east side of the rift and was spilling southeastward to feed the Kahuku flow. At the head of the Kahuku flow the lava plunged over the steep slope of a buried cinder cone making a spectacular double cascade some 500 feet long and 200 feet wide. The rate of flow in the cascade was probably of the order of 35 miles an hour. Near the base of the cascade the highly fluid lava struck a bump on the channel floor, and the liquid was directed upward and outward into the air. At first view, from a distance, it appeared to Bender to be a fountain in the river, but on closer inspection its true nature was obvious.

A party composed of Geological Survey and National Park personnel reached the vent area on the afternoon of June 6. The cascade at the head of the Kahuku flow was still active, but the speed of flow had greatly decreased, not exceeding 10 miles an hour on the steepest slope. Fluctuations in the volume of flowing lava were obvious and occurred at approximately half-hour intervals. During the night of June 6 the lava fountains along the rift were low and sporadic. Increases in activity continued to occur about every half hour and progressed downslope along the rift. Only once was the increase in lava output preceded by a loud blowing noise and shower of incandescent cinder from the large spatter cone at 8,800 feet altitude.

On the morning of June 7 activity along the rift was still weak. Above 8,600 feet altitude the vents were fuming strongly, but no lava was being poured out. Below that altitude fountaining continued, but none of the fountains was more than 25 feet high, and most were only a few feet.

About 3:00 P.M. Davis, Cox, and Macdonald crossed the still hot pond of shelly pahoehoe which had fed the Kahuku flow and approached within 15 feet of the lava river. At 8,440 feet altitude two branches of the river plunged over a 25-foot cascade and joined at its foot.

Most of the river was moving only 3 or 4 miles an hour and was largely crusted over with a skin of wrinkled and ropy pahoehoe. In the cascade, however, the speed of flow was estimated at 30 miles an hour, and the crust was broken up to reveal the incandescent liquid beneath. Measurements with an optical pyrometer on the hot lava in the cascade yielded temperatures from 1030° to 1040° C.

Below the cascade the lava river flowed directly along the eruptive fissure, burying several lava fountains which occasionally shot through the river. Near the foot of the cascade there was a dome-shaped fountain which averaged about 10 feet across at its base and 5 feet high. This fountain resembled the dome of water which forms over the mouth of some artesian wells. Its bright orange hemisphere looked like half an orange set on the lava river. Just downstream from the dome fountain the rush of the liquid lava leaving the cascade gave rise to a hydraulic jump, with a standing wave 4 to 8 feet high.

About 500 feet down the rift from the cascade a small lava fountain was shooting 10 to 25 feet high. It was not a continuous jet, but consisted of repeated spurts of lava which separated in the air into large blobs. This fountain was typical of many which could be seen on down the rift. At the base of the fountain lava was flowing out pulsatingly, the pulses coming every 1 to 2 seconds, giving rise to a heaving motion much like that commonly observed in a pot of boiling thick porridge. A small lava shield was building up around the vent, but most of the lava was flowing down the slope of the shield to join the main river. The latter closely paralleled the erupting fissure for about a quarter of a mile then joined a large stream of lava flowing toward Kona.

Fluctuations in the amount of lava output came at roughly half-hour intervals. Following surges, the level of the lava in the river dropped, exposing along the banks rows of hot flexible lava stalactites which swayed back and forth in the blasts of gas or as their ends touched the flowing liquid much like willow roots along a creek. Many of them eventually were broken off, probably as they became more brittle with cooling, and floated away in the stream.

About 4:30 P.M. on June 7 there commenced a revival of activity along the entire rift. By 7:00 P.M. sporadic lava fountaining could be seen at a distance along the fissure near 10,000 feet altitude, and a little red lava could be seen moving in the head of the Hookena-Magoon Ranch flow. Along the fissure below 8,900 feet altitude the amount of fountaining and lava outpouring had increased. The surges in the lava river grew in size until, during peaks, the river channel was filled to the brim and locally overflowed sending tongues of pahoehoe rolling toward the observers. The height of the standing wave of the hydraulic jump below the cascade increased to about 12 feet and that of the dome fountain to about 8 feet. The temperature of the lava appeared to increase with the activity, and at 7:20 P.M. pyrometer measurements on both the cascade and the dome fountain gave temperatures of 1070° C. Some of the lava spilled eastward and formed a stream across the lower end of the former lava pond to the head of the Kahuku flow. Most of it, however, continued to westward.

As darkness came, many flames were visible over the vents along the rift. Most of them were at vents from which lava was no longer issuing, but some were at spattering vents. No flames were observed at vents from which lava was flowing in abundance. Most of the flames were greenish-yellow, but some were pale greenish-blue. The average length of the flames above the mouths of the conelets was about 5 feet, but some were as much as 20 feet long.

The revival of activity continued until about 2:00 A.M. on June 8. After that the strength of activity gradually decreased. At 6:00 A.M. the rift was still moderately active, but much less so than on the previous evening. A roaring gas vent was heard occasionally at about 8,400 feet altitude. The cascade at the head of the Kahuku flow was no longer active, and crossings of the flow itself at two places revealed it to be completely dead.

G. D. Robinson and B. J. Loucks reached the Ohia Lodge flow on the afternoon of June 6 and spent most of the night observing it in the area between the highway and the sea. About half a mile below the highway the channel divided into two branches, the southernmost of which was the more active. A short distance farther downslope the southerly channel again divided, so that there were three channels. Surges in activity were observed at approximately half-hour intervals. During lulls in the activity the lava movement was largely restricted to the central channel, but during the larger surges all three channels became very active. Will-o-the-wisps were again observed over the flow. On June 7 the Ohia Lodge flow was still very active, the principal movement at the highway being in a lava river which was flowing in a channel about 15 feet deep near the northern edge of the flow. William Stearns reported that a new spur on the southern side of the flow, about 5 or 6 miles long, was advancing slowly.

On June 8 a small overflow occurred on the southern side of the Ohia Lodge flow about a quarter of a mile above the highway. The tongue advanced only a few hundred yards before rejoining the main flow. On June 9 the flow appeared to have become distinctly more sluggish. The flow was again visited on June 10 by Robinson and Wentworth, in company with H. R. Joesting and J. H. Swartz of the Geological Survey and Juliette Wentworth. Conditions were much the same as they

had been when last seen by Robinson on the morning of June 8. However, in the interim, lava had been newly added, by repeated overflows of the channel, to the surface of much of the flow in the vicinity of the road. Several surges of activity were observed during the evening, the intervals between surges ranging from 13 to 45 minutes. Pyrometer measurements by Robinson on large glowing blocks in the river and on the surface of the river itself yielded temperatures ranging from 840° to 940° C. Cherry-red lava exposed in a cave in the older stationary aa margin of the flow gave a temperature of 675° C.

On June 11 Macdonald and D. H. Hubbard examined the flow where it entered the sea. No movement could be detected in the major part of the flow on the coastal flat, and the volume of steam being formed at the ocean was small. Lava was still pouring over the escarpment a quarter of a mile inland, but it was rather dull red in color and appeared much more viscous than during earlier observations. The speed of the lava on the steep cascade was only about half a mile an hour. Two strong surges of lava at the cascade were observed, one at 2:30 and the other at 4:30 P.M. At the foot of the cascade the lava turned southward and spread out to form a big aa flow which was advancing seaward along the southern edge of the older flow at a rate of approximately 1,000 feet an hour. The front of this flow was the largest the writers have observed in Hawaii. It was about 1,000 feet wide, at least 50 feet high, and very active. One after another, blocks up to 10 feet in diameter became detached from the front of the flow and rolled to the base. The blocks were accompanied and followed by trains of finer incandescent debris, and patches of incandescent lava were revealed as the blocks broke away from the front. Clouds of pale brown dust arose from the pulverization of the fragments rolling down the flow front. A hundred yards from the active front the radiant heat was so great that the observers' faces were scorched, and cameras became so hot they were difficult to hold.

At 3:00 to 4:00 A.M. on the morning of June 12 there was widespread overflowing of the channel of the Ohia Lodge flow at the level of the highway. Later in the morning and during the afternoon the glow in the flow was dull and lava movement was small. Shortly after 9:00 P.M. a bright glow was seen inland from the road, and by 10:15 a new surge of lava was producing flooding on the northern side of the flow. This appears to have been the last big surge. Movement in the flow at the highway stopped on June 13, although on June 14 cowboys of the C. Q. Yee Hop Ranch reported lava still moving in the flow 6 miles above the highway. At about noon on June 15 the pilot of a Navy plane reported lava bubbling from the lower 200 yards of the source fissure and fume being liberated along about 3 miles of fissure. From that time on, glow at the source area was observed nearly every night until June 22. On the afternoon of June 22, John Peoples of the U. S. Coast Guard flew over the source area and reported hot bubbling lava and a large amount of fume along the rift.

The last well-authenticated observation of glow at the source was by Finch, at 1:00 A.M. on June 23, and the eruption is believed to have come to an end on that date. Aerial observations on later days revealed much fume along the fissures but no signs of moving lava. Fume liberation continued abundant through the remainder of June.

A further discussion of special features of the eruption will appear in the next VOLCANO LETTER.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR APRIL–JUNE, 1950

VOLCANOLOGY

April

The northward tilt that started early in March continued through April. The northward tilt of 3.2 seconds of arc in April, when coupled with the 6 seconds in the same direction in March, indicates a distinct pressure increase under Kilauea Volcano.

Seasonal westward tilt ceased on March 14 and an eastward tilt set in to continue until the last of April. If an eastward tilt indicates a pressure increase under Mauna Loa then there has been a simultaneous increase of pressure under Kilauea and Mauna Loa.

Of the 77 earthquakes recorded during April, 61 were recorded at Kilauea and 56 on the Mauna Loa seismograph. The Kilauea total is larger than usual and points to uneasiness at Kilauea. However, the foci of most of the shakes were shallow and many were under the northern end of the caldera. The shallowness and location of foci far from the volcanic axis at Halemaumau appear to decrease their significance as an indication of impending activity.

Some of the cracks in the vicinity of the Halemaumau rim opened slightly. A more-or-less expected accompaniment of the continued pressure build-up was the spreading of some of the cracks on the caldera floor that are connected with the rift system of Kilauea.

May

The monthly total of earthquakes for May was 102. During the first half of the month more of the earthquakes originated under Kilauea than Mauna Loa, but during the latter half Mauna Loa quakes predominated. As far as earthquakes were concerned it appeared as though uneasiness had shifted from Kilauea to Mauna Loa. Many of the shakes originated under the upper end of the southwest rift of Mauna Loa.

During the first 2 weeks of May there was a slight east-southeast tilt. Then a distinct north-northeast tilt set in to continue until May 29. Following the strong earthquakes of May 29 there was a tilt of 2.4 seconds of arc to the southwest, or opposite the usual direction for the latter part of May.

June

A total of 279 earthquakes was recorded on the Kilauea seismograph during June. Owing to the frequent dismantling of the Mauna Loa seismograph during the progress of the flank eruption the total for that instrument is unknown but probably about the same as for Kilauea. Most of the earthquakes originated along the southwest rift of Mauna Loa.

There was an accumulation of 6.4 seconds of arc tilt to the northeast during the first 14 days of June, then a slight northwest tilt for the rest of the month. It is interesting to note that a marked decrease in the rate of output of lava from the southwest rift of Mauna Loa coincided roughly with the cessation of rapid northeast tilt.

SEISMOLOGY

Earthquake Data, April–June, 1950

(Based on Bosch-Omori seismograph on rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms

* For definition of local seismicity, see Volcano Letter 371.

The data for the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory of the U. S. Geological Survey. Time is Hawaiian Standard, 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year.

20. April 5, 04 : 50, feeble. Felt locally. Kilauea quake.
21. April 8, 00 : 35, feeble. Mauna Loa shake.
22. April 23, 01 : 15, very feeble. Kilauea.
23. April 25, 10 : 09, very feeble. Mauna Loa.
24. April 27, 23 : 53, very feeble. Kilauea.
25. April 28, 02 : 26, feeble. Kilauea.
26. April 29, 21 : 11, very feeble. Mauna Loa.
27. May 3, 03 : 48, very feeble.
28. May 3, 12 : 08, very feeble. Mauna Loa.
29. May 3, 22 : 19, very feeble. Kilauea.
30. May 4, 01 : 01, very feeble.
31. May 4, 04 : 35, feeble.
32. May 4, 05 : 51, slight. Felt at Kapapala.
33. May 4, 05 : 54, very feeble. Felt at Kapapala.
34. May 4, 06 : 02, very feeble. Felt at Kapapala.
35. May 4, 07 : 31, very feeble.
36. May 6, 03 : 47, very feeble.
37. May 7, 03 : 10, very feeble. Mauna Loa.
38. May 8, 12 : 01, very feeble.
39. May 8, 12 : 41, very feeble. Mauna Loa.
40. May 11, 13 : 06, very feeble.
41. May 11, 19 : 38, feeble. Mauna Loa.
42. May 13, 09 : 27, very feeble. Mauna Loa.
43. May 14, 18 : 39, feeble. Mauna Loa.
44. May 18, 10 : 47, very feeble. Mauna Loa.
45. May 18, 14 : 44, very feeble. Mauna Loa.
46. May 19, 00 : 02, very feeble. Mauna Loa.
47. May 20, 01 : 57, very feeble. Mauna Loa.
48. May 26, 01 : 45, very feeble. Mauna Loa.
49. May 27, 11 : 33, very feeble. Kilauea.
50. May 28, 08 : 27, very feeble. Mauna Loa.
51. May 29, 15 : 17, strong. Upper southwest rift of Mauna Loa. Widely felt. All instruments dismantled. Damage to water tanks, stone walls, etc., in Kona.
52. May 30, 14 : 37, very feeble. Mauna Loa.
53. May 30, 17 : 28, slight. Mauna Loa.
54. June 1, 13 : 59, very feeble. Mauna Loa.
June 1, 21 : 04, harmonic tremor of Mauna Loa eruption starts. Recorded continuously through June 3, then with lesser amplitude and intermittently until afternoon June 13.

Earthquakes accompanying the first 13 days of the Mauna Loa eruption.

Most of the quakes originated on the southwest rift of Mauna Loa.

Serial Numbers	Date	Number of Shakes
55– 58, inclusive	June 2	4
59– 73, inclusive	3	39
74– 91, inclusive	4	39
92–107, inclusive	5	28
108–115, inclusive	6	23
116–126, inclusive	7	15
127–133, inclusive	8	7
134–143, inclusive	9	10
144–146, inclusive	10	3
147–158, inclusive	11	23
159	12	6
160–164, inclusive	13	7
165–168, inclusive	14	13

169. June 15, 10 : 14, slight.
170. June 16, 16 : 03, very feeble.
171. June 16, 23 : 13, very feeble.
172. June 17, 06 : 31, very feeble.
173. June 19, 09 : 22, very feeble. Felt locally. 7 miles deep, east slope of Mauna Loa near Ohaikea.
174. June 21, 07 : 06, moderate. Felt locally. Kilauea.
175. June 21, 08 : 03, very feeble.
176. June 21, 08 : 29, very feeble.
177. June 26, 19 : 56, feeble. Felt at Naalehu.

TELESEISMS

April 18, 05 : 00, slight. Southwest of Galapagos.
April 30, 01 : 00, slight. North of Easter Island.
May 25, 15 : 27, slight. New Hebrides.
June 24, 12 : 34, slight. New Hebrides.

MICROSEISMS

Microseisms were moderate on April 4–5, 29–30, and May 10–11. They were present though slight on other days throughout the quarter.

CRACK MEASUREMENTS

Accompanying the rapid northward tilt during March, April, and May there was a distinct opening of some of the cracks on the caldera floor that are roughly aligned with the southwest rift of Kilauea. At one station there was an opening of 4 millimeters and at another the opening amounted to 9 millimeters. Such an opening is an expected accompaniment of the doming indicated by tilt. A portion of the crack at the tourist station on the east rim of Halemaumau opened 8 millimeters between March 31 and June 30.

TILTING OF THE GROUND

The strong northward tilt which started in March continued until May 29 and amounted to 11.4 seconds of arc. A distinct southerly tilt followed the large earthquake of May 29. Northward tilt was resumed on June 5. Between June 5 and June 17 there was a rapid northward tilt amounting to 3.8 seconds. From June 17 to the end of the month, northward tilt was about normal for this season of the year.

The lack of normal westerly tilt that was noted in March continued until April 10 when a positive eastward tilt commenced that continued until June 14 except for some rapid fluctuations from May 29 until June 8. There was an unusually rapid eastward tilt of 5.9 seconds between June 7 and June 14. From June 14 to June 30 there was a slight westward tilt, which is opposite to the normal direction for this season of the year.

Table of Tilt at Seismograph Vault on Northeast Rim of Kilauea Caldera

Week Beginning	Amount	Direction
April 2	0.2″	N 45° E
9	0.3″	N 45° E
16	1.0″	N
23	1.4″	N 60° E
30	1.8″	N 16° E
May 7	0.5″	W
14	1.2″	N 37° E
21	1.0″	N 7° E
28	1.7″	S 40° W
June 4	3.5″	N 70° E
11	3.0″	N 51° E
18	0.3″	N 27° E
25	0.1″	E

TEMPERATURE MEASUREMENTS

The temperature of the steam well at the Sulfur Bank was constant at 204° F. in April, May, and June.

MAGNETIC OBSERVATIONS

Routine magnetometer measurements were continued at intervals of approximately 1 month. H. R. Joesting and J. H. Swartz of the Geological Survey's Geophysics Branch spent a week at the Observatory during the eruption of Mauna Loa in June, making additional measurements and calibrating instruments.

Until May 9 most of the stations on the line along the Mauna Loa truck trail showed a decrease in vertical magnetic intensity with respect to the base station near the rim of Kilauea caldera at Uwekahuna. The next measurements, on June 9 and 12, showed a marked increase in the strength of attraction at most of the stations. Several of the stations showed a very rapid rise between June 9 and 12. It is possible that the beginning of this rise may have coincided roughly with the beginning of the Mauna Loa eruption.

PUBLISHED BY THE UNIVERSITY OF HAWAII

THE JUNE 1950 ERUPTION OF MAUNA LOA

By GORDON A. MACDONALD and R. H. FINCH

Part II

SPECIAL FEATURES

LAVA FLOWS

The lava of the 1950 eruption of Mauna Loa ranges from basalt to olivine basalt. The first lava erupted along the upper part of the rift contains very few olivine phenocrysts, and no dunite inclusions were observed. In contrast, the lavas erupted later from the portion of the rift below 11,000 feet altitude contain many phenocrysts of olivine up to about 5 millimeters long. Angular inclusions of dunite, up to about 3 centimeters across, are fairly common in the lavas from the lower vents. It appears probable that the marked difference in abundance of olivine phenocrysts in the early and late lavas is the result of sinking of olivine crystals in the magma column before the eruption. The first lavas liberated at the upper vents were derived from the upper part of the magma column, which had been impoverished in olivine. Later the lava was derived from a lower level in the magma column, in which the abundance of olivine phenocrysts had been increased by sinking of crystals from higher levels. A similar, but even more marked, difference has been found between the early and later lavas of the 1840 eruption of Kilauea (Macdonald, 1944).

Figure 1 is a map showing the distribution of the lava flows. All of the flows except the upper flow (no. 2) and the Kahuku flow (no. 7) have been plotted from vertical air photos taken at the request of the Volcano Observatory by Richard O. Mahan for the R. M. Towill engineering firm in Honolulu.

The accompanying table shows the approximate area and volume above sea level of each of the major lava flows of the 1950 eruption and the estimated average thickness of each flow. The areas were scaled from the map of the flows. The average thickness of several separate segments of each flow was estimated from ground observations at several points along the flows and from the appearance in the aerial photographs, then the average thickness of the whole flow was calculated from these values. The volumes were calculated by using the scaled areas and the estimates for average thickness of successive portions of the flows. It is believed that any error in thickness and volume is on the conservative side. The total area of the flows above sea level is 35.6 square miles, and the volume is on the order of 514 million cubic yards. It is estimated that more than 100 million cubic yards of lava flowed out under the ocean and is now lost to view. The total volume of lava erupted, therefore, was very probably more than 600 million cubic yards, or somewhat more than the estimated volume (600 million cubic yards) of the largest previous historic eruption, the 1859 lava flow of Mauna Loa (Stearns and Macdonald, 1946, p. 79). It is estimated that between one-half and two-thirds of the total volume of lava was poured out during the first 36 hours of the 1950 eruption.

AREA, THICKNESS, AND VOLUME OF 1950 LAVA FLOWS ABOVE SEA LEVEL

NAME OF FLOW	NUMBER ON MAP (FIG. 1)	AREA	AVERAGE THICKNESS	VOLUME
		Sq. miles	*Feet*	*Cu. yds.*
Upper rift . . .	1	3.74	4.5	17,000,000
Upper west flank	2	1.25	7.6	11,000,000
Hookena	3	6.73	8.3	59,000,000
Magoon Ranch	4	5.74	9.3	55,000,000
Punaluu	5	7.25	13.5	101,000,000
Ohia Lodge . .	6	8.47	27.6	241,000,000
Kahuku	7	1.44	12.0	18,000,000
Keokeo	8	1.00	12.0	12,000,000

TEMPERATURE MEASUREMENTS

Approximately 75 readings were made with an optical pyrometer during the eruption. Of these, about one-third were made during daylight hours and are of little value. Comparison of readings made during daylight with those made at night indicates that the extraneous illumination during daytime results in readings which are consistently too high. Most daylight readings appear to be between 50° and 100° C. higher than read-

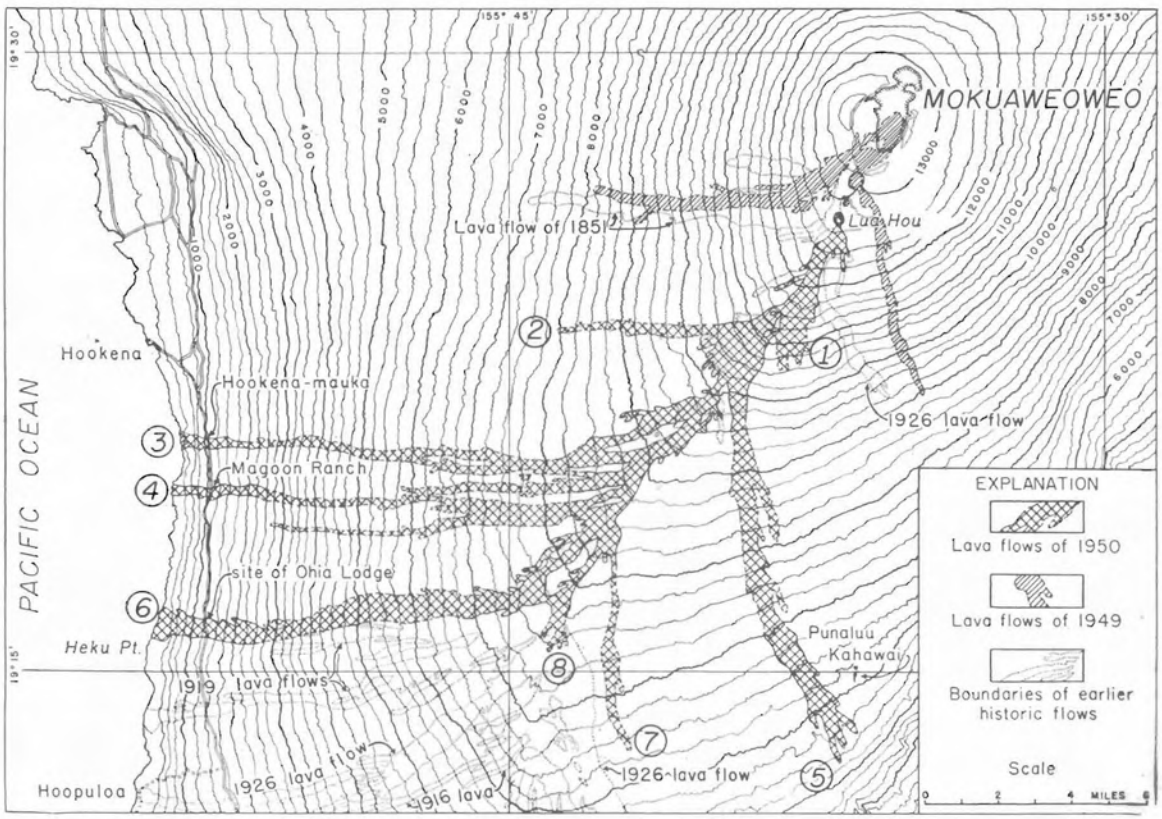

FIGURE 1. Map of a portion of the southwest rift of Mauna Loa showing the 1950 and some earlier historic lava flows.

ings on the same object at night. The values cannot, however, be successfully corrected, because the amount of extraneous light was variable and undetermined. Only the night readings have been used. The values obtained at night were quite consistent. Repeated readings on the same near-by object at intervals of a few seconds showed variations of only a few degrees. On the other hand, readings on the surface of the lava river showed a range of approximately 100°, owing at least in part to variations in the amount and thickness of crust on it.

Only a few of the pyrometer readings were made under close approximations to "black body" conditions. Therefore a small correction for the coefficient of light absorption of gray bodies should be applied. The amount of the correction has not been determined, but, for leucite basanite of Nyamuragira, Verhoogen (1948, p. 131) found it to be about 20° at 1,000° C. It is probable, therefore, that the observed temperatures given in the accompanying table should be increased by about 20°.

It is noteworthy that the temperatures of the dome fountain and of the river at the vents are of the same order of magnitude as those obtained by Verhoogen (1948, pp. 133–136) at Nyamuragira. In comparison, the temperature at the surface of the Kilauea lava lake in 1916 was about 1,000°, that at a depth of 1 meter was about 860°, and that at a depth of 13 meters was about 1,170°. The latter temperature was believed to be higher than that of the magma rising through the conduits (Jaggar, 1917). The high temperature of 1,100° measured in the throat of the inactive spatter cone on June 7, 1950, probably was partly the result of gas heating.

There probably was very little lowering of apparent temperature by crust on the very turbulent lava in the river at the vents, and the actual temperature of emission of the lava may be taken as close to 1,070°. On the other hand most of the readings on the lava river at the highway probably were to some degree affected by the presence of crust on the river. The actual internal temperature of the river at the highway was probably near the upper end of the range of observed temperatures—in the vicinity of 950°. Thus the lava of the Ohia Lodge flow cooled about 100° in traversing the 10 miles from the vents to the highway. At 950° it was still fluid and free-flowing. At 675° it had become immobile. The temperatures of 850° to 870° measured in cracks in the stagnant aa on June 2 may have been appreciably higher than the internal temperatures because of surficial heating by burning gases. During the 1949 eruption of Mauna Loa, lava with a temperature of about 760° was found to be still capable of a little movement (Macdonald and Finch, 1949, p. 5).

TEMPERATURE MEASUREMENTS

OBJECT MEASURED	NUMBER OF READINGS	TEMPERATURE °C. RANGE	TEMPERATURE °C. AVERAGE	DATE
Cascade in lava river at vents . . .	5	1030–1070	1050	June 7
Dome fountain in river at vents . .	3	1060–1080	1070	June 7
Lava river of Ohia Lodge flow near highway	16	850–980	916	June 2–4
Lava river of Ohia Lodge flow about ½ mi. from ocean	3	910–930	920	June 3
Lava river of Ohia Lodge flow near highway	15	840–940	898	June 10
Glowing lava in flaming crack in aa at nearly motionless edge of flow at highway (flow had crossed highway about 6 hours earlier) .	3	850–870	860	June 2
Glowing lava in crack in aa at stationary margin of flow at highway (flame absent) .	Several	.....	675	June 10
Glowing throat of spatter cone at vents (not active when readings were taken, but active a few hours earlier, and still emitting gas) . .	3	1090–1110	1100	June 7

RADIATION STUDIES

Two series of counts with a Geiger-Muller counter were made on June 2 and 5 at 11 stations along the highway at and near the Ohia Lodge flow. The number of clicks per minute varied considerably, but the averages close to the flow and on the flow are a little less than those at a distance from the flow. The averages are as follows:

500 to 1,000 feet from flow . . . . . 21 clicks per minute
10 to 300 feet from flow . . . . . 20 clicks per minute
On flow 75 to 250 feet from edge . 17 clicks per minute

It is possible that the higher temperature on and near the flow affected the sensitivity of the instrument, reducing the count. However, at no time was the temperature of the wand holding the tube high enough to be unbearable, or even particularly uncomfortable, to the unprotected hand of the operator. The evidence appears to indicate that there was no marked increase in radiation as the flow was approached, and, therefore, that the lava was not appreciably radioactive at the level of the highway. No counter readings were made at the vents.

Samples of lava collected where the flow crossed the road showed no radioactivity when tested by Dr. Harvey E. White of the University of California.

TILTING OF THE GROUND

Indications of a pressure build-up under both Kilauea and Mauna Loa volcanoes in February, March, April, and May were given by the tilt curves obtained at the Whitney Laboratory of Seismology on the northeast rim of Kilauea Caldera. Normally there is a seasonal southwest tilt during the first 5 months of the year (Powers, 1947, p. 2). In 1950, however, seasonal tilt was exceeded by oppositely directed volcanic tilt so that south tilt ceased on February 9 and west tilt on March 19.

A rapid northward tilt started on March 6 and continued until the end of June, except for a southward tilt of 2.2 seconds of arc from May 29 to June 5. Over half of this southward tilt, or 1.2 seconds, accompanied a strong earthquake on May 29. The northward tilt from March 6 until May 29 amounted to 11.5 seconds of arc. The 77 earthquakes recorded in April, a majority of which originated at Kilauea, together with the strong north tilt, indicated a distinct uneasiness of Kilauea Volcano.

A positive easterly tilt which followed the cessation of seasonal west tilt on March 19 continued through May 28. The 102 earthquakes recorded during May, a majority of which originated under Mauna Loa, together with the easterly tilt, indicated that Mauna Loa had become more uneasy than Kilauea. There was a sharp westerly tilt on May 29 and 30 following the strong quake on May 29. Despite some fluctuations there was an accumulation of 6.0 seconds of arc of east tilt from May 31 to June 14. It is interesting to note that strong east tilt accompanied the outbreak of Mauna Loa and continued until there was a noticeable decrease in lava output. Evidence is accumulating that there is a correlation between east tilt and Mauna Loa eruptions. In 1950 east tilt set in 2 months and 12 days prior to the outbreak of Mauna Loa. Distinct east tilt preceded the 1949 eruption by 2 months and 8 days.

HARMONIC TREMOR

Very conspicuous harmonic tremor (Finch, 1944) was recorded on the seismographs at Kilauea, on the east slope of Mauna Loa, and at Kealakekua in Kona for over an hour after the eruption began. In the following discussion the records from the Kilauea seismograph on the northeast rim of Kilauea Caldera only are used. During the summit eruptions in 1940 and 1949 the Kilauea instrument, 22 miles from the site of the eruption, recorded harmonic tremor for 5 and 12 hours, respectively. The tremor was recorded for a similar number of hours during earlier eruptions. Though the upper eruption source of the 1950 outbreak was at a distance of 24 miles, or a little greater than in 1940 and 1949, the maximum double amplitude recorded in 1950—5 millimeters—was several times that of earlier years. The period of this large-amplitude early tremor was 0.5 seconds.

Instead of the tremor slowly dying out after a few hours, as it usually does, in 1950 it continued to be recorded intermittently until June 13, although about 4 hours after the initial outbreak at 12,600 to 11,250 feet altitude most of the lava was issuing from vents between 10,500 and 8,000 feet, about 30 miles from the Kilauea seismograph.

After the first few hours the amplitude of the tremor decreased greatly, but the double amplitude still ranged

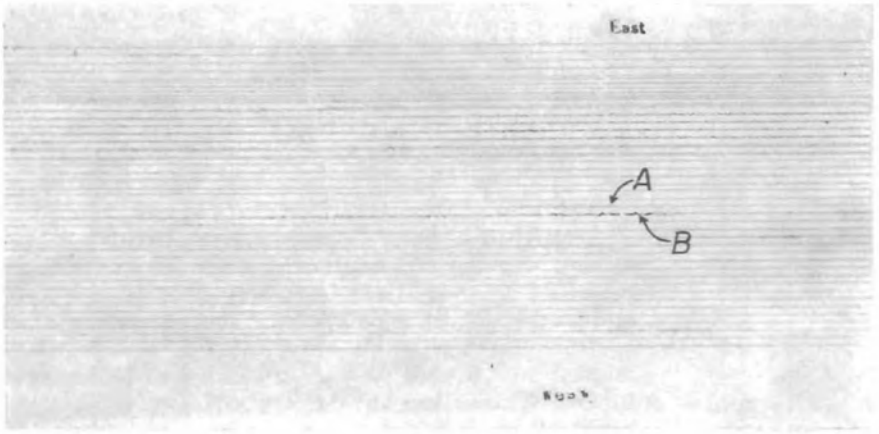

FIGURE 2. Harmonic tremor as recorded 30 miles from eruption source on June 2, 1950. A is the record of an earthquake, and B is due to an artificial disturbance.

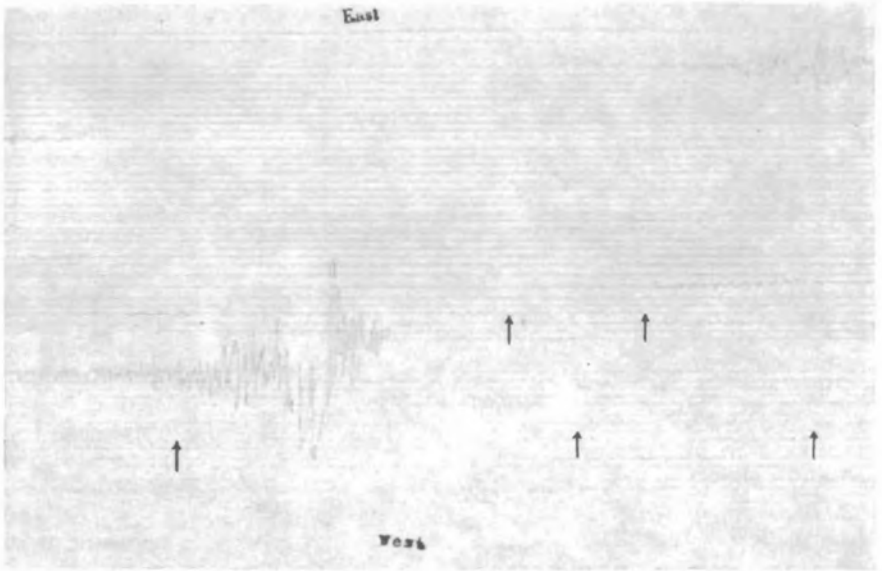

FIGURE 3. From the record of June 3, showing five spells of unusual harmonic tremor with a period of about 2 seconds. Arrows point to the beginning of each spell.

up to 0.7 millimeter (Fig. 2), which is equal to or larger than recordings in 1940 and 1949. The period of the tremor ranged up to 1.5 seconds.

The large amplitudes of the harmonic tremor at the onset of the eruption, and the fact that tremors continued after the distance to the source increased from 24 to 30 miles, indicated that the rate of output of lava was greater than usual.

On June 3 it was noticed that the harmonic tremor was not continuous, indicating fluctuations in the volume of lava being emitted. Direct observations both at the source and where the lava crossed the road showed fluctuations in volume.

Whether the harmonic tremor is produced by movements of lava in the primary conduits under Mokuaweoweo, the summit crater of Mauna Loa, or in the eruption fissures is not known, though evidence favors the latter. As noted above, in most eruptions harmonic tremor is recorded for a few hours only. In the 1942 flank eruption, harmonic tremor was recorded for a few hours during the preliminary activity at the summit (distance 22 miles) and then for 7 days after the lava broke out along the northeast rift at a distance of only 14 miles from the recording instrument. The facts that the tremor ceased being recorded a little before activity at the summit stopped and resumed, to continue for 7 days, after the lava broke out at a distance of 14 miles, indicate that the tremor originates in the eruption fissures.

On June 2 another type of harmonic tremor, apparently not previously recorded at the Hawaiian Volcano Observatory, was noticed (Fig. 3). The most frequent period of this type of tremor is roughly 2 seconds. Fourteen spells of this type of tremor were recorded on June 3, and 13 on June 4. Smaller numbers were recorded on other days, with the last on June 12.

EARTHQUAKES

Earthquakes and tilting of the ground surface during March and April caused speculation as to the possibility of an eruption at Kilauea. In May, however, quakes of Kilauea origin became less numerous and the number with Mauna Loa origin predominated. Many of the Mauna Loa quakes originated under the upper end of the southwest rift.

The following table shows the number of earthquakes per week recorded at the northeastern rim of Kilauea Caldera during May and June:

Week Beginning	No. of Quakes
April 30	30
May 7	21
14	18
21	9
28	58
June 4	158
11	60
18	11
25	7

A larger number of earthquakes during the early part of a flank eruption than during a summit eruption is to be expected because of the greater length of fissuring. In 1950 there was a progressive fissuring of the southwest rift for a distance of 13 miles. Normally, when both Mauna Loa and Kilauea are quiet, only five or six earthquakes per week are recorded.

LACK OF LITTORAL EXPLOSION

The absence of large littoral explosions or the formation of much ash where the lava entered the ocean was a striking feature of the 1950 eruption. Many aa flows entering the sea cause violent steam explosions which throw into the air large amounts of ash and which build littoral cones of ash and cinder (Macdonald, 1944). This happened in 1840, 1868, 1919, and 1926 (Jaggar, 1919, 1926). Many pahoehoe flows enter the water quietly, with only moderate evolution of steam, because the quickly formed pahoehoe skin provides an insulation which separates the very hot lava inside from the water. Aa flows, on the other hand, typically have a much broken and discontinuous surficial layer which permits the water easy access to the hot interior, with resultant strong explosions. A minor amount of such activity apparently did occur during the 1950 eruption. On June 3, D. C. Cox, going down the southern edge of the Ohia Lodge flow with D. A. Davis and C. K. Wentworth, noticed an increase in the amount of falling ash as they approached the coast and came under the steam cloud. Also, some of the moving pictures taken from the sea show small puffs of dark cloud, almost certainly ash, mixed with the white steam. However, littoral explosion and ash-making were very minor, certainly not nearly comparable with those in 1919 and 1926. Probably this was because the main lava rivers entering the sea were hotter and had a more unbroken surface than those of the 1919 and 1926 flows, thus preventing such rapid and easy entrance of the water to the hot interior. Once the flow into the ocean was well established a continuous crust may have formed over the lava river, acting as an insulator in

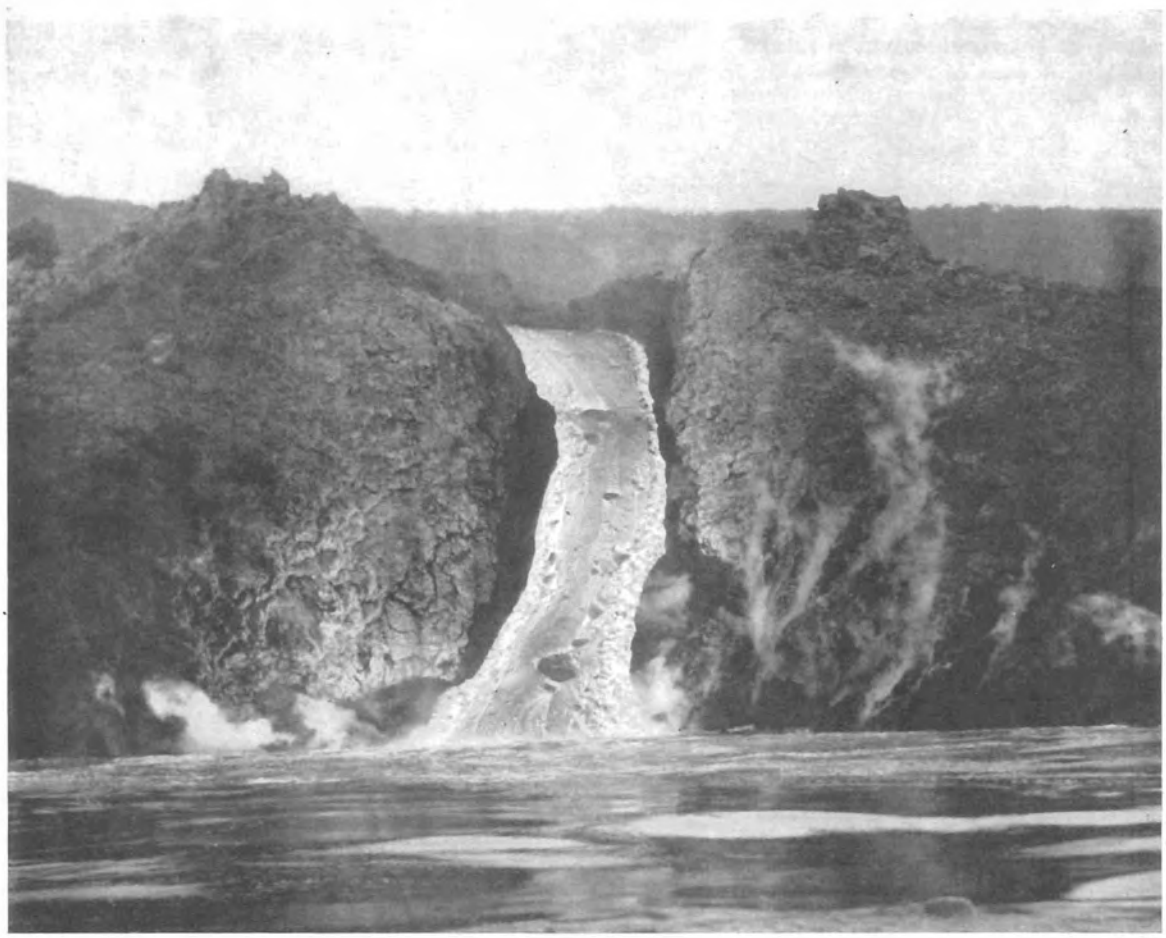

Figure 4. A lava river of the Ohia Lodge flow entering the sea. When such a river with practically unbroken surface entered the ocean, it produced but little steam. Bursts of steam were produced whenever blocks projecting above the surface of the river struck the water.—Photo by T. Matsumoto; courtesy Trans-Pacific Airlines.

much the same way as does the pahoehoe skin. Figure 4 shows such a lava river entering the sea and producing but very little steam. Whenever a block of appreciable size (some appear as dark objects in Figure 4) that was carried along by the lava river entered the water, it did produce a large burst of steam.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY–SEPTEMBER, 1950

VOLCANOLOGY

July

The southwest rift vents of Mauna Loa emitted conspicuous amounts of fume during July.

A total of 69 earthquakes was recorded in July. Of these 59 were recorded at Kilauea and 25 at Mauna Loa. A majority of the earthquakes were of Kilauea origin, and they originated at shallow depths near the northern edge of Kilauea Caldera.

A slight westward tilting, or opposite in direction normal for this season of the year, indicates a pressure decrease under Mauna Loa. Northward tilt during July was greater than normal and indicates an increase of pressure at Kilauea.

The southwest rift vents of Mauna Loa were inspected on July 11. Large quantities of fume were being liberated.

August

In August, as in July, Kilauea was more active seismically than Mauna Loa. A total of 320 earthquakes was recorded in August. Of these, 312 were on the seismograph at Kilauea and 30 on the seismograph on the east slope of Mauna Loa. Most of the quakes originated at shallow foci under the northern end of Kilauea Caldera. Shaking was nearly continuous on August 2, when 241 quakes were recorded. Only three of these 241 quakes were felt. An earthquake accompanied by a roar was felt at Naalehu at 10:58 A.M., August 11. Another perceptible quake with epicenter low down under the northeast slope of Mauna Loa was felt in Hilo and at Kilauea at 12:18 P.M., August 27.

Tilt in the east–west direction during August was of the usual seasonal value. Rapid north tilt which started on July 15 continued until August 16. From August 17 to the end of the month there was a slight accumulation of south tilt. The accumulation of northward tilting since the first of the year, 9 seconds of arc, indicates a pressure increase preceding, during, and after the June eruption of Mauna Loa.

Fume was observed over the southwest rift of Mauna Loa on several days during the month.

Landslides from the Halemaumau rim were observed on August 29.

September

A total of 25 earthquakes was recorded in September. Of this number, 21 were recorded at Kilauea and 13 on the Mauna Loa seismograph.

East tilt was less than usual for September and may be taken as an indication of a slight pressure decrease under Mauna Loa. North tilt was normal for this season of the year.

Fume was observed over the southwest rift of Mauna Loa several times during the month. Following heavy rains on Mauna Loa on September 29 and 30 large fume clouds developed over the June, 1950, eruption source. The mixed steam and fume clouds started reports that Mauna Loa was erupting.

237. Aug. 10, 07:35, very feeble.
238. Aug. 11, 10:58, feeble. Felt at Naalehu.
239. Aug. 13, 05:15, very feeble. Kilauea.

240. Aug. 19, 05:12, very feeble. Felt locally. Kilauea.
241. Aug. 27, 12:18, feeble. Felt locally and at Hilo. North slope Mauna Loa.
242. Aug. 28, 10:25, very feeble. Upper northeast rift Mauna Loa.
243. Sept. 15, 07:42, very feeble. Kilauea.
244. Sept. 16, 21:51, feeble. Felt locally and at Hilo. Northeast rift Mauna Loa.
245. Sept. 30, 17:06, very feeble. Mauna Loa.

TELESEISMS

July 8, 16:09, slight. Near Easter Island.
July 12, 01:27, slight. Aleutians.
July 29, 06:58, slight. Molucca Passage.
July 29, 13:58, slight. Solomon Islands.
Aug. 6, 16:57, slight. Mindanao, P. I.
Aug. 15, 04:24, strong. Burma border.
Sept. 10, 05:25, slight. New Hebrides.
Sept. 28, 20:36, moderate.

MICROSEISMS

Microseisms were strong on August 13, 14, and 15, and moderate on August 16 and from September 11 to 19. On other days they were slight.

CRACK MEASUREMENTS

One end of the crack near the tourist station on the east rim of Halemaumau opened 1 centimeter from June 30 to September 30. At a greater distance from the end of the crack the opening was 2 millimeters. Other cracks measured showed but very little movement.

TILTING OF THE GROUND

A slight westerly tilt in July may be taken as an indication of a pressure decrease under Mauna Loa. Normally there is an east tilt in July. During August and September usual seasonal tilt obtained.

Except for a south tilt August 17 to 21, north tilt was continuous and in a little greater amount than normal for this season of the year.

Table of Tilt at Seismograph Vault on Northeast Rim of Kilauea Caldera

Week Beginning		Amount	Direction
July	2	0.9″	N 15° W
	9	0.5″	S 64° W
	16	1.0″	N 6° E
	23	1.0″	N 20° W

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE VOLCANO LETTER

No. 510 **U. S. Geological Survey** **October–December, 1950**

PUBLISHED BY THE UNIVERSITY OF HAWAII

THE DECEMBER 1950 SUBSIDENCE AT KILAUEA

By R. H. FINCH

At noon on December 8, 1950, after several weeks of generally normal seismic conditions, the frequency of occurrence of earthquakes recorded by the seismographs suddenly increased. Simultaneously a rapid southwesterly tilt started at the Whitney Station on the northeast rim of Kilauea.

The origins of the early earthquakes were in the vicinity of Kokoolau Crater (Fig. 1), 4 miles from the Whitney Station, under the upper end of the system of fissures between the east and southwest rifts of Kilauea. During the night of December 8–9, earthquakes continued to originate in the region of the early shakes; others showed greater distances as though there was a progressive cracking to the southwest. By early morning on December 9 many of the quakes were being plainly felt at Kapapala (Fig. 1). The indicated origin of some of the stronger shakes on this date was a little to the east of Kamakaia Hills. The strongest quake of the series occurred at 21:25, December 10, with an indicated origin also a little to the east of Kamakaia Hills, and was generally felt over the eastern half of Hawaii.

The epicenters of the quakes were distributed over a linear extent of 15 miles, from the Chain of Craters Road to the upper end of the 1823 lava flow. The indicated depth of focus of many of the earthquakes was 4–5 miles.

The total number of earthquakes recorded during the period of rapid subsidence, December 8–14, was at least 656. The maximum number of quakes in any one day was more than 200 on December 10. For several hours each day on December 8, 9, and 10 quaking was so nearly continuance that it was impossible to separate the records of numerous small quakes. The following table shows the number of earthquakes by day:

DATE	NUMBER OF QUAKES
Dec. 8	133+
9	149+
10	200+
11	112
12	33
13	17
14	12

On December 11 a small crack trending NNE–SSW with a few millimeters downthrow on the Kilauea Caldera side was noted on the road near Kokoolau Crater. Two small cracks trending NE–SW were later observed about 2 miles to the southwest of Kokoolau Crater.

The fact that the earthquakes accompanied a rapid subsidence of the entire top of Kilauea was shown by tilt records. A seasonal northeasterly tilt usually continues until the latter part of December, when a seasonal change to the southwest usually occurs. A rapid southwesterly tilt at the Whitney Station started on December 8 and continued for 4 days with a cumulative total of 14.5 seconds of arc. During the same 4 days the cumulative total at the Uwekahuna Station (Fig. 1) was 22.1 seconds of arc to the east-southeast. In both cases tilting was much more rapid than normal seasonal tilting. These values place the maximum subsidence a little to the northeast of Halemaumau, about the same position as that of the maximum subsidence of 1920–24 determined by Wilson[1] on the basis of leveling. Calculations indicate that the maximum subsidence in 1950 was in excess of 1 foot. Figure 2 shows the tilt curves obtained at the Whitney Station. The

[1] WILSON, R. M. GROUND SURFACE MOVEMENTS AT KILAUEA VOLCANO HAWAII. Hawaii Univ. Res. Pub. No. 10. 1935.

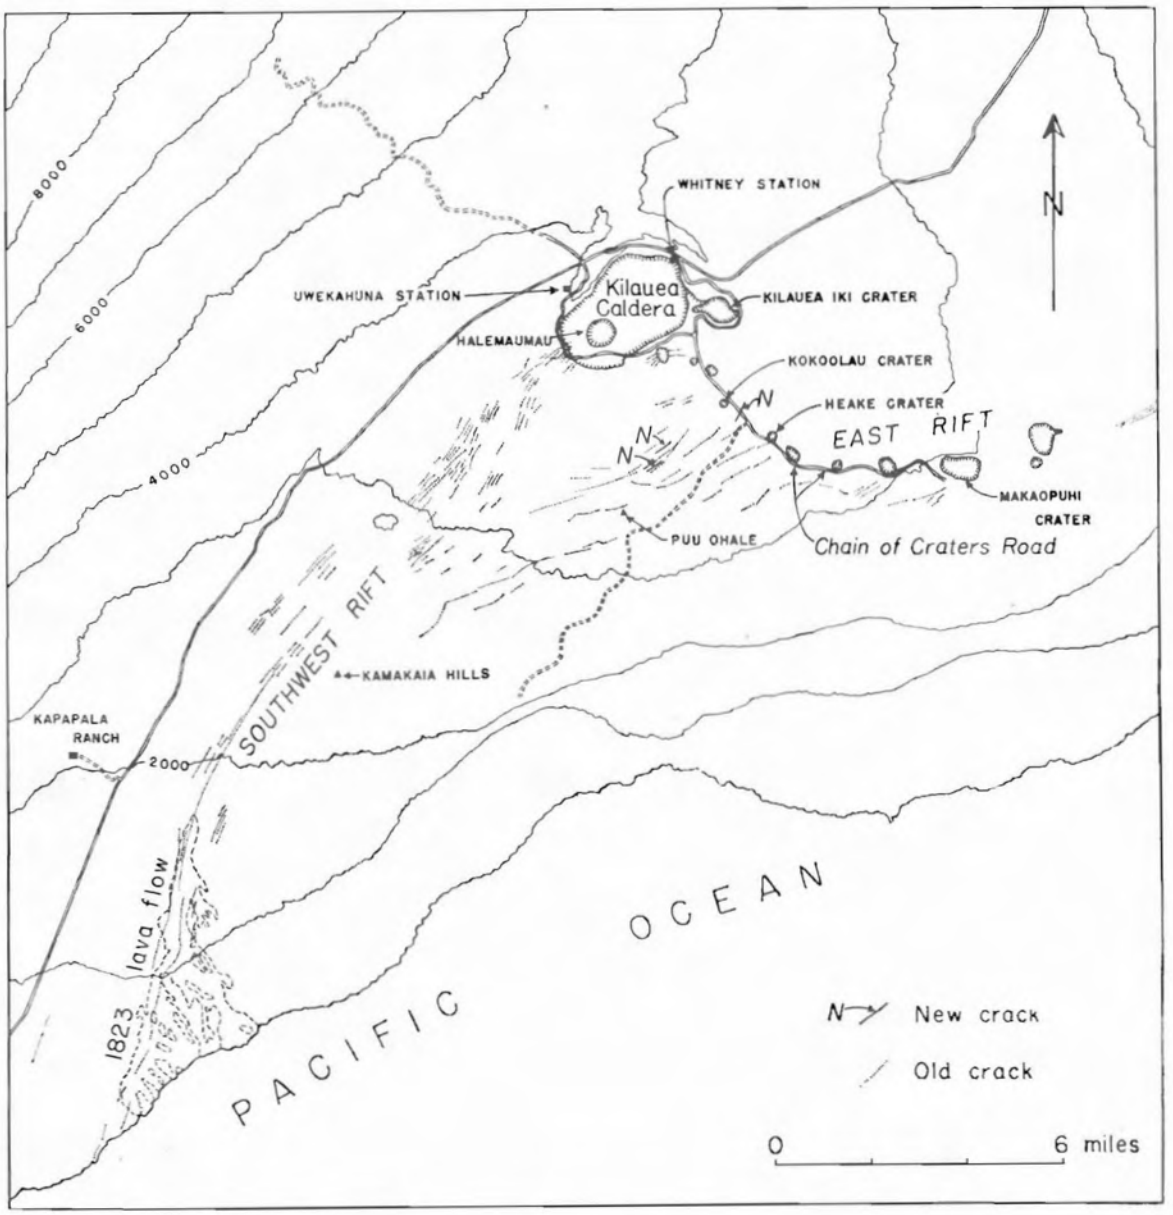

FIGURE 1. Map of Kilauea Caldera and vicinity. The 656 earthquakes recorded during the December, 1950, subsidence originated along the rift zone extending from Kokoolau Crater to beyond the Kamakaia Hills. New cracks were observed at places marked N.

sinking implied by the 14.5 seconds of arc south–southwest tilt is less than the implied tumescence during the 5 months from March to July, 1950, when there was a tilt of 21 seconds to the north–northeast.

Tilting, earthquakes, and cracks at the surface indicate that a considerable area, probably several miles in diameter around Kilauea Caldera, subsided. The location of the earthquakes and the new cracks indicate that a triangular block bounded by the east and southwest rifts and a line from Kokoolau Crater to the upper end of the 1823 lava flow underwent a greater movement than adjacent areas.

Several short spells of harmonic tremor recorded on December 10 and 11 indicate that there was some movement of magma at a depth of 4 or more miles (the depth of focus of many of the earthquakes). Tilt records indicate that pressure continued to build up under Kilauea for nearly 2 months after Mauna Loa ceased to erupt in June, 1950. Whether the rapid pressure decrease in December was accompanied by a retreat of the lava into the depths or by a more or less horizontal drainage into the southwest rift or elsewhere is not known. The writer favors the possibility of retreat of the lava column to depth.

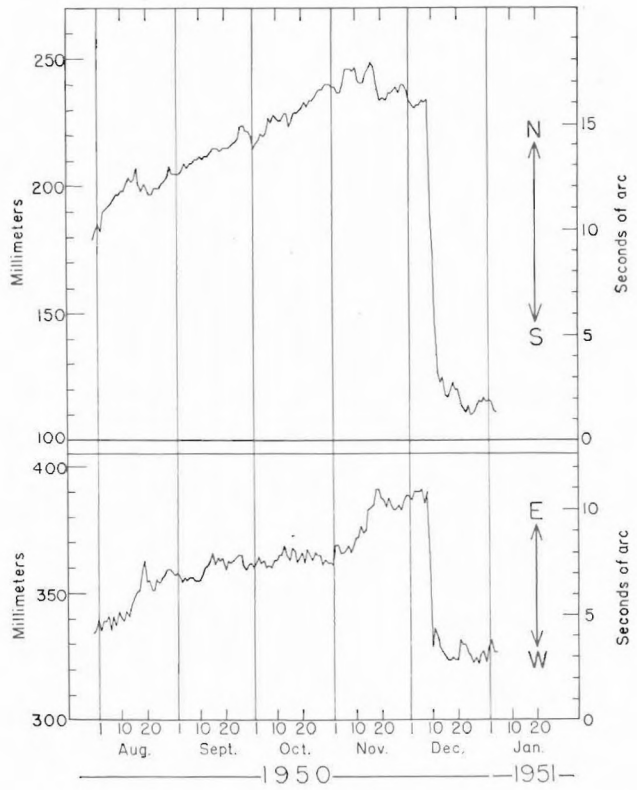

FIGURE 2. Graph of ground tilting at the Whitney Laboratory of Seismology at the northeast rim of Kilauea Caldera from August to December, 1950, showing the rapid south and west tilt on December 8 to 12. The resultant tilt for these 4 days was 14.5 seconds of arc to the south–southwest. Tilting at normal rates preceded and followed the rapid tilting.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR OCTOBER–DECEMBER, 1950

VOLCANOLOGY

October

Only 25 earthquakes were recorded in October. Of these, 24 were recorded at Kilauea and 19 on the Mauna Loa seismograph. A slight earthquake that was felt all over the island of Hawaii on October 11 originated at a depth of about 25 miles under the east slope of Mauna Loa.

Northward tilting of the ground was about normal for this season of the year and eastward tilting was less than usual.

The vents of the 1950 lava flows on the southwest rift of Mauna Loa continue to liberate fume. The fume was especially conspicuous on October 19.

November

Both Mauna Loa and Kilauea continued quiet during November. Kilauea has had no surface manifestation of activity in more than 16 years. There have been two spells of subterranean activity during these 16 years with sufficient magnitude to be easily detected by seismographs and tiltmeters. One was in November–December, 1944, and the other in April, 1950.

Forty earthquakes were recorded in November. Of these, 38 were recorded at Kilauea and 20 on the Mauna Loa instrument. Many of the quakes originated at shallow depths under the northern end of Kilauea Caldera. A continuous tremor was recorded on all seismographs on the island from 13:17 to 13:37 on November 17.

Northeastward tilting of the ground was about normal until November 16. Following heavy rains on November 15, 16, and 17 there was a slight southwest tilt. For the month as a whole there was a slight eastward tilt.

Landslides from the Halemaumau rim were common in November. The heavy rains of November 15, 16, and 17 produced conspicuous steam clouds in Halemaumau.

A conspicuous cloud was observed over the 1950 flow vents from Mauna Loa on November 15.

December

The total number of earthquakes recorded in December was 701. Of this total, 656 were recorded during 7 days—December 8–14. Owing to the frequent dismantling of the Mauna Loa seismograph no total can be given for that station.

A total of 1,702 earthquakes was recorded during 1950.

The rapid subsidence of Kilauea that began on December 8 may be taken as an indication of a sinking of the lava column under Kilauea. There had been a definite increase of magmatic pressure under Kilauea for 2½ months prior to the outbreak of Mauna Loa on June 1. The pressure build-up, as indicated by north tilt, continued definitely until the middle of August and probably until November 19. The rapid subsidence began, then, about 3 weeks after the cessation of the pressure build-up.

Tilting of the ground was slight in December except for the 14.5 seconds of arc south–southwest tilt accompanying the December 8–14 subsidence.

Conspicuous clouds were observed over the southwest rift of Mauna Loa on December 12 and less conspicuous ones on several other days.

Several landslides from the Halemaumau rim were observed.

During strong winds on December 26 most of the Kau Desert was obscured by dust clouds.

443–447	Dec. 14

290. Dec. 9, 05:43, moderate. Widely felt. East of Mauna Iki. 4–5 miles deep.
323. Dec. 9, 20:45, widely felt. Instruments dismantled. Near Kamakaia Hills.
325. Dec. 10, 05:57, moderate. 4–5 miles deep, near Kamakaia Hills.
326. Dec. 10, 08:23, moderate. Below Kamakaia Hills.
369. Dec. 10, 17:29, moderate. Kamakaia Hills.
370. Dec. 10, 17:57, moderate. Near Puu Ohale.
379. Dec. 10, 21:25, strong. Widely felt. Instruments dismantled. Kamakaia Hills.
421. Dec. 11, 12:53, moderate. 4–5 miles deep below upper end 1823 lava flow.
431. Dec. 12, 06:28, moderate. Depth shallower than preceding quakes.
448. Dec. 15, 02:13, very feeble. Kilauea.
449. Dec. 16, 07:17, feeble.
450. Dec. 18, 05:54, very feeble. Felt plainly at Naalehu. Above South Point.
451. Dec. 20, 23:19, feeble.
452. Dec. 21, 20:00, very feeble.
453. Dec. 21, 21:17, feeble.
454. Dec. 22, 03:07, slight. Felt locally. Mauna Loa.
455. Dec. 22, 04:07, very feeble. Kilauea.
456. Dec. 26, 02:55, moderate. 8 miles deep south of Kilauea Iki. Widely felt.
457. Dec. 27, 18:58, very feeble.

TELESEISMS

Oct. 5, 06:21, moderate. Costa Rica.
Oct. 7, 17:34, slight. Moluccas.
Oct. 21, 00:04, slight. West coast of Mexico.
Oct. 23, 06:24, slight. Guatemala.
Nov. 2, 05:40, moderate. Felt at Darwin, Australia.
Nov. 7, 16:28, moderate. Solomon Islands.
Nov. 9, 16:36, very slight.
Nov. 11, 00:04, very slight.
Dec. 2, 10:01, moderate. New Hebrides.
Dec. 4, 06:38, slight. New Britain.
Dec. 9, 12:26, slight.
Dec. 13, 16:00, slight.
Dec. 14, 04:40, very slight.

MICROSEISMS

Microseisms were strong on November 3, December 2–13, and December 26–31. They were of slight or moderate amplitude on other days.

CRACK MEASUREMENTS

A majority of the cracks that were measured around the rim of Halemaumau showed distinct openings. Quite likely some of the openings were due to earthquakes. Cracks on the crater floor that are more or less aligned with the southwest rift closed slightly during the sinking spell of December 8–14. During this same spell some of the old cracks by Kokoolau Crater, near where new cracks appeared at the surface, showed distinct openings.

TILTING OF THE GROUND

Seasonal northeast tilt continued until November 17 when a southwest tilt set in. This change in direction came about 1 month earlier than usual and was probably due to unusually heavy rains on November 15, 16, and 17. Seasonal southwest tilt continued through the end of the year, except for the rapid southwest tilt December 8–12.

Table of Tilt at Seismograph Vault on Northeast Rim of Kilauea Caldera.

Week Beginning	Amount Seconds	Direction
October 1	1.21	N 5° E
8	0.54	N 63° E
15	0.60	N 36° W
22	0.86	N 8° W
29	0.60	N 79° E
November 5	0.95	N 50° E
12	2.28	E
19	1.02	S 70° W
26	0.86	S 34° E

THE VOLCANO LETTER

No. 511 **U. S. Geological Survey** **January–March, 1951**

PUBLISHED BY THE UNIVERSITY OF HAWAII

BEGINNING OF GEOMAGNETIC OBSERVATIONS AT HAWAIIAN VOLCANO OBSERVATORY

By G. A. MACDONALD

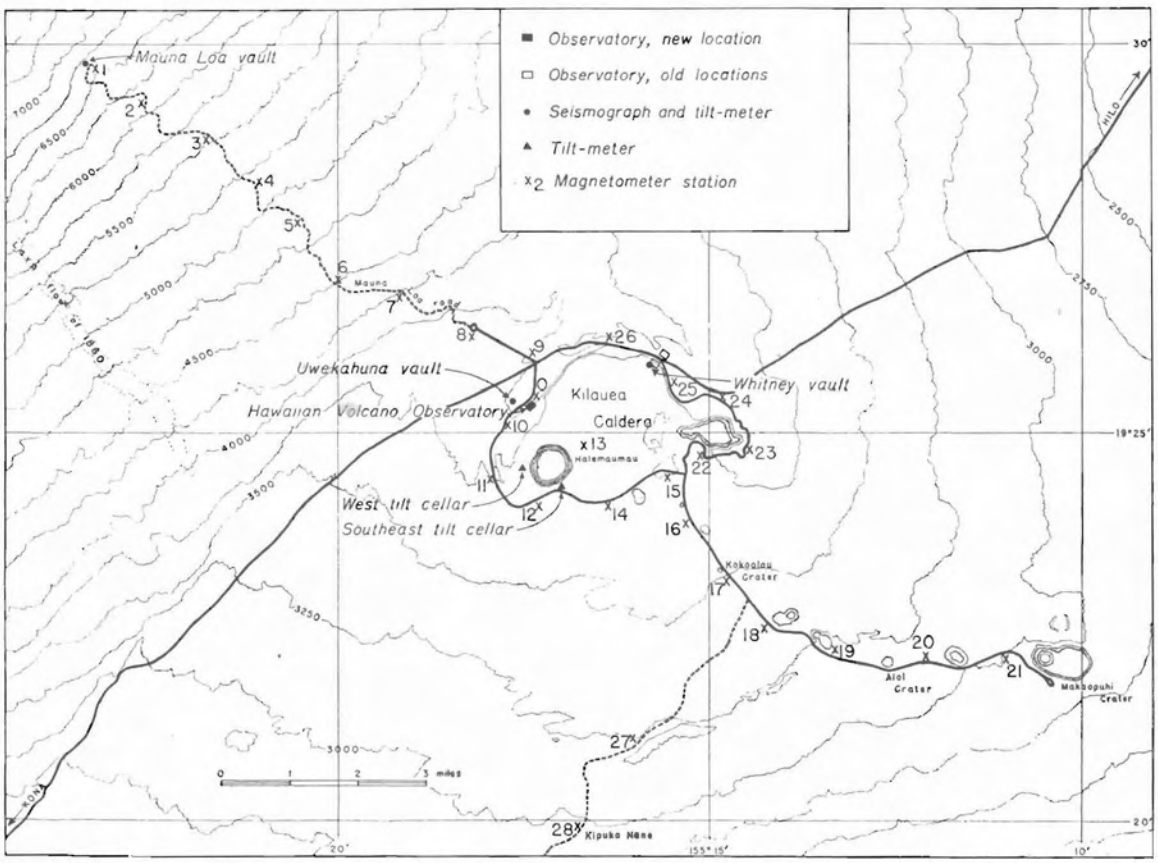

FIGURE 1. Kilauea Caldera and environs, showing locations of Observatory and permanent magnetometer stations.

For the past several years the staff of the Hawaiian Volcano Observatory has wanted to start geomagnetic measurements at Kilauea and Mauna Loa volcanoes. Results obtained by workers on volcanoes in other areas, especially Japan (Kato, 1933–35; Takahasi and Hirano, 1941), have suggested that magnetic measurements in Hawaii might give information on magmatic conditions and movements beneath the surface and, in addition, might supplement other methods in predicting eruptions. Preliminary studies by Omer (1945) suggested some correlation between volcanic conditions on the island of Hawaii and small variations in the magnetic field at Honolulu, nearly 200 miles away.

The opportunity to begin magnetic studies came early in 1950 when two Wolfson vertical magnetometers were made available to the Volcano Observatory by the Geophysics Branch of the U. S. Geological Survey. H. R. Joesting and J. H. Swartz of the Geophysics Branch, accompanied by R. E. Wilcox of the General Geology Branch of the Geological Survey, spent the first 3 weeks of February, 1950, at the Observatory setting up procedures to be followed, calibrating instruments, and instructing Observatory personnel in their use. Joesting and Swartz have kindly read and criticized the manuscript of this paper.

A series of permanent observation stations was established during February and March on Kilauea and on the lower slopes of Mauna Loa. The location of the

stations is shown in Figure 1. The number of stations is not as great as might be desired, but is limited by the amount of time available for the work.

Each station was set at a point where closely spaced set-ups of the magnetometer showed the magnetic field to be reasonably regular over an area of approximately 100 square feet. At each station three concrete hubs were set and small pits drilled in them to receive the ends of the magnetometer tripod legs. The tripod legs are kept at a fixed length when the stations are occupied, and each leg is placed on the same hub in successive readings at each station. The leveling screws also are turned out as nearly as possible to the same distance for each set-up. Thus the position of the instrument, both horizontally and vertically, is as nearly as possible the same for successive readings at a given station.

It is planned to occupy each station approximately once a month, but during some months the Observatory staff has not had time to occupy all of the stations. The stations are so widely distributed that considerable time is needed for travel between them. All the readings of each set are made on one day, or on 2 successive days.

The procedure is as follows. One instrument is set on station 0, near the Volcano Observatory at the western edge of Kilauea Caldera (Fig. 1). After the reading at station 0 is obtained, the instrument is taken to each of the other stations and readings obtained at them. Readings are made with the north end of the balance pointed first east and then west; the average of the two sets of readings is used, thus compensating for any small errors in orientation and leveling of the instrument. Immediately after the first instrument is removed from station 0, the second instrument is set up at that station and it is read at frequent intervals throughout the time the first instrument is in use at the other stations. From the readings at station 0, a curve of diurnal variation is constructed which is used in correcting the readings at the other stations. At the end of the traverse the first instrument is again set on station 0, and, after correcting for diurnal variation, any closing error is distributed linearly throughout the time of operation. The instrument is recalibrated for sensitivity in the laboratory following each series of readings. The corrected scale readings are then converted into gammas, and the strength of the magnetic attraction at each station is recorded in terms of difference in gammas from that at station 0.

In some respects the program is not ideal, but it represents the best which the limited available time and small size of the Observatory staff allow at present. If results appear to justify it, it is hoped that the program can be expanded and improved in the future. The data obtained thus far are shown in the accompanying table.

Joesting and Swartz again visited the Volcano Observatory in June, 1950, during the eruption of Mauna Loa for the purpose of checking on the progress of the investigation and the operation of the instruments. Of the measurements listed in the table, those for June 12 were made by them. The others were made by members of the Observatory staff, principally C. K. Wentworth and the writer, aided during March and April by J. B. Orr of the National Park Service. On March 8 and 9, 1951, F. C. Farnham of the Geophysics Branch made measurements with an absolute magnetometer at station 0 close to the Volcano Observatory and at a newly established station close to the seismograph station at St. Joseph's School in Hilo.

It is too soon to attempt much interpretation of the results. It is believed possible that the rise of hot magma

underground may cause a detectable change in the vertical component of the magnetic field at the surface. It will be noted in the accompanying table that several of the stations (1 to 9) which lie on the line between the Observatory and the Mauna Loa seismograph showed a decrease in magnetism as related to station 0. Mauna Loa erupted on June 1, and there is some possibility that the decrease in magnetism at these stations on Mauna Loa may have been in some way related to the then-impending eruption. However, the distance of the closest station from either the eruptive axis of the volcano (beneath the summit caldera) or the locality on the southwest rift where the eruption took place is so great (13 and 20 miles, respectively) that the apparent correlation is regarded with little confidence.

Early in July, soon after the end of the Mauna Loa eruption, a line of three stations was established running southeastward for 1.5 miles from a point on the recently active rift. It is planned to make readings at these stations at intervals of about 6 months during the next few years to determine whether any definite discernible effect results from cooling of the magma in the rift.

Variations at the stations on Kilauea have thus far been rather irregular. It appears that during the past year volcanism at Kilauea may have been at its lowest ebb in the historical period, and hence that the time of commencement of the magnetic program may have been exceptionally favorable in respect to detection of any changes which may accompany the return of surficial volcanic activity.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JANUARY–MARCH, 1951

VOLCANOLOGY

January

The year 1951 commenced with both Mauna Loa and Kilauea volcanoes quiescent. During the month of January, 18 earthquakes were recorded at the Whitney vault on the northeastern rim of Kilauea Caldera; 8 of these were recorded also on the seismograph on the lower east slope of Mauna Loa. This was the smallest number of earthquakes recorded during any month since October, 1947.

At the Whitney vault ground surface tilting was in the main southward, following the usual seasonal pattern for this time of year. From January 7 to 17, however, there was a sharp northward tilting of approximately 2 seconds of arc. Most cracks in the vicinity of Kilauea Caldera opened or closed very little. Cracks near the southeastern edge of Halemaumau continued to open.

Conspicuous steam clouds rose from Halemaumau on January 22, after heavy rains.

February

Mauna Loa and Kilauea continued quiet during February. The seismograph at the northeastern rim of Kilauea Caldera recorded 25 earthquakes during the month; 16 of these were recorded also on the Mauna Loa seismograph. An earthquake felt in the vicinity of Kapapala at 10: 55 A.M. on February 14 originated at a depth of about 7 miles on or near the Kaoiki fault zone near Ainapo on the southeastern flank of Mauna Loa. At 7: 26 on the morning of February 16 a somewhat stronger earthquake was felt from Naalehu to Hilo. It had its origin about 15 miles below a point on the northeast rift zone of Mauna Loa near Puu Ulaula. Most of the small earthquakes during the month originated at Kilauea.

Tilting of the ground at the northeast rim of Kilauea Caldera continued southward, as is normal for this season of the year. There was almost no accumulation of east–west tilt during the month. However, because there is normally a westward tilting at this time of the year, the absence of tilting may indicate a small increase of volcanic pressure beneath Mauna Loa.

The vents of the 1950 eruption of Mauna Loa were visited on February 9 and 10. Steam was issuing from the fissures from 10,200 to 11,500 feet altitude, and large amounts of sulfurous fume were being liberated in the vicinity of 10,000 feet. The source cracks were still warm, but no heat could be detected in most of the thin flows near the vents. The thick flows near the highway in Kona are still hot beneath the surface. Fume was visible on the southwest rift from the Volcano Observatory on the afternoon of February 16.

During heavy rains in late February, spectacular steam clouds rose from Halemaumau, giving evidence that the vent of Kilauea Volcano is still very hot only a short distance below the surface.

March

The period of quiet at Hawaiian volcanoes which began in late December continued through March. The seismograph at the northeast rim of Kilauea Caldera recorded 27 earthquakes during the month, 2 more than were recorded during February. Only 14 of these were recorded at the Mauna Loa station. A quake which was felt in the Volcano district and Hilo on the evening of March 14 originated at a depth of about 7 miles on the east rift zone of Kilauea, 5 miles east–northeast of Makaopuhi Crater. At 6: 41 A.M. on March 20 another earthquake was felt by a few persons in the Puueo district of Hilo. This quake had its origin about 6 miles below the eastern slope of Mauna Loa, 3 miles east of Kulani Cone. From March 15 to 19 several small earthquakes originated on the western slope of Mauna Loa near Kealakekua, possibly on the fault which runs out to sea at the northern edge of Kealakekua Bay.

Tilting of the ground surface at the northeastern rim of Kilauea Caldera continued southward through March. Southward tilting is normal during this part of the year. However, from March 7 to 17 the tilting was distinctly more rapid than normal, indicating a slight decrease of volcanic pressure beneath Kilauea Caldera. This, like the short spell of northerly tilting in January, indicates fluctuation of pressure, demonstrating that the lava column beneath Kilauea Caldera is still mobile. Slight westward tilting also occurred during the month, as is usual at this season.

Table of Tilt at Seismograph Vaults on Rim of Kilauea Caldera

Week Beginning		Whitney Vault (Northeast rim)		Uwekahuna Vault (West rim)	
		Amount	Direction	Amount	Direction
December	31	0.9″	S 45° W	0.4″	S 56° W
January	7	0.8″	N 38° E	0.7″	S 26° W
	14	0.7″	N	1.5″	N 70° W
	21	2.0″	S 35° E	2.4″	N 15° W
	28	0.6″	S 37° W	0.2″	N 27° E
February	4	1.2″	S 45° W	1.2″	S 70° E
	11	1.5″	N 38° E	1.5″	S 58° W
	18	1.5″	S 35° E	2.3″	N 78° E, S 52° W
	25	1.6″	S 42° W	2.4″	N 78° E
March	4	2.1″	S 26° W	1.5″	E
	11	4.1″	S 5° W	0.7″	S 15° E
	18	1.2″	S 16° W	0.5″	S 79° E
	25	0.6″	W	0.4″	N 63° E

TILTING OF THE GROUND

At the Whitney Laboratory of Seismology, situated at the site of the original Volcano Observatory building on the northeastern rim of Kilauea Caldera, ground tilting was in the southward direction, normal for this season of the year, except for a brief period of fairly strong northward tilting from January 7 to 17 and another less marked period of northward tilting from February 10 to 21. There was a slight eastward tilting in January and almost no accumulation of east–west tilt in February. However, since the normal seasonal tilting is westward in February, both the January and February records indicate a small increase in volcanic pressure beneath Mauna Loa. Normal westward tilting continued through the month of March. Records of tilting at the Uwekahuna vault are not yet long enough to determine the normal pattern of seasonal tilting at that locality.

CRACK MEASUREMENTS

The only crack which showed much change in width during the 3-month period preceding March 31 is the one which crosses the tourists' observation platform at the southeastern edge of Halemaumau. That crack opened 1.1 centimeters at the northern end, the amount of opening decreasing southward to zero at a point between measuring stations 8 and 9, south of the observation platform. Crack 37, on the floor of Kilauea Caldera about a quarter of a mile southeast of Halemaumau, opened 1 millimeter; crack 101-A, near Chain of Craters Road about 0.2 mile northwest of Devil's Throat, closed about the same amount.

TEMPERATURE MEASUREMENTS

The temperature of the steam well at the Sulphur Bank measured 204.5° F. on December 31 and January 30, and 205° F. on March 1 and March 31.

SEISMOLOGY

Earthquake Data, January–March, 1951

(Based on Bosch-Omori seismograph on rim of Kilauea Caldera)

* For definition of local seismicity, see Volcano Letter 371.

The data for the following local disturbances were determined from seismograph stations operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The arrival times are given to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory at the northeast rim of Kilauea Caldera. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

1. Jan. 3, 03:39, very feeble.
2. Jan. 6, 04:58, slight. Southwest rift of Mauna Loa at about 8,000 feet altitude.
3. Jan. 26, 06:40, very feeble.
4. Feb. 14, 10:55, slight (moderate, Mauna Loa), felt at Kapapala. Kaoiki fault near Ainapo, about 7 miles deep.
5. Feb. 16, 07:26, slight (moderate, Mauna Loa), felt from Hilo to Naalehu. Northeast rift of Mauna Loa near Puu Ulaula, about 15 miles deep.
6. Feb. 16, 18:58, very feeble.
7. Feb. 20, 20:01, very feeble.
8. Feb. 20, 20:47, very feeble.
9. Feb. 20, 21:47, very feeble.
10. Feb. 21, 21:26, very feeble.
11. Feb. 23, 03:41, very feeble.
12. Feb. 24, 17:39, very feeble.
13. Feb. 26, 01:28, very feeble (feeble, Kona).
14. Feb. 26, 09:21, very feeble.
15. Feb. 28, 14:13, very feeble.
16. Mar. 5, 03:53, very feeble.
17. Mar. 5, 03:56, very feeble.
18. Mar. 5, 09:33, very feeble.
19. Mar. 5, 16:44, very feeble. Northeast rift of Mauna Loa.
20. Mar. 8, 16:30, very feeble. Nearly under Hilo, about 25 miles deep.
21. Mar. 14, 03:47, very feeble. Hilina fault, southeast of Kilauea Caldera.
22. Mar. 14, 03:48, feeble. East rift of Kilauea.
23. Mar. 14, 20:50, slight, felt in Hilo and Volcano areas. East rift of Kilauea 3 miles east–northeast of Napau Crater, about 7 miles deep.
24. Mar. 15, 04:38, very feeble (feeble, Mauna Loa). West slope of Mauna Loa near Kealakekua.
25. Mar. 15, 11:34, very feeble.
26. Mar. 15, 16:43, very feeble (slight, Kona). West slope of Mauna Loa near Kealakekua.
27. Mar. 20, 06:42, feeble, felt in Puueo. East slope of Mauna Loa 3 miles east of Kulani Cone, about 6 miles deep.
28. Mar. 24, 06:28, no record at Kilauea (very feeble, Kona). West slope of Mauna Loa.
29. Mar. 24, 22:33, very feeble.

TELESEISMS

Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey.

Jan. 13, 12:20, slight. About 150 miles east of Alaska Peninsula.
Jan. 17, 11:17, slight. Southeastern New Guinea.
Feb. 19, 12:38, moderate. About 500 miles west of Easter Island.
Mar. 10, 12:06, slight. Fiji Islands region.

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE KILAUEA EARTHQUAKE OF APRIL 22, 1951, AND ITS AFTERSHOCKS

By GORDON A. MACDONALD

At 2:52 Hawaiian time, on the afternoon of April 22, the southern part of the island of Hawaii experienced the strongest earthquake in this area since 1929, and possibly since 1908. The epicenter of the quake lay just east of Kilauea Caldera. The intensity of V, on the modified Mercalli scale, was essentially uniform for 30 miles northeast and southwest of the epicenter, to Hilo and Naalehu, respectively. This uniformity of intensity over such a broad area indicates that the origin of the earthquake was at a considerable depth, probably 25 to 30 miles. It was impossible to determine either the epicenter or the depth of origin instrumentally, because all the seismographs of the local net were dismantled by the beginning of the preliminary waves. The operator of the Hilo seismograph station, Brother Bernard T. Pleimann of St. Joseph's School, reached the dismantled instrument and reassembled it in time to record the coda of the earthquake. Shaking continued on the Hilo instrument for 16 minutes.

The preliminary determination of epicenter, issued by the U. S. Coast and Geodetic Survey on April 24, gives the time at the origin as 00:52:21 on April 23, Greenwich time, and the magnitude on the Gutenberg-Richter scale as 6.5 as determined at Pasadena and 6.0 at Berkeley.

The earthquake was felt generally over the island of Hawaii and by many persons on the islands of Maui and Oahu. Damage resulting from the quake was slight. On the southern part of the island of Hawaii many small objects were overturned, and some dishes were broken. Many, but not all, pendulum clocks were stopped. A water pipe was broken at the Volcano Observatory, and a plate glass window at Glenwood was cracked. Water slopped over the rims of some tanks. Small earth slips occurred in road cuts between Kilauea Caldera and Hilo, and north of Hilo along the Hamakua Coast. Several rock slides occurred on the walls of Kilauea Caldera and a very large number on the unstable walls of Halemaumau crater. All the latter were small. No large blocks of the crater rim were displaced, although many cracks near the rim were widened appreciably. The crack which crosses the tourist area at the southeast rim of the crater opened 6 mm. at the time of the earthquake and 3 mm. more during the period of aftershocks. Small slides continued in Halemaumau for about a week after the big earthquake. Small rock avalanches occurred on the walls of Alae and Makaopuhi craters, on the east rift zone of Kilauea, and Superintendent F. R. Oberhansley of Hawaii National Park reported rock falls at the cliffs of Hilina Pali and Puu Kapukapu, on the southern shore of the island. Minor cracking of the highway occurred at the northeast rim of Kilauea Caldera, ¼ mile southeast of the Whitney Laboratory (Fig. 1), apparently caused by settling of a thin fill under the pavement when the block at the edge of the caldera moved forward slightly. Cracking in the soil also was observed at several places north and east of Kilauea Caldera, apparently caused by lurching of the soil. No surface faulting was observed.

The Bosch-Omori seismograph at the Whitney Laboratory on the northeast rim of Kilauea Caldera (Fig. 1) and the vertical seismograph at Uwekahuna were dismantled. The vertical seismograph was back in operation at 15:20, but resumption of recording on the Bosch-Omori seismograph was delayed until 16:45 by electric power failure caused by the earthquake. The wire suspensions on the heavy mass of one component of the Hawaiian-type seismograph at the Mauna Loa station were broken, and the mass, weighing approximately 225 pounds, was deposited on the floor of the vault, 3 feet from its proper position. At the Uwekahuna vault, the wire suspensions on both components of a semiportable tiltmeter were broken and the horizontal pendulums, each weighing 35 pounds, dropped onto the pier. The breaking of the wire suspensions, which have considerable strength under normal conditions of lateral swing of the pendulums, suggests a vertical dancing of the pendulums. This, together with the dismantling of the vertical seismograph, which is seldom dismantled even by strong earthquakes, appears to indicate a high angle of emergence of the earthquake vibrations, consonant with a deep origin nearly beneath Kilauea Caldera.

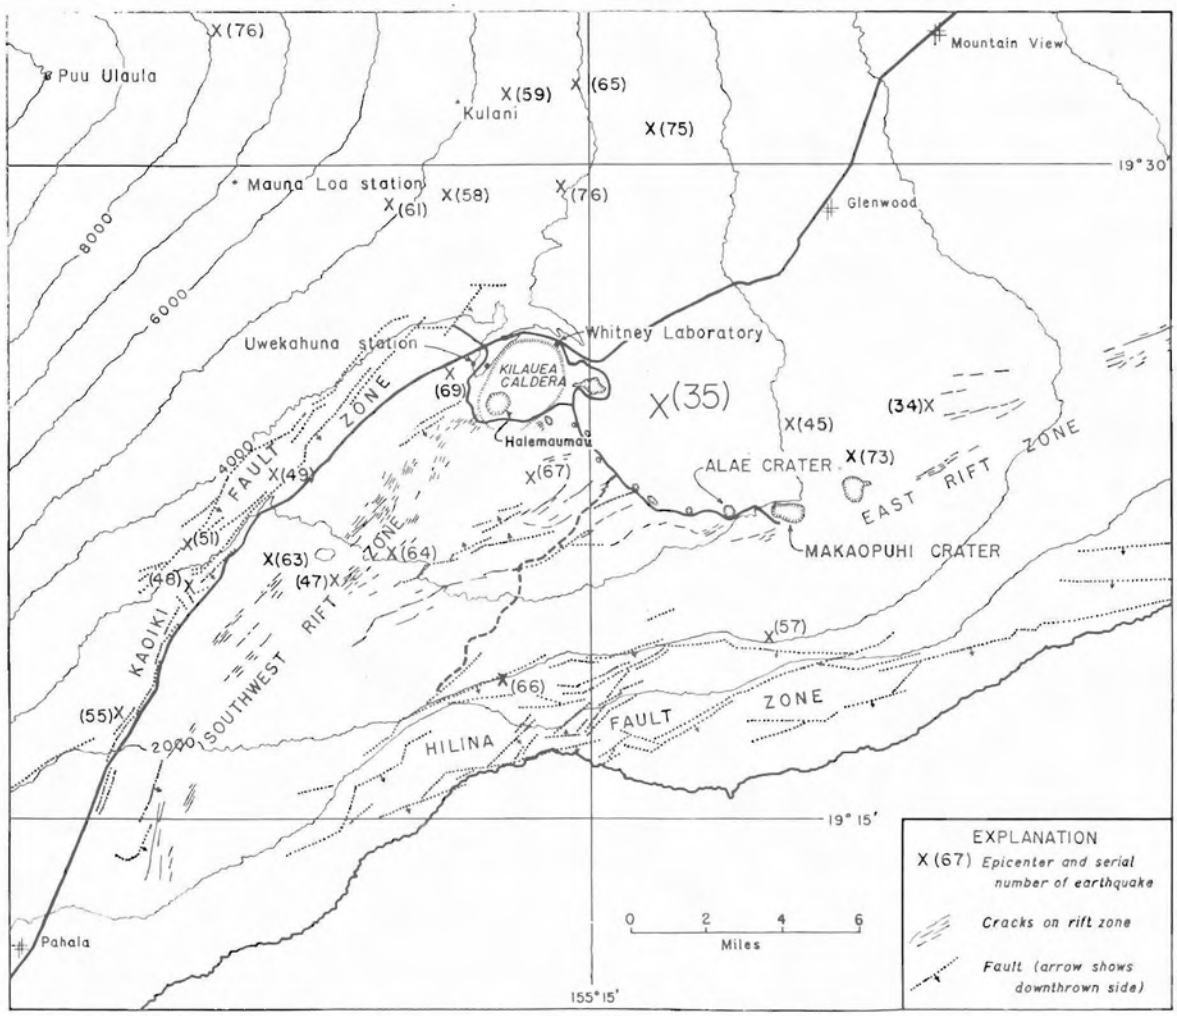

FIGURE 1. Map of Kilauea Caldera and vicinity, showing the epicenters of the large earthquake of April 22 and its aftershocks in relation to fault zones and the rift zones of Kilauea volcano. The epicenter of earthquake 35 was estimated on non-instrumental grounds and its location is only approximate.

Damage to the seismographs and tiltmeters made it impossible to determine with certainty the direction of tilt during the earthquake, but it probably was southeastward at the Whitney station and eastward at Uwekahuna. The direction of first motion of the earthquake was south and east at the Whitney station, and down at the vertical seismograph at Uwekahuna. It is believed that the earthquake accompanied a marked subsidence at Kilauea, probably caused by a decrease of volcanic pressure at depth. Subsidence is suggested by the direction of first motion, the probable direction of tilt, and the observed generalization that the strongest local earthquakes generally, if not always, accompany subsidence rather than tumescence. It is interesting that the subsidence was immediately followed by the beginning of rapid northward tilting of the ground at the Whitney station, apparently indicating restoration of the pressure. This rapid northward tilting continued until June 8 (see section on Volcanology, page 4).

At 04:53:53 H.S.T. on April 22, the major earthquake was preceded by a moderate earthquake which originated at a depth of about 21 miles on the east rift zone of Kilauea volcano, 10 miles east of the caldera (Fig. 1, location 34).

During the 7 days following the major shock, 108 earthquakes were recorded on the Volcano Observatory seismographs. Of these, 71 occurred on April 22 and 23. More than half were tremors, too small to permit identification of separate phases in the record. Figure 2 is a graph of daily seismicity from April 20 to 30, derived by assigning a numerical value to each earthquake, depending on its intensity, and totaling these values for each day. The scale of seismicity in use at the Hawaiian Volcano Observatory is an arbitrary one, based on the amplitude of the record produced by the earthquake on the seismographs. It has previously been described by A. E. Jones.[1] The grades of earthquake intensity and numerical values assigned to them are listed in the accompanying table.

As indicated in the table, earthquakes of seismicity value 1 to 4 correspond approximately to the same numerical grades in the Rossi-Forel and modified Mercalli scales of earthquake intensity. However, because the Volcano Observatory scale is based on instrumental effects, the correspondence to the other intensity scales and the descriptions of non-instrumental effects in the table are not always exact.

All earthquakes producing a double amplitude of os-

[1] JONES, A. E., CHART OF KILAUEA SEISMICITY. Volcano Letter 371: 1–3. 1932.

cillation of more than 60 mm. on the Bosch-Omori seismograph are classified as strong, and receive the same seismicity rating. Thus the big earthquake of April 22 received the same seismicity value as the much smaller "strong" earthquakes which took place on April 23 and 26. If allowance were made for this, the seismicity on April 22 would be somewhat increased. The high seismicity on April 22 and 23 results principally from the large number of very small aftershocks (tremors and very feeble earthquakes) on those days.

Most of the aftershocks were too small to be located, phase arrivals not being recognizable on the seismograms, or recognizable only on the record of one station. Only 19 could be located with reasonable certainty. The epicenters of these are shown in Figure 1, in which the number accompanying the cross indicating the epicenter is the serial number of the earthquake for the current year. The date, time, and intensity of the earthquake are given following its serial number in the table in the section on Seismology, pages 4 and 5. All the located aftershocks were of comparatively shallow origin. The deepest was that at 03:57 on April 26 (Serial No. 73), at a depth of about 11 miles on the east rift zone of Kilauea. Most of the others originated at depths of 3 to 8 miles.

In general, the aftershocks fall into two groups, one distributed along the rift zones of Kilauea volcano, and the other associated with the Kaoiki fault zone along the southeast slope of Mauna Loa and the prolongation of the Kaoiki zone northeastward beyond any recognized surface fault offsets. It is of interest to note that the northeastward continuation of the Kaoiki fault was suggested years ago by H. O. Wood,[2] who also found an apparent clustering of earthquakes along this line. The Kaoiki fault zone lies at, or close to, the surface contact between Kilauea and Mauna Loa volcanoes. The earthquake activity along this zone possibly resulted from relative downward movement of Kilauea along the Kaoiki faults in response to decrease of volcanic pressure beneath Kilauea.

[2] Wood, H. O. A consideration of recent earthquakes local to Hawaii, and of the seismological problem they indicate. Hawaiian Volcano Obs. Bul. 3(5): 56–57. 1915.

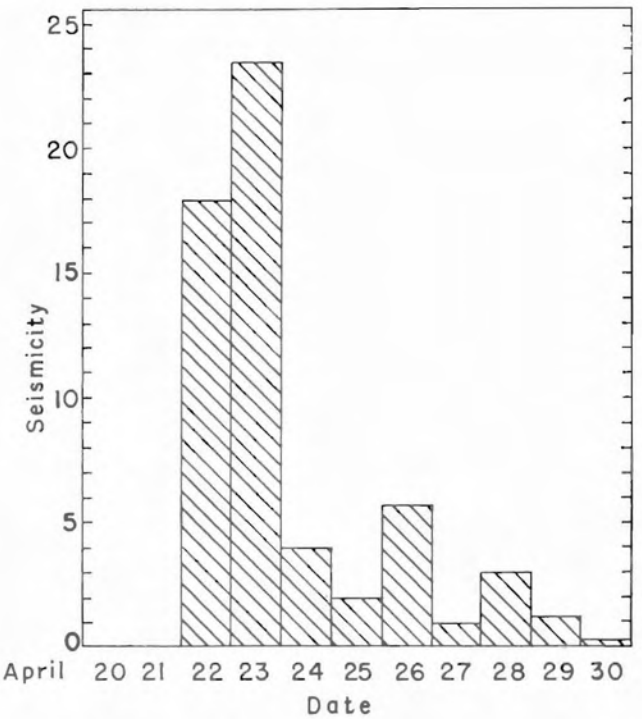

Figure 2. Graph showing seismicity at the Whitney Laboratory, at the northeast rim of Kilauea Caldera, during late April, 1951.

Many of the small aftershocks, which could not be definitely located, appear almost certainly to have originated beneath Kilauea Caldera or along one of the rift zones in the immediate vicinity of the caldera. Two of the quakes originated along the Hilina fault zone near the southern coast of Kilauea.

Comparison of earthquake intensity scales

Hawaiian Volcano Observatory scale			Description of non-instrumental effects	Approximate grade in Rossi-Forel and modified Mercalli scales
Designation	Double amplitude of motion on Bosch-Omori seismograph*	Seismicity value		
	mm.			
Tremor	< ½	¼	Not felt.	
Very feeble	½–4	½	Not felt or only very rarely felt by very few persons in especially favorable positions, usually lying down.	
Feeble	4–11	1	Not felt or felt only by a few persons in favorable positions.	I
Slight	11–25	2	Felt by many persons at rest. Hanging objects may swing.	II
Moderate	25–60	3	Felt generally, by persons in or out of doors. Hanging objects swing.	III
Strong	> 60	4	Felt by everyone or nearly everyone. Objects swing. Dishes, doors, and windows rattle. Minor damage may result.	IV–V

* Static magnification of Bosch-Omori seismograph is approximately 115.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR APRIL–JUNE, 1951

VOLCANOLOGY

April

The volcanic quiescence of the first quarter of the year continued into April. It was shattered on April 22 by the heavy earthquake and swarm of aftershocks described on previous pages. Seismographs of the Hawaiian Volcano Observatory recorded 132 earthquakes during the month of April. Of these, 108 were aftershocks of the big earthquake of April 22. The Kilauea origin of most of the shakes is shown by the fact that 125 of them were recorded on the instruments at the rim of Kilauea Caldera and only 89 of them at the Mauna Loa station.

The distinct uneasiness of Kilauea volcano was further shown by the commencement, on June 24, of fairly rapid tumescence of the volcano, expressed by northward tilting at the Whitney Laboratory at a rate considerably in excess of the normal rate for that time of year. It should be noted also that the reversal from southward to northward tilting came nearly a month earlier than usual.

May

The rapid northward tilting of the ground at the northern rim of Kilauea Caldera, which commenced in April, continued throughout May. By the end of the month a total of 6 seconds of arc of northerly tilting had accumulated. This rate is approximately twice as great as the normal rate of northward tilting at this season of the year, and indicates a continued increase of volcanic pressure beneath Kilauea. Some cracks on the floor of the caldera and along the Chain of Craters road opened slightly during the month, possibly in response to tumescence of the mountain.

Volcano Observatory seismographs recorded 41 earthquakes during May. Of these, 36 were recorded at the Whitney Laboratory and 20 at the Mauna Loa station. A feeble earthquake, felt by a few persons in the Volcano district just after noon on May 17, originated under Kilauea volcano, about 6 miles south of the crater.

June

The marked northward tilting of the ground at the northern edge of Kilauea Caldera continued into early June. After June 8, however, the rate of northward tilting decreased to about normal for this season of the year. During late May, the rate of eastward tilting was approximately normal for that season. However, on June 3, it became appreciably greater than normal and continued above normal for the remainder of the month, indicating an increase of volcanic pressure beneath the summit area of Mauna Loa.

During June, 42 earthquakes were recorded on the seismographs. Of these, 28 were recorded at the Whitney Laboratory and 29 at the Mauna Loa station. Slight earthquakes were felt by some persons from the Volcano district to Hilo at 10:49 P.M. on June 7 and 8:32 A.M. on June 11. Both originated on the east rift zone of Kilauea volcano, the first near Pauahi crater, and the second 6 miles southwest of Pahoa. A series of small earthquakes (mostly tremors) on June 18 and 19, recorded only on the Mauna Loa seismograph, indicate some movement on the northeast rift zone of Mauna Loa.

The northern end of the crack which crosses the observation area at the southeast rim of Halemaumau crater opened another 3 mm. during June. Other cracks in the vicinity also opened slightly.

The temperature of the steam at the Sulphur Bank well remained at 205° F. from March 31 to July 2.

TELESEISMS

Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey.

April 30, 05:35, slight. Celebes region.
May 19, 04:59, slight.
May 19, 06:45, slight.
June 16, 23:54, slight. Three hundred miles off the Oregon coast.

Table of Tilt at Seismograph Vaults on Rim of Kilauea Caldera

Week Beginning	Whitney Vault (Northeast rim) Amount	Whitney Vault (Northeast rim) Direction	Uwekahuna Vault* (West rim) Amount	Uwekahuna Vault* (West rim) Direction
April 1	0.5″	N 45° W	0.9″	S 74° W
8	0.8″	S 63° E	0.3″	N 45° W
15	1.3″	S 85° W	0.2″	S 72° W
22	1.4″	N 22° E	1.4″	S 62° W
29	0.4″	N 27° W	0.6″	N 74° W
May 6	1.0″	N 7° W	1.1″	N 81° W
13	1.2″	N 17° E	.....	.....
20	1.1″	N 18° E	2.8″	S 9° E
27	1.9″	N 15° E	0.4″	S 19° E
June 3	1.0″	N 60° E	1.4″	S 17° E
10	1.6″	S 86° E	2.1″	N 3° W
17	0.4″	N 56° E	1.4″	N 17° W
24	1.4″	N 52° E	0.6″	N 53° W

* Record previous to May 13 from a small, semiportable tiltmeter. During early May, a pair of heavy, horizontal pendulums was installed, and the record after May 20 is from this new instrument. The record for the week starting May 13 is considered unreliable because of improper operation of the east-west pendulum.

SEISMOLOGY

Earthquake Data, April–June, 1951

(Based on Bosch-Omori seismograph on northeast rim of Kilauea Caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms
April 1	3	1	0	0	0	0	1.25	0
8	7	1	1	0	0	0	3.25	0
15	3	1	0	0	0	0	1.25	0
22	67	26	3	4	1	3	55.75	0
29	11	1	0	0	0	0	3.25	1
May 6	0	2	2	0	0	0	3.0	0
13	8	4	1	0	0	0	5.0	1
20	5	3	0	0	0	0	2.75	0
27	1	2	0	0	0	0	1.25	0
June 3	3	0	0	1	0	0	2.75	0
10	4	2	0	1	0	0	4.0	1
17	9	2	1	0	0	0	4.25	0
24	4	1	0	0	0	0	1.5	0

* For definition of local seismicity, see Volcano Letter 371.

The data for the following local disturbances were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The arrival times are given to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory at the northeast rim of Kilauea Caldera. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

30. Apr. 4, 10:43, very feeble.
31. Apr. 13, 01:19, very feeble, felt at Waimea. About 8 miles southwest of Waimea, shallow.
32. Apr. 13, 14:53, feeble. East flank of Kilauea.
33. Apr. 15, 13:36, very feeble.
34. Apr. 22, 04:54, moderate, felt at Kapapala and from Volcano district to Hilo. East rift of Kilauea 7 miles S 15° E of Glenwood, 21 miles deep.
35. Apr. 22, 14:52, very strong, felt all over Hawaii Island and on Maui and Oahu. East rift of Kilauea near the caldera, 25 to 30 miles deep.
36. Apr. 22, 15:25, very feeble.
37. Apr. 22, 15:27, very feeble.
38. Apr. 22, 15:41, very feeble.
39. Apr. 22, 15:49, very feeble.

40. Apr. 22, 15 : 50, very feeble.
41. Apr. 22, 15 : 51, very feeble.
42. Apr. 22, 16 : 08, very feeble.
43. Apr. 22, 16 : 14, very feeble.
44. Apr. 22, 16 : 49, very feeble.
45. Apr. 22, 17 : 19, feeble. East rift of Kilauea 7 miles east of the caldera, about 8 miles deep.
46. Apr. 22, 17 : 30, very feeble.
47. Apr. 22, 18 : 46, very feeble. Southwest rift of Kilauea near Mauna Iki, about 5 miles deep.
48. Apr. 22, 20 : 30, tremor (very feeble, Mauna Loa).
49. Apr. 22, 21 : 11, tremor (very feeble, Mauna Loa).
50. Apr. 22, 23 : 30, very feeble.
51. Apr. 22, 23 : 40, very feeble. Kaoiki fault near Ainapo.
52. Apr. 23, 00 : 17, very feeble.
53. Apr. 23, 02 : 46, very feeble.
54. Apr. 23, 03 : 04, very feeble. Kaoiki fault near Kapapala.
55. Apr. 23, 03 : 27, very feeble.
56. Apr. 23, 04 : 37, very feeble.
57. Apr. 23, 04 : 40, slight. East rift of Kilauea 2 miles south of Makaopuhi, 4 miles deep.
58. Apr. 23, 04 : 41, slight. Three miles north of Kilauea Caldera, about 5 miles deep.
59. Apr. 23, 04 : 44, feeble. Near Kulani cone, about 7 miles deep.
60. Apr. 23, 05 : 24, very feeble.
61. Apr. 23, 05 : 48, slight. Five miles northwest of Kilauea Caldera, about 6 miles deep.
62. Apr. 23, 06 : 13, very feeble.
63. Apr. 23, 06 : 36, strong, felt in Volcano district. Southwest rift of Kilauea 2 miles southwest of Mauna Iki, 5 miles deep.
64. Apr. 23, 21 : 53, very feeble. Southwest rift of Kilauea near Puu Koae, about 5 miles deep.
65. Apr. 23, 22 : 16, very feeble. Two miles southwest of Kulani cone, about 5 miles deep.
66. Apr. 23, 22 : 18, very feeble.
67. Apr. 24, 01 : 14, very feeble.
68. Apr. 24, 01 : 29, very feeble.
69. Apr. 24, 11 : 30, very feeble. Near Bird Park, about 11 miles deep.
70. Apr. 25, 11 : 41, very feeble.
71. Apr. 25, 22 : 38, very feeble.
72. Apr. 26, 00 : 57, tremor (very feeble, Mauna Loa).
73. Apr. 26, 03 : 58, strong, felt in Volcano district. East rift of Kilauea near Makaopuhi, about 12 miles deep.
74. Apr. 26, 05 : 51, feeble. Waimea plain about 6 miles east of Waimea.
75. Apr. 28, 07 : 38, slight. Four miles east of Kulani cone, shallow.
76. Apr. 29, 16 : 19, very feeble. About 3 miles southeast of Kulani cone.
77. May 6, 08 : 53, very feeble, felt by one person in Volcano district, and some in Pahala and Naalehu. Kaoiki fault zone, 3 miles southwest of Pahala.
78. May 7, 12 : 36, very feeble.
79. May 8, 00 : 38, feeble.
80. May 10, 15 : 24, feeble. East rift of Kilauea near Puu Huluhulu, shallow.
81. May 13, 00 : 24, very feeble.
82. May 14, 18 : 41, very feeble. Southwest rift of Kilauea near Mauna Iki, shallow.
83. May 15, 22 : 10, very feeble.
84. May 17, 12 : 12, feeble.
85 May 18, 03 : 00, very feeble.
86. May 20, 13 : 34, very feeble.
87. May 20, 16 : 16, very feeble.
88. May 25, 03 : 10, very feeble.
89. May 30, 21 : 59, very feeble.
90. May 31, 09 : 13, very feeble.
91. June 3, 04 : 45, tremor (very feeble, Mauna Loa).
92. June 4, 14 : 36, no record at Whitney vault (very feeble, Kona).
93. June 7, 22 : 50, slight, felt in Volcano district and by a few in Hilo. East rift of Kilauea near Pauahi crater, shallow.
94. June 11, 08 : 33, slight, felt generally from Hilo to Volcano district. East rift of Kilauea 6 miles west of Pahoa, about 7 miles deep.
95. June 11, 19 : 23, tremor (very feeble, Mauna Loa).
96. June 12, 12 : 12, tremor (very feeble, Mauna Loa).
97. June 14, 11 : 12, very feeble.
98. June 15, 13 : 19, very feeble. Probably beneath Kilauea Caldera.
99. June 17, 12 : 01, very feeble (slight, Mauna Loa). Nine miles west of Mokuaweoweo, about 16 miles deep.
100. June 19, 05 : 15, feeble.
101. June 22, 08 : 11, tremor (very feeble, Mauna Loa).
102. June 23, 01 : 14, very feeble.
103. June 27, 07 : 27, very feeble.
104. June 27, 11 : 49, tremor (very feeble, Mauna Loa).

VOLCANO NOTES AND NEWS

This new feature of the VOLCANO LETTER is intended to furnish the reader with notices of recent volcanic activity all over the world, notices of recent publications of special importance to the field of volcanology, and brief statements of what other workers in volcanology are doing. No attempt will be made to be exhaustive in the treatment of any of these. Available space necessitates brevity. Accounts of volcanic activity will be credited to the person submitting them, or to the source from which they are drawn. Persons everywhere are urged to send in brief accounts of volcanic activity or statements of research programs in which they, or fellow workers, are involved. Communications should be addressed to the Director, Hawaiian Volcano Observatory, Hawaii National Park P. O., Hawaii.

ERUPTION OF OSHIMA VOLCANO

Prof. Hisashi Kuno of Tokyo University writes that the Oshima volcano became active on July 16, 1950. Oshima occupies an island of the Idzu group, about 60 miles south of Tokyo. The volcano had been dormant since 1940. The 1950 activity built a new cinder cone on the rim of the old crater of Miharayama, a large cone in the caldera of Oshima volcano. The new cinder cone reached a height of 100 meters above its base. Lava issued from the base of the new cone and filled the bottom of the old Mihara crater. On September 13, several tongues of lava overflowed the rim of Mihara crater and reached the floor of the caldera. The temperature of the lava was 1200°C. in a lava fountain, 1090° at the origin of one of the flows which spilled out of the crater, and about 900° at a point where the flow had nearly ceased moving. The viscosity of the lava was 3×10^5 c.g.s. at a point where the temperature was about 1000°. The eruption ended abruptly on September 23. The erupted lava is augite-hypersthene basalt, closely similar to that of the 1778 eruption.

The total amount of erupted material, including cinder, was estimated by S. Marauchi [*Natural Science and Museum* 17 (4) : 19. 1950] as 48,000,000 tons.

ERUPTION OF SANTIAGO VOLCANO

Santiago volcano, in southwest Nicaragua, resumed solfataric activity early in 1946, after 19 years of dormancy. The fumes, containing sulfur dioxide and sulfuric acid, have been causing great damage to near-by coffee plantations. An investigation of the activity and of the accompanying crop damage was made in April, 1951, by Ray E. Wilcox of the U. S. Geological Survey. Plans are going forward in cooperation with the U. S. Department of Agriculture for alleviation of injury to the coffee plantations by the volcanic fumes.

PERSONNEL CHANGES AT HAWAIIAN VOLCANO OBSERVATORY

Ruy H. Finch, Director of the Hawaiian Volcano Observatory since 1940, retired late in February and was succeeded by Gordon A. Macdonald. Mr. Finch first came to the Observatory in 1919, at a time when it was operated by the United States Weather Bureau. From 1919 to 1926, he served as assistant to Dr. T. A. Jaggar. When the Observatory was taken over by the Geological Survey in 1924, Finch transferred to the Survey. He was temporarily in charge of the Observatory, during the absence of Dr. Jaggar, throughout most of the great steam explosions of Kilauea volcano in 1924. We owe the excellent record of that eruption largely to his personal observations and to his organization of volunteer observers to keep a 24-hour watch on the volcano. In 1926, the Survey sent Finch to establish the volcano observatory at Mount Lassen, in northern California. From 1926 to 1935, he operated the Lassen Observatory and studied other volcanoes in the Cascade Range. In 1931 and 1932, he was the leader of expeditions to study Akutan and Shishaldin volcanoes in the Aleutian Islands. Finch left the Lassen Observatory in 1935, when it was taken over by the National Park Service, and became an apple grower near Watsonville, California. In 1940, Dr. Jaggar retired as Director of the Hawaiian Volcano Observatory, and Ruy Finch was recalled as his successor. Through the war years, the work of the Observatory was greatly curtailed by reductions in staff and other restrictions. In spite of these and other difficulties, Finch managed to keep the operations going on a basis sufficient to insure the all-important continuity of records. His prediction of the 1942 eruption of Mauna Loa was an outstanding success.

Ruy Finch's retirement culminates a lifetime of service and important contributions to the science of volcanology. Following his retirement, Finch returned with his family to Watsonville, where he is again an orchardist. His long experience and intimate knowledge of Hawaiian volcanoes, as well as his pleasant personality and keen wit, will be greatly missed by the Observatory staff. Even in retirement, Ruy's great interest in volcanoes is certain to continue, and we have every reason to expect further contributions by him to the science of volcanology.

Early in May the staff of the Hawaiian Volcano Observatory was augmented by the appointment of Dr. C. K. Wentworth as full-time geologist. From 1935 until his retirement in early May, 1951, Wentworth served as geologist for the Honolulu Board of Water Supply. Since 1949, he has held a part-time appointment at the Volcano Observatory. During the next few months his principal scientific activity is expected to lie in the Observatory's geomagnetic program, in field studies of volcanic features, and in instrumentation.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director

Chester K. Wentworth, Geologist

John C. Forbes, Laboratory Mechanic

LaVieve G. Forbes, Secretary, part-time

University of Hawaii:

T. A. Jaggar, Geophysicist

Seismograph Station Operators:
Hilo Station:

Brother B. T. Pleimann, St. Joseph's School

Kealakekua Station:

Howard M. Tatsuno, Konawaena School

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE KONA EARTHQUAKE OF AUGUST 21, 1951

By GORDON A. MACDONALD and CHESTER K. WENTWORTH

INTRODUCTION

The earthquake which shook the island of Hawaii early on August 21 probably was the strongest since 1868, when a series of violent earthquakes did great damage in Kau. A special study of the quake has been made by the staff of the Hawaiian Volcano Observatory, and a detailed report will be published elsewhere. Lack of space limits us to a summary here.

A great many persons have aided us in the investigation. It is impossible to mention individually all who have given us information. Special mention should be made of Howard M. Tatsuno and Sister Mary Thecla, seismograph operators at Kealakekua and Hilo, respectively; Miss Nancy R. Wallace, Mrs. Alfred E. Hansen, and Allan P. Johnston, who reported on many of the aftershocks; Homer A. Hayes, who furnished information on damage and on other subjects; Mark Sutherland, John Iwane, and Masuoka Nagai, who supplied information on damage, especially to tanks; Commander C. A. George and Roland White, of the U. S. Coast and Geodetic Survey, who supplied copies of the seismograms of the major quake at Barbers' Point, Oahu, and of the tide gauge records from Honolulu and Hilo harbors. Dr. T. A. Jaggar has read and approved the manuscript. To these and all other persons who aided the investigation, we extend our sincere thanks.

NARRATIVE

At 57 minutes past midnight on August 21, residents of the island of Hawaii were awakened by a violent earthquake. The violence was greatest in central Kona, from Kealakekua to Hookena (Fig. 1). In the vicinity of Napoopoo the initial movement appears to have been largely up and down, with some swaying in an east–west direction, changing as the quake continued to what appeared to observers to be a somewhat circular motion. Noise was intense as doors and windows rattled, dishes and furniture crashed to the floor, water tanks collapsed, and rocks rolled from banks and stone walls. Landslides rushed down the famous burial cliff, Pali

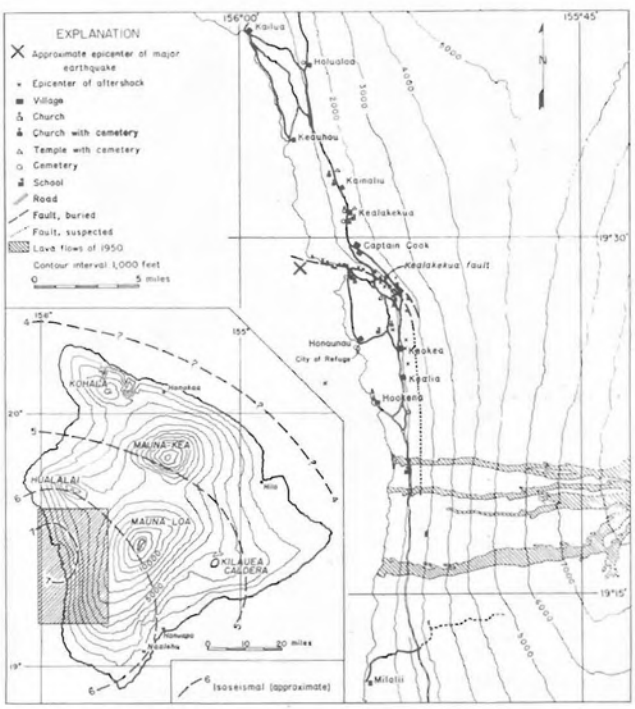

FIGURE 1. Map of the central Kona district showing the location of places mentioned in the text, the approximate locations of the epicenters of the major earthquake of August 21, 1951, and the aftershocks for which reasonably good locations were obtained. The inset map of the island of Hawaii shows the location of the area (shaded) covered by the other map and the approximate position of the isoseismal lines for the major earthquake.

Kapu o Keoua, at Kealakekua Bay. Within moments several houses, churches, and a school building were destroyed or badly damaged, many other houses slightly damaged, about 200 water tanks destroyed or damaged, many miles of stone wall thrown down, roads partly blocked by rock slides, road pavements and shoulders badly cracked, headstones in cemeteries shifted or over-

turned, and telephone and electric power lines broken. Fortunately, only two small fires broke out, and only two persons received minor injuries.

The ocean was observed withdrawing from shore at Napoopoo, and most of the inhabitants of the village were quickly evacuated to higher ground in fear of a large tsunami, or "tidal wave." A small tsunami actually did occur, but it was too small to do any damage. At Napoopoo the water surface fell about 4 feet, then rose again about 2 feet above its normal level. At Milolii the water level dropped about 3 feet, then rose 3 or 4 feet above its normal position, floating a canoe off the beach. The tide gauges at Honolulu and Hilo showed a distinct disturbance of the water in the harbors.

The earthquake was felt fairly strongly by persons on the most distant parts of the island of Hawaii and weakly by many persons on the island of Maui, and even in Honolulu, more than 180 miles from its origin. Damage extended for more than 50 miles along the highway, from Holualoa to Honuapo (Fig. 1). It was greatest in the 12-mile interval from Kealakekua to Hookena; but as far away as Naalehu, 37 miles from the epicenter of the earthquake, dishes, groceries, and bottles were thrown from shelves, stone walls collapsed, and some damage was done to structures. At Kilauea Caldera, 45 miles from the epicenter, a few objects were overturned, pavement was cracked, and numerous landslides were started on the walls of Halemaumau crater and the main caldera.

The intensity of the earthquake on the modified Mercalli scale of 1931, based on damage and other effects of the quake, was about 7 in the area near the epicenter, decreasing to 4 at the most distant parts of the island, and 2 at Honolulu. The approximate distribution of the intensity is shown by the isoseismal lines on the insert in Figure 1.

DAMAGE BY THE EARTHQUAKE

Many buildings in the Kona area were in some degree damaged by the earthquake. Most structural damage was minor, however. Some houses shifted as much as 3 or 4 inches on their foundations, and many were so twisted that it was difficult or impossible to open or close doors and windows. In nearly all houses dishes and other objects were thrown to the floor, and in stores from Holualoa to Pahala canned goods and bottles were thrown from shelves.

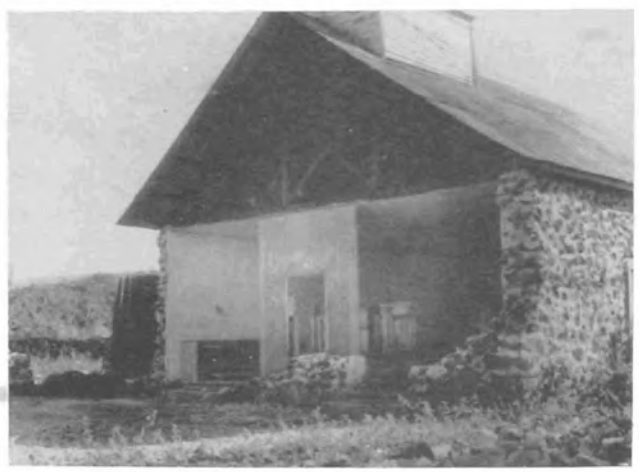

FIGURE 2. Church at Hookena Beach, the front (western) wall destroyed by the earthquake of August 21, 1951. The walls are of lava rock and coral-lime mortar. The debris of the fallen wall has been cleared away.

FIGURE 3. Honaunau School. Note the badly deformed window casings, resulting from the earthquake. In the foreground are the fragments of a large water tank.

As a class, masonry structures suffered the most damage. At Hookena the western wall of the Mission church, constructed of stone and coral-lime mortar, was thrown to the ground (Fig. 2). The upper parts of both the eastern and western walls of the Catholic church, half a mile north of Hookena, were thrown down. These walls, however, were very weakly constructed. The walls of St. Paul's Church, near Kainaliu, were badly cracked, and there was minor cracking of the lintels and interior plaster of Kahikolu Church at Napoopoo. The tower of Central Kona Church at Kealakekua separated slightly from the main building, and its plaster was cracked.

Only a few frame structures were badly damaged. At Hookena the underpinning of two old houses gave way and the houses dropped to the ground. Near Kealia two other houses were similarly damaged. At Kaimalino, 0.8 mile south of Kealia, a shop building slumped downslope when high posts supporting it at the back gave way. A service station at Keokea was damaged in the same manner. All these instances of damage to frame buildings can be traced to the failure of underpinning which was unsound because of age, poor material, or inadequate bracing. The most striking example of all was the Honaunau School, where failure of the underpinning allowed the building to collapse partly and slump to the ground, deforming it so badly that it is considered a total loss (Fig. 3). The failure there appears to have resulted from very inadequate bracing in an east–west direction, approximately parallel to the direction of sway during the earthquake.

As in big earthquakes elsewhere, a large proportion of the damage to buildings resulted from inferior or inappropriate materials, or poor construction. Unreinforced stone or brick masonry structures are especially subject to damage by strong earthquakes, though even in them the use of good mortar and adequate bracing of the structure greatly reduces the risk of damage. In frame structures footings should be firm, materials

FIGURE 4. Stone wall partly destroyed at the City of Refuge, Honaunau. The wall is approximately 10 feet high. The damaged portion is part of that rebuilt in recent years.

sound, and cross bracing, particularly of the underpinning, should be adequate in all directions. The best insurance against earthquake damage is good construction.

The most serious damage was that to water tanks. Kona's water supply comes from rain caught on roofs and stored in tub-type wooden tanks. Of a total of more than 1,000 such tanks in the heavily shaken area, about 200 were destroyed or badly damaged. The loss of water supply seriously endangered the health and comfort of the community. Tank damage extended from Keauhou to Milolii, but was most severe from Captain Cook to Hookena. Tanks showed all degrees of failure, from the development of slight leaks to complete collapse (Fig. 3).

A more detailed report on the damage to tanks will appear in the next Volcano Letter. In summary, it may be said here that the commonest features contributing to tank failure appear to have been poor footings and inadequate cross bracing of the underpinning.

Loose stone walls were greatly damaged by the earthquake. Although the principal damage occurred in the area from Keauhou to 3 miles south of Hookena, isolated instances of wall damage were observed all the way from Naalehu to Honokahau, 5 miles north of Holualoa. It is estimated that a total of many miles of wall will have to be rebuilt.

As with other types of structures, well-built walls proved surprisingly resistant to earthquake. In the construction of many of the older walls, occasional slabs of rock were laid largely or entirely through the wall, to help bind the wall together. These walls showed much less damage than those in which the loose rocks were stacked up with few or no binding slabs. It is interesting to note that the remaining portions of the well-built ancient walls of the City of Refuge, at Honaunau, were undamaged, whereas the recently reconstructed portions of the walls partly collapsed (Fig. 4).

Damage in cemeteries included the shifting, rotation, or overturning of headstones (Fig. 5) and the breaking of some grave caps. In cemeteries from Kealakekua to Honaunau most of the overturned headstones fell westward, though in a few cemeteries nearly as many fell eastward. This resulted partly from lesser stability of the stones in that direction because of the north–south orientation of the longer dimension of their bases and the general westward slope of the terrain, and partly from the east–west direction of shaking.

Damage to roads included cracking of pavement, cracking and slumping of shoulders, and caving of road banks, partly obstructing the roads. Cracking and slumping of the pavement and shoulders took place only on fills (Fig. 6). Some settling and cracking of the pavement appears to have been caused merely by compaction of the underlying fill during the jostling by the earthquake. At other places fills across small gullies were unstable because the batter (departure from vertical) of the edges of the fill were too steep, causing the downslope face of the fill to cave away. At many places the western shoulder moved slightly seaward, away from the pavement, producing cracks along the edge of the pavement or a few inches beyond the edge of the pavement and parallel to it.

A few bank cavings and pavement cracks were found as far away as Kilauea Caldera, 45 miles from the epicenter. However, most road damage is concentrated in the area near the epicenter. The distribution of damage caused by caving of banks, cracking of pavement, and collapse of stone walls along the main highway is shown graphically in Figure 7.

INSTRUMENTAL DATA

The time of occurrence of the earthquake is given by the U. S. Coast and Geodetic Survey's notice of Preliminary Determination of Epicenter at 00:56:57 H.S.T. The preliminary waves started recording on the Bosch-Omori seismograph in the Whitney Laboratory at the northeast rim of Kilauea Caldera at 00:57:09.5. The duration of the preliminary waves at the Whitney Laboratory was 9.5 seconds, corresponding with a distance of origin of approximately 47 miles. The Bosch-Omori seismograph was dismantled shortly after the arrival of the secondary waves. All other seismographs on the island of Hawaii were dismantled by the preliminary waves.

FIGURE 5. Overturned headstones in the cemetery of the Central Kona Church at Kealakekua were thrown westward from their foundations, but the base plate beneath the headstone in the foreground was shifted 2 inches eastward.

The direction of the first movement of the ground at Kilauea Caldera was east–southeast and up, that at the Mauna Loa and Kona stations was east–northeast. At the Kona station the suspensions of the east–west component of the seismograph were broken, and the weight dropped on the floor 2 feet west of the pier. Thus the only usable instrumental data we have on the location of the origin of the earthquake are a distance of approximately 47 miles from the Whitney Laboratory, and rough bearings of west–northwest from Kilauea Caldera and west–southwest from the Mauna Loa and Kona stations. These, together with the distribution of damage, are sufficient to demonstrate that the origin lay offshore west of the general Napoopoo–Honaunau area.

AFTERSHOCKS

The major earthquake was followed by a very large number of aftershocks, ranging in size from tiny tremors barely detectable by the seismographs to strong, generally felt earthquakes of an intensity as great as 4 near their epicenters. Mrs. H. Masuhara, at Keei, counted 109 felt earthquakes between 00:57 and 09:00 o'clock on August 21. The repair of damages to the Kona seismograph was not completed until 15:15 o'clock on August 23, so the total number of aftershocks during the first 2 days is not known. During the first 24 hours after it was restored to operation the Kona seismograph recorded 90 earthquakes. By midnight on August 31 it had recorded 494 quakes and by September 30 nearly a thousand. Most of the larger of these aftershocks produced good records at four or more of the five seismograph stations and could be located with fair certainty. Epicenters of 36 of these aftershocks are shown in Figure 1.

ORIGIN OF THE EARTHQUAKE

The northeastern edge of Kealakekua Bay is a scarp formed by a fault along which the lower slope of Mauna Loa has been moving downward in relation to the rest

FIGURE 6. Cracking of pavement and slumping of fill at the western edge of the highway near Hookena.

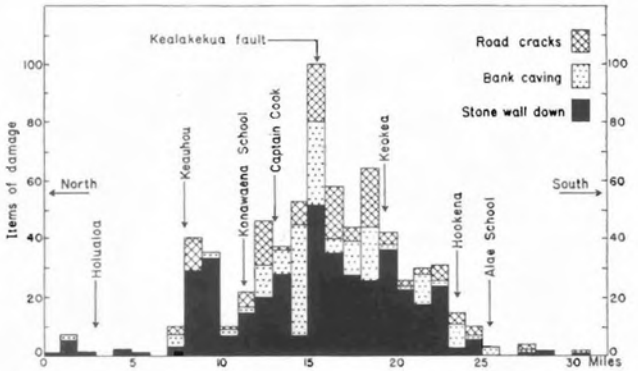

FIGURE 7. Diagram showing the frequency distribution of three of the principal types of earthquake damage along the main highway. The arrows indicate the position on the highway of villages and other features. Note the centering of damage close to Kealakekua Fault.

of the mountain. This fault has been named the Kealakekua Fault.* The total displacement on the Kealakekua Fault is not known, but it is at least 500 feet. Most of the fault scarp has been mantled with later lava flows from Mauna Loa. West–northwestward the fault disappears under the ocean (Fig. 1). Southeastward the scarp runs inland and bends southward. Beyond upper Keei the fault scarp loses its definite identity, but for several miles farther south the abnormally steep western slope of Mauna Loa is suspected, at least in part, to be a reflection of this fault scarp, deeply buried.

Most of the epicenters of the located aftershocks (Fig. 1) lie close to the known portion of the Kealakekua Fault. A few lie close to the suspected southward continuation of the fault. In view of the origin of the great majority of the aftershocks on the Kealakekua Fault, it is highly probable that the major earthquake also was caused by movement on this fault. This is confirmed by the distribution of damage caused by the earthquake. In Figure 6 the peak of the bell-shaped distribution curve corresponds closely with the location of the Kealakekua Fault. Taking into consideration the distance of origin of the earthquake from Kilauea Caldera, the probable epicenter has been placed approximately 3 miles west–northwest of Napoopoo, at north latitude 19° 29′, west longitude 155° 58′. This location is also consistent with the prevalent directions of overturning and rotation of headstones in cemeteries.

In a sense, of course, all earthquakes originating on the island of Hawaii are volcanic. The movements on the Kealakekua Fault which gave rise to the earthquakes of August and September may be related in some way to either an increase of pressure under Mauna Loa and resulting rise of the central part of the volcano, or a readjustment resulting from the great outpouring of lava in June, 1950. Any such relationship is, however, purely conjectural. There is as yet no direct evidence that the earthquakes were related to any specific eruptive episode, past or future.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY–SEPTEMBER, 1951

VOLCANOLOGY

July

Seismically, Hawaiian volcanoes were quiet during the month of July. Only 29 earthquakes were recorded on the Volcano Observatory's seismographs. One of these, a tremor recorded at 11:28 A.M. on July 28 on the seismograph operated by Howard Tatsuno at Konawaena School, was not recorded at any other station. Seventeen earthquakes were recorded at the Whitney Laboratory beneath the Volcano House, and 15 at the Mauna Loa station. A feeble earthquake at 4:07 A.M. on July 1 originated on the southwest rift of Mauna Loa beneath a point near Sulphur Cone. Another at 11:20 P.M. on July 5 originated beneath Kilauea Caldera probably within 3 miles of the surface.

Northward tilting of the ground surface at the northeastern edge of Kilauea Caldera continued throughout the month and amounted to nearly 4 seconds of arc. This rate of tilting is more than twice the average for this season of the year and indicates a continued distinct increase of volcanic pressure beneath Kilauea. Tilting in an east–west direction has shown minor oscillation during the month but no appreciable net change.

Most of the cracks on the floor of Kilauea Caldera opened or closed very little during July. However, the crack which crosses the observation area at the southeast rim of Halemaumau crater opened another 3 millimeters, making a total opening of 46.5 millimeters, or nearly 2 inches, during the past year.

On July 25 small amounts of sulphurous fume were issuing at the 1940 cinder cone in Mokuaweoweo, and a little steam was issuing near the north edge of the 1940 cone and at places on and near the 1949 cone.

August

The outstanding event of the month was the big earthquake of August 21 in Kona. This earthquake and its aftershocks have been discussed on preceding pages. During the remainder of August 21, following the major earthquake at 00:57 A.M., the seismographs at the Volcano Observatory recorded 135 earthquakes. During the month a total of 264 earthquakes was recorded at Kilauea, and 268 at the Mauna Loa station. Of these, 235 occurred after the major earthquake of August 21. The Kona seismograph recorded 494 earthquakes between the time it was repaired and restored to service at 3:15 P.M. on August 23, and midnight on August 31.

The strongest of the earlier aftershocks took place at 1:29, 4:00, 8:03, 9:57, 10:12, 18:32, and 22:48 on August 21; at 6:38 and 17:15 on August 22; and at 16:08 on August 31. Many others were felt in central Kona.

At 17:48 on August 28 a small earthquake originated beneath the east slope of Mauna Loa near Mountain View, and at 18:04 on the same day a smaller one originated just east of Kilauea Caldera. Beginning at 6:02 on the morning of August 23 the seismograph at the Whitney Laboratory of Seismology recorded 21 minutes of continuous tremor, indicating subterranean movement of magma. However, there were no other indications of volcanic unrest during the month.

Northward and eastward tilting of the ground at the Whitney Laboratory were at a rate approximately normal for that season of the year.

On August 14, Chief Ranger E. K. Field and Ranger Elroy Bohlin, of Hawaii National Park, flew over Mokuaweoweo and reported the 1940 cinder cone to be fuming mildly.

September

Earthquake activity continued abundant during September. Most of the activity centered in the Kona area. The Kona seismograph recorded 471 earthquakes during the month, bringing the total number of earthquakes since the big quake early on August 21 to 965. Most of the Kona earthquakes were too small and shallow-seated to be recorded on the seismographs at Kilauea Caldera, 42 miles away. During September the seismograph at the Whitney Laboratory recorded 110 earthquakes, and the Mauna Loa seismograph recorded 106.

Most of the Kona earthquakes originated along the fault which runs out to sea at Napoopoo, forming the great cliff at the north side of Kealakekua Bay. Several earthquakes originated beneath points along the southwest rift zone of Mauna Loa, between 9,000 feet altitude and the summit. A few had their origins beneath the crater and rift zones of Kilauea, and a small shake felt in Hilo at 11:48 P.M. on September 24 had its focus on the northeast rift of Mauna Loa. From September 23 to 26 several earthquakes originated beneath Hualalai volcano. One of these, at 7:01 P.M. September 23, was strong enough to dismantle the Kona seismograph. On September 16, about 20 earthquakes originated along the Kaoiki fault, which forms the line of cliffs northwest of the highway between Bird Park and Pahala. The one at 1:43 A.M. was felt strongly at Kapapala and less strongly at Naalehu and Pahala. Rocks were shaken down from road cuts on the Mauna Loa truck trail. Rock slides were started in Halemaumau and continued at intervals for several days.

The north end of the crack across the observation platform at the southeast rim of Halemaumau opened a quarter inch during the month. Other cracks on the floor of Kilauea Caldera showed little change in width.

Northeastward tilting continued throughout the month at the Whitney Laboratory. The direction and rate of tilting were normal for that season of the year.

The temperature of the steam at the well at Sulphur Bank, near the Volcano House, remained at 205° F. from July 2 until September 30. On September 9, temperature measurements were made on the Ohia Lodge (1950) lava flow in south Kona, near the highway. Temperatures of hot cracks, from 12 to 18 inches below the surface, ranged from 120° C. to about 400° C.

SEISMOLOGY

Earthquake Data, July–September, 1951

The data for the following local disturbances were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The arrival times are given to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory at the northeast rim of Kilauea Caldera. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

105. July 1, 04:07, very feeble. Southwest rift of Mauna Loa near Sulphur Cone.
106. July 5, 23:20, feeble. Beneath Kilauea Caldera, shallow.
107. July 17, 09:52, very feeble.
108. July 19, 19:12, very feeble.
109. Aug. 2, 19:24, very feeble.
110. Aug. 3, 01:40, very feeble.
111. Aug. 6, 23:07, very feeble.
112. Aug. 10, 04:31, feeble. East rift of Kilauea near Napau Crater.
113. Aug. 21, 00:57, strong, intensity 7, much damage in Kona. About 3 miles west-northwest of Napoopoo, probably on Kealakekua Fault.
114. Aug. 21, 01:29, strong. Felt strongly in Kona. Origin near No. 113.
115-135. Aug. 21, very feeble and feeble earthquakes, with origin in Kona.
136. Aug. 21, 03:50, slight. Kona. Felt from Kona to Volcano district.
137. Aug. 21, 04:00, moderate. Kona. Felt from Kona to Volcano district.
138-148. Aug. 21, feeble and very feeble earthquakes, with origin in Kona.
149. Aug. 21, 06:03, slight. Kona.
150-154. Aug. 21, very feeble. Kona.
155. Aug. 21, 08:03, moderate. Kona.
156-161. Aug. 21, feeble and very feeble. Kona.
162. Aug. 21, 09:38, slight. Kona.
163. Aug. 21, 09:57, strong. Felt from Kona to Volcano district. Kona.
164. Aug. 21, 10:12, strong. Kona.
165-167. Aug. 21, very feeble.
168. Aug. 21, 18:32, strong. Kona.
169. Aug. 21, 21:07, very feeble. Kona.
170. Aug. 21, 22:48, strong. Kona. Felt from Kona to the Volcano district.
171. Aug. 22, 02:14, slight. Kona.
172-174. Aug. 22, feeble and very feeble. Kona.
175. Aug. 22, 06:38, moderate. Kona. Felt from Kona to Kapapala.
176-180. Aug. 22, feeble and very feeble. Kona.
181. Aug. 22, 16:04, slight. Kona.
182. Aug. 22, 16:38, very feeble. Kona.
183. Aug. 22, 17:15, strong. Kona. Felt from Kona to Volcano district.
184. Aug. 22, 17:28, slight. Kona. Felt as far as Naalehu.
185-187. Aug. 22, feeble and very feeble. Kona.
188-190. Aug. 23, feeble and very feeble. Kona.
191. Aug. 24, 00:25, very feeble. Kona, Kealakekua Fault.
192. Aug. 24, 23:59, very feeble. Kona.
193. Aug. 25, 10:22, feeble. Kilauea.
194. Aug. 25, 11:14, very feeble (Kona feeble). Kealakekua Fault.
195. Aug. 26, 03:29, very feeble. Kealakekua Fault.
196. Aug. 26, 08:04, very feeble. Kona, Kaholo Pali.
197. Aug. 26, 08:11, very feeble (Kona slight). Kealakekua Fault.
198. Aug. 26, 19:40, very feeble. Kona, 2.3 miles S 75° E of Napoopoo.
199. Aug. 27, 04:31, very feeble (Kona feeble). Kealakekua Fault.
200. Aug. 27, 16:01, very feeble. Kealakekua Fault.
201. Aug. 27, 21:58, very feeble (Kona slight). Near Keokea.
202. Aug. 28, 11:44, very feeble. Kealakekua Fault.
203. Aug. 28, 14:24, very feeble. Kealakekua Fault.
204. Aug. 28, 17:48, feeble. About 3 miles east-southeast of Mountain View. Felt in Mountain View and Volcano district.
205. Aug. 28, 18:04, very feeble. Southwest rift of Kilauea near Kilauea Iki.
206. Aug. 28, 20:28, very feeble (Kona feeble). Kealakekua Fault.
207. Aug. 29, 06:02, very feeble (Kona feeble). Kealakekua Fault.
208. Aug. 29, 19:43, very feeble (Kona slight). Kona.
209. Aug. 29, 21:25, very feeble (Kona feeble). Kealakekua Fault. Felt in Kona.
210. Aug. 30, 07:23, very feeble (Kona moderate). Kealakekua Fault. Felt strongly in Kona.
211. Aug. 30, 14:23, very feeble. Kona.
212. Aug. 31, 16:08, very feeble (Kona strong, intensity 5). Kealakekua Fault. Felt strongly in Kona.
213. Aug. 31, 18:51, very feeble (Kona feeble). Kona, about 3.5 miles west of Hookena.
214. Sept. 1, 12:29, feeble (Kona slight). Kealakekua Fault.
215. Sept. 1, 23:21, very feeble (Kona feeble). About 0.8 mile north of Kealia.
216. Sept. 2, 18:35, very feeble (Kona feeble).
217. Sept. 3, 00:37, very feeble. Kona.
218. Sept. 4, 00:48, very feeble. Kona.
219. Sept. 4, 05:10, very feeble (Kona moderate).
220. Sept. 4, 14:13, very feeble (Kona strong, intensity 4). Felt strongly in Kona.
221. Sept. 4, 16:16, very feeble. Kilauea Caldera.
222. Sept. 4, 22:28, very feeble (Kona strong, intensity 3). Felt as far as Naalehu.
223. Sept. 6, 01:29, very feeble (Kona slight).
224. Sept. 8, 14:50, very feeble. Kilauea Caldera.
225. Sept. 8, 23:27, tremor (Kona feeble).
226. Sept. 9, 13:58, tremor (Kona moderate).
227. Sept. 10, 01:50, very feeble. Kilauea.
228. Sept. 10, 12:55, very feeble. Kona.
229. Sept. 11, 00:26, feeble. East rift of Kilauea near Puu Huluhulu.
230. Sept. 11, 12:44, very feeble. Kona.

September 27, 09:40, moderate. Vancouver Island.

VOLCANO NOTES AND NEWS

Eruption of Oshima Volcano

The last issue of the Volcano Letter carried a brief account of the 1950 eruption of Oshima volcano, Japan. That eruption ended on September 23, 1950. A new eruption commenced early in 1951. The following notes on the new eruption were furnished by Dr. Hisashi Kuno, of Tokyo University, during a brief visit at the Hawaiian Volcano Observatory during his journey to Princeton University, where he will spend the next year in research on the pyroxene group of minerals.

The eruption started on February 4, 1951. Pyroclastic activity built a new cinder cone overlapping the northwest side of the 1950 cinder cone, on the rim of Mihara crater. On February 27 lava issued at the foot of the cone, filled the crater of Mihara-yama, and overflowed the rim. A fluid pahoehoe flow spread over the floor of the Oshima caldera. This flow continued for 2 or 3 days, then the outpouring of lava ceased, although weak Strombolian pyroclastic activity continued at the cone.

On March 10 another flow spread over the caldera floor, and barely passed the western margin of the caldera. At about this time the inhabitants of the village of Nomashi erected a wall 10 feet high across a low gap in the caldera wall in an attempt to prevent the lava from spilling out through this gap and pouring down onto the village. The lava level did not rise quite to the wall, so that the effectiveness of the wall was not tested.

On March 25 another small flow issued, pyroclastic activity continued at the cone until about June 30, but there were no more lava flows.

The old inner pit of the Mihara crater had been completely filled. Just before the end of the eruption, in June, collapse occurred at the site of the former inner pit, forming a new pit. On July 22 the volcano was quiet. The new inner pit was approximately 150 meters deep. The new cinder cone had been broken into two parts by subsidence, and the southern part had collapsed to form a small collapse crater.

Eruption in Tonga Islands

Captain R. J. Jensen, Pan American World Airways, reports observing volcanic activity on the island of Fonualei, in the Tonga group, on August 21. He writes, "The volcanic activity seemed to be located in the north-central portion of the island, with considerable smoke and a little flame. Large lava flows were evident, some of which were entering the sea. The smoke column rose to about 5,000 feet and was carried to the northwest by a southeasterly wind."

Eruption of Mt. Etna

A brief dispatch by Associated Press states that an eruption of Mt. Etna commenced on the night of September 28, 1951, at a vent about 9,300 feet above sea level. However, on September 29 the lava flow appeared to have halted. The last previous eruption of Etna was in November, 1950.

Eruption of Mt. Lamington

Reports on the catastrophic eruption of Mt. Lamington, in New Guinea, have thus far been vague and incomplete. The greatest amount of information on it yet seen by the writer is contained in an article in the June, 1951, number of *Walkabout* magazine by Dr. N. H. Fisher, chief geologist of the Australian Dominion Geological Survey and formerly in charge of the volcanological observatory at Rabaul. Accompanying the article is a series of photographs of Mt. Lamington and its vicinity, taken by the Royal Australian Air Force.

Mt. Lamington is situated near the northeast coast of Papua about N 75° E of Port Moresby. It is about 7 miles west of the west end of the Hydrographer's Range, which also is of volcanic origin. The volcanic chain extends on southeastward to Normanby and Ferguson islands. In 1943 and 1944 explosive eruptions occurred in the Goropu Mountains, 80 miles southeast of Mt. Lamington, but Lamington itself had not previously been active in historic time.

On January 21, 1951, the volcano burst into violent explosive activity. The writer has been informed that some earthquake activity preceded the outburst. Editorial comment accompanying the aerial photographs in *Walkabout* magazine states that 2,000 feet of the mountain disappeared during the eruption. It is estimated that about 4,000 persons lost their lives. Dr. Fisher briefly characterizes the eruption as a classic example of the pelean type of eruption, accompanied by glowing clouds, and he remarks on the similarity of events to those at Mount Pelée in 1902. Photographs show devastation of the type typical of glowing clouds, with trees laid over in subparallel alignment by the blasts and large areas covered with ash. An excellent photograph by G. A. Taylor on the cover of the magazine shows the fuming crater of Mt. Lamington and the dome which apparently rose in it during the eruption. Mr. Taylor, the resident volcanologist, is keeping a continuous photographic and seismic record of the eruption.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

PUBLISHED BY THE UNIVERSITY OF HAWAII

DESTRUCTION OF WATER TANKS DURING THE KONA EARTHQUAKE OF AUGUST 21, 1951

By CHESTER K. WENTWORTH

INTRODUCTION

The following report on damage to water tanks in Kona during the earthquake of August 21, 1951, is based partly on field examination of the results of the earthquake and partly on an analysis, submitted to the Hawaiian Volcano Observatory by tank owners and builders, of 90 completed questionnaires giving data on individual damaged tanks. It is expected that much additional data will be transmitted as repairs proceed. The writer wishes to thank all those who have aided the study by submitting their reports or contributing information on tank damage. Special mention should be made of John Iwane, Extension Service, University of Hawaii; Mark Sutherland, Principal of Konawaena School; George T. Imai, Hawaii Road Department; and M. Nagai, Captain Cook Coffee Company, each of whom furnished information on a large group of tanks. The present report is only a summary statement of the results of the study. A more detailed report is planned for presentation elsewhere. For an account of other damage during the earthquake, see Volcano Letter No. 513.

WATER TANKS IN KONA

No accurate count of water tanks in Kona is known. From the recorded population of North and South Kona, which approaches 10,000, and from the total dependence on tank storage, it is a fair assumption that the number of tanks may be nearly 2,000. Many dwellings have two or more tanks. In addition to these, tanks at schools and other such buildings and tanks supplying range cattle must total several hundred.

Reliance on roof catchment and water tanks for water supply in the Kona district has been general since the building of frame structures and the replacement of native Polynesian living patterns. The native economy was supplied by a few sources of brackish water along the coast at a very small per capita daily consumption, with general use of coconut juice for drinking and of rainfall when it came. The annual rainfall along the coast is about 25 to 30 inches, but, owing to the great height and mass of Mauna Loa, the dryness of the leeward (kona) slope is ameliorated by rains due to the daytime sea-to-land breeze, which produce an annual amount of around 100 inches in a narrow belt at the 3,000 foot contour. However, the porosity of the surface rocks and the seasonality of rains are such that there are no perennial streams which reach to low altitudes, and geologic studies have indicated that adequate ground-water bodies do not exist within depths accessible under present economic conditions.

Small tanks might suffice for the few dwellings in the high-rainfall belt, but in the chief populated areas family storage of 8,000 or 10,000 gallons is usual, and many dwellings have more. Use of various urban facilities plus requirements of home gardens and attendant processing, without reference to general agriculture or stock-raising, raises the per capita consumption to 50 or more gallons per day, or perhaps 8,000 gallons per month, for a family of five. Large tanks are required to support such usage over periods when rainfall can supply only part of the required amount. Occasional water shortage, starting with larger and less foresighted families, is an almost chronic state of affairs.

DAMAGE TO TANKS

From data not yet completely gathered, it appears that about 200 tanks were seriously damaged by the earthquake. Many of these were either demolished or so displaced and distorted that they cannot be restored to use. In many cases, failure of the bottom or development of large side leaks resulted in total loss of water. Unless prompt action has been taken to repair and refill these tanks, a large proportion of them will be lost through drying and further deterioration.

The principal direct cause of damage was failure of footings. It is quite evident that the footings, while adequate to support the direct static load, were in most cases not sufficiently fixed in position, nor were the columns of the understructure adequately tied to the footings. The usual footing block is likely to move during the rocking to which the whole frame is sub-

jected during an earthquake, with progressive yielding and increase of movement to a point where the frame itself fails.

Next in importance as a cause of failure was yielding of the frame to diagonal deformation and shifting of the tank on its joists. The cylindrical, barrel-type tank depends on the tangential tension in the hoop rods both to hold the staves in watertight contact and to hold the periphery of the bottom planks tightly in the groove of the lower end of the staves. This mode of construction provides at best a very effective watertight container in continuous tension, supported directly on the joists under its floor planking. It does not provide, and would be seriously impaired by, bracing or local tying to the supports. Such a tank is best for static load; it would not be suitable for installation on a vehicle or on a ship.

MODE OF CONSTRUCTION AND PLACEMENT

The common household tank is erected with its upper edge just under the level of the eaves of the building whose roof provides the catchment. In a one-story house, the sink and wash-basin taps are often no more than 5 feet below this level, and the water of a tank more than 5 feet deep is only partly available for gravity flow to such fixtures and is not able to supply a shower bath on the same floor. Not uncommonly, small houses are built with an upper, main dwelling floor and a paved, open basement, in which laundry fixtures and a toilet or bathroom can receive water from the whole tank, even when, at some seasons, the water may be too low to supply the upstairs kitchen sink. Such hydraulic requirements necessitate placing the tank where its bottom is 6 or 8 feet and its top as much as 15 feet or more above ground.

This placement means that tanks carrying from 8 tons (2,000 gallons) to 20 tons (5,000 gallons), or even 50 tons (10,000 gallons), of water are often supported with their center of gravity 10 or 12 feet above the ground and on a base which may be little more than that dimension from side to side. A 2,000-gallon tank on six footings results in a load of about 2,700 pounds per footing; a 5,000-gallon tank on 12 footings imposes a load of about 3,300 pounds per footing. From data reported, it appears that many of the tanks of 10,000- to 25,000-gallon capacity have loads on individual footings of 4, 5, or even 6 tons! Such loads are several times that commonly carried by the columns under a small frame house, and the height of the tank is much greater in comparison to the breadth of the whole base. Tanks that are close enough to the ground to require no legs or columns may have no systematic arrangement of footings under the sills, and, in some instances, the bottom planks of the tank rest on joists (or beams) that in turn lie directly on the ground or on concrete or rock footings with no cross members parallel to the bottom planks. In such an arrangement, the bottom of the tank is in a precarious position if there is any differential movement of the footings and is ill-protected against even ordinary settling, much less a severe earthquake.

Most of the larger tanks, because of need to support the ends of the joists within the circle of the tank chimes, are supported on a sill or beam pattern that is six- or eight-sided, and the outer columns are six, eight, or more in number. These columns are usually braced from near the bottoms to the tops of adjacent columns and may or may not have bracing toward the center of the tank. Most commonly the bracing is spiked or bolted to either the outside or inside of the columns, resulting in an off-center effect which tends to develop a torque in the columns.

CAUSES OF DAMAGE

Of 90 tanks for which complete data have been received, 43 are reported demolished or totally destroyed. Of the others, a number of bottoms collapsed, other tanks developed general leakage which caused total loss of water, and many were sufficiently dislodged and deformed to necessitate complete and expensive rebuilding. In some instances, breaking of pipe fittings released all the water but could be repaired without great expense.

There is very little eye-witness account of the progressive destruction of individual tanks, but it is clear that the interrelated failure of bracing and footings was the chief cause of destruction. A few persons heard slopping of water in and from the tanks for an appreciable interval before final collapse. No marked correlation could be shown between age of the tank and damage, and only in a few instances was it clear that pre-existing impairment was responsible. So many nearly new tanks (all in good condition) were destroyed that it appears that the stresses developed by general shaking, with lateral components up to 0.2 or 0.3 of the value of gravity, could not be met by the existing bracing, and that, likewise, the footings became progressively displaced and hastened the destruction. Such stresses are comparable to tilting the tank and understructure to an angle of about 16 degrees and submitting them to repeated vertical loading and unloading. Under such conditions, it is not surprising that many of the structures failed.

The possibility of failure was further indicated by the general loads carried by the footings. In some small tanks the load per footing was as little as 1 ton, but the usual load, as in a 5,000-gallon tank on 9 footings, was 2 tons or more. In some of the larger tanks, as, for example, one at Honaunau School (Fig. 1), the load per footing was more than 12,000 pounds, or 6 tons. Lateral shaking of a mass imposing such heavy unit loads was too much for the bracing, and, after initial displacement of critical bracing or footings, the whole structure was quickly thrown down, and the tank was demolished.

RECOMMENDED CONSTRUCTION

As it is planned to present elsewhere a more detailed statement on damage to tanks and possible improvement in the design of tanks and foundation, only a few comments are included here. It is not likely that any feasible modes of construction will entirely eliminate damage from earthquakes which may occur in the Kona district. It is believed, however, that marked improvement is possible without an expenditure disproportionate to the value of the tank, if earthquake risk is kept in mind.

(1) Whenever possible, water-storage tanks should be based on the ground on a leveled, preferably concreted, surface. Founding wholly or partly on fill should

FIGURE 1. Wreckage of 23,500-gallon water tank at Honaunau School. The tank, approximately 20 years old, stood at the southwest corner of the main school building. The concrete footings seen in the background each bore a load of more than 6 tons. The tank appears to have collapsed because of failure of the supporting structure, probably due to inadequate bracing. Photo by G. A. Macdonald.

be avoided unless the entire filled area is enclosed in carefully designed, solid retaining walls and is prepared for unit loads of two or three times those from the tank. Lacking such preparation, the tank should be carried on an over-all timber crib or mat of adequate size and spacing. Increased availability of electricity and domestic-service pressure installations makes possible the basing of more large tanks on the ground.

(2) If the understructure consists of sills on columns, the lower ends of the columns should be completely tied together for compression and tension up to at least half the unit load. In the case of a simple square deck on four columns, the columns should be tied at their feet and each of the four sides braced diagonally from column bottoms to tops and through the center between opposite columns. As far as possible, bracing and cross tying should be kept in the two planes parallel to the sills and joists, respectively, with secondary truncating sills to approximate the form of a circle under large tanks. Without adequate internal bracing in the two rectangular directions, the bracing of a six- or eight-sided array of columns around the periphery results in off-center reactions and is likely to cause structural failure and destruction of the tank.

(3) Footings of concrete or large flat stones should be anchored in the ground or to the rock by imbedding them to a depth equal to their area or by rods and grouting which develop bearing resistance against lateral stresses of half the unit vertical load. Concrete piers should be tied pier to pier unless they are deeply imbedded.

(4) Wherever possible, the footing surface should be level. If this is not possible, the long columns should be tied at the level of the footings of the short columns, and the bracing should be completed at this level.

(5) Sills should be fixed at the top by drift pins, and bolts and timber fasteners should be used in the framing of supports for all but the smallest tanks. Whenever possible, braces should be paired or framed into the plane of the columns to avoid introducing torque into the stresses.

(6) Frequent inspection, painting or creosoting, and repair of defective parts will provide longer assurance of reasonable safety, as with any other structures.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR OCTOBER–DECEMBER, 1951

VOLCANOLOGY

October

Uneasiness, which was manifest at Mauna Loa during September, continued throughout October. Earthquakes originated beneath the summit area of the mountain and along both the northeast and southwest rift zones, as well as on the Kealakekua fault near Napoopoo and the Kaoiki fault from Honuapo to Ohaikea. Starting at 22:03 on October 8, Volcano Observatory seismographs recorded 16 minutes of continuous volcanic tremor probably caused by movement of molten lava underground. This was followed at 4:45 on October 9 by a moderate earthquake which appears to have originated at a depth of 25 to 30 miles beneath the summit area of Mauna Loa. This earthquake was felt by some persons in all parts of the southern portion of the island of Hawaii, from Kealakekua to Hilo. A smaller earthquake at 5:23 on the same morning originated deep beneath the upper end of the southwest rift of Mauna Loa.

During most of the month, eastward tilting at the Whitney Laboratory of Seismology at the Volcano House was at a rate about normal for that season of the year. However, from October 28 to 30 it was much more rapid than usual. The rapid tilt may have been caused by a heavy rainfall just preceding it, or it may have resulted from an increase of volcanic pressure beneath Mauna Loa. Abnormally rapid northward tilting during the same period may have been caused by an increase of pressure beneath Kilauea.

On October 24, I. C. Manus, Superintendent of Construction and Maintenance for the Kulani project, reported a long period of continuous trembling of the ground at the summit of Mauna Loa. This appeared on the seismographs as a series of closely spaced, but separate, small earthquakes. Mr. Manus also reported an apparent increase in the amount of steam being liberated at vents within Mokuaweoweo Caldera. On October 31, aircraft reported a large cloud of steam rising from the southwest rift of Mauna Loa between 8,000 and 12,000 feet altitude. This is the area in which the vents of the 1950 eruption are situated. Fume liberation at the vents has been continuous since the end of the eruption. On October 20, Acting Superintendent I. J. Castro and Ranger Elroy Bohlin, of Hawaii National Park, observed from the air steam and fume rising at eight localities along the rift between 9,000 and 12,000 feet altitude. The reported increase of the steam cloud on October 31 probably resulted from the heavy rains of October 26 to 28 coming in contact with still-hot lava near the vents, coupled with better than usual visibility of the steam because of the unusually high humidity.

During October, the seismographs at Kilauea Caldera recorded a total of 73 earthquakes. That at Konawaena School recorded 139 earthquakes, most of them aftershocks of the big earthquake of August 21.

November

Hawaiian volcanoes continued uneasy through the month of November. During the month, 73 earthquakes were recorded at the stations on the rim of Kilauea Caldera, which is more than twice the average number recorded during times of quiet. The seismograph at the Mauna Loa station recorded 53 earthquakes. Ground tilting during the month was, at an average rate, approximately normal for that season of the year. However, moderately strong oscillations of tilt in the east-west direction suggest fluctuations in pressure beneath Mauna Loa.

An earthquake of about intensity 6 in the modified Mercalli scale occurred on the morning of November 8. The time of arrival of the first waves at the Whitney Laboratory was

09 : 34 : 24, and the time of origin of the quake was approximately 09 : 34 : 12. All of the seismographs operating on the island of Hawaii were dismantled by the quake, the Mauna Loa instrument being dismantled by the preliminary waves. The earthquake was felt over all of the island, strongly over the southwest part. At Kahuku Ranch headquarters, 9.5 miles north of South Point, dishes were thrown from shelves and stone walls were extensively damaged. The intensity decreased very rapidly away from the epicenter. At South Point and at Kaalualu, 10 miles southeast of Kahuku Ranch headquarters, there was no damage to stone walls, and, even in the homestead area 4 miles southeast of ranch headquarters, the damage was very small. The decrease was even more rapid westward. Two and a half miles west of the ranch headquarters, stone walls along the highway were undamaged. Instrumental data and field investigations place the epicenter of the earthquake on the southwest rift zone of Mauna Loa at about 4,500 feet altitude, approximately 5 miles north of Kahuku Ranch headquarters. The Kahuku fault, one of the major fractures in the southwest rift zone, trends nearly north and south just west of the ranch headquarters. The area of damage to stone walls was distinctly elongated parallel to the Kahuku fault, suggesting that the earthquake was caused by movement on that fault. The rapid decrease of damage at increasing distance from the epicenter suggests a very shallow origin of the quake, but no surface fault displacement has been found.

During November, the seismograph at Konawaena School in Kealakekua recorded a total of 110 earthquakes. Most of them originated within 10 miles of the seismograph station, and the majority probably resulted from movement along the Kealakekua fault. On November 7, at 20:11, a small quake originated beneath the summit region of Hualalai volcano. On November 21, at 9:59, a small earthquake occurred beneath the Waimea Plain a few miles west of Kamuela. Nearly all the other local earthquakes recorded during the month had their origins in Kilauea and Mauna Loa volcanoes.

On November 23, two observers in the Kona area reported what appeared to them to be smoke near the summit of Mauna Loa. E. K. Field, Chief Ranger, and R. L. Jeffery, Superintendent of Construction and Maintenance, of Hawaii National Park, were at the summit of Mauna Loa at the time and reported conditions at and near the summit to be normal. The "smoke" observed from Kona appears to have been steam rising in the vicinity of the vents of the 1950 lava flows, probably caused by heavy rain on November 20 to 22.

December

The uneasiness of Mauna Loa and Kilauea during October and November persisted into early December. During the latter part of the month, the volcanoes were relatively quiet although oscillations in east-west tilting at the Whitney Laboratory still suggested some fluctuation in pressure beneath Mauna Loa.

Between December 3 and 7, the ground surface at the Whitney Laboratory tilted rapidly southward by an amount of 4.4 seconds of arc, and by December 16 an additional tilting of 0.6 seconds had taken place. This was followed, however, by a rapid partial recovery of 2.6 seconds by December 25. The net southward tilt during the month was 2.2 seconds of arc. This suggests a decrease of pressure beneath Kilauea.

During December, most of the earthquake activity originated at Kilauea volcano. The seismograph at the Whitney Laboratory, on the northeast rim of Kilauea Caldera, recorded 37 earthquakes. This number only slightly exceeds the average during quiet periods. The Mauna Loa seismograph recorded only 21 earthquakes. The Kona seismograph recorded 62 earthquakes during the month. Most of these originated close to the station, many of them probably on the Kealakekua fault.

At 20:19 on December 6, a strong earthquake was felt over all of the southeast part of the island. It originated at a depth of 3 or 4 miles on the east rift zone of Kilauea volcano, about 14 miles east of the caldera and 7 miles southwest of Pahoa.

TELESEISMS

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is Hawaiian Standard time.

October 21, 11 : 46, slight. Formosa.
October 21, 17 : 41, slight. Formosa.
November 6, 06 : 53, slight. Kurile Islands.
November 8, 04 : 02, moderate. Aleutian Islands.
December 7, 18 : 35, slight. Indian Ocean, about 900 miles southeast of Madagascar.
December 25, 15 : 03, slight. Off coast of southern California.
December 27, 23 : 34, slight. Guerrero, Mexico.
December 30, 12 : 50, moderate. Pacific Ocean, west of Easter Island.

The data for the following local disturbances were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The arrival times are given to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory at the northeast rim of Kilauea Caldera. If the intensity was greater at one of the other stations, the name of that station and the intensity rating are given in parentheses after the rating at the Whitney station, except that where the earthquake was not recorded at the Whitney station the parentheses are omitted.

276. Oct. 1, 09 : 17, tremor (Kona very feeble). Central Kona.
277. Oct. 3, 22 : 56, tremor (Kona very feeble). Central Kona.
278. Oct. 4, 06 : 01, very feeble (Kona feeble). Central Kona.
279. Oct. 4, 19 : 03, tremor (Kona very feeble). Central Kona.
280. Oct. 5, 02 : 09, tremor (Kona very feeble). Central Kona.
281. Oct. 5, 08 : 42, very feeble, felt at Kapapala and Naalehu. Kaoiki fault near Hilea.
282. Oct. 6, 02 : 44, very feeble (Kona feeble). East edge of Kealakekua Bay.
283. Oct. 6, 04 : 36, feeble, felt at Kapapala and Naalehu. Kaoiki fault, about 4 miles northeast of Kapapala.
284. Oct. 6, 08 : 35, very feeble (Mauna Loa slight). Kaoiki fault, about 3 miles northeast of Kapapala.
285. Oct. 6, 13 : 34, tremor (Kona very feeble). Central Kona.
286. Oct. 7, 01 : 28, very feeble, felt at Naalehu. Near Hilea.
287. Oct. 7, 05 : 14, tremor (Kona very feeble). Central Kona.
288. Oct. 8, 07 : 16, Kona, feeble, no record on other instruments.
289. Oct. 9, 01 : 40, Kona, feeble, no record on other instruments.
290. Oct. 9, 04 : 45, slight, felt from Kona to Hilo. Central Kona.
291. Oct. 9, 05 : 23, feeble (Kona moderate), felt at Kealakekua. Central Kona.
292. Oct. 10, 02 : 31, tremor (Kona very feeble).
293. Oct. 11, 15 : 05, very feeble. Kilauea (?).
294. Oct. 11, 21 : 30, very feeble (Kona moderate), felt at Kealakekua. Central Kona.
295. Oct. 12, 10 : 12, very feeble (Kona slight). Central Kona.
296. Oct. 12, 16 : 06, tremor (Kona very feeble).
297. Oct. 14, 16 : 37, very feeble. Kilauea.
298. Oct. 14, 19 : 52, very feeble, felt at Naalehu.
299. Oct. 15, 02 : 43, very feeble. Central Kona.
300. Oct. 15, 19 : 47, very feeble.
301. Oct. 17, 08 : 49, tremor (Kona very feeble). Central Kona.
302. Oct. 17, 21 : 12, slight (Mauna Loa moderate), felt at Volcano and Hilo. Northeast rift of Mauna Loa, near the 3,000-foot contour.
303. Oct. 19, 01 : 00, very feeble, felt at Volcano. Northeast rift of Mauna Loa (?).
304. Oct. 20, 11 : 58, very feeble.
305. Oct. 20, 19 : 10, tremor (Kona very feeble).
306. Oct. 20, 21 : 01, very feeble (Kona feeble). Central Kona.
307. Oct. 23, 10 : 42, tremor (Kona slight), felt at Kealakekua. Central Kona.
308. Oct. 24, 13 : 14, very feeble (Kona feeble). Central Kona.
309. Oct. 24, 13 : 15, very feeble, felt at summit of Mauna Loa.
310. Oct. 25, 02 : 42, very feeble.
311. Oct. 25, 05 : 22, very feeble.
312. Oct. 27, 21 : 05, very feeble.
313. Oct. 28, 06 : 53, tremor (Kona very feeble). Central Kona.
314. Oct. 29, 02 : 07, very feeble. Central Kona.
315. Oct. 29, 23 : 49, very feeble. Kaoiki fault, about 3 miles northeast of Hilea.

316. Nov. 1, 20:48, very feeble.
317. Nov. 3, 06:26, very feeble.
318. Nov. 4, 19:24, very feeble. Northeast rift of Mauna Loa.
319. Nov. 6, 10:44, very feeble. Kilauea.
320. Nov. 6, 11:08, very feeble. Kilauea.
321. Nov. 7, 20:11, very feeble. Near summit of Hualalai.
322. Nov. 7, 22:46, very feeble.
323. Nov. 8, 09:34, strong. Intensity 6 at Kahuku. Felt all over southern part of island. Epicenter on southwest rift of Mauna Loa at about 4,500 feet altitude.
324. Nov. 8, 10:16, very feeble.
325. Nov. 8, 14:10, tremor (Kona slight). Central Kona.
326. Nov. 8, 14:22, very feeble, felt at Kealakekua.
327. Nov. 8, 16:33, very feeble. Kilauea.
328. Nov. 8, 23:27, tremor (Kona very feeble). Central Kona.
329. Nov. 9, 00:55, very feeble. Hilina fault, near Puu Kapukapu.
330. Nov. 10, 14:16, very feeble. Southwest rift of Mauna Loa at about 11,000 feet altitude.
331. Nov. 11, 03:52, very feeble.
332. Nov. 11, 07:08, slight, felt in Hilo. East rift of Kilauea, near Pauahi Crater.
333. Nov. 12, 07:01, very feeble. Kaoiki fault near Ainapo.
334. Nov. 13, 00:41, very feeble. Kilauea.
335. Nov. 16, 02:57, very feeble. Kilauea.
336. Nov. 16, 20:54, very feeble.
337. Nov. 17, 14:50, Kona feeble, no record on other instruments; felt in Kealakekua.
338. Nov. 18, 01:31, tremor (Kona very feeble), felt at Kealakekua.
339. Nov. 18, 02:47, tremor (Kona slight), felt at Kealakekua. Central Kona.
340. Nov. 18, 11:18, very feeble. Kilauea Caldera, near Uwekahuna.
341. Nov. 19, 18:58, very feeble.
342. Nov. 20, 17:43, tremor (Kona very feeble.) Central Kona.
343. Nov. 21, 06:22, very feeble.
344. Nov. 21, 10:00, very feeble. Waimea Plain, near Kamuela.
345. Nov. 21, 22:23, very feeble.
346. Nov. 22, 17:37, very feeble. East slope of Mauna Loa, about 3 miles east of Kulani Cone.
347. Nov. 23, 08:22, slight (Kona moderate), felt from central Kona to Kahuku. Kealakekua fault, about 5 miles west of Napoopoo.
348. Nov. 25, 06:17, tremor (Kona very feeble).
349. Nov. 25, 21:41, tremor (Kona very feeble). Central Kona.
350. Nov. 26, 12:35, very feeble. East rift of Kilauea, near Makaopuhi Crater.
351. Nov. 26, 21:25, tremor (Kona very feeble). Central Kona.
352. Nov. 28, 09:36, very feeble.
353. Nov. 28, 11:41, very feeble.
354. Dec. 1, 06:09, very feeble. Central Kona.
355. Dec. 2, 12:00, very feeble.
356. Dec. 3, 08:33, very feeble.
357. Dec. 5, 05:20, very feeble. Kilauea Caldera.
358. Dec. 6, 20:19, strong, felt from Kapapala to Hilo and east Puna. East rift of Kilauea, about 7 miles southwest of Pahoa.
359. Dec. 9, 16:37, feeble. Near Kilauea Caldera.
360. Dec. 11, 02:12, very feeble.
361. Dec. 11, 13:58, very feeble.
362. Dec. 12, 16:51, very feeble.
363. Dec. 13, 03:06, tremor (Kona feeble). Central Kona.
364. Dec. 13, 21:54, very feeble. Kilauea Caldera.
365. Dec. 14, 19:22, tremor (Kona very feeble). Central Kona.
366. Dec. 15, 01:36, very feeble.
367. Dec. 15, 23:16, very feeble.
368. Dec. 17, 15:48, very feeble.
369. Dec. 19, 05:30, very feeble.
370. Dec. 23, 09:31, very feeble. Kilauea Caldera.
371. Dec. 25, 09:50, very feeble.
372. Dec. 26, 23:06, very feeble.
373. Dec. 28, 16:17, tremor (Kona very feeble). Central Kona.
374. Dec. 29, 08:45, Kona feeble, no record on other instruments. Central Kona.
375. Dec. 29, 17:32, very feeble, felt at Naalehu and Kapapala. Kaoiki fault, near Pahala.
376. Dec. 30, 02:00, Kona feeble, no record on other instruments. Central Kona.
377. Dec. 31, 15:49, tremor (Kona feeble). Central Kona.

VOLCANO NOTES AND NEWS

ACTIVITY OF PARICUTIN VOLCANO

Paricutin volcano began its spectacular life on February 20, 1943, in the state of Michoacán, western Mexico. The new volcano is situated in the midst of a volcanic field containing hundreds of older, but geologically young, cinder cones and lava cones. During its first weeks, the activity of Paricutin was largely pyroclastic, and, by the time it was a year old, the resulting cinder cone was 1,100 feet high. Since then the upward growth of the cone has been slow, and on February 21, 1950, the summit of the cone stood approximately 1,300 feet above its original base. Lava flows commenced early in the history of the volcano and have continued intermittently ever since. At the end of June, 1950, the total area covered by Paricutin lava was about 24.2 square kilometers.*

* Carl Fries, Jr., and Celedonio Gutiérrez, activity of paricutin volcano from january 1 to june 30, 1950. Amer. Geophys. Union Trans. 32: 227–230. 1951.

Brief summaries of the activity of Paricutin volcano appear at approximately 6-month intervals in the American Geophysical Union Transactions. Carl Fries, Jr., of the U. S. Geological Survey, has kindly supplied a statement on the current state of activity of Paricutin. The Mexican Institute of Scientific Investigation and the U. S. Geological Survey are maintaining a watch over Paricutin on a cooperative basis. Two Mexican observers are constantly at the observatory, gathering data on eruptive activity, lava movement, weather, and any other pertinent occurrences. Mr. Fries visits the volcano every 2 months to gather the data sheets, make special measurements, and collect lava samples. His last visit was in mid-November, 1951.

In May, 1951, a new pyroclastic eruptive vent formed low on the northeast flank of the main cone. This new vent was very active and formed a separate crater on that flank of the cone. During the following months, the vent gradually moved up the flank, and its crater coalesced with the main crater. By November the depression on the northeast flank had been filled by deposition of pyroclastic fragments, and the profile was once again that of a simple cone.

Lava has continued to issue from the Nuevo Juatita vent at the northeast base of the cone, flowing northeastward around the Equijuata and Capatzun cinder cones. By October it had reached a point about 2½ miles from the vent, near the site of the former town of San Juan Parangaricutiro, when the flow of lava was interrupted at the vent, and the flow front ceased advancing. Solidification at the vent caused the formation of a new lava cascade just west of the former one, and during November two prongs of Lava were invading the base of Equijuata cinder cone near Tourist Lookout.

Activity of the eruptive vents in the crater of the main cone has, for the past 6 months, been of such an intermittently explosive nature that it has not been possible to climb the cone with any probability of safety. It has been dangerous even to approach the base of the cone.

ALEUTIAN-ALASKAN VOLCANO STUDIES

Dr. H. A. Powers, who is in charge of the U. S. Geological Survey's volcanological program in the Aleutian Islands, reports that the field team from the General Geology Branch, which is studying and mapping the volcanoes of the Aleutian Islands and Alaska Peninsula, completed the reconnaissance mapping of the Rat Group during the summer of 1951. This completes the mapping of all the American Aleutians west of the 180th meridian. Eastward, work has been completed on northern Kanaga, northern Adak, Great Sitkin, Umnak, and the Pavlof Group. The investigation will be continued until all the young volcanic areas have been studied.

ALEUTIAN VOLCANIC ACTIVITY

Great Sitkin volcano, in the Andreanof Group of the Aleutian Islands, has continued to steam throughout the past year, according to observations by Austin E. Jones, seismologist in charge of the seismological observatory maintained on Adak Island by the Geophysics Branch of the U. S. Geological Survey. The steam cloud is visible intermittently from Adak. It is not apparent whether this represents fluctuation in volume of steam output or fluctuation in meteorological conditions that condense the steam.

No fume or ash clouds have appeared from Great Sitkin since the series of eruptions which ended about November 29, 1950. During this eruptive period, which began November 5, 1950, several ash showers and fume were produced. Jones estimated that one ash eruption produced possibly as much as 20,000 cubic meters of ash. Flashes of light were observed several times at night by military personnel on Great Sitkin Island, but they were not seen from Adak. Prior to this activity, the last small ash falls and fume clouds were seen on December 30, 1949, and January 7, 1950.

In spite of the frequency of military air travel along the Aleutian Chain, information on minor activity of the different volcanoes is very random because the cloud and fog screen is so persistent. Minor ash showers and fume emission are known to have occurred during 1951 from Gareloi, Kanaga, Great Sitkin, Akutan, and Shishaldin. Others may have shown minor activity which has not been reported. It is certain, however, that no major eruptions have escaped notice.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Chester K. Wentworth, Geologist, part-time
John C. Forbes, Laboratory Mechanic
LaVieve G. Forbes, Secretary, part-time

Seismograph Station Operators:

Hilo Station:
Sister M. Thecla, St. Joseph's School

Kona Station:
Howard M. Tatsuno, Konawaena School

University of Hawaii:

T. A. Jaggar, Geophysicist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcances in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE VOLCANO LETTER

No. 515 **U. S. Geological Survey** **January–March, 1952**

PUBLISHED BY THE UNIVERSITY OF HAWAII

THE SOUTH HAWAII EARTHQUAKES OF MARCH AND APRIL, 1952

By GORDON A. MACDONALD

At 11:38 Hawaiian Standard time on March 13 a strong earthquake (Fig. 1, No. 78) originated beneath the ocean south of the island of Hawaii, 23 miles S 19° W of the coastal village of Kalapana. The earthquake was felt all over the southern portion of the island, its intensity along the south shore being estimated at 4 in the modified Mercalli scale. At 18:20 on March 14 a similar earthquake (Fig. 1, No. 80) originated in the same general area. These quakes were the forerunners of a great swarm of earthquakes that began on March 16 and continued throughout April.

On March 16 the seismographs of the Hawaiian Volcano Observatory recorded 39 earthquakes, all probably originating in the offshore area south of the island. On the following days the number of quakes rapidly increased, reaching a peak of 395 on March 20. Figure 2 indicates the daily seismicity at the Volcano Observatory through the rest of March and April. The daily seismicity was determined by assigning a seismicity value to each earthquake, depending on its size, and totaling the values for each day. Each strong earthquake was assigned a seismicity value of 4. The method is described in Volcano Letter 512.

The decrease in number of quakes from foci south of the island was less rapid than the increase and at a fairly regular declining rate. In Figure 2 the marked hump in the curve on April 5–7 is caused by a series of earthquakes originating on the east rift zone and beneath the caldera of Kilauea volcano. This swarm of Kilauea earthquakes was essentially past by April 8, although a few quakes of Kilauea origin were recorded through the remainder of April.

At the end of April the total number of earthquakes recorded since March 13 was 4,553. Most of these were small, and many were tremors too small to permit the recognition of phases in the seismogram. Based on the records from the Bosch-Omori seismograph in the Whitney Laboratory of Seismology, at the northeast rim of Kilauea Caldera, 31 are classed as moderate and 18 as strong. Several of the strong earthquakes were felt generally over the southern portion of the island. All the strong quakes and many of the smaller ones were felt in the area from Kapapala to and beyond Naalehu (Fig. 1). It is estimated that, during the height of the activity, 20 to 30 earthquakes a day were felt at Naalehu. The number of quakes felt decreased rapidly northeastward, and at Kapapala residents felt only a small proportion of those felt at Naalehu. A still smaller number was felt in the Kilauea Caldera area. It is noteworthy that very few of the earthquakes were felt at Kalapana despite the closeness of that village to the epicenters of many of the quakes. The shocks were much more generally felt in the region nearly in line with the presumed submarine fault on which they originated than they were in areas at similar distances approximately normal to the fault.

None of the earthquakes caused any important damage to property, although several of the large ones caused slight shifting or overturning of small objects on shelves. A strong quake (Fig. 1, No. 148) at 17:58 on March 17 caused a small tsunami ("tidal wave") at Kalapana. At approximately 18:00 waves swept inland about 600 feet, entering the yard of the Kalapana School. At the time, storm waves were not of sufficient size to account for the incursion of the water. This small tsunami produced no record on the tide gauge at Hilo, and no damage was done. However, the writer considered it advisable to issue a warning to all communities along the southeast shore of the island that as long as the swarm of submarine earthquakes continued there was a possibility that a large quake of shallow origin might be accompanied by a destructive tsunami. On the basis of this warning, the Department of Public Instruction ordered the Kalapana School closed and the children transported to school elsewhere until the undersea earthquakes ended.

Approximately 185 of the swarm of earthquakes yielded seismograms on which the emergence of the P and S phases could be recognized with sufficient certainty at several stations to permit reasonably certain location of the epicenter. These epicenters are indicated in Figure 1. All the epicenters were located by means of

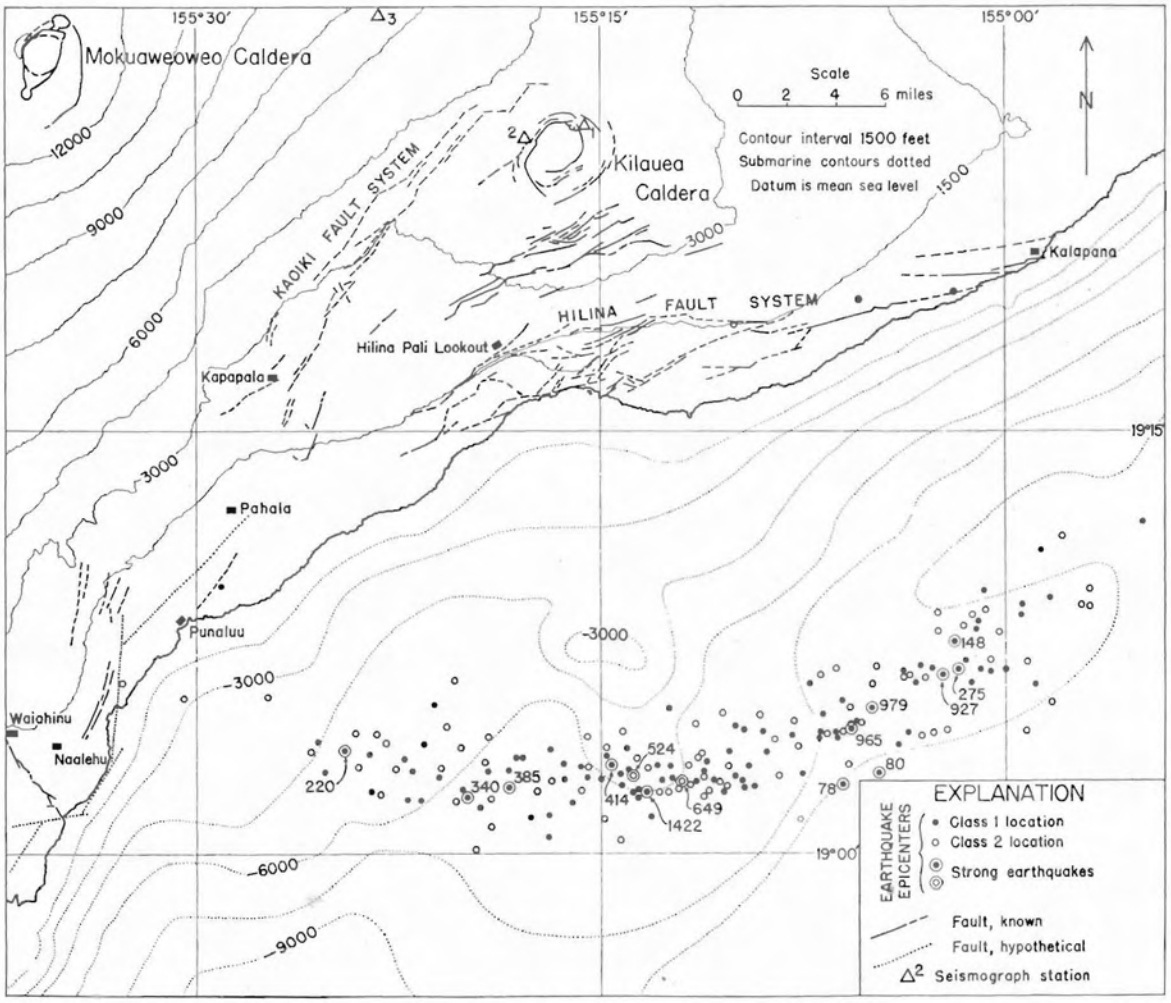

FIGURE 1. Map of part of the southeast coast of the island of Hawaii, showing the locations of epicenters of earthquakes during March and April, 1952, and the positions of known and hypothetical faults above sea level. Class 1 locations are from good agreement of all data; class 2 are satisfactory agreement of data. Serial numbers of the strong earthquakes are indicated. Seismograph stations shown are (1) Whitney Laboratory of Seismology, (2) Uwekahuna station, and (3) Mauna Loa station. The broad bulge in the submarine contours south of Kilauea Caldera probably marks a submarine shield volcano with a ridge extending eastward along a rift zone.

the distance indicated by the interval S — P, using at least three stations. Records from the Whitney Laboratory, the Mauna Loa station, and the Hilo station were used in practically all the locations, and the locations of the strong earthquakes were checked by means of the records of the Kona station. Checks on many locations were obtained from the records of the vertical seismographs and the Imamura strong-motion seismograph at Uwekahuna. In addition, a portable seismograph was operated by John C. Forbes at Naalehu on March 26, at Punaluu on March 28, and at the Hilina Pali lookout station on April 1. The writer wishes to thank Miss Constance Conard, teacher at Naalehu School, for permission to operate the seismograph in the basement of her cottage at the school, and Wayne Richardson and the Hawaiian Agricultural Company for the use of the company's beach house in which to operate the seismograph at Punaluu.

Two classes of epicentral locations are shown in Figure 1. In locations of class 1 there was good agreement of the data from all stations. In locations of class 2 the agreement was less perfect although still close. Instances in which agreement of the data was poor were rejected, and those epicenters are not shown in Figure 1. Because of the unfavorable distribution of seismograph stations in respect to the earthquake epicenters, depth determinations are too uncertain to be used for comparative purposes.

Submarine contours based on the soundings shown on U. S. Coast and Geodetic Survey chart 4115 (7th edition, June 1940) show a broad dome with its apex 21 miles nearly due south of the summit of Kilauea volcano. Soundings are inadequate to give a detailed picture of this feature, and it is highly desirable that many more soundings be obtained off the island of Hawaii. Existing soundings are, however, adequate to give a rather definite generalized picture. A few old, isolated soundings, that are not accordant with adjacent new soundings, and probably are erroneous in position, have been rejected in contouring.

The contours are shown by dotted lines in Figure 1. The dome is probably a shield volcano, lying against the side of the Kilauea shield just as Kilauea does against the side of Mauna Loa. The broad nose projecting east-

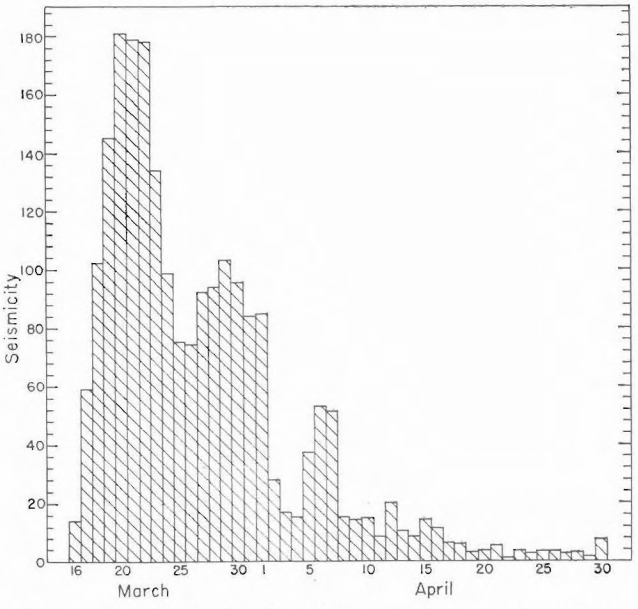

FIGURE 2. Graph showing daily seismicity at the Whitney Laboratory of Seismology from March 16 to April 30, 1952.

ward, shown by the minus-9,000-foot contour, probably is a ridge built along an eastward-trending rift zone like that of Kilauea. It is noteworthy that this probable submarine volcano lies almost exactly on a line drawn through the summits of Hualalai and Mauna Loa volcanoes.

The distribution of epicenters in Figure 1 clearly indicates that the earthquake swarm was caused by movements along a line or narrow zone nearly parallel to the south coast of the island. The eastern portion of the line lies approximately along the axis of the eastward-trending submarine ridge, and the entire line may mark a rift zone crossing south of the summit of the submarine shield, as does that of Kilauea. If so, the movements that caused the earthquakes may have accompanied subterranean magma movement or eruption of the submarine volcano. Careful watch was kept throughout the earthquake period for any signs of submarine eruption. On March 28 a cowboy employed by the Kapapala Ranch reported seeing three puffs of cloud rising from the ocean south of the island at 14:32, 14:50, and 15:10, respectively. These were not reported by any other observer. The ocean south of the island was kept under observation for the next several days from the Volcano Observatory and on March 29 and April 1 from the Hilina Pali lookout. Both binoculars and a telescope were employed. Several times puffs of cloud seen from the Observatory at first appeared to be rising from the ocean, but each time further observation showed them to be merely developing puffs of the common coastal cumulus. From Hilina Pali no clouds were seen to rise from the ocean, nor was any disturbance of the ocean surface observed.

It is, of course, entirely possible that eruption in several thousand feet of water might not produce any visible evidence at the surface. Pressure of overlying water might prevent vesiculation of sufficient degree to produce pumice or scoria light enough to float to the surface. Steam generated by contact of the hot lava with ocean water probably would be cooled and condensed as it rose through the overlying cold water, and magmatic gases might be entirely dissolved. Thus, neither floating pumice nor rising gases might be visible at the surface. On the other hand, it appears unlikely that eruption could have occurred without producing some record of volcanic tremor on the seismographs. Such tremor characteristically accompanies eruptions of Mauna Loa and Kilauea, but it was totally absent from the records during March and April, 1952. Furthermore, even in deep water the heating of the immediately surrounding water and, possibly, the introduction of toxic gases probably would cause the death of many fish, which would float ashore as they did in the vicinity of the 1950 lava flows that entered the ocean. (It is interesting to note that, although specific identifications of these fish are not yet available, many of them obviously came from depths well below those reached in ordinary fishing.)

A more probable interpretation is that the line indicated by the epicenters in Figure 1 marks a fault, or more probably a group of faults, crossing the south slope of the submarine shield volcano much as the Hilina fault system does the south slope of Kilauea volcano above sea level, and that the earthquakes were caused by movement along this fault zone. The probability is increased by the occurrence during the past year of repeated movements along the other similar fault systems on the flanks of both Kilauea and Mauna Loa. It is noteworthy that three of the located earthquakes of the March-April group originated along the Hilina fault system, probably as a result of adjustment along that system in response to movement on the faults farther south. Displacement on the faults of the Hilina system

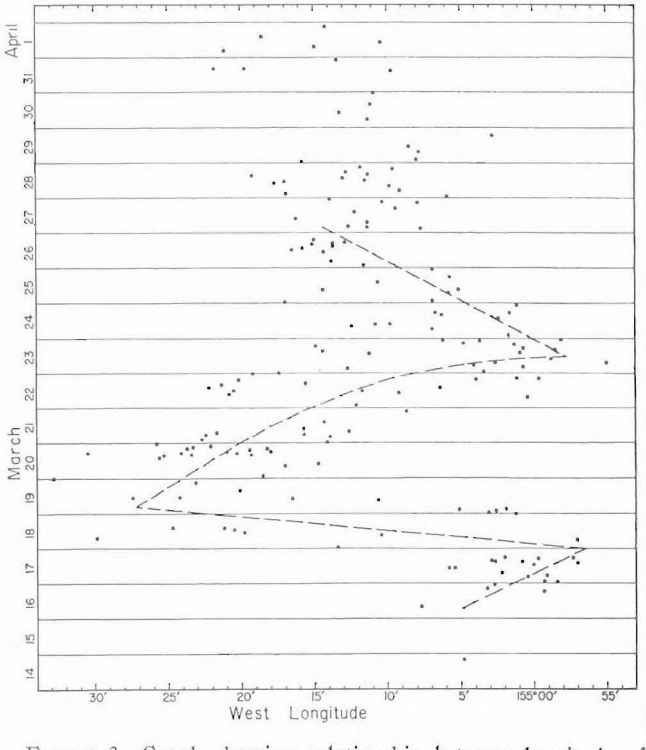

FIGURE 3. Graph showing relationship between longitude of focus and time of occurrence of the earthquakes, the epicenters of which are shown in Figure 1. The dots represent the actual earthquakes, and the dashed line shows approximate median curve.

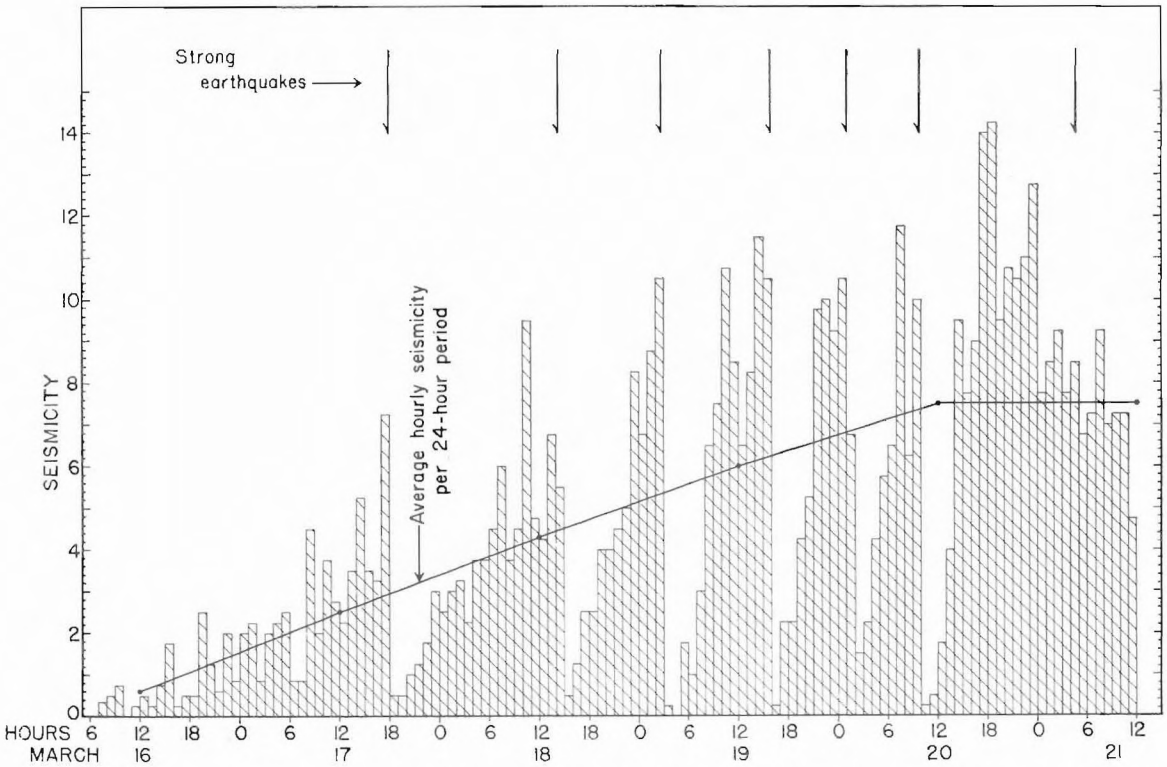

FIGURE 4. Graph showing, by means of columns, the hourly seismicity at the Whitney Laboratory of Seismology from March 16 to 21, 1952, and, by means of black dots, the average hourly seismicity for each day. The line connecting the dots indicates the trend of average hourly seismicity. The single-barbed arrows at the top of the figure indicate the time of occurrence of strong earthquakes.

has resulted in a rise of the central part of the island in relation to the undersea portion. It is probable that on the offshore faults also, the predominant movement has been a rise of the island in relation to the adjacent ocean basin.

The migration of the epicenters indicates that fault movement commenced at about longitude 155°06′W, shifted eastward to about longitude 154°57′, then westward as far as 155°32′ on March 19 and 20, then again eastward. From March 25 on, the located quakes mostly lay near the central portion of the zone of activity, with no definite shifting indicated. The migration of earthquake activity back and forth along the fault zone is shown graphically in Figure 3, in which the longitudes of the epicenters shown in Figure 1 are plotted against time.

The seismicity values may be taken as a roughly quantitative indication of the energy release by the earthquakes. During the first few days of the earthquake swarm, the average rate of energy release appears to have increased at an essentially uniform rate, suggesting a fairly uniform increase in the strain, the release of which was responsible for the earthquakes. In Figure 4, the curve representing the average hourly seismicity during each 24-hour period rises as a nearly straight line from March 16 to March 20. After March 20 the curve flattens into a nearly horizontal plateau. In detail, however, the energy release was not uniform. The plotting of hourly seismicity in the columnar graph (Fig. 4) indicates in general a succession of progressive increases of energy release, terminated by one or more strong earthquakes and followed by a period of a few hours of relative quiet. Thus, although the strain on the fault system appears to have accumulated at a fairly regular rate, the release of the strain was not regular but periodic. Probably the accumulation of strain on the faults, because of frictional resistance to movement on the fault planes, proceeded at a rate greater than the rate of release of the strain, until finally the accumulated strain was relieved by a large movement causing a large earthquake. After each fairly complete release the accumulated strain gradually increased again until another climax was reached.

The earthquake swarm of March and April, 1952, somewhat resembled that of 1868 although on a smaller scale. During late March of 1868 residents of southern Hawaii experienced great numbers of earthquakes, reportedly reaching dozens, or even hundreds, a day. They were most severe in the region from Kapapala to Waiohinu. This activity was climaxed on April 2, 1868, by a violent earthquake of about intensity 10 (Wood, 1914: 192) that leveled nearly every building in the area. The big earthquake was accompanied by a mud flow at Wood Valley, between Kapapala and Pahala, that buried a village and killed 31 persons. At the same time a great tsunami seriously damaged every coastal village along the southeast shore of the island, destroying 108 houses and the lives of 47 people (Brigham, 1909: 118). The great earthquake was followed, a few days later, by eruption of both Kilauea and Mauna Loa volcanoes.

The location of the origin of the great earthquake of April 2, 1868, is uncertain. Movement on a fault just west of Waiohinu is reported to have offset a wagon road the width of the road horizontally (Wood, 1914:

199). However, the very large tsunami that accompanied the earthquake suggests that part of the movement occurred offshore. It is not impossible that the big 1868 quake and many of its attendant smaller shocks originated on the same fault system that caused the quakes of March, 1952. It appears more probable, however, that they originated on the faults in the vicinity of Waiohinu and Naalehu and their seaward extensions.

The possibility of a train of events similar to that of 1868 was borne strongly in mind during the earthquakes of March, 1952. As already stated, the possibility of a damaging tsunami was pointed out. However, lack of strong ground tilting and the absence of earthquakes originating beneath the caldera or rift zones of either volcano during the principal part of the 1952 earthquake swarm suggested that volcanic eruption was not imminent.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JANUARY–MARCH, 1952

By GORDON A. MACDONALD

VOLCANOLOGY

January

Hawaiian volcanoes remained quiet during January. The seismograph beneath the Volcano House, at the northeast rim of Kilauea crater, recorded a total of 54 earthquakes during the month, and the Mauna Loa seismograph recorded only 19. Thus, the number of earthquakes recorded at Kilauea was somewhat greater than the average, and earthquake activity centered at Kilauea rather than at Mauna Loa. However, most of the Kilauea earthquakes had very shallow origins and probably were related to shallow-seated readjustments rather than to deep volcanic forces. A strong earthquake at 01 :58 on the morning of January 26 originated on the group of faults near Hilina Pali, about 3 miles east of Puu Kapukapu. Slight aftershocks at 02 :52 on the same morning and 00 :07 on January 27 originated at the same locality. At 06 :26 on January 23 an earthquake, felt in the northern portion of the island, originated beneath Waimea Plain about 5 miles east-southeast of Kamuela.

Southward tilting of the ground at the northeast rim of Kilauea crater was at a rate approximately normal for this season of the year. Reversal from eastward to westward tilting took place about January 23, approximately a month later than the average, suggesting some accumulation of volcanic pressure beneath Mauna Loa during early January.

February

Earthquake activity was moderately abundant at Hawaiian volcanoes during the month of February. A total of 55 earthquakes was recorded on the seismographs of the Hawaiian Volcano Observatory. Of these, 54 were recorded at Kilauea crater and 39 at the Mauna Loa seismograph station. Thus, the earthquake activity centered at Kilauea, whereas Mauna Loa was relatively quiescent. Most of the Kilauea earthquakes originated on the east rift zone, between Makaopuhi Crater and a point 10 miles farther east. Several others originated close to Kilauea crater. All were of shallow origin.

An earthquake at 01 :16 on February 2 was felt generally in Hilo and by some persons in nearly all parts of the island. It originated at a depth of about 30 miles, nearly under Kaumana. A smaller earthquake at 20 :30 on February 1, felt by many persons in Kona, originated in central Kona, probably on the Kealakekua fault near the north edge of Kealakekua Bay. Other earthquakes on February 13 and 14 had their origin in the same general area. A quake felt at Kapapala at 22 :40 on February 23 had its epicenter on the southwest rift of Mauna Loa, near 8,500 feet elevation.

Slight westward and moderate southward tilting of the ground continued throughout the month at the seismograph station beneath the Volcano House, at the northeast edge of Kilauea crater. Both are normal for this season of the year.

Early in February a large rock slide occurred on the southwest wall of Halemaumau crater, south of the visitors' lookout point. The scar left by the slide was first observed on the morning of February 9, but the slide is believed to have taken place during or immediately following a strong earthquake at 21 :55 on February 7. Halemaumau was not visible from the Volcano Observatory on February 8 because of rain clouds filling Kilauea crater. The slide removed a layer of rock about 500 feet wide and 450 feet high from the upper part of the crater wall. It was followed by many smaller slides, the largest of which occurred near noon on February 21. Altogether, the slides deposited more than 2 million cubic feet of broken rock on the floor of Halemaumau and caused the rim of the crater to move back as much as 10 feet.

March

The outstanding event of the month of March was the beginning of the great swarm of earthquakes, originating off the south shore of the island, that is described on foregoing pages. East-west tilting at the Whitney Laboratory during March was irregular, and there was practically no accumulation of tilt in either direction. North-south tilting also was irregular, but there was an accumulation of 0.8 second of southward tilt during the month. This southward tilting was normal for that season of the year, but the rate was somewhat less than usual.

Small rock slides continued on the southeast wall of Halemaumau crater. The north end of the crack that crosses the tourist observation area opened 8 mm. during the month.

TELESEISMS

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori or Sprengnether vertical seismograms, in Hawaiian Standard time.

January 12, 10 : 28, slight. Fox Islands, in Aleutian Archipelago.
March 3, 15 : 33, strong. Near the east coast of Hokkaido Island, Japan.
March 5, 06 : 08, slight. Off east coast of Hokkaido.
March 9, 06 : 58, slight. Near south coast of Kamchatka.

Earthquake Data, January–March, 1952

(Based on Bosch-Omori seismograph on northeast rim of Kilauea Caldera)

TEMPERATURE MEASUREMENTS

On March 20 the Territorial Highway Department installed a recording thermometer on the Ohia Lodge flow of the 1950 eruption of Mauna Loa. The thermal element is placed in a hot crack at a site just inland from the position of the old highway that was buried by the flow. The flow is approximately 50 feet thick at that point.

K. B. Hirashima, testing engineer for the Territorial Highway Department, states that a temporary installation with the thermal element at a depth of 18 inches yielded a temperature reading of 860°F. The permanent installation at a depth of 3 feet indicated a temperature of 960°. It is planned to keep a record of the rate of temperature drop over the next several years. The temperature recorded is much higher than at comparable depths over most of the flow, as has been demonstrated in cuts several feet deep excavated along the course of the new highway which crosses the flow. The high temperature at the thermometer installation is caused by gases rising from the lower part of the thick flow.

The data for the following local disturbances were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The times are arrival times at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea Caldera. They are given to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

1. Jan. 2, 06:47, very feeble.
2. Jan. 8, 05:40, no record at Kilauea (Kona very feeble).
3. Jan. 10, 00:22, very feeble.
4. Jan. 11, 02:33, very feeble.
5. Jan. 12, 04:23, very feeble.
6. Jan. 12, 20:54, very feeble. Kilauea Caldera.
7. Jan. 15, 05:13, very feeble.
8. Jan. 17, 07:36, very feeble.
9. Jan. 23, 00:54, very feeble.
10. Jan. 23, 04:10, very feeble. Kilauea Caldera, shallow.
11. Jan. 23, 06:27, very feeble, felt at Kukuihaele. Waimea Plain, about 5 miles east-southeast of Kamuela.
12. Jan. 23, 07:54, feeble. Near Kilauea Iki.
13. Jan. 23, 11:13, very feeble. Kilauea.
14. Jan. 23, 11:54, very feeble.
15. Jan. 24, 07:03, very feeble. Kilauea.
16. Jan. 24, 07:14, very feeble.
17. Jan. 24, 13:26, very feeble. Kilauea Caldera.
18. Jan. 24, 18:24, very feeble. Kilauea Caldera.
19. Jan. 25, 03:04, very feeble. Kilauea Caldera.
20. Jan. 25, 03:06, very feeble.
21. Jan. 25, 16:53, no record at Kilauea (Kona feeble). Central Kona.
22. Jan. 25, 19:44, very feeble. Kilauea Caldera.
23. Jan. 25, 20:55, no record at Kilauea (Kona very feeble). Central Kona.
24. Jan. 26, 01:58, strong. Hilina fault system, about 3 miles east of Puu Kapukapu.
25. Jan. 26, 02:52, slight. Same as No. 24.
26. Jan. 27, 00:07, slight. Hilina fault system.
27. Jan. 27, 18:52, tremor (Kona feeble). Central Kona.
28. Jan. 27, 18:59, very feeble (Kona slight). Central Kona.
29. Feb. 1, 20:30, very feeble (Kona feeble), felt at Captain Cook. Central Kona.
30. Feb. 2, 01:16, moderate, felt over most of the island, strongly at Hilo. Nearly under Kaumana, about 30 miles deep.
31. Feb. 2, 03:46, very feeble.
32. Feb. 2, 05:58, tremor, felt in Kukuihaele.
33. Feb. 2, 06:19, very feeble.
34. Feb. 2, 13:05, very feeble.
35. Feb. 6, 06:20, very feeble.
36. Feb. 6, 18:42, feeble. East rift of Kilauea near Makaopuhi.
37. Feb. 6, 20:52, very feeble.
38. Feb. 6, 22:10, very feeble.
39. Feb. 7, 04:27, slight. East rift of Kilauea near Makaopuhi, shallow.
40. Feb. 7, 21:22, very feeble.
41. Feb. 7, 21:23, feeble. East rift of Kilauea.
42. Feb. 7, 21:55, strong. East rift zone of Kilauea, 1 mile east of Napau Crater, shallow.
43. Feb. 8, 02:02, tremor (Kona very feeble).
44. Feb. 13, 20:36, very feeble (Kona moderate). Central Kona, probably on Kealakekua fault.
45. Feb. 14, 15:46, tremor (Kona slight). Central Kona.
46. Feb. 14, 15:50, tremor (Kona slight). Central Kona.
47. Feb. 15, 14:47, tremor (Kona very feeble).
48. Feb. 15, 23:04, tremor (Kona very feeble). Central Kona.
49. Feb. 19, 11:20, very feeble, felt at Kapapala. Southeast slope of Mauna Loa near Kapapala.
50. Feb. 19, 19:26, very feeble.
51. Feb. 21, 06:15, slight, felt from Volcano district to Pepeekeo. East rift of Kilauea about 2 miles east of Napau crater, shallow.
52. Feb. 22, 17:10, very feeble. Kilauea.
53. Feb. 22, 21:34, very feeble.
54. Feb. 23, 01:47, very feeble. Kilauea.
55. Feb. 23, 22:41, very feeble, felt at Kapapala. Southwest rift of Mauna Loa at about 8,500 feet altitude.
56. Feb. 24, 10:20, very feeble (Mauna Loa feeble). North slope of Mauna Loa, about 11 miles north of Mokuaweoweo.
57. Feb. 24, 11:22, very feeble. Kilauea Caldera.
58. Feb. 24, 11:47, very feeble.
59. Feb. 24, 11:54, very feeble.
60. Feb. 25, 08:28, very feeble.
61. Feb. 26, 12:36, very feeble.
62. Mar. 1, 11:59, very feeble. Kilauea Caldera.
63. Mar. 2, 14:36, very feeble. Kilauea Caldera.
64. Mar. 6, 20:44, feeble, felt at Hilo and in Volcano district. Hilina fault system, about 2 miles northwest of Ka Lae a Puki.
65. Mar. 9, 05:59, very feeble.
66. Mar. 9, 07:51, very feeble.
67. Mar. 9, 10:51, very feeble.
68. Mar. 9, 13:57, slight. Hilina fault system, about 2.5 miles northwest of Kaena Point.
69. Mar. 9, 14:01, very feeble.
70. Mar. 10, 13:45, very feeble.
71. Mar. 11, 10:10, very feeble.
72. Mar. 12, 03:37, very feeble.
73. Mar. 12, 16:28, very feeble.
74. Mar. 12, 16:54, feeble (Kona slight). Central Kona.
75. Mar. 12, 17:07, very feeble.
76. Mar. 12, 17:11, very feeble.
77. Mar. 12, 22:17, very feeble.
78. Mar. 13, 11:38, strong, felt from Volcano district to Naalehu. Off south shore, at 19°02.4′N, 155° 06.2′W.
79. Mar. 14, 17:45, very feeble. Kilauea.
80. Mar. 14, 18:21, strong, felt from Hilo to Kapapala. Off south shore, at 19°02.8′N, 155°04.8′W.

81. Mar. 14, 19:06, very feeble.
82. Mar. 14, 19:09, very feeble.
83. Mar. 15, 22:16, very feeble. Kilauea Caldera.
84-1427. Mar. 16-31, Earthquakes originating mostly off the south shore of the island, and mostly very feeble to slight. Moderate and strong earthquakes of this group and earthquakes of other origin are listed separately below.
88. Mar. 16, 15:53, feeble, felt in Volcano district. Kilauea Caldera, shallow.
95. Mar. 16, 22:45, very feeble. Hilina fault system, 2 miles west of Kupaahu, at 19°19.7'N, 155°02.0'W.
148. Mar. 17, 17:58, strong, felt at Naalehu, caused small tsunami at Kalapana. Off south shore, at 19°07.5'N, 155°02.0'W.
167. Mar. 18, 04:50, very feeble. Kilauea.
183. Mar. 18, 08:03, very feeble. Kilauea Caldera.
199. Mar. 18, 10:53, moderate, felt at Naalehu. Off south shore, at 19°00.1'N, 155°19.8'W.
212. Mar. 18, 13:01, moderate. Off south shore at 19°06.1'N, 155°20.5'W.
220. Mar. 18, 14:18, strong. Off south shore, at 19°04.6'N, 155°24.7'W.
275. Mar. 19, 02:55, strong, felt at Naalehu. Off south shore, at 19°06.5'N, 155°01.8'W.
283. Mar. 19, 08:05, very feeble. Kilauea.
340. Mar. 19, 15:51, strong. Off south shore, at 19°02.0'N, 155°20.1'W.
385. Mar. 20, 01:22, strong. Off south shore, at 19°02.3'N, 155°18.5'W.
414. Mar. 20, 09:51, strong, felt at Naalehu. Off south shore, at 19°03.2'N, 155°14.7'W.
466. Mar. 20, 20:16, moderate, felt at Naalehu. Off south shore, at 19°03.5'N, 155°23.7'W.
494. Mar. 20, 23:48, moderate, felt at Naalehu. Off south shore, at 19°02.2'N, 155°23.6'W.
524. Mar. 21, 04:35, strong, felt at Naalehu. Off south shore, at 19°02.7'N, 155°13.9'W.
567. Mar. 21, 14:25, moderate. Off south shore, at 19°04.3'N, 155°14.3'W.
649. Mar. 22, 02:05, strong, felt at Naalehu. Off south shore, at 19°02.5'N, 155°12.1'W.
668. Mar. 22, 06:19, moderate. Off south shore, at 19°07.8'N, 155°00.4'W.
762. Mar. 22, 19:20, moderate, felt at Naalehu. Off south shore, at 19°06.4'N, 155°03.9'W.
808. Mar. 23, 06:52, moderate, felt at Naalehu and Pahala. Off south shore, at 19°11.7'N, 154°55.0'W.
842. Mar. 23, 15:05, moderate, felt at Naalehu and Kapapala. Off south shore, at 19°02.8'N, 155°14.4'W.
894. Mar. 24, 02:02, moderate, felt at Naalehu. Off south shore, at 19°08.0'N, 155°01.7'W.
927. Mar. 24, 13:29, strong, felt at Naalehu. Off south shore, at 19°06.3'N, 155°02.4'W.
954. Mar. 25, 00:30, moderate. Off south shore, at 19°01.3'N, 155°17.0'W.
965. Mar. 25, 07:04, strong, felt at Naalehu. Off south shore, at 19°04.3'N, 155°05.8'W.
979. Mar. 25, 09:17, strong, felt at Naalehu. Off south shore, at 19°05.2'N, 155°05.1'W.
1016. Mar. 26, 04:40, moderate, felt at Naalehu. Off south shore, at 19°03.3'N, 155°13.8'W.
1083. Mar. 27, 04:31, moderate, felt at Naalehu. Off south shore, at 19°03.1'N, 155°12.6'W.
1128. Mar. 27, 22:44, moderate, felt at Naalehu and Pahala. Off south shore, at 19°02.2'N, 155°13.9'W.
1166. Mar. 28, 11:57, moderate, felt at Naalehu. Off south shore, at 19°03.3'N, 155°11.5'W.
1200. Mar. 29, 02:42, moderate, felt at Naalehu. Off south shore.
1317. Mar. 30, 13:53, strong. Off south shore.
1422. Mar. 31, 22:00, strong, felt at Naalehu. Off south shore, at 19°02.2'N, 155°13.4'W.

VOLCANO NOTES AND NEWS

CONDITIONS AT PARÍCUTIN VOLCANO

A letter from Celedonio Gutierrez, the Geological Survey's permanent observer at Parícutin volcano, Mexico, addressed to Ray E. Wilcox of the Geological Survey's volcano investigations unit, tells of unprecedented absence of activity. During January and February there were several explosions stronger than any previously observed during the life of Parícutin. On February 25 eruptive activity ceased and was renewed only by a few weak surges between that time and March 4. From March 4 until the date of the letter, March 29, the volcano remained totally inactive, with not even noises or fume emission. A subsequent letter confirms total inactivity through April 29, 1952. Wilcox states that this is the first complete cessation of activity in the 9 years since the birth of Parícutin.

ALASKAN VOLCANOES

Austin E. Jones, seismologist in charge of the Geological Survey's Aleutian volcano observatory on Adak Island, has supplied the following notes obtained during January from Capt. V. Seidelhuber of a U. S. Navy tanker operating in Aleutian waters.

April 1951—On a moonlit night, glow was reflected high above Shishaldin volcano, the most active vent on Unimak Island.

October 1951—Lower slopes of Akutan showed fresh black ash on top of the snow, but the summit of the volcano was concealed in cloud.

December 20, 1951—A high column of white smoke (steam) rose above the summit of Makushin volcano, Unalaska Island, and the snow on the volcano was gray with ash.

January 17, 1952—A column of grayish-brown fume was rising from the crater on the summit of Gareloi volcano.

TSUNAMI OF MARCH 3, 1952, IN HAWAII

A violent earthquake off the east coast of the Japanese island of Hokkaido, at 01:23 on March 4 (Greenwich Civil time), caused extensive property damage and heavy casualties. It was accompanied by a tsunami ("tidal wave") which contributed greatly to the damage. This wave was recorded on the tide gauge in Honolulu harbor. According to Comdr. C. A. George, Supervisor of the Pacific District, U. S. Coast and Geodetic Survey, the arrival time at Honolulu was 11:15 Greenwich Civil time, or 23:15 on March 3 by Hawaiian Standard time, and the amplitude of the wave was about 6 inches. The wave was recorded at Hilo also, with about the same amplitude. The wave traveled from Japan to Hawaii at an average speed of approximately 450 miles an hour.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Chester K. Wentworth, Geologist, part-time
John C. Forbes, Laboratory Mechanic
LaVieve G. Forbes, Secretary, part-time

Seismograph Station Operators:

Hilo Station:

Sister M. Thecla, St. Joseph's School

Kona Station:

Howard M. Tatsuno, Konawaena School

University of Hawaii:

T. A. Jaggar, Geophysicist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

HIBOK-HIBOK VOLCANO, PHILIPPINE ISLANDS, AND ITS ACTIVITY SINCE 1948

By ARTURO ALCARAZ, LEOPOLDO F. ABAD, and JOSE C. QUEMA[1]

PART I

INTRODUCTION

Hibok-Hibok is one of several active volcanoes in the Philippines. Since the start of its present activity in September, 1948, it has aroused world-wide interest, not only from the scientific but also from the humanitarian point of view, because of the profound effects of the activity on the inhabitants of Camiguin Island where the volcano is located. About 500 persons died and property damage amounting to several hundred thousand pesos was sustained as a result of the most recent eruptive phase of its activity which occurred on December 4 and 6, 1951. The high loss in human lives ranks the Hibok-Hibok disaster as one of the most appalling natural disasters to have visited the Philippines in the last 40 years, since the eruption of Taal volcano on the island of Luzon in 1911.

GEOGRAPHY

Hibok-Hibok volcano is on the island of Camiguin. The island is roughly pear shaped, with its longer axis trending northwest-southeast, and lies between 9°05′N and 9°16′N, and between 124°38′E and 124°48′E (Fig. 1). Its total area is about 237 square kilometers. Camiguin is barely 10 miles off the north coast of the large island of Mindanao, and politically it is a part of the Province of Oriental Misamis in Mindanao.

At present, access to Camiguin Island is by sea transportation only, as it has no airfield. Small interisland boats call almost daily at Mambajao, which has the best port facilities on the island. However, due to the proximity of the town to Hibok-Hibok volcano, shipping activities are shifting to Binone, a barrio on the east side of Camiguin quite removed from the present dangers arising from the activity of the volcano.

[1] Geophysicist, Weather Bureau; Mining Engineer, Bureau of Mines; and Geologist, Bureau of Mines, respectively. Published by permission of the Committee on Volcanology, Department of Agriculture and Natural Resources, Philippine Islands.

The island is mountainous. Coastal plains are very narrow and in most places absent. However, because of the fertility of the volcanic soil, a large portion of the island is under cultivation. Plantations of coconut and abaca can be seen everywhere, even on the slopes of the volcanoes. The main occupations of the people are farming and fishing.

There is no real dry season in Camiguin in spite of a very pronounced maximum-rainfall period in winter. The average annual rainfall is about 97 inches. From November to April, the prevailing winds are northeasterlies; in May, the easterlies or trade winds; and from June to October, the southwesterlies. Typhoon frequency for the island is less than 7 per cent of the number that affects the Philippines annually.

According to the *Census Atlas of the Philippines* for the year 1948, the population of the island is 69,599, distributed in four municipalities as follows: Mambajao, 25,193; Sagay, 18,061; Catarman, 16,845; and Mahinog, 9,500. A fairly good road runs along the north coast, from the barrio of Naasag northeast-southeastward to Guinsiliban and then northwestward, following the south coast to barrio Bonbon, almost encompassing the island except for about 3 or 4 miles around the base of Mount Vulcan. Extension of the road from Naasag to Bonbon was under construction in 1950. However, because of the activity of Mount Hibok-Hibok, sections of the road from Baylao to Agoho, both barrios of Mambajao, are now covered by volcanic debris brought down by freshets from the slopes of the volcano and, as was the case on December 6, 1951, laid down by an ash flow.

The main topographical features of Camiguin Island are two moderately high volcanic peaks: Mount Mambajao, with an elevation of 5,620 feet, and Mount Catarman, the site of the present activity, with an elevation of 4,370 feet (Fig. 1). There are also numerous smaller peaks, all of volcanic origin. At the northwest

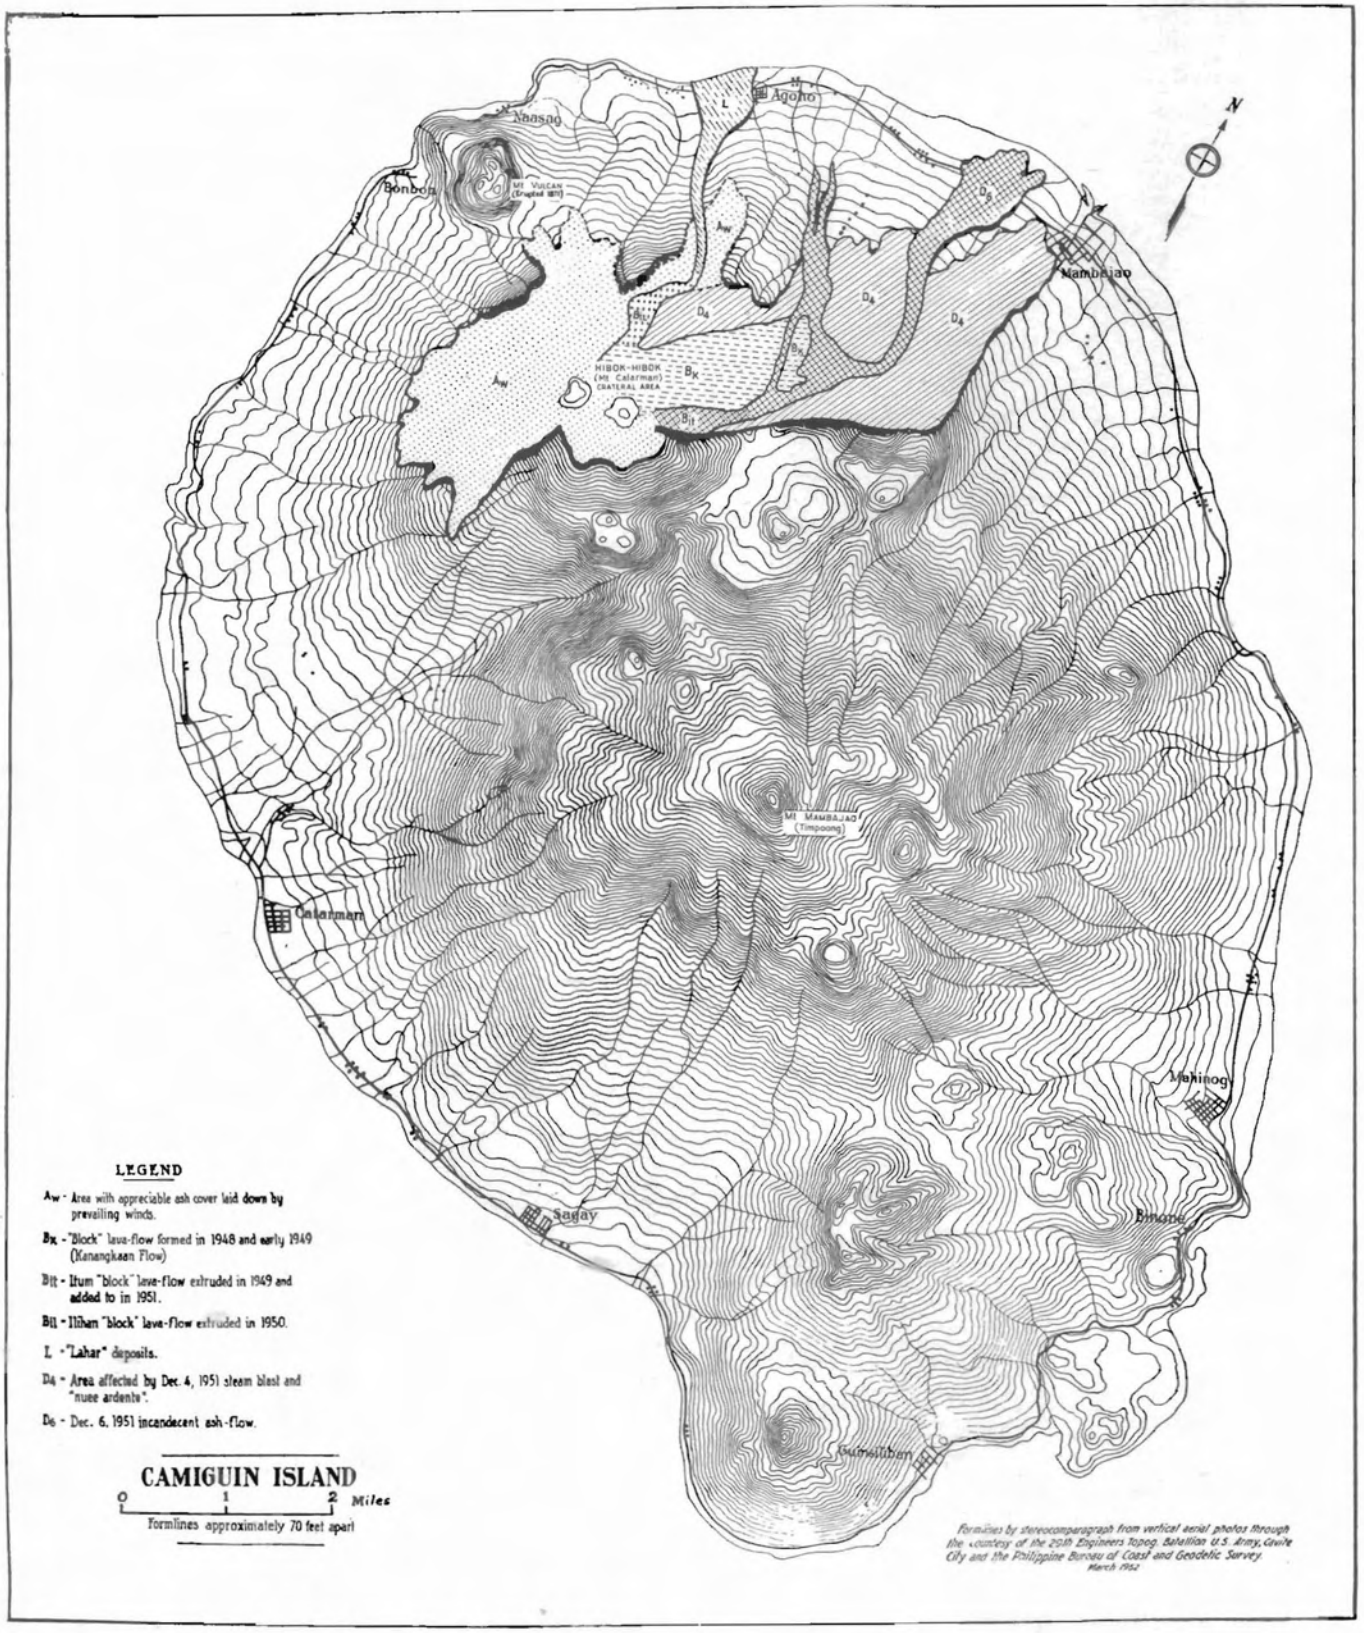

FIGURE 1. Map of Camiguin Island, showing the location of Hibok-Hibok volcano (Mt. Catarman) and the principal deposits of its recent activity.

end of the island, jutting out a little way to sea, is Mount Vulcan, a volcanic cone built up in 1871 at the base of Mount Catarman. Vulcan is about 1,500 feet high.

Hibok-Hibok is a native name given to Mount Catarman. There was really no need of any name for the volcano other than that of Mount Catarman which appears in published maps of the Archipelago, but "Hibok-Hibok" gained wide usage, and the volcano is now known locally and abroad by that name. The approximate geographical co-ordinates of the present active crater area are 9°12′N and 124°40′E.

GEOLOGY

The island of Camiguin is made up entirely of volcanic formations and was apparently built upon a submarine platform which is made evident by lines connecting isobaths at approximately the 200-fathom depth. The platform appears to be a segment or an extension of the Misamis Peninsula, from which the island is separated by 10 miles of water. The area is spotted with numerous submarine elevations, which form rocky shoals and bases of coral islets.

The rock forming the platform is not definitely known. However, there are evidences that it is probably basalt as is now to be found at southeast Camiguin and at the north tip of Misamis Peninsula. Lejay (1938) found strong positive anomalies at the tip of the peninsula and offered the explanation that the heavy materials, the presence of which is revealed by samples at the surface, must probably be in great quantity in the root. In Camiguin, however, the areal extent of the basaltic formations is limited to a sixth part of the island and can be found only in the southeastern section.

West of the basalt area from the Sagay-Mahinog line of contact are younger extrusives and most recent volcanics. They are mostly andesitic agglomerates, lava sheets, and pyroclastics and constitute the formations which built up in sequence the stratovolcanic peaks of Mambajao, Catarman, and Vulcan. The latest extrusives from Vulcan in 1871 and Hibok-Hibok in 1948 were grayish, dense to partly vesicular porphyritic andesites with numerous feldspar and ferromagnesian phenocrysts. The extrusives must have come out in a state approaching that of solids, as there is practically no evidence of any rapid cooling.

Only one hot spring is known to exist on the island. It is located at the foot of Mount Vulcan, about 1½ miles southwest of barrio Naasag. This spring is at mean sea level and thus approachable only during low tide. The water has a temperature below boiling point and comes welling out in very small quantities on the rocky beach. The water is not hard. At two places close to Mount Catarman can be found mineral springs issuing at ordinary temperature. The water tastes like the well-known Vichy mineral water of France.

PAST VOLCANIC ACTIVITY IN CAMIGUIN

The island of Camiguin bears plenty of evidences that in the past it must have been one of the more active volcanic centers of the Archipelago. Mounts Catarman and Mambajao and numerous smaller cones were built, no doubt, by past eruptions. There is no clear mention in records at hand, however, of any previous volcanic activities other than the eruption of 1871, which produced Vulcan, and the appearance of solfataras in 1897 and 1902 in the same area as the present activity. In fact, until the present activity, it was thought that Mount Catarman (Hibok-Hibok) was dormant.

The Camiguin Eruption of 1871. In January, 1871, earthquakes were felt on the north end of Camiguin Island. The number frequency and intensity of the shocks gradually increased by February, and rumbling subterranean sounds were heard to accompany the tremors. Landslides and fissuring also occurred with the earthquakes, destroying trees and plantations. On April 30, after the shocks suddenly ceased, an explosion occurred. From a spot close to the sea and north of the old town of Catarman (now known as barrio Bonbon) on the west-northwest foot of Mount Catarman, a tremendous explosion was heard, and, at the same time, a shower of stones, earth, and ashes was ejected from the recently made openings. Destruction was complete within a radius of 2 miles from the new crater. The eruption continued for about a week, after which it declined into a relatively quiet eruptive state. A volcanic cone, which was later called Camiguin volcano or Vulcan, began to form.

The activity continued for about 4 years, after which time the cone reached a height of approximately 1,500 feet, with a base nearly 1 mile in diameter. Grabau (1921) listed this eruption as one of the few occasions in historic times on which the growth and development of a volcano has been witnessed by man. It was Parícutin 72 years ahead in the Philippines.

After the eruption, the town of Catarman was rebuilt on its present site (formerly barrio Guiob), some 8 miles southeast of the old site. Vulcan is quiescent at present, with the cone partly eroded. It does not seem to be affected at all by the activity of the adjacent Hibok-Hibok. In the past decade or so, Vulcan's activity apparently has been limited to emission of an insignificant amount of steam from crevices in the crater area and visible from a distance on cold, clear mornings only.

Solfataras of 1897 and 1902. In 1897, in about the same area as the present activity of Hibok-Hibok, there issued white sulphurous vapors that caused destruction to the agricultural lands on the northeast and southwest slopes of Mount Catarman. According to the account of this activity by Reverend Saderra Maso, S.J. (1903), the solfataric activity continued up to 1902. On July 9 of that year, hollow sounds were heard coming from the mountain although there was no apparent change in the appearance of the volcano. During the night of July 27 there was a thunderstorm around Mount Catarman, and the people were surprised the following morning to note that a new solfataric vent had formed opposite the crest which separated it from the old one. The activity of the new vent lasted 8 to 10 days, during which frequent subterranean sounds were heard.

Published accounts of these solfataric activities have made no mention of associated earth tremors. However, because of recent information gathered from two old residents of Camiguin who witnessed the events in 1897 and 1902, it is now believed likely that there were local tremors associated with the activities.

PRESENT ACTIVITY

The present activity of Mount Catarman, now popularly known as Hibok-Hibok (= quivering, in dialect) volcano, may be said to have begun during the last week of August, 1948, when the vicinity of the volcano started experiencing a series of earth tremors especially perceptible at the barrios on the northeast slopes. With the local tremors, there occurred frequent slides of the soil mantle on the volcano's slopes facing the town of Mambajao. The landslides and earthquakes increased in frequency, and, on the afternoon of September 1, there occurred the first crateral outburst from the general area of the sulphur pits (most probably the vents of the 1897–1902 solfataric action of Mount Catarman). Since then, Hibok-Hibok has been in more or less continual activity punctuated by eruptive phases.

In over 3 years of activity, a certain cycle of behavior of Mount Hibok-Hibok is discernible, the cycle being (1) a short period of emission of a considerable amount of smoke from the crater and slides of volcanic materials, with or without accompanying tremors; (2) explosions, or steam blasts, concomitant with the emission of heavy clouds of steam, ashes, and other fragmentary volcanic materials, with a strong possibility of the development of "nuées ardentes d'explosion vulcanienne" (Lacroix, 1930); (3) disgorging of incandescent materials, emission of ash and smoke in large amounts, formation of agglomeratic flows, and occasional minor crateral outbursts; (4) decrease in amount of smoke and other ejecta from the crater (possibly due to engulfment of the lava column). From phase 4 the activity again goes back to phase 1, the whole cycle being completed in a period of from 9 to 14 months.

The above cycle seems to have been the pattern of behavior of Hibok-Hibok in the past 3 years, with each cycle apparently culminating in a steam blast, or blasts, of varying intensity. The period covered by each phase varies, whereas the phase itself may either be accentuated or subdued in a particular cycle. Dates of eruptions of the volcano can really be regarded as times when the cycle was at phase 2, such as September, 1948; June, 1949; September, 1950; and December, 1951.

Seismic Activity. There was no seismograph on Camiguin Island at the start of the present activity of Mount Hibok-Hibok, so the tremors that preceded the initial blast of September 1 were unrecorded. However, the tremors were of perceptible intensities and were felt by the people living close to the volcano. The distribution in time and intensity of these tremors, judging from information gathered on Camiguin Island, was one of progressively shorter intervals and increasing intensity up to the time of the initial blast, when they practically ceased, although a few weak tremors were felt in the vicinity of the volcano after September 1.

A low-magnification seismograph was installed at Mambajao in February, 1951. No unusual local seismic activity has been recorded by the instrument, however, except for occasional single tremors of volcanic origin. The absence of any swarm of tremors, macroseismic or microseismic, before the eruptive phase of later cycles is noteworthy. The December 4, 1951, steam blast, for example, was without any apparent attendant seismic activity. Why that was so is a matter for conjecture. Perhaps the seismic disturbances that may have resulted from lava surges beneath the volcano were, or are, of such small magnitude as to be undetectable by a low-magnification instrument such as had been installed at Mambajao. Nevertheless, it seems logical to expect that, toward the time of release of any large confined pressure such as must exist in the magma chamber before a steam blast, there should be tremors that are strong enough to be perceptible even without instruments.

Could it be that what Fenner (1950) wrote about the Katmai eruption finds application to paroxysmal activities of Mount Hibok-Hibok? In discussing the possibilities of exothermic reactions in magmas and the large quantities of heat that may be developed, he said that ". . . in the Katmai eruption the explosions occurred after the magma rose to the surface and was lying in an open crater, and that during this period a great amount of heat was evolved and large quantities of cold rock from the crater walls were engulfed by the magma and reacted with it. The later explosions developed in the synthetic magma so produced." If the explosions manifested by Hibok-Hibok were precipitated by exothermic reactions that took place while the magma was close to the surface, then it is not hard to see why there was no detectable seismic activity associated with those explosions. That the magma was near or in the open crater just before Hibok-Hibok explosions or steam blasts seems to be supported by the observed characteristics of phase 1, the phase preceding paroxysmal activity of the volcano.

Steam Blasts. The explosive crateral outbursts of Mount Hibok-Hibok may be termed steam blasts. There is evidence that a blast, or a series of blasts, of great violence are a characteristic feature of the present activity of the volcano.

The first steam blast happened at five o'clock in the afternoon of September 1, 1948. From eye-witness accounts, it was gathered that something (presumably a dull, explosive sound) drew people's attention to Hibok-Hibok, and they were appalled to see a dense black cloud enveloping the mountain. Its development was rapid, and within a minute or two the town of Mambajao, about 4½ miles distant, was engulfed in darkness. Pisolitic ash began to fall on the town, throwing the people into consternation. The eruption cloud dissipated in about ½ hour. The following day, September 2, there were two similar outbursts, but they were not as strong as that of the day before.

Those who saw the eruption cloud from afar were in agreement in that it was a cauliflower- or mushroom-shaped cloud that shot out from Hibok-Hibok. The destruction caused by this blast and by others later was localized in the northeast sector of the volcano, probably because of the fact that the Hibok-Hibok crater is not located at the crest of Mount Catarman but at a slightly lower elevation on its northeast flank.

The possibility of a fissure eruption of the nature suggested by Jaggar (1949) for Mount Pelée may be discounted on the basis of field evidences. Coconut trees and other vegetation were blown down or scarred, and the trees that were left standing quite close to the source

FIGURE 2. Steam blast of July 3, 1951, with its accompanying glowing cloud (nuée ardente d'explosion vulcanienne).

of the blast were flayed. Subsequent examination of the devastated area revealed rock fragments and, in one instance, a piece of stick embedded in a coconut trunk. The trees were felled with a definite directional pattern, all pointing away from the crater except for slight modifications due to topography. The area destroyed by the blast of September 1 was roughly 8 square kilometers. About 70 per cent was arable and cultivated for coconuts, hemp, and food crops. Because of the precursory tremors and landslides, occurrences entirely new to most of the island's inhabitants, people living close to the volcano left before the violent outburst, and thus there were practically no casualties. Two persons, caught at the fringe of the affected area, suffered second- and third-degree burns but survived.

In later months, other steam blasts of much lesser intensity occurred, but there were none with important consequences until 9 months later, when the cycle mentioned earlier repeated itself. In June, 1949, 9 months after the initial outburst, Hibok-Hibok again produced a number of steam-blast eruptions. They were of relatively weak intensity, however, and produced no profound effects in the vicinity of the crater. The direction of localized lateral effect of these blasts was almost due east, or about 30 degrees south of the 1948 direction. The shift may have been due to the earlier formation of an enormous black lava flow (Kanangkaan Flow) along the latter direction which may have strengthened that portion of the crater that fed the flow and produced a change of configuration at the crater that directed the new blasts in a more easterly direction.

The steam blasts corresponding to the 1950 cycle occurred in September. These blasts produced effects similar to those of 1948. There were the same directional arrangement of felled trees, the searing of vegetation, and the deposition of an appreciable ash layer inside the affected area. As in 1949, there was again a shifting of the direction of localized destruction. The devastated area was a section north of the crater, or a shift of about 45 degrees to the north of the 1948 direction. The shift was a logical one since it was the direction of easiest relief after the other portions of the Hibok-Hibok crater, away from the crest of Mount Catarman, had been bolstered by extrusions.

Up to the time of the 1950 steam blasts, the temperatures involved must have been quite low, at least not much above that which could cause the ignition of dry inflammable materials. The unfortunate victims claimed by the steam blast of September 15, 1950, died of extensive burns or asphyxiation, but their clothing did not catch fire nor did the nipa and bamboo houses within the devastated area.

The steam blasts of the 1951 cycle exceeded those of former cycles in intensity and destructiveness. Without attendant tremors or unusual crateral activity, the steam blast that caused more extensive property damage and exacted a toll of about 500 lives came during the morning of December 4, 1951 (Fig. 3). The temperature involved was much higher than in previous blasts. Trees were blown down and charred on their exposed sides, houses enveloped in the eruption cloud burst into flames, persons caught were mummified, and the thick ash layer laid down was unbearably hot below its surface even a few days later. An idea of the force of the blast may be obtained from the fact that a coconut tree 10 inches in diameter was wrapped U-shaped around a mango tree 18 inches in diameter, about 3 miles from the crater. A hill on the direct line of the blast was swept bare of vegetation and covered by a thick layer of ash, and coconut trees were blown away and piled up like match sticks at the leeward side of the hill. Furthermore, the alignment of the felled trees, the apparent ineffectiveness of topography to localize effects, and the impact pits of airborne boulders found miles away from the crater all attest to the fact that there was an explosion of considerable magnitude. The eruption cloud was visible for

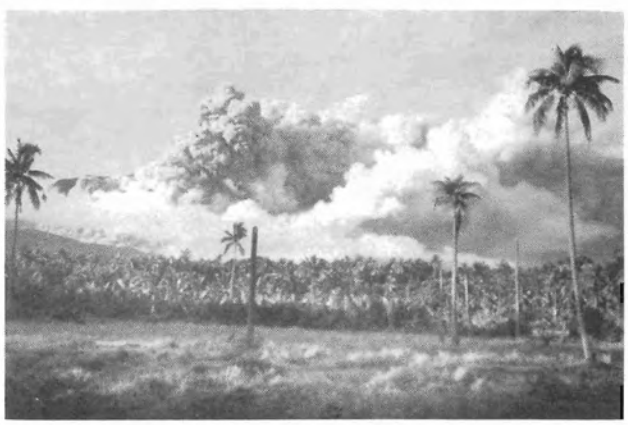

FIGURE 3. Steam blast of December 4, 1951, looking toward the southwestern outskirts of Mambajao. Photo by Hibok-Hibok Studio.

about 100 miles and, according to eye-witnesses, was remarkably like the explosion cloud of atomic bombs.

(To be continued in Volcano Letter 517)

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR APRIL–JUNE, 1952

By GORDON A. MACDONALD

VOLCANOLOGY

April

The big swarm of earthquakes that started in mid-March came essentially to an end about April 20. During the period from March 13 to April 30 seismographs of the Hawaiian Volcano Observatory recorded 4,553 earthquakes. Most of them were caused by movement along a line lying south of the southeast shore of the island of Hawaii, from approximately 15 miles south of Kalapana to 11 miles southeast of Punaluu. (See Volcano Letter 515.)

Early in April a series of earthquakes commenced on the east rift of Kilauea volcano, from the caldera to a point about 8 miles southwest of Pahoa. This activity was accompanied by northward tilting of the ground at the northeast edge of the caldera, indicating a small increase of pressure beneath Kilauea. At the close of the month the uneasiness of Kilauea volcano appears to have subsided, although occasional earthquakes were still occurring both on Kilauea and off the south shore of the island.

Mauna Loa remained quiet throughout April.

May

Seismographs operated by the Hawaiian Volcano Observatory at Kilauea Caldera recorded 157 local earthquakes during May. This was a great decrease in number as compared to the 3,366 quakes recorded in March and 928 recorded in April, but it was still nearly five times the number recorded during a normal month without volcanic activity.

A few earthquakes continued to originate in the region south of the island of Hawaii, from which came a large majority of the quakes during March and April. Many small earthquakes originated at shallow depths in the vicinity of Kilauea Caldera and along the east rift zone of Kilauea near the caldera. Others, including one felt strongly at Kapapala and Naalehu on May 21, originated on the Kaoiki fault, which lies along the lower slope of Mauna Loa between Kilauea Caldera and Pahala.

Several small- to moderate-sized earthquakes originated approximately along the line connecting the summit of Mauna Loa with the submarine volcanic mountain 10 miles south of Puu Kapukapu, near the south shore of the island. That line coincides with a minor rift zone of Mauna Loa that erupted in prehistoric times but has had no historic eruptions.

The strong earthquake at 12:12 on May 23 originated on the Kealakekua fault near Napoopoo, apparently close to the place of origin of the big quake of August 21, 1951. (See Volcano Letter 513.) It was felt all over the island of Hawaii and by some persons on the island of Maui. Damage in the central Kona area included dishes, groceries, and bottles of liquor knocked from shelves, cracks in pavements, slides from roadcuts, some water tanks damaged, some windows broken, and tombstones overturned. The intensity near the epicenter was 6 in the modified Mercalli scale. The breaking of dishes extended as far as Naalehu, where the intensity was 5.

During May there was a small accumulation of northeastward ground tilting at the Whitney Laboratory of Seismology, at the northeast edge of Kilauea Caldera. The reversal from southwestward to northeastward tilting, which occurs every year in the late spring, was somewhat earlier than usual. This probably resulted from a small increase of volcanic pressure beneath Kilauea and possibly also beneath Mauna Loa.

At the end of May both volcanoes were uneasy, but as yet there was no recognized indication of eruption coming in the near future.

June

Kilauea volcano became active shortly before midnight on June 27. During the early part of June, earthquakes had been considerably more numerous than in normal, quiet times, although much less numerous than during March and early April. Many of the earthquakes originated in Kilauea volcano, but others originated in Mauna Loa and along the Kaoiki fault, and a few continued to come from the zone off the south shore of the island. The Kilauea earthquakes all were of shallow origin. Ground tilting at the northeast rim of Kilauea Caldera was weakly northward from mid-May to mid-June, at about the rate normal for that season of the year. At Uwekahuna, on the west rim of the caldera, there was weak northwestward tilting. There was an accumulation of 1.4 seconds of northward tilting at the northeast rim of the caldera between June 21 and 27. Although fairly rapid, that tilting was not greater either in amount or in rate than several similar spasms of tilting during the past several years. For the past 2 months Kilauea had been recognized to be uneasy, but during mid-June there was no indication that it was more uneasy than it had been for some time, or that it was more uneasy than Mauna Loa. No pattern of earthquake foci commencing at a depth of 20 miles or more and gradually approaching the surface, such as has been observed preceding other eruptions, was recognized, nor was there any abnormal amount of tilting. Beyond a general uneasiness of the volcano, the eruption came unheralded.

The eruption began at approximately 23:39 on June 27, with a rush of gas from a newly opened fissure extending in a northeast-southwest direction entirely across the floor of Halemaumau crater. During the first few hours, the lava fountains formed a continuous "curtain of fire" 2,700 feet long, along the opened fissure. The largest fountain was at the southwest end of the chain. At 23:50 the top of this fountain was visible above the rim of Halemaumau from the Volcano Observatory at Uwekahuna. It must then have been more than 700 feet high. Clouds of choking sulphur dioxide fume and a dense fall of pumice covered the southern portion of Kilauea Caldera.

About eight million cubic yards of lava were released during the first 6 hours of the eruption. By daylight on June 28 the new lava fill in Halemaumau was about 50 feet deep, and all signs of former features on the crater floor, including the remnants of the cones of the 1931 and 1934 eruptions, were deeply buried. After that the rate of lava extrusion greatly decreased, but extrusion continued at a rate approximating one million cubic yards a day through the rest of June and July.

The eruption will be described in detail in a future number of the Volcano Letter.

SEISMOLOGY

Teleseisms

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori horizontal or Sprengnether vertical seismograms, in Hawaiian Standard time.

Local Earthquakes

The data for the following local disturbances were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. In this and the previous issue of the Volcano Letter, geographical coordinates are given for some earthquakes to a tenth of a minute, but it is not intended to imply that degree of accuracy in the location. The probable error of location for those quakes is 1 to 2 minutes. The times given are arrival times at the Whitney Laboratory of Seismology on the northeast rim of Kilauea Caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

1428–1886. April 1–May 31. Earthquakes mostly originating off the south shore of the island and mostly very feeble to slight. Moderate and strong earthquakes of this group and earthquakes of other origin are listed separately below.

1529. April 3, 05 : 09, feeble. Kaoiki fault near Ohaikea.
1531. April 3, 06 : 23, very feeble. Kilauea, east rift.
1532. April 3, 06 : 27, very feeble. Kilauea, east rift.
1547. April 4, 11 : 09, slight. Kilauea, east rift near Napau crater.
1548. April 4, 11 : 19, feeble. Kilauea, east rift near Napau crater.
1554. April 4, 16 : 08, feeble. Kilauea Caldera, shallow.
1555. April 4, 20 : 08, feeble. Hilina fault zone, about 1.8 miles N 10° W of Ka Lae a Puki, shallow.
1569. April 5, 11 : 23, moderate. Kilauea, east rift near Makaopuhi, about 13 miles deep.
1571. April 5, 14 : 16, moderate. Off south shore of Hawaii.
1587. April 5, 21 : 04, moderate. Kilauea, east rift near Napau crater.
1596. April 6, 03 : 44, slight. Kilauea, east rift near Napau crater.
1597. April 6, 04 : 06, feeble. Kilauea, east rift about 1.5 miles west of Kalalua crater.
1612. April 6, 15 : 10, moderate. Off south shore of Hawaii.
1623. April 6, 20 : 53, slight. Kilauea Caldera, shallow.
1631. April 6, 22 : 58, strong. Kilauea Caldera, shallow. Felt generally in Volcano district.
1639. April 7, 01 : 31, feeble. Kilauea Caldera, shallow.
1640. April 7, 01 : 54, feeble. Kilauea, east rift about 1 mile east of Makaopuhi crater.
1645. April 7, 03 : 59, slight. Kilauea Caldera, shallow.
1653. April 7, 06 : 05, moderate. Kilauea, east rift near Puu Huluhulu, shallow.
1656. April 7, 06 : 44, slight. Kilauea Caldera, shallow.
1668. April 7, 12 : 15, very feeble. Kilauea, east rift near Alae crater.
1669. April 7, 12 : 53, strong. Kilauea, east rift near Makaopuhi crater, about 12 miles deep. Felt from Naalehu to Volcano.
1670. April 7, 13 : 00, moderate. Off south shore of Hawaii.
1671. April 7, 23 : 55, moderate. Kilauea, east rift near Alae crater, about 7 miles deep.
1701. April 10, 16 : 56, moderate. Hilina fault zone at Poliokeawe Pali, 3.5 miles N 45° W of Kaena Point. Felt at Naalehu.
1703. April 10, 22 : 52, slight (Mauna Loa, moderate). Deep (20 miles?) beneath the SW rift of Mauna Loa near the 9,200-foot contour. Felt strongly from Naalehu to Volcano, moderately at Hilo, and slightly as far as Paauhau and Kukuihaele.
1705. April 11, 07 : 34, feeble. Kilauea, east rift near Makaopuhi.
1711. April 12, 01 : 29, feeble. Kilauea, east rift about 2 miles east of Napau crater, shallow.
1715. April 12, 05 : 53, strong. Kilauea, east rift, 1 mile NW of Heake crater, about 13 miles deep. Felt at Naalehu and Kapapala.
1716. April 12, 06 : 22, moderate. Off south shore of Hawaii.
1719. April 12, 16 : 55, very feeble. Kilauea, east rift near Puhimau crater.
1721. April 12, 19 : 40, slight. Kilauea, east rift near Puu Huluhulu. Felt in Volcano district.
1726. April 13, 12 : 29, feeble. Kilauea, east rift near Puhimau crater.
1729. April 13, 21 : 04, very feeble. Kilauea, east rift about 2 miles east of Kalalua crater, shallow.
1734. April 14, 08 : 37, slight. Kilauea, east rift about 2 miles east of Kalalua crater, shallow.
1736. April 14, 12 : 25, very feeble. Kilauea, east rift near Kalalua crater.
1737. April 14, 16 : 56, very feeble. Kilauea, east rift near Kalalua crater.
1739. April 15, 07 : 51, feeble. East rift of Mauna Loa, shallow.
1745. April 15, 17 : 56, slight. Kilauea, 2 miles WSW of Puu Ohale, about 6 miles deep.
1746. April 15, 17 : 59, slight. Kilauea, 3 miles WSW of Puu Ohale, about 5 miles deep.
1750. April 16, 00 : 58, feeble. Kilauea, east rift near Makaopuhi crater.
1752. April 16, 07 : 08, moderate. Off south shore of Hawaii.
1780. April 21, 17 : 45, moderate. Off south shore of Hawaii, 16 miles S 10° W of Apua Point.
1813. May 3, 18 : 16, moderate. Off south shore, at 19° 12.5′ N, 155° 20.8′ W.
1816. May 6, 06 : 35, feeble. Off south shore, at 19° 09.2′ N, 155° 19.3′ W. Felt at Kapapala.
1830. May 10, 19 : 14, strong. Kilauea Caldera, about 7 miles deep.
1839. May 13, 22 : 50, slight. Southeast slope of Mauna Loa.
1842. May 15, 04 : 10, feeble. Hilina fault system, at 19° 18.4′ N, 155° 09.7′ W.
1849. May 19, 01 : 16, slight. Off south shore, at 19° 02.7′ N, 155° 07.2′ W.
1851. May 19, 04 : 08, slight. Southeast slope of Mauna Loa, at 19° 20.2′ N, 155° 28.9′ W.
1856. May 21, 17 : 13, moderate. Southeast slope of Mauna Loa, at 19° 18.1′ N, 155° 28.3′ W.

1863. May 23, 12:13, strong. Kealakekua fault, about 3.5 miles west of Napoopoo, central Kona, about 6 miles deep. Coordinates: 19° 29′ N, 155° 59′ W. Magnitude 6 assigned at Pasadena, California. Felt all over the island of Hawaii and on the island of Maui. Minor damage in central Kona.
1866. May 24, 03:32, feeble. Kilauea Caldera, shallow.
1882. May 29, 13:20, feeble. Kilauea Caldera, shallow.
1883. May 31, 05:00, very feeble. Off south shore, at 19° 02.4′ N, 155° 20.7′ W.
1884. May 31, 06:52, feeble. Southeast slope of Mauna Loa, at 19° 19.7′ N, 155° 25.9′ W.
1888. June 1, 01:05, moderate. About 4 miles NNE of Whitney Laboratory.
1895. June 3, 21:12, slight. About 4 miles NNE of Whitney Laboratory, on hypothetical extension of Kaoiki fault. Felt in Volcano district.
1919. June 10, 16:25, slight. Summit of Mauna Loa, shallow. Felt at Kapapala.
1920–1923. June 11, very feeble. Kilauea Caldera, shallow.
1924. June 11, 08:01, slight. Off south shore, at 19° 00.7′ N, 155° 16.3′ W.
1925. June 11, 08:12, feeble. Kilauea Caldera (?).
1931. June 13, 06:57, slight. About 4 miles NE of Whitney Laboratory. Felt in Volcano district.
1939. June 14, 10:44, slight. Kilauea Caldera, shallow. Felt in Volcano district.
1953. June 17, 16:37, very feeble. East slope of Mauna Loa.
1954. June 18, 05:17, slight. Off south shore, at 19° 02.1′ N, 155° 19.8′ W.
1955. June 18, 05:20, feeble. Off south shore.
1957. June 19, 16:03, strong. SW rift of Kilauea about 0.5 mile NE of Mauna Iki, shallow.
1958. June 17, 16:20, slight. SW rift of Kilauea near Ponohohoa.
1959. June 19, 16:27, moderate. Kilauea, SW rift near Kamakaia Hills.
1960–2024. June 19–26. Very feeble quakes, nearly all apparently originating in the vicinity of Kilauea Caldera at very small depths.
2025. June 26, 07:53, very feeble. Near summit of Mauna Loa.
2026. June 26, 17:23, very feeble. Near Kapapala, shallow, probably on Kaoiki fault. Felt strongly at Kapapala.
2027–2047. June 26–27. Very feeble earthquakes, apparently originating in the vicinity of Kilauea Caldera at very small depths. Continuous volcanic tremor started at approximately 23:37:30 on June 27, at about the time glow was first observed at Halemaumau, and appears to mark the beginning of eruption.
2048. June 27, 23:39, very feeble. Kilauea Caldera.
2049. June 27, 23:49, very feeble. Kilauea Caldera.
2050. June 27, 23:51, very feeble. Kilauea Caldera.
2051. June 27, 23:58, slight. Kilauea Caldera.
2052. June 28, 00:20, very feeble.
2053. June 28, 00:31, very feeble.
2054. June 28, 00:47, moderate. Kilauea Caldera.
2055–2063. June 28–30. Very feeble and feeble earthquakes accompanying the eruption of Kilauea volcano.

VOLCANO NOTES AND NEWS

DIDICAS VOLCANO

During March, 1952, a passing ship reported submarine volcanic activity at Didicas Rocks, about 38 miles north of Cape Engano on northern Luzon in the Philippine Islands. Previous activity during 1856 and 1857 had resulted in the formation of a cone about 700 feet high, but the cone had been almost completely destroyed by wave erosion previous to the current eruption.

The *Manila Bulletin* for June 20, 1952, states that on March 20 the new cone was about 200 feet high. On June 17 observers were flown over the volcano in a U. S. Navy plane. The cone was then about 3,000 by 4,800 feet across and 800 feet high. At the summit of the cone the principal crater was about 0.25 mile in diameter, and a new crater had opened on the southwest flank of the cone. The column of white cloud from the volcano was visible 70 miles away.

The explosive phase of the eruption appeared to be vulcanian in character. Angular rock fragments ejected from the crater fell on the outer slopes of the cone and rolled down them, accompanied by clouds of yellowish dust. Large chunks of black material, apparently solidified lava, were observed to be perched unstably on the crater rim, occasionally falling down the outer slope or back into the crater. Ash from the volcano was falling on Calayan Island, 25 miles to the north, but not in sufficient quantity to cause damage. Photographs suggest that the structure may be a domical protrusion, with craters blasted in it by explosion and its flanks mantled with pyroclastic debris.

ALEUTIAN VOLCANOES

Austin E. Jones, seismologist in charge of the Geological Survey's observatory on Adak Island, has supplied the following notes on the activity of Aleutian volcanoes during 1951.

Gareloi, which was weakly active during 1950, was quieter during 1951. At Kanaga volcano, light wisps of steam were noted on quiet, probably humid days. At Great Sitkin a steam column, 1,000 to 2,000 feet high at times, was reported, but no ash was observed. Korovin volcano was steaming in November, 1951. G. R. MacCarthy reported a large, dense column of mingled dark fume and steam at Cleveland volcano on November 1. The volcano was also reported smoking during December. Lieutenant Sinclair, of the ship TAKL 36, reported running through muddy water for 2 miles 3.7 miles off the island of Bogoslof on September 21. G. R. MacCarthy visited Bogoslof early in November and reported that there were no signs of activity for many years past. An officer of one of the TAKL ships reported that Pogromni volcano was not active on July 2, but that it was smoking on July 5 to 7.

In July, Shishaldin volcano was reported "throwing fire and glowing." In September and probably during early October, glow was seen from ships, but on October 15 A. E. Jones could distinguish no activity from a plane passing 50 miles to the north. On October 15, a column of steam half as high as the cone stood above the crater of Frosty volcano.

Pavlof volcano was reported to be in minor explosive activity during August, 1950, the activity culminating in November and

continuing through the winter. R. D. Jones, of the Fish and Wildlife Service, saw it active on January 15, 1951. On April 1, it was reported in rhythmic explosive activity, but in mid-May R. D. Jones found it quiet and reported it as quiet until late fall. In October, fresh ash was reported on the north slope, and later R. D. Jones reported that on November 13 a sudden small explosion was seen, and it continued active through the rest of the winter.

On August 9, A. E. Jones saw the volcanoes from Pavlof to Douglas, and, although an ash fall near Katmai had been reported a few days before, he could see no signs of activity.

CATALOGUE OF VOLCANOES

Catalogue of the Active Volcanoes of Indonesia, by Dr. M. Neumann van Padang, is Part I of the *Catalogue of the Active Volcanoes of the World, including Solfatara Fields*. Published in 1951 by the International Volcanological Association, part of the cost of printing was borne by a grant-in-aid from UNESCO. It is available from Professor Francesco Signore, General Secretary of the Association, Via Tasso 199, Napoli, Italy, for the price of $5.00 (U. S.).

The project of a catalogue of the active and recently active volcanoes of the earth was initiated at the first meeting of the Association in 1922. Its execution has been long delayed for various reasons, not the least of which is the difficulty of editing in multiple languages. The decade of turmoil accompanying World War II necessitated temporary abandonment of the project. Dr. B. G. Escher, president of the Association for the period 1948–1951, deserves sincere congratulations for having successfully revivified the project so soon after the end of the war.

The volcanoes of the world have been divided geographically into 19 principal groups, which are delineated on the map accompanying *Catalogue of Active Volcanoes of the World*, by W. Q. Kennedy and J. E. Richey, issued in 1947 as a supplement to *Bulletin Volcanologique*, series 2, volume 7. The Indonesian volcanoes constitute group 6. Within the group are nine subgroups, and within each subgroup each volcano is assigned a number. Thus the volcanoes of Java are subgroup 3, and the serial number 6, 3–25 represents the volcano Merapi on Java.

Part I of the Catalogue contains 271 pages. The description of each volcano includes its name, location, and height; a short description of the form and structure of the volcano; a list of known eruptions, made compact by the use of standard symbols to describe the activity; a description of the rock types comprising the volcano and a table of chemical analyses when available; and a brief bibliography of the principal literature dealing with the volcano. Maps of the entire region and the subregions are given, as well as black and white maps, cross sections, and sketches of many of the individual volcanoes. Some of the individual maps are less distinct than could be desired, because of direct reproduction from earlier publications, without redrawing. Even so, they are of great aid in following the text, and their large number is highly commendable.

The publication will undoubtedly prove of great value as a reference work, and the author deserves the gratitude of the volcanological profession for having undertaken and accomplished the enormous task of compilation represented by it. It is sincerely hoped that additional sections of the Catalogue will appear in the near future.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
LaVieve G. Forbes, Secretary, part-time

Seismograph Station Operators:

Hilo Station:

Sister M. Thecla, St. Joseph's School

Kona Station:

Howard M. Tatsuno, Konawaena School

University of Hawaii:

T. A. Jaggar, Geophysicist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE VOLCANO LETTER

No. 517 **U. S. Geological Survey** **July–September, 1952**

HIBOK-HIBOK VOLCANO, PHILIPPINE ISLANDS, AND ITS ACTIVITY SINCE 1948

By ARTURO ALCARAZ, LEOPOLDO F. ABAD, and JOSE C. QUEMA[1]

PART II

Glowing Clouds (nuées ardentes). Glowing clouds made up of highly heated ash, volcanic breccia, and gases have been observed at various times during the present activity of Hibok-Hibok. Three types may be distinguished: (1) small clouds of hot ash and dust, (2) "nuées ardentes d'avalanche," and (3) Lacroix's (1930) "nuées ardentes d'explosion vulcaniennes."

The "small clouds of hot ash and dust" are not really in the nuée ardente class, but they are considered here as a type so as to cover all sorts of volcanic clouds observed. They are produced when extruded lava blocks break off and fall or roll down and, darting and bounding on the steep slopes of the volcanic cone, stir up the deposited ash and other comminuted debris along their paths. This type is often observed during phase 3 of the Hibok-Hibok cycle of activity.

When, however, a large volume of material comes down from the cone, as when an unstable section gives way, an avalanche is started and a "nuée ardente d'avalanche" results. Van Bemmelen's (1949) description of this type of glowing cloud as observed in eruptions of some Indonesian volcanoes fits quite well that observed at Hibok-Hibok. According to him, such a "nuée ardente" consists of a heavy fraction of incandescent debris and an accompanying lighter fraction of hot air, volcanic gases, sand, and dust, whirling upward. The former follows depressions and gullies on the flank of the volcano, while the latter may override bounding elevations and spread over the adjacent terrain. Such most likely was what happened on September 15, 1950, during the eruptive phase of Hibok-Hibok.

The barrio of Ilihan, where the volcano claimed most of its victims in 1950, is situated at a rise fronting the mouth of a ravine on the north-northeastern slope of Hibok-Hibok. The "nuée ardente d'avalanche" followed the ravine and, upon reaching a bend, spilled over the rise and into Ilihan with still sufficient force to uproot coconut and abaca trees. Inspection of the devastated area revealed farm animals strewn around stiff in death, half-buried in volcanic dust. The houses stood defiant with their gay printed curtains and festive buntings fluttering in the breeze. The 2-inch accumulations of ash on the floor and around the yards showed the suffocating atmosphere that asphyxiated and burned so many victims. Vegetation was seared brown. The dried grasses lay flat, as if a giant roller had passed over them. Abaca and some coconut trees were blown down away from the volcano. The directional pattern of the fallen trees, the flattened grasses, and some wrecked houses strongly suggest a sudden violent blast from the direction of the volcano. And yet 50 yards downstream the grass was

FIGURE 4. Hibok-Hibok crater, looking northwest from the southern part of the island.

[1] Geophysicist, Weather Bureau; Mining Engineer, Bureau of Mines; and Geologist, Bureau of Mines, respectively. Published by permission of the Committee on Volcanology, Department of Agriculture and Natural Resources, Philippine Islands.

green, and the trees were not turned brown by heat. Chickens were scratching the ground for worms in the yard of an empty house!

At Hibok-Hibok the "nuées ardentes d'avalanche" would be most likely to occur when the cone would have built up the maximum talus, and such a condition is perhaps attained during phase 4 of the cycle of activity.

When the activity of the volcano reaches what may be termed the main or gas phase (phase 2 in the Hibok-Hibok cycle), an explosion may produce a glowing cloud that has been described as "nuée ardente d'explosion vulcanienne." This type of glowing cloud differs from "nuée ardent d'avalanche" in that it is accompanied by an upward-rising cauliflower cloud of volcanic ash and travels along the slopes and across small topographic rises with tremendous speed. The December 4, 1951, blast produced such a "nuée ardente d'explosion vulcanienne," to which can be attributed the high toll in human lives exacted by the volcano that day.

The felled coconut trees showed a radial pattern away from the volcano, indicating that the direct blast from the volcano was the active force that leveled the trees. However, on the floor of Mabini Valley (southwest of Mambajao), the axis of which lies at an angle of about 20 degrees from the direction of the crater, the trees were felled along the axis of the devastated valley (Fig. 5). The force of the blast that felled these trees must have moved along the valley axis. This inference was supported by the distribution of ash accumulations inside the valley which were thicker along the valley floor.

The writers see in the "nuée ardente d'explosion vulcanienne" produced by the steam blast of December 4, 1951, the active cause of the seemingly unrelated destructive effects observed in the devastated area. It was the dense, boiling, heavily charged, ash-laden glowing cloud that people of Mambajao witnessed developing rapidly from the volcano that fateful morning at the same time that a cauliflower-shaped cloud was seen over Camiguin Island by distant witnesses. It was the same glowing cloud that charred and mummified its victims, set fire to combustible materials along its path, felled coconut and other trees, and deposited a thick layer of incandescent ash that remained unbearably hot below its surface for days after.

FIGURE 5. Coconut trees blown down parallel to the axis of Mabini Valley by the blast of December, 1951.

At an early morning hour on December 6, 41 hours after the foregoing blast, a series of explosions rent the crater area of Hibok-Hibok and lighted up the volcano vicinity. The detonations were audible at Mambajao. With the emission of incandescent materials, a dense, dark eruption cloud formed about the volcano, made more awesome by strong electrical discharges about and within it. Almost immediately it was noted that a section from the volcano almost extending to the sea and about a kilometer or so north of Mambajao was aglow. Examination of the affected area revealed that the glow came from a very thick flow of incandescent ash and pumiceous rock boulders which had set fire to combustibles along its path. Three more victims, who remained in the danger zone in spite of warnings, were added to the number who perished on December 4.

Block Lava Flows. After the initial steam blast of September, 1948, an apparently inexhaustible amount of rock material was observed being extruded from Hibok-Hibok. This material broke off from the crater area and, coming down the volcano slope, broke further into smaller pieces as it hit protruding points or other obstacles along its descent. Nighttime observations showed the extrusives to be red-hot, and, when large fragments broke up, the fresh surfaces glowed brighter, evincing higher temperature.

The new extrusives consisted chiefly of blocky, grayish, porphyritic andesites with numerous feldspar and ferromagnesian phenocrysts. Xenoliths of the older formations traversed by the rising magma were very much in evidence in the extruded block lava, especially in those that were emitted during the first days of formation of the flow. They ranged in size from less than an inch to more than a foot in diameter and were at various stages of assimilation by the younger rock. The edges of the andesitic xenoliths were in most instances marked by a profusion of ferromagnesian minerals (predominantly hornblende). In the case of tuffaceous xenoliths, there was a tendency to form vugs or cavities, which are generally lined by fairly well-developed crystals.

The top of the flow was made up of loose, large and small, jagged and angular blocks, evidently the product of rupture of a highly viscous, almost solid, effluent magma. Some of the blocks were slightly scoriaceous, and those that may have come in contact with the soil mantle of the cone had a reddish, partly vitreous veneer. In the main, however, the blocks had smooth faces and sharp edges and were unagglutinated. This description is at variance to that of the upper part of the typical flow as observed at Hawaiian and Sicilian volcanoes. The Hibok-Hibok flows are of the type termed block lava by Finch (1933).

The lava flow that formed in 1948 and early 1949 was designated for convenience the Kanangkaan Flow (after a sitio subsequently overridden by the flow) to distinguish it from two smaller ones formed subsequently, after the former had stopped advancing.

Movement day by day, and even hour by hour, of the Kanangkaan Flow was clearly notable during its initial stages. During that period the flow was moving faster than in latter stages, and it was possible to note the forward movement of a particular block on the top of the flow within an hour's observation. Further evidence of

FIGURE 6. Coconut trunk about 10 inches in diameter bent around the trunk of a mango tree by the force of the blast of December, 1951, in Mabini Valley about 1 kilometer west of Mambajao.

motion in the Kanangkaan Flow was furnished by the extension of the flow to over 2 miles from the crater in about 8 months, or an average rate of movement of nearly 65 feet a day. The thick lower portion of the flow has not been accessible to close observation, but, judging from the absence of any notable breakthrough of the inner portion, the writers are of the opinion that, while the lava inside the blocky shell of the flow could have retained much of its original temperature for a long period, its state was closer to being plastic than fluid, and that movement of the flow had been accomplished by shearing of the highly viscous interior over a simultaneously advancing rock mat formed by the breaking and sliding down of blocks at the snout of the flow.

It is estimated that the Kanangkaan Flow in 8 months' time (September, 1948, to April, 1949) attained a volume of 900,000,000 cubic feet, or 40,000,000 tons. After advancing about 3 miles, further forward movement was arrested when the front of the flow encountered a spur of Mount Mambajao that crosses its path. The spur, however, was perhaps not the main or only reason for the halt of its advance. It is likely that the viscosity of the lava and the much gentler slope of the last mile or so had some contributory effect. At any rate, upon cessation of any forward movement of the Kanangkaan Flow, a cone was built up at the crater area whose height was limited to about 200 feet by the maximum talus possible on that part of its base resting on the Kanangkaan Flow. The formation of this cone apparently was due to a change in the direction of easiest relief for the lava that was feeding the flow. The pressure necessary to cause further forward movement of the Kanangkaan Flow undoubtedly became greater than the pressure sufficient to break through the crater end of the flow, and thus relief of the extrusive pressure was effected in the latter.

In June, 1949, a new extrusion of incandescent material from the crater area was observed to take a different direction. This time such activity was toward barrio Itum, and thus the block lava flow that was being formed in that direction was called the Itum Flow. This flow did not attain an appreciable volume or areal extent and, being close to the enormous Kanangkaan Flow, could hardly be noted in aerial maps. The Ilihan Flow, a third block lava flow from the Hibok-Hibok crater area, was formed during the activity of September, 1950. It was small, like the Itum Flow, and nowhere approached the topographic significance of the Kanangkaan Flow. However, after the direction of extrusion shifted toward Ilihan in late 1950, there was a reshifting of the activity toward Itum again in December, 1951, and as a consequence new extrusives are now being added to the 1949 Itum Flow.

Mud Flows or "Lahars." The term "lahar" as used in Indonesia refers to mud flows containing volcanic debris and breccia transported by water. As the term has gained acceptance in scientific circles, its use in this paper was deemed proper, especially since the mud flows in the Hibok-Hibok area bear very close resemblance to those described from Indonesian volcanoes.

At the onset of the Hibok-Hibok activity, danger from lahars to the communities along the drainage channels in the northeast sector of the volcano, especially after heavy rains, was suspected. Subsequent events proved this danger to be real and of definite importance in any safety consideration for the affected area. Approximately 1.5 square miles, mostly of arable land, are now covered by varying thicknesses of volcanic sediments brought down the slopes by rains. The barrio Agoho, once a thriving community, is now abandoned by its inhabitants because of the large accumulation of water-borne sediments that have buried most of the houses in the barrio (Fig. 7).

The first lahar in the Hibok-Hibok area occurred simultaneously with, or immediately after, the initial explosion of September 1, 1948. As far as could be gathered from eye witnesses, there was a wall of mud, water, and debris that came rushing down along the upper course of a water channel draining the northeast sector of Mount Catarman. In the space of a few hours the water was gone, leaving a thick deposit of mud, sand, gravel, boulders, and organic debris along the channel. This flood was noteworthy not only because of its profound effect on the old stream channel, which it widened considerably, but because it posed the question of from where the large volume of water necessary to cause the observed effects of the flow could have come. There was

FIGURE 7. Part of Agoho barrio destroyed by a lahar, as it looked on December 18, 1950.

practically no rain in the Mambajao area during the time of the eruption or for a few days preceding it. It is quite probable that some pond of water at or close to the present crater area was breached, though the existence of such a pond before the eruption could not be ascertained. Water that may have resulted from the condensation of steam released by the blast could have been a contributory source.

Subsequent floods were, more or less, related to rains. After moderate or heavy rains, especially in the vicinity of Mount Catarman, water draining from that area carried down rocks and other detrital materials and deposited them fan-wise on the gentle slopes near the sea coast. At the sea-coast barrio Agoho, the sediments from lahars have reached a depth of over 10 feet in most places, and the coastline has jutted appreciably seaward as a result of the delta being formed by the sediments carried out to sea by the floods. On a few occasions when the lahar formed soon after eruptive phases, the flow was hot and even steaming. There have been no casualties from floods, as the people living close to the channel ways were repeatedly warned of such dangers.

SUMMARIZING STATEMENTS

The continued activity of the stratovolcano Hibok-Hibok since 1948 is characterized by paroxysmal periods, each period being a part of a certain discernible cycle of behavior and featuring steam blasts that commonly produce "nuées ardentes d'explosion vulcanienne." This is the most dangerous type of glowing cloud and is capable of widespread destruction of life and property.

Glowing clouds caused by small rock slides and avalanches have not been particularly destructive unless channeled by favorable topography or given further impetus in inhabited areas by wind currents.

Precursory seismic activity was most pronounced before the initial crateral outburst in 1948 but was wanting or inappreciable in later paroxysmal periods. This observation seems to indicate that not too much reliance should be placed on seismic activity to presage further paroxysmal periods, if any, of Mount Hibok-Hibok.

Cold and hot mud flows, or lahars, have formed, especially after heavy rains, and have presented another source of danger to the inhabitants living along the drainage channels in the north and northeast sectors of the volcano.

The formation of block lava flows is another characteristic feature of Hibok-Hibok activity. The destructive effects on the arable land overrun by these lava flows present a sociological and economic problem to the people who thereby lose their agricultural means of livelihood.

The scientific investigation of the volcano is directed toward minimizing the destructive effects of subsequent eruptions on property and human lives. Therefore, the economic and social effects of the volcano's activity on the people within the area of devastation and danger are of national concern. These people should be rehabilitated and given opportunities to start anew in places removed from volcanic dangers. To remain within the danger zone of an active volcano is to live on borrowed time.

ACKNOWLEDGMENTS

The writers are deeply grateful to many persons who in one way or another have helped them in the course of their field investigations. However, to Father Arthur F. Shea, S.J., former parish priest of Mambajao, mere acknowledgment seems inadequate as he was not only most helpful in furnishing valuable observations of the volcano's activity but was a constant companion of the writers in the field. Thanks are due Eugenio Omahoy, Weather Bureau observer at Camiguin Island, for his field assistance and continued observation of Hibok-Hibok.

To Dr. Casimiro del Rosario, Director of the Weather Bureau, Dr. Mateo H. Tupas, and Juan S. Teves, senior geologists of the Bureau of Mines, and the members of the Committee on Volcanology, the writers are also indebted for helpful advice.

Field investigation of the Hibok-Hibok activity of December, 1951, was made possible by funds granted by the Committee on Volcanology for that purpose.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY–SEPTEMBER, 1952

By GORDON A. MACDONALD

VOLCANOLOGY

July

The eruption of Kilauea volcano that began on the evening of June 27 continued through July, August, and September. A fuller account of the eruption will appear in the next issue of the Volcano Letter.

During early July a large fountain was active near the southwest edge of the crater, reaching its climax in size on July 3 and 4, when some bursts reached a height of 600 feet. This fountain alternated in activity with a sinkhole at the same locality into which poured a stream of lava that moved across the crater floor from the central fountains.

Fountains near the northeast edge of the crater floor continued active until July 5, building small spatter cones which later in the month were gradually obliterated, partly by collapse and partly by burial with new lava. A chain of small fountains, containing as many as 20 individual jets, extended across the southwest portion of the crater floor during the first 2 weeks of the eruption. About July 11 the activity of this fountain chain became restricted largely to the central portion of the crater, where two principal fountains began building a large spatter cone that still remains a conspicuous feature on the crater floor. The highest of the cone segments stands about 50 feet above the central pool of lava.

A circulating lake of lava developed around the central fountains. Rivers of lava issued through gaps in the central cone and spread through the lake. Where these spreading lava currents met, and along the edges of the lake, the current plunged downward. The down-plunging current carried with it fragments of the crust, and small temporary lava fountains formed where the crust was pulled under. Around the edges of the lake the spattering of these small fountains built up a wall as much as 15 feet high which confined the liquid lake lava at an elevation several feet above the surrounding black bench of solidified lava. Occasionally, the wall broke down locally and allowed a stream of molten lava to spread over the black bench.

August

Early in August the activity remained much as it had been in late July. Two large fountains played in coalescing craters in a central cinder cone about 50 feet high. The height of the fountains averaged about 40 feet, but occasional bursts reached heights of 400 feet and, rarely, as much as 550 feet. Four rivers of lava poured through gaps in the cone walls on the northeast, east, south, and west sides and fed an active lava lake with an area of about 34 acres.

On August 9 the south lava river became blocked, and the north and northeast rivers increased greatly in volume, plunging over spectacular cascades as much as 20 feet high. On August 11 the south river became re-established, and the east river was blocked by a partial collapse of the cone. By August 12 the east river was flowing again, but the northeast river had in turn been choked off. On August 13 the west and south rivers became active. These changes accompanied a gradual cooling and apparent increasing stickiness of the lava. Cessation of the south river was followed by draining of the southern portion of the lava lake, leaving a broad irregular-floored basin about 20 feet deep. On August 18 the south river again overflowed the cone wall, and new lava refilled the basin left by the earlier drainage.

Late on the evening of August 18 the northernmost of the two fountains died down greatly and by midnight it showed no signs of activity. It returned to activity early on August 19 but remained small for several days. By August 22 the height of each fountain averaged about 20 feet, with some showers of glowing fragments reaching as high as 200 feet. On August 23 lava was no longer flowing from the central cone over the surrounding crater floor, and the lava lake surrounding the cone had become inactive. The two fountains were small and sporadic, throwing showers of glowing fragments to heights of about 150 feet. They had built beehive-shaped conelets of spatter around themselves in the twin craters of the large cinder cone, and a lava lake about 120 feet across had formed in the crater of the cinder cone nearly between the two spatter conelets. This condition persisted until the end of the month.

September

From September 1 to 18 both conelets in the crater of the large cinder cone continued active, but the northern conelet was much more active than the southern one. Bursts of glowing lava fragments were thrown into the air to a height of 150 or, rarely, 200 feet. Many of these fragments fell back onto the top and sides of the conelet, gradually building it up to a height of 50 feet, overtopping the wall of the surrounding cinder cone.

Through this period the lava at the surface of the lake flowed slowly from the north to the south edge where it sank, producing fountains 10 to 15 feet high against the south bank.

Throughout the month small lava flows appeared from time to time on the floor of Halemaumau outside the big cinder cone. These welled up quietly, with very small fountains or none at all. On September 4 two of these small flows issued on the floor north and east of the cinder cone. On September 5 another appeared on the floor northwest of the cone and still another at the foot of the west wall of the crater, apparently squeezed up along the fissure between the old crater wall and the mass of new lava filling the bottom of the crater. Small flows issued on the floor southeast of the cone on September 8, northeast of the cone on September 12, at the west wall on September 16, and both northwest and northeast of the cone on September 17.

On September 19 the activity of the two conelets became reversed, with the southern one more active than the northern one. At the same time the movement of lava in the lake also reversed, rising at the south edge, to flow northward, sink, and produce fountains along the north bank. Spatter from the edge fountains and occasional small overflows had built up a low cone around the lake, the surface of which stood about 20 feet higher than the surrounding crater floor.

At 1:45 on the morning of September 20 lava started to spill over the south rim of the lake. This overflow rapidly increased in volume, breaking down the south wall of the lake cone and sending a big flow over the southern part of the floor of Halemaumau. At 10:12 A.M. the north rim of the lake also was overflowed, and a second big flow spread out to coalesce with the first one east of the cinder cone. The northeast overflow lasted only a few hours, but the southern one continued until about midnight. This outpouring of lava was the greatest since August 22.

On September 22 the northern conelet again became dominant, and the circulation in the lava lake reversed, again taking a north-south direction. Explosive activity at the southern conelet ceased entirely, and since then it has been fuming quietly. The north conelet built up to a height of 65 feet, and by September 26 its top was nearly sealed over. On that afternoon, about 4 o'clock, the top and part of the northeast side of the cone suddenly was blown off, and explosions hurled fragments of hot lava 400 feet into the air. The lava lake showed violent agitation, and its level rapidly dropped about 15 feet. Within a few minutes both lake and conelet returned to their normal state of activity, with bursts from the conelet reaching heights of 100 to 150 feet.

About 4:15 P.M. on September 27 molten lava again appeared at the foot of the northwest wall of Halemaumau, and within 2 hours a flow had spread out in both directions along the foot of the wall for a distance of 1,800 feet. By 8:00 P.M., movement in this flow had greatly decreased, but activity at both the north conelet and the lava lake was increasing markedly. At 8:35 P.M. a series of about a dozen violent blasts suddenly commenced at the north conelet, throwing incandescent cinder to a maximum height of 550 feet. The surface of the lava lake surged violently, and, following the explosions, its level gradually dropped about 15 feet, revealing glowing grottoes hung with a fringe of stalactites in the banks. As on the previous day, activity soon returned to normal.

Through the closing days of the month the northern conelet and lava lake continued moderately active, with the southern conelet fuming gently. At night, showers of glowing fragments thrown up from the north conelet could be seen to reach heights of 150 to 200 feet. Tongues of pale yellowish and

bluish flame as much as 25 feet long played above the conelet.

Measurements on September 24 indicated that the average thickness of the fill of new lava in Halemaumau produced by this eruption had reached 288 feet, and the volume of new lava was 58 million cubic yards. In comparison, the volume produced by the 1934 eruption was 9.5 million cubic yards. The average depth of the crater below the visitors' observation area is 482 feet. The rise of the floor of the crater has resulted only partly from flooding by new lava. In part the floor has been elevated bodily, apparently by the injection of new lava into the lower, still-mobile portion of the new fill.

Through the first half of September the ground at the seismograph station beneath the Volcano House tilted eastward at a rate considerably greater than normal for this season of the year. This probably resulted from a doming up of Mauna Loa caused by an increase of volcanic pressure beneath. From September 17 to 30, however, there was no further eastward tilting. Several earthquakes felt in Kona during the month appear to have originated on the Kealakekua fault in central Kona, and may have resulted from readjustments caused by changes in volcanic pressure. A quake felt widely over the southern portion of the island at 4:45 A.M. on September 2 originated in the vicinity of Kilauea crater.

SEISMOLOGY

Earthquake Data, July–September, 1952

(Based on Bosch-Omori seismograph on northeast rim of Kilauea Caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms
July 6	†	1	2	3	2	0	14.5	0

14	†	1	0	0	0	0	0.5	0
21	†	4	0	0	0	0	2.0	0
28	†	4	1	0	0	0	3.0	0

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

† Continuous tremor.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori horizontal or Sprengnether vertical seismograms, in Hawaiian Standard time.

July 21, 01:59, strong. Tehachapi, California.
July 28, 22:19, slight. Southern California (?).
Aug. 20, 05:39, moderate. Off coast of Oregon.
Sept. 9, 03:29, slight. Near coast of Costa Rica.

Local Earthquakes

The data for the following local disturbances were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The times given are arrival times at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea Caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

2064. July 1, 04:16, very feeble.
2065. July 3, 09:05, feeble (Mauna Loa, slight).
2066. July 3, 12:26, feeble (Mauna Loa, slight).
2067–2069. July 5, no record at Kilauea (Kona, very feeble). Central Kona.
2070. July 6, 15:38, very feeble (Hilo, feeble). Felt at Kukuihaele.
2071. July 6, 22:56, feeble. Felt at Kukuihaele.
2072. July 7, 04:43, slight. Felt at Hilo and Kukuihaele.
2073. July 7, 06:16, very feeble.
2074. July 9, 06:54, slight. Felt in Volcano district.
2075–2076. July 9, 08:10, slight. Twin earthquake. Felt at Hilo, Volcano, and Naalehu. Hilina fault system (?).
2077. July 12, 13:53, moderate (Kona, strong). Felt from Kona to Hilo. Origin in central Kona.
2078. July 14, 16:45, tremor (Mauna Loa, very feeble).
2079. July 16, 12:32, feeble.
2080. July 17, 17:44, tremor (Mauna Loa, very feeble).
2081. July 17, 18:14, tremor (Mauna Loa, very feeble).
2082. July 21, 11:49, tremor (Mauna Loa, very feeble).
2083. July 22, 02:46, no record at Kilauea (Kona, very feeble).
2084. July 27, 14:51, no record at Kilauea (Mauna Loa and Hilo, very feeble).
2085. July 29, 01:30, no record at Kilauea (Mauna Loa, very feeble).
2086. July 29, 10:51, no record at Kilauea (Mauna Loa, very feeble).
2087. Aug. 1, 12:33, slight.
2088. Aug. 2, 15:17, no record at Kilauea (Kona, very feeble).
2089. Aug. 2, 16:10, slight.
2090. Aug. 3, 14:49, no record at Kilauea (Kona, very feeble).
2091. Aug. 3, 18:08, no record at Kilauea (Mauna Loa, very feeble).
2092. Aug. 4, 04:00, no record at Kilauea (Kona, very feeble).
2093. Aug. 5, 18:21, tremor (Mauna Loa, very feeble).
2094. Aug. 9, 10:31, feeble (Mauna Loa and Hilo, slight).
2095. Aug. 10, 18:06, no record at Kilauea (Mauna Loa, very feeble). East rift of Mauna Loa.
2096. Aug. 11, 12:21, tremor (Mauna Loa, very feeble).
2097. Aug. 12, 20:16, tremor (Mauna Loa, Hilo, and Kona, very feeble).
2098. Aug. 13, 00:52, tremor (Mauna Loa, feeble).
2099. Aug. 14, 14:08, slight. Felt at Volcano, Kapapala, and Naalehu. Off south shore.
2100. Aug. 16, 21:07, moderate. Off south shore of Hawaii.
2101. Aug. 18, 13:59, slight (Mauna Loa, moderate). Kaoiki fault (?).

2102. Aug. 25, 21 : 20, very feeble.
2103. Aug. 30, 12 : 34, tremor (Mauna Loa, very feeble).
2104. Aug. 31, 05 : 39, very feeble.
2105. Sept. 2, 04 : 45, feeble. Felt at Glenwood, Volcano, Naalehu, Kona. Kilauea Caldera.
2106. Sept. 3, 12 : 47, tremor (Mauna Loa, very feeble).
2107. Sept. 6, 20 : 51, no record at Kilauea (Kona, feeble). Central Kona.
2108. Sept. 8, 02 : 27, no record at Kilauea (Kona, very feeble).
2109. Sept. 9, 20 : 21, no record at Kilauea (Kona, very feeble).
2110. Sept. 10, 07 : 50, no record at Kilauea (Kona, very feeble).
2111–2112. Sept. 12, no record at Kilauea (Kona, very feeble).
2113. Sept. 14, 08 : 11, very feeble. Felt at Kukuihaele.
2114. Sept. 14, 18 : 21, no record at Kilauea (Kona, very feeble).
2115. Sept. 17, 12 : 41, tremor (Kona, feeble). Felt in Kona.
2116. Sept. 18, 14 : 15, tremor (Kona, very feeble).
2117. Sept. 19, 15 : 57, no record at Kilauea (Kona, very feeble).
2118. Sept. 19, 20 : 58, no record at Kilauea (Kona, very feeble). Felt in Kona.
2119. Sept. 20, 06 : 53, no record at Kilauea (Kona, very feeble). Felt in Kona.
2120. Sept. 22, 02 : 23, very feeble.
2121. Sept. 22, 12 : 27, very feeble.
2122. Sept. 24, 11 : 45, no record at Kilauea (Kona, feeble). Felt in Kona. Origin in central Kona.
2123. Sept. 26, 14 : 56, very feeble.
2124. Sept. 27, 07 : 22, tremor (Kona, slight). Felt in Kona. Central Kona, probably Kealakekua fault.
2125. Sept. 27, 20 : 36, very feeble.
2126. Sept. 30, 04 : 10, no record at Kilauea (Kona, very feeble). Felt in Kona.
2127. Sept. 30, 20 : 57, very feeble.

VOLCANO NOTES AND NEWS

RECENT ERUPTION ON SAN BENEDICTO ISLAND, REVILLA GIGEDO GROUP, MEXICO

By HOWEL WILLIAMS

The Revilla Gigedo Islands lie 350 to 600 miles west of the Mexican mainland, approximately on latitude 19°N, in line with the principal chain of volcanoes that includes Orizaba, Popocatepetl, Nevado de Toluca, Paricutin, and Colima. All the islands, with the possible exception of one which may be composed of granite, consist of volcanic rocks. The two easternmost islands, Socorro and San Benedicto, include several volcanoes that have been active during recent geologic time. The last eruption on Socorro took place in 1848, and solfataric activity still continues there.

San Benedicto Island, site of the latest eruptions, is approximately 3 miles long in a north-south direction and ¾ mile in maximum width. The north end consists of the remnants of a group of coalescing cones of scoria, now deeply eroded and craterless. After these cones had become extinct, activity migrated southward to build a cone of white pumice, known as the Ash Heap, to a height of 975 feet. Shortly thereafter a new vent opened in the saddle between the Ash Heap and the old cone cluster. First a pumice cone was built; then a domical mass of columnar lava rose into the crater. Finally, owing to withdrawal of magma in the conduit, the top of the dome subsided to form a conical depression known as Herrera Crater.

The vent of the new volcano lies between those of the Ash Heap and Herrera Crater, on a north-south fissure that continues southward to the vents on Socorro Island. Just when activity began is uncertain but probably during July, 1952. The first eruptions to be reported were on August 12, by which time a large cone had already been formed. News of the activity reached the mainland on August 27. On September 13 Robert S. Dietz and Ruy H. Finch flew to the volcano. It was then about 1,000 feet high and almost a mile across at the base. The intensity of the eruptions had diminished greatly. Every 20 minutes or so, cauliflower clouds of steam and ash rose from the crater, and the odor of sulphuretted hydrogen was strong. On September 20 the volcano was revisited by Dr. Dietz, this time accompanied by the writer. By that time the cone was 1,500 feet high. Discharge of ash had come to an end; instead, lazy puffs of steam, mingled with hydrogen sulphide, rose only a few hundred feet above the crater rim at intervals of a few minutes, and on the floor of the crater was a small biscuit-shaped mass of blocky lava, a miniature plug. Clearly, there had been no further explosive discharge of debris since the plug rose to the surface. Apparently the volcano was approaching extinction; not only was the throat sealed by the plug, but the vapor pressure was reduced to a few atmospheres. By this time, the volcano is probably dead.

The San Benedicto eruption is especially significant as being the first historic pumice eruption in the eastern part of the Pacific Ocean. Proper identification of the nature of the pumice must await detailed microscopic study, but the white color of the ejecta and the refractive index of the glass suggest that the material is either rhyolite or dacite. Almost surely most of the new cone was built during the first few weeks, before it was seen. The first explosions seem to have been of vulcanian type, the ejecta being hurled to great heights by strong gas pressure. Subsequently, as the vapor pressure diminished, the vulcanian explosions grew weaker and were accompanied by explosions that lifted the ejecta only a short distance above the crater rim so that they then swept down the outer flanks of the cone as glowing avalanches. Finally, as the vapor pressure continued to decrease, a mass of stiff, viscous lava slowly rose from the conduit onto the crater floor. Few volcanoes have grown as rapidly; few have had such a short life.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
LaVieve G. Forbes, Secretary, part-time

Seismograph Station Operators:

Hilo Station:

Sister M. Thecla, St. Joseph's School

Kona Station:

Howard M. Tatsuno, Konawaena School

University of Hawaii:

T. A. Jaggar, Geophysicist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcances in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE VOLCANO LETTER

No. 518 **U. S. Geological Survey** **October–December, 1952**

PUBLISHED BY THE UNIVERSITY OF HAWAII

THE 1952 ERUPTION OF KILAUEA

By GORDON A. MACDONALD

OPENING PHASE OF THE ERUPTION

Late in the evening of June 27, 1952, Kilauea Volcano resumed eruptive activity after a quiescence of nearly 18 years. The last previous eruption began on September 6 and ended on October 9, 1934.

The exact time of the outbreak is uncertain, but it appears to have been very close to 11:40 P.M. Continuous volcanic tremor commenced on the Volcano Observatory seismographs at 11:37:30 P.M., and it is probable that molten lava reached the surface within a very few minutes after that. At 11:35 on June 27, Mrs. John R. Fox was awake in the living room of her home on the northeastern rim of Kilauea Caldera, from which there is an excellent view of Halemaumau Crater. She noticed nothing unusual. About 11:40 she entered another room, the window of which was open, and almost immediately heard a loud whistling roar (probably caused by the escape of gas at Halemaumau). Alarmed, she returned immediately to the living room and saw a bright orange glow over Halemaumau.

At approximately 11:40 P.M., Col. B. W. Rushton, Commanding Officer of Kilauea Military Camp, pointed out a bright reddish glow in the direction of Halemaumau to John Forbes of the Volcano Observatory staff. This, Forbes immediately identified as caused by eruption of Kilauea. John and LaVieve Forbes went immediately to the Volcano Observatory at Uwekahuna, where they telephoned me at about 11:45.

At the time the Forbes reached the Observatory, the top of a huge lava fountain was clearly visible above the rim of Halemaumau at its southwestern edge. At the beginning of the eruption the floor of Halemaumau pit was approximately 800 feet below the level of the southwestern rim; therefore, this fountain must have been more than 800 feet high! By the time I reached the Observatory, at about 11:55, the fountain itself was no longer visible, but scattered incandescent fragments still were being thrown above the rim, many of them landing outside the pit and bursting in flashes of red on the caldera floor southwest of Halemaumau.

After picking up the needed equipment, the Forbes' and I, accompanied by Cpl. Gordon Poulson of Kilauea Military Camp, proceeded immediately to Halemaumau by the road around the southwestern edge of the caldera. The fume cloud was so dense that visibility was very limited, and the fall of pumice on the road was so abundant that at times it nearly stopped the forward progress of the car. Some of the pumice blocks were as much as 10 inches across. Choking sulfur fumes were annoying but not serious so long as the car windows were kept closed.

We finally reached the southeastern rim of Halemaumau at 10 minutes past midnight. A continuous line of lava fountains, 2,600 feet in length, was playing along a fissure that extended in a northeast-southwest direction entirely across the floor of Halemaumau Crater and about 50 feet up the northeastern wall (Fig. 1-A). Most of the fountain jets ranged from 50 to 100 feet high, but at the foot of the southwestern wall was a fountain 400 feet high. Showers of liquid ejecta from the big fountain struck the adjacent wall and trickled down it in a fiery cascade. Several minor fountains, a few feet in height, were present also on the northern part of the floor in the vicinity of the 1934 cones (Fig. 1-A). Liquid lava was spreading from them as well as from the fountains along the main fissure and had already covered the entire floor of the crater.

The pool of lava was very fluid, and waves from the fountain chain swept entirely across its surface and up

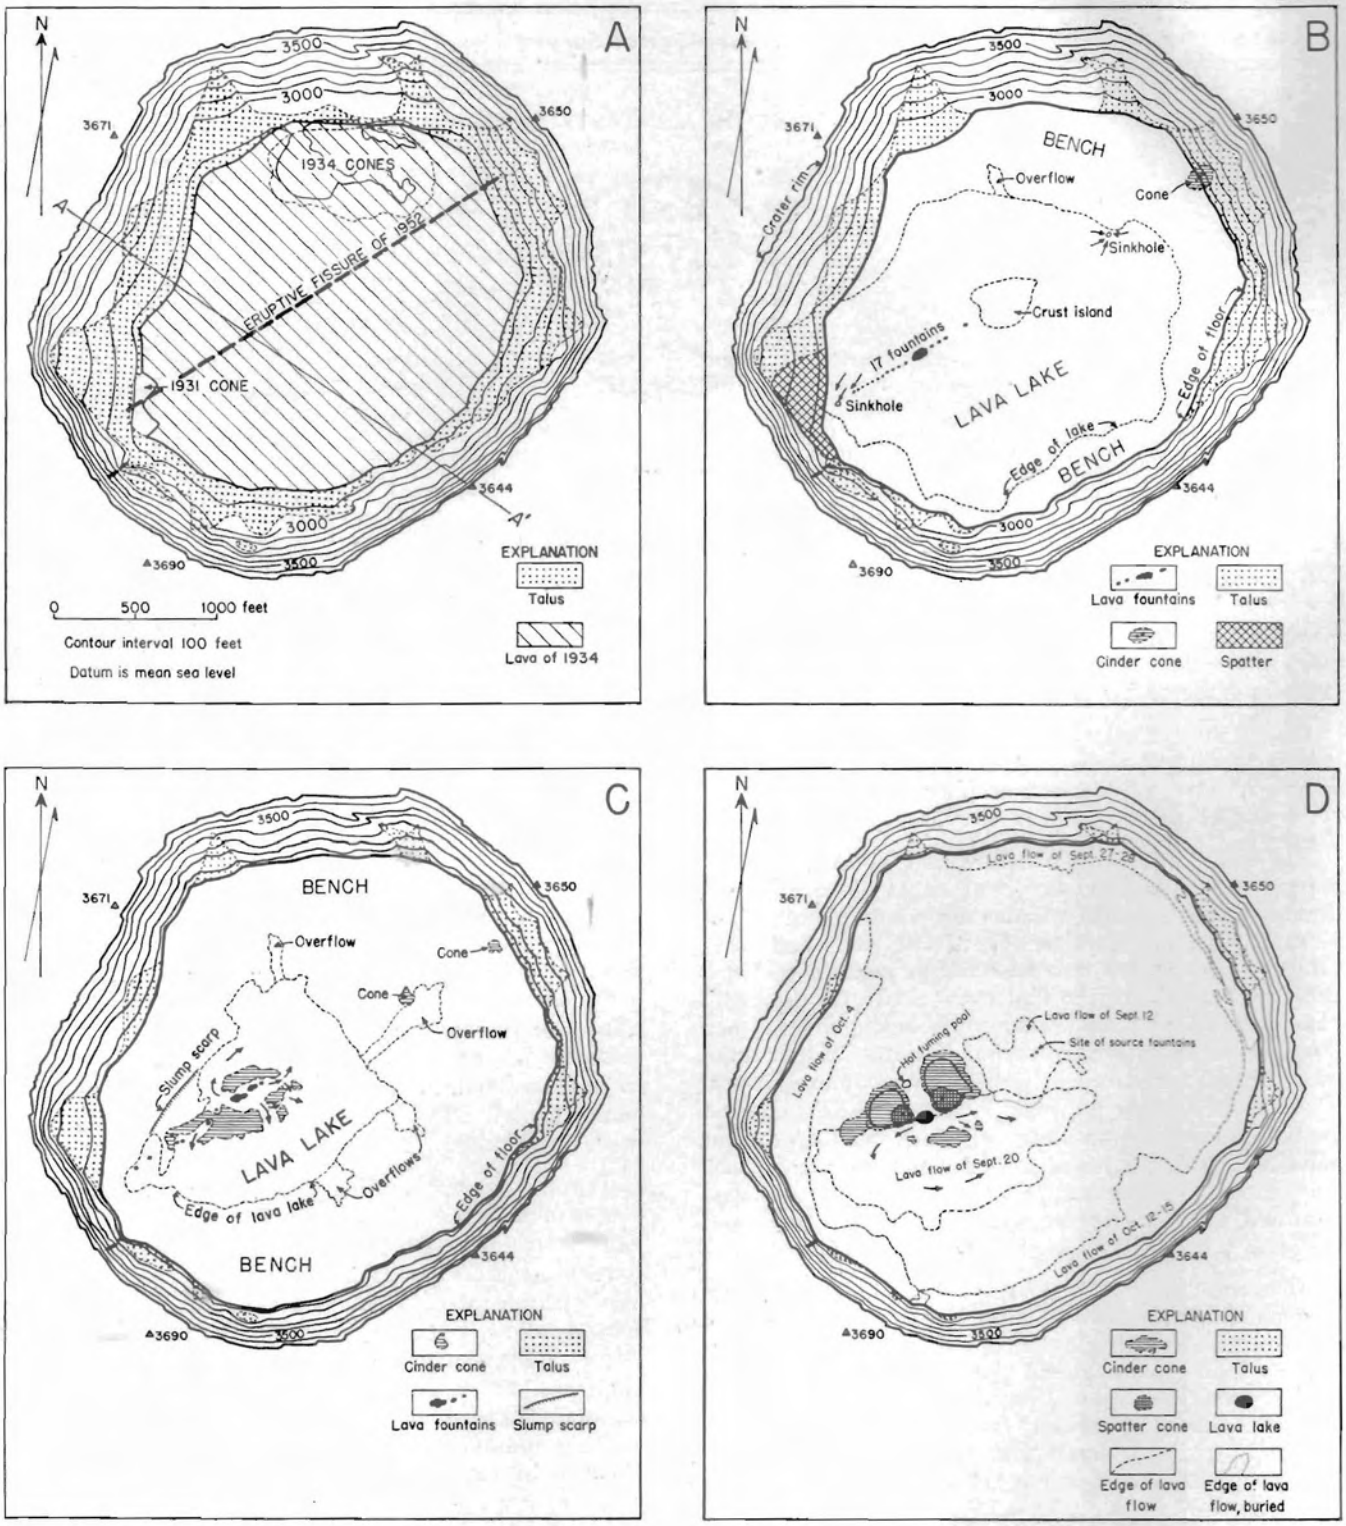

FIGURE 1. Maps of Halemaumau Crater, showing successive stages of the 1952 eruption. A. Conditions in mid-June, just before the eruption. against the walls. Evanescent sinkholes developed near the edge of the pool, accompanied by small lava fountains. Each continued active for only a few minutes, then disappeared, to be replaced by another at some other point. Visibility in Halemaumau was poor because of the large amount of fume, but during brief glimpses of the northern part of the floor, the 1934 cones could not be seen. It is probable that they were already buried and that the liquid pool had attained a depth of more than 30 feet within the first half hour of the eruption. If so, the volume of lava extruded during that brief interval was at least 4,000,000 cubic yards.

The molten lava quickly crusted over, but movement of the underlying liquid tore the crust apart along myriads of lines which revealed the brightly glowing material beneath (Fig. 2). From time to time small whirlwinds moving across the lake picked up fragments of the hot crust 3 or 4 feet across, lifted them 15 or 20 feet into the air, and sent them spinning off across the surface.

The lava fountains continued to decrease rapidly in size. By 1:15 A.M. on June 28, the southwestern fountain was only 250 feet high, and by 3 o'clock it had shrunk to 100 feet (Fig. 3). At 3:15 this fountain and the southwestern part of the fountain chain for 150 feet from the wall had become inactive except for occasional very small bursts, and the next 150 feet of the fountain chain was very weak. At 4:00 the entire southwestern half of the fountain chain was totally inactive, and along the next quarter of the fissure the fountains were very small. Along the northeastern quarter of the fissure the fountains were still 50 to 75 feet high. By 4:10 the active fountains were nearly restricted to the northeasternmost eighth of the fissure, and volcanic tremor had nearly ceased recording on the seismographs. Activity had reached a very low ebb, and for a short time it looked as though the eruption might be ending.

THE PHASE OF THE LARGE LAVA LAKE

About 4:20 A.M. on June 28, small fountains resumed activity along the southwestern quarter of the fissure. These fountains were largely a mere bubbling of liquid lava, liberating very little gas, although abundant gas liberation continued at the northeastern fountains. At 5 A.M. activity was restricted to three blowing vents at the base of the northeast wall talus and the new small fountains in the southwestern part of the crater, with a few small, sporadic bursts along the intervening portion of the fissure. Very little fume was being given off. Daylight brought a clear view of the floor of the crater and confirmed the complete burial of the 1934 cones. The new lava fill was estimated to be about 50 feet thick and to have a volume of approximately 8,000,000 cubic yards.

At approximately 6 A.M. one of the small fountains near the southwestern edge of the crater floor began to grow in size. By 6:15 it was a strong dome-shaped fountain 25 feet across. The typical lava fountains are semi-explosive in nature, resembling a jet from a hose playing spasmodically into the air, and liberate a cloud of gas. This fountain, however, was nonexplosive, with little gas liberation, and resembled half an orange placed flat side down on the surface of the lava lake, appearing somewhat like the dome of water that sometimes is observed above the aperture of a freely flowing artesian well. Crusts of the surrounding lava lake were drawn in toward the fountain and foundered around its edge. By 7:15 the fountain occasionally was reaching heights as great as 50 feet (Fig. 4).

At 6:30 a double fountain jet in a small cone built on the lower slope of the northeastern talus was spurting to heights of 30 to 40 feet and throwing occasional bursts of spatter as high as 60 feet. A sluggish lava stream issued through a breach in the southeastern wall of the conelet and ran down its side at a speed of about 5 miles an hour. Another small vent 50 feet farther northeast was spurting from time to time and sending a trickle of lava down the western side of the conelet. Both vents were roaring and liberating distinctly more blue fume than the southwestern fountain. Two small fountains about 200 feet southwest of the northeastern conelet were spurting sporadically.

Through the morning of June 28, the southwestern fountains gradually increased in size, and the northeastern fountains decreased. At 11 A.M. a small flow of aa was issuing from the northeasternmost vent of the northeast conelet. This single small flow, which continued for the balance of the day, was the only aa observed during the entire eruption. By noon the northeastern fountains had become very small, and the principal southwestern fountain had grown to about 75 feet high and 100 feet across at the base. It was no longer a dome-shaped fountain of gently rising liquid but, instead, was a typical semi-explosive, flinging fountain. Fifty feet northeast of it a new small fountain played nearly continuously, and 100 feet farther northeast another played spasmodically. Around the fountain group concentric waves spread out in the crust of the lake over a radius of 500 feet. A slump scarp 10 to 15 feet high had formed around most of the circumference of the lake, a few feet to 50 feet from its margin, owing to shrinkage of the central part of the lake.

At 3 P.M. the fountains near the southwestern wall had become small and sporadic, but a new fountain just northeast of them, about 300 feet from the southwest wall, was playing to an average height of 150 feet. The amount of gas being given off had increased greatly. The northeast fountains remained about the same as they had been at noon, but about 600 feet southwest of them a prominent sinkhole had developed. Lava streamed toward it from all directions. As it was drawn toward the sinkhole, the crust was broken and torn apart, and, as the fragments reached the sink, they tilted on edge and plunged beneath the surface. Small sporadic fountains played in the sinkhole.

At many other places on the lake the crust was rifted open from time to time, often repeatedly along the same line. There, also, crust fragments were drawn in, tilted up, and plunged under. Generally, this was followed by a row of tiny fountains, lasting only a few seconds, over the place where the crust fragments disappeared.

During the evening of June 28 the fountain 300 feet from the southwest wall continued to grow, until by midnight it was playing steadily to heights around 150 feet, with occasional flings reaching 300 feet. Late in the evening a very active sinkhole developed at the southwestern edge of the lake over the course of the eruptive fissure. A river of lava about 25 feet wide flowed into it from the area of the nearby fountains, and small edge fountains played sporadically in and around it. The northeast sinkhole continued active.

By midnight the vents at the northeast edge of the crater had built narrow-throated conelets and were blowing explosively with loud booming noises, and throwing showers of ejecta to a height of 150 feet. Banners of pale-blue flame 5 to 15 feet long played intermittently over the mouth of the conelets.

Activity continued much the same through June 29 and 30. By noon of June 29, the slump scarp around the edge of the lake had been reburied, and a bench of semi-solid pahoehoe crust was beginning to grow around the edge, gradually restricting the size of the central lava lake. The bench was at about the same level as the general surface of the lake, and as the level of the latter slowly rose during the succeeding days, repeated small overflows moved out across the bench from the edge of the lake, or from fractures within the bench itself. From time to time fragments as much as 150 feet across became detached from the bench and formed islands in the lake. These islands moved across the lake toward the fountains, presumably carried along by a return circulation in the lower part of the lake. They appeared, however, to be floating, rising and falling with the level of the liquid around them.

The two prominent sinkholes continued active. Directly following the engulfment of especially large or numerous crust fragments fountaining within the sinks increased notably. However, these sinkholes appeared to be primary fountain vents in their own right as well. Small sporadic fountains played within the sink even when crustal foundering was not marked, and, from time to time, sinking gave place entirely to fountain action.

On June 29, sporadic fountains played along most of the length of the eruptive fissure southwest of the northeast sinkhole. Along this line lava moved slowly inward and sank, dragging the crust with it and producing a puckered cicatrice extending all the way from the northeast sinkhole to the big southwestern fountain.

By the afternoon of June 29, the conelet at the northeastern edge of the lake had grown to a height of about 50 feet. At 12:30 A.M. on June 30, a small glowing spot appeared on the eastern wall of the conelet, apparently caused by melting of the cone wall from within, and a few minutes later a small pahoehoe flow started to issue from this aperture. At 1:00 the walls of the conelet collapsed, liberating a small flood of very hot lava from the interior of the conelet. At the same time the northeast fountains increased in size from scattered showers of ejecta barely visible above the rim of the conelet to a strong jet about 150 feet high. The conelet quickly commenced rebuilding and by late afternoon had again nearly sealed itself. Similar activity occurred for the next several days, the cone alternately sealing nearly or completely over and reopening as the top, weakened by melting, collapsed. Occasional small flows spread over the crust bench near the conelet. The northeastern vents finally became inactive on July 6.

On June 30, a large fountain, averaging about 150 feet in height, was playing about 500 feet from the southwest edge of the lake, and on both sides of it along the line of the fissure were 16 smaller fountains (Fig. 1-B).

Early on June 29, a crust island about 150 feet across became detached from the marginal bench at the northern edge of the lake and moved slowly southward. On the evening of June 30, the island reached the main fountain area, about 800 feet northeast of the southwest sinkhole (Fig. 1-B). About 6:30 P.M. it moved over the northeasternmost small fountain and immediately started to disappear, partly by crumbling away at its edges and partly by foundering and being overflowed by fluid lava. The disintegration of the large island produced two small islands, which assumed positions just east and northwest of the principal fountain. By the night of July 1, these islands appeared to be grounded. Instead of rising and falling with the surrounding liquid, as they had previously, they remained essentially stationary. The liquid lava around them rose and fell with the surges from the fountains, alternately exposing and concealing a brightly glowing band at their bases.

The crust bench had gradually widened until by the afternoon of June 30 it was encroaching on the northeast sinkhole. On the afternoon of July 1, the sinkhole ceased to function and was replaced by a constant fountain 75 to 150 feet high. Spatter from this fountain accumulated on adjacent portions of the crust bench, and a small cone began to grow around the fountain. On July 2, the conelet was widely breached on the eastern side, and small flows from the fountains were moving over the bench nearby. On July 3, the conelet was about 20 feet high and possessed a rounded shape resembling that of a bee-hive. By July 4, the cone was nearly sealed in, and after that time it exhibited no more fountain activity.

On the morning of July 2, the activity of the southwestern sinkhole was weak. At 10:55 A.M. it suddenly reversed and became a large fountain that grew in size until, at 11:30, it was throwing ejecta regularly to a height of 200 feet and, rarely, as much as 300 feet (Fig. 5). At the same time, the central fountains increased in activity and became explosive, throwing rocket-like bursts as high as 250 feet. These bursts were accompanied by loud detonations. By mid-afternoon a large lava flow about 10 feet thick, was moving eastward from the southwest fountain along the base of the crater wall, and another was advancing northeastward between a pressure ridge on the crust bench and the central fountains. By 2:30 P.M. the whole central portion of the lake appeared to be heating up, and at 3:30 overflows from the lake were spreading over the marginal bench all around the northern and western sides. At 3:40 the southwest fountain abruptly stopped, then

spurted up briefly three times—the last spurt occurring at 3:45 . It remained inactive for the remainder of the afternoon. At 7 P.M. its site was overflowed by a southwestward spreading of the lava lake. About 9 P.M. the sinkhole resumed sluggish activity.

At 5:30 A.M. on July 3, the southwest sinkhole again suddenly became a fountain which grew rapidly to a height of 400 feet. Again, as on the previous day, the central fountains became noisily explosive. The strong fountaining lasted until about 7 A.M., then died down until all activity was very weak. By 7:30 the southwest sinkhole was again in sluggish operation, and the central fountains were gradually regaining their former size. Conditions continued much the same for the remainder of the day.

Weak sporadic fountaining began again at the southwest sinkhole at 10:15 P.M. By 10:40 the height of the fountain had increased to 100 feet, and by 11:45 it had reached 400 feet. Ranger Elroy Bohlin reported that the fountain continued big until 3:30 A.M. on July 4, playing steadily, like a jet of water from a hose, to heights of about 400 feet. Occasional bursts went above the rim of the pit—a height of more than 600 feet. Pumice fell on the road at the southwestern edge of the caldera. This was the strongest fountain activity after the first few hours of the eruption. As in the previous spasms, the central fountains were very noisy, sending long rocket-like strings of molten lava high into the air. The whole central lake and part of the marginal bench were inundated by new flows. At 3:30 both the big southwest fountain and the central fountains suddenly died down, nearly disappearing within a few minutes.

Through the morning of July 4, the southwest sinkhole was alternately moderately active and sluggish. About 3 P.M. it again became a fountain, which, by 3:30, was reaching heights similar to those of the night before. Again, the central fountains also became very active, shooting long string-like "rockets" as high as 250 feet, with loud detonations. Balloon-like balls of lava as much as 20 feet in diameter rose in the central fountain pits until they appeared to be almost detached from the underlying lava, then burst to release a large puff of pale-brown gas. The strong activity was short lived, and by 4:15 P.M. activity had returned to normal. Still another flare-up of the southwestern fountain occurred at 4 A.M. on July 5, but the fountain reached a height of only 200 feet. After that, no further big increases of the southwest fountain occurred, though for several days conditions there alternated between sinkhole and fountain activity.

The bench of semi-solid pahoehoe around the edge of the crater gradually widened, decreasing the area of the central lake of fluid lava (Fig. 1-B). On the morning of June 28, the lake extended from wall to wall of the crater and had an area of approximately 100 acres. By July 1, the bench at the north side ranged from 400 to 700 feet wide, and the area of the lava lake had been reduced to 68 acres.

CONE-BUILDING PHASE

During the first few days of the eruption, the deep pool of fluid lava around the central fountains offered no place for the accumulation of fountain ejecta, and cone building was impossible. By the night of June 30, however, there appears to have been a sufficient accumulation of pasty material in the lower part of the lake to support the crust islands on the two sides of the fountains. Spatter from the fountains accumulated on the islands, initiating the cone-building phase of the eruption. Building was slow at first, and by the morning of July 5 the island just west of the central fountain had been built up to a height of only 25 feet, partly because the underlying material was not strong enough to support it and allowed it to sink to some extent as it built up. Further evidence of the mobile character of the lake bottom is seen in the gradual southwestward shifting of the island along the edge of the fountain chain.

During the next few days, as the islands grew in height, they occasionally became unstable. The lower portion on the side toward the fountain was prevented from building and even was eaten away by the fluid lava surging against it. As the upper portion accumulated more and more spatter, the face toward the fountain became very steep, or even overhanging. Sometimes this unstable condition was relieved by a slumping off of the steep face, but at other times the entire island leaned slowly fountainward, rocked majestically in the surge, and eventually rolled slowly over.

On the afternoon of July 7, an arcuate rampart of spatter 150 feet long and 20 feet high had formed on the east side of the principal fountain, and a similar one appeared on the southwest side. By July 9, the substratum of the lake had become sufficiently firm to consistently support the accumulations of spatter that grew around the fountains, and the true phase of cone building began. By July 10, the cone surrounding the main central fountain was 30 to 50 feet high, and lava streams were spilling through gaps in it eastward and northward. The average height of the fountain within the cone was about 50 feet, but some bursts went as high as 200 feet. Southwest of the main fountain, smaller fountains were building a row of low spatter cones.

On July 5, a steep-sided wall of spatter (a so-called lava ring) started to form around the edge of the lava lake, and by July 6, the lake stood about 10 feet above the surrounding bench. At the southwestern edge of the crater floor a small, nearly circular lake 300 feet across behaved somewhat independently from the main lake. This lake was fed by the large southwest fountain at the site of the former sinkhole and a group of smaller associated fountains. Usually, the latter were arranged along an arc, concave to the northeast, extending northwestward about 75 feet from the large fountain. The southwest lake was enclosed in its own lava ring and, on the morning of July 6, stood about 10 feet above the level of the main lake.

Occasional overflows of both the main lake and the southwest lake sent tongues of lava onto the marginal bench. These overflows gradually raised the level of the

bench. As the eruption progressed, it became evident, however, that only a small part of the rise of the marginal bench was the result of overflow of lava onto its surface. Even when no overflow occurred, the bench rose at a rate approximately equal to the rise of the central lava lake. Obviously, the rise of the bench must have been caused largely by the addition of plastic material beneath it. This may have resulted from an isostatic adjustment whereby the increasing depth of the lake caused the still mobile substratum to flow outward and elevate the bench—a process that was really nothing more than the tendency of a fluid mass, however viscous, to assume a uniform surface level.

On July 12, the cone around the main central fountain was about 60 feet high, and lava rivers spilled from it both eastward and westward to feed the main lava lake. Another cone was forming around a slightly smaller fountain about 300 feet farther southwest. From this cone a lava stream escaped southward, then turned northeastward to join the lava from the larger fountain (Fig. 1-C). The southwestern pool was a true independent lava lake with a constant sinkhole at its northeastern edge around a permanent fountain, and a gradual outward movement of the lava all over the surface from the source fountains to the edge. Occasional crustal foundering and marked downflow occurred at various points all around the rim, followed by evanescent rim fountains.

Over the next few days, the two central cones grew in diameter until, by July 14, they coalesced, though the southern fountain pit remained isolated from the larger northern one. On July 17, the wall between the two pits broke down, and the central cone became a single structure having a fountain pit elongated southwestward and containing both the large central fountains. Flows continued to spill from it southward, westward, northeastward and eastward, feeding the surrounding lava lake (Fig. 6). The lake had an area of 30 acres and was very active. Currents of lava moved outward from the gaps in the cone to the edge of the lake, where they plunged downward, carrying with them fragments of the crust. Crustal engulfment occurred occasionally over all the lake surface but was commonest at two general locations, namely, at the edge of the lake, and along lines where flows from different gaps in the cone merged. The engulfment of each large crust fragment was followed by small short-lived fountains. At the edge of the lake the accumulation of spatter from these fountains built the lava ring, which, in succeeding weeks, confined the liquid of the lake at a level as much as 20 feet above the adjacent marginal bench.

On July 15, a small fountain at the northern edge of the southwest lake had built a beehive-shaped cone 30 feet high. The southwest fountains had, however, become very weak, and on July 16 the main lake overflowed into the southwest lake (Fig. 1-C). The southwest fountains again became strong on July 18, and continued active until July 22. On July 23, however, they became small and sporadic, and after July 24 they disappeared altogether, leaving the south lake as a lobe of the main lake fed by lava streaming southward from the central fountains.

A general overflow of the main lava lake began at 12:15 on July 20, and continued until midnight. Flows moved outward across the bench to, or nearly to, the crater walls on the northwest, north, and northeast sides, completing the obliteration of the cones at the former northeast sinkhole and the foot of the northeast talus, which had been partly destroyed already by collapse and burial by new lava.

On July 29, several small flows issued along the edge of the bench at, or close to, the wall of the crater. The molten lava apparently rose along the boundary of the new lava plug in the bottom of the crater. These were the first of several similar flows at intervals during most of the remainder of the eruption.

Activity continued essentially the same until August 7. The average size of the central fountains decreased to about 40 feet, but their explosiveness increased somewhat, and occasional explosive bursts reached great heights. Northrup Castle reported that, about midnight on August 5, one explosive burst from the northerly of the two fountains reached a level above the rim of the crater. Similar bursts were observed at 7:45 P.M. on August 6, and 8:30 P.M. on August 7. These bursts reached a height of about 550 feet. The greater explosiveness may have resulted from some increase in viscosity of the escaping lava. A gradual decrease in the amount of lava being poured out caused a retreat of the margins of the lava lake, which, between August 1 and 7, moved inward 50 to 75 feet.

The cone reached its maximum development early in August. On August 11, it was 65 feet high and approximately 800 feet in basal diameter.

DECLINING PHASE OF THE ERUPTION

There now began a period of fluctuating but gradually decreasing lava output. An apparent decrease in the amount of superheat in the lava caused a tendency to increased viscosity and clogging of the vents. On August 9, the southern gap in the cone became clogged, and the north and northeast lava rivers increased greatly in volume, plunging over spectacular cascades as much as 20 feet high. On August 11, the south river became re-established, and the east river was blocked by a partial collapse of the adjacent cone wall. By August 12, the east river was flowing again, but the northeast river had, in turn, been choked off. On August 13, the west and south rivers became inactive. Cessation of the south river was followed by draining of the southern lobe of the lava lake, leaving a broad basin about 20 feet deep with a nearly flat irregular floor. On August 18, lava overflowed the south wall of the cone and re-established the south river, refilling the basin.

Late in the evening of August 18, the northern of the two central fountains decreased greatly in size, and by midnight it showed no signs of activity. It returned early on August 19, but remained small for several days. By August 22, both fountains averaged about 20 feet high, with some showers of glowing ejecta reaching heights of 200 feet.

On August 23, lava was no longer flowing from the central cone, and the lava lake surrounding the cone had become inactive. The two fountains were small and sporadic, throwing showers of glowing fragments as high as 150 feet. Around themselves they had built beehive-shaped conelets of spatter 20 feet high within the crater of the cinder cone, and a nearly circular lava lake about 120 feet in diameter had formed nearly between the two conelets. This condition persisted throughout the remainder of the eruption (Figs. 1-D, 7).

By August 25, activity had become very weak, but on August 29 it began to regain its strength. In early September, it was again spectacular; loud roaring and whistling gas release accompanied explosive bursts that threw showers of glowing cinders to heights of 150 to 200 feet. On the night of September 2, small glowing spots appeared on the floor north and east of the central cinder cone, and by the morning of September 3 two flows were issuing at those localities and spreading sluggishly over the adjacent floor. The northerly flow was fed by a tiny fountain spurting 5 or 6 feet into the air about 400 feet north of the north central conelet.

From September 1 to 18, the more northerly of the two central vents was the more active, and its conelet gradually grew to a height of 50 feet, overtopping the rim of the surrounding cinder cone. Throughout this period the lava at the surface of the small lava lake flowed slowly from the north to the south edge, where it sank, producing fountains 10 to 15 feet high against the south bank. On September 19, the activity of the two conelets became reversed, with the southern one the more active. Simultaneously, the lava in the lake reversed its movement, rising at the southern edge to flow northward and sink along the north bank. Spatter from the edge fountains and occasional small overflows had built up a low, flat cone around the lake, the surface of which stood about 20 feet higher than the surrounding floor of the crater of the cinder cone.

At 1:45 A.M. on September 20, lava started to spill over the southern rim of the lake. The overflow increased rapidly in volume, breaking down the southern wall of the lava cone containing the lake and sending a big flow over the southern part of the floor of Halemaumau. At 10:12 A.M. the northeastern rim of the lake also was overflowed, and a second flow spread out to coalesce with the first one east of the cinder cone. The northeastern overflow lasted only a few hours, but the southern one continued until about midnight. This was the most voluminous single outpouring of lava after August 22.

On September 22, the northern central vent again become dominant, and again the circulation in the lava lake reversed, returning to its first direction of movement from north to south. Explosive activity at the southern conelet ceased entirely, and for the remainder of the eruption the conelet fumed quietly.

The northern conelet gradually built up to a height of 65 feet, and by September 26 its top was nearly sealed over. On that afternoon, at about 4 o'clock, the top and part of the northeastern side of the conelet suddenly were blown off. Charles Bell reported that three or four explosive bursts of ejecta reached heights of about 400 feet. This was accompanied and followed by violent oscillation of the lava in the lake, the level of which rapidly dropped about 15 feet. Within a few minutes both the lake and the conelet had returned to their normal state of activity, with bursts from the conelet reaching heights of 100 to 150 feet.

A similar series of events occurred on the evening of September 27. At 8:35 P.M. a series of about a dozen violent blasts that threw incandescent cinder to a maximum height of about 550 feet suddenly commenced at the north conelet. The surface of the lava lake surged violently, and following the explosions its level gradually dropped about 15 feet, revealing glowing grottoes hung with fringes of stalactites in the banks. As on the previous day, activity returned to normal within a few minutes.

Throughout the month of September, small flows continued to issue from time to time on the floor of Halemaumau outside the central cinder cone. These welled up quietly, with very small fountains at their vents, or none at all, and very little evidence of gas liberation. Two on September 4 have already been mentioned. On September 5, another appeared on the floor northwest of the cinder cone, and still another issued at the foot of the western wall of Halemaumau. Small flows issued on the floor southeast of the cone on September 8, northeast of the cone on September 12, at the western wall on September 16, both northwest and northeast of the cone on September 17, and at the foot of the northwestern wall on September 27. On the night of October 3, a flow broke out at the foot of the southwestern wall of Halemaumau and spread rapidly around the edge of the crater floor for a distance of 2,200 feet. The final edge flow of the eruption broke out at the foot of the southeastern wall of Halemaumau on the afternoon of October 12 and continued until October 15, eventually extending halfway around the crater, a distance of 4,600 feet (Fig. 1-D).

During the first half of October, the lava lake and the north central conelet continued active, the latter throwing frequent sporadic showers of glowing ejecta to heights of 50 to 100 and, rarely, 200 feet. On the afternoon of October 5, a series of explosive bursts similar to those of September 25 and 27 reached a height of 450 feet. Surface circulation in the lava lake continued from north to south. Fountains up to 15 feet high formed along the southern bank, where crusts were being carried down by the descending liquid, and other smaller fountains appeared from time to time at the northern edge.

Throughout the last two weeks of October, the northern conelet was largely sealed over, and only occasional small bursts of glowing fragments could be seen. The cloud of gas liberated at the conelet became markedly more conspicuous, denser, and white in color, in contrast to the thin, bluish fume liberated in earlier stages with a more open vent. At night, banners of pale blue or yellowish flame as long as 25 feet flickered over the conelet.

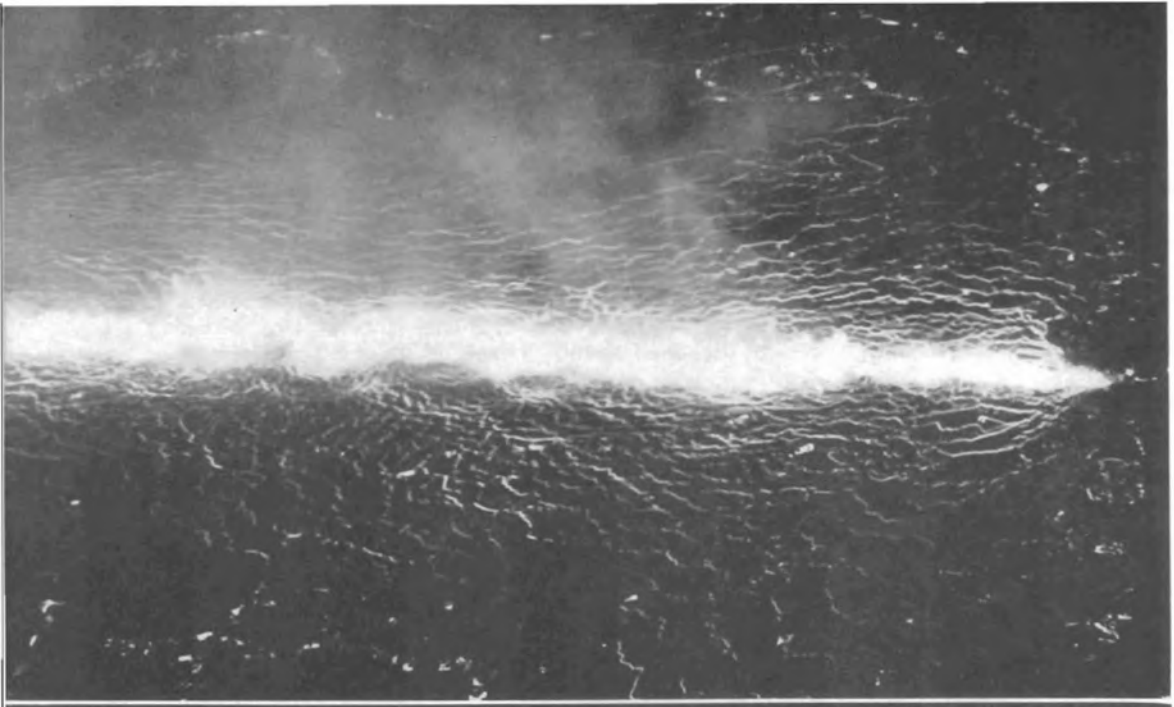

FIGURE 2. Lava fountains along the fissure in the northeastern portion of Halemaumau and brightly glowing cracks in the thin crust of the liquid lava lake, at 3 A.M. on June 28. The fountains range from about 20 to 50 feet high. Waves in the liquid can be seen near the fountains. Photo by C. K. Wentworth.

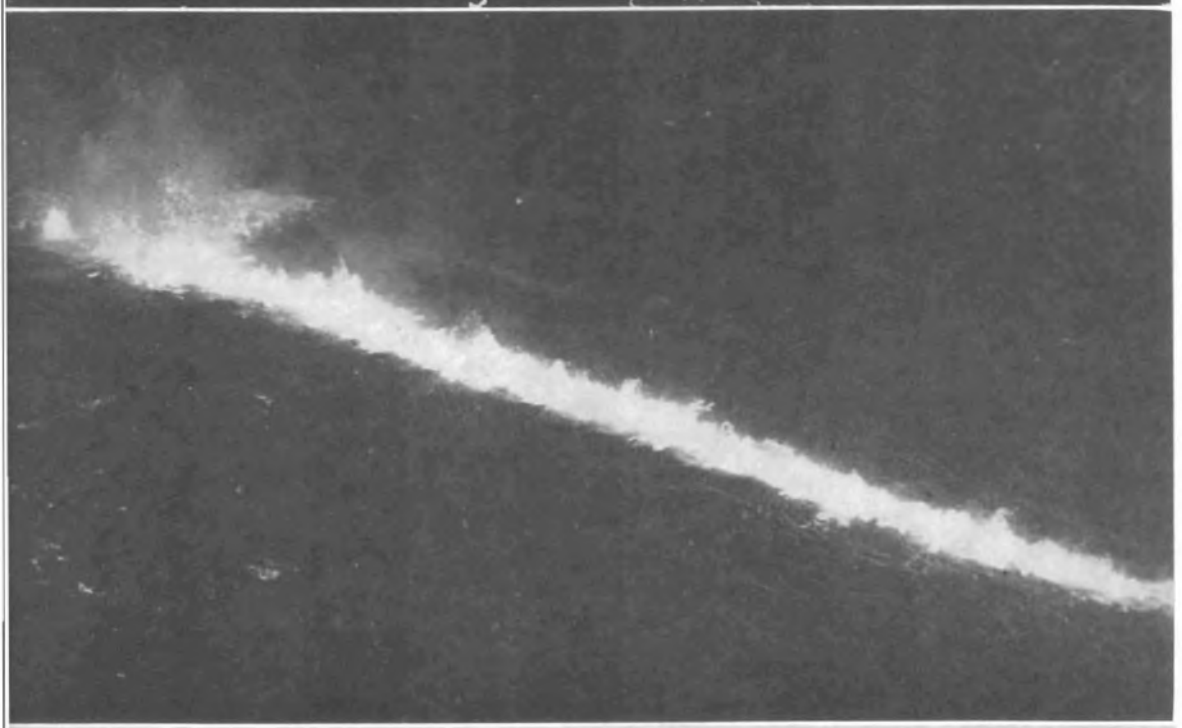

FIGURE 3. Lava fountains along the fissure across the southwestern portion of the floor of Halemaumau, at 2:15 A.M. on June 28. The large fountain at the left-hand edge is the big southwestern fountain, which had then decreased in height to about 150 feet.

FIGURE 4. The lake of liquid lava and the fountain at the southwestern edge of Halemaumau at 7:20 A.M. on June 28. The fountain is about 50 feet high. Waves in the lake are clearly visible.

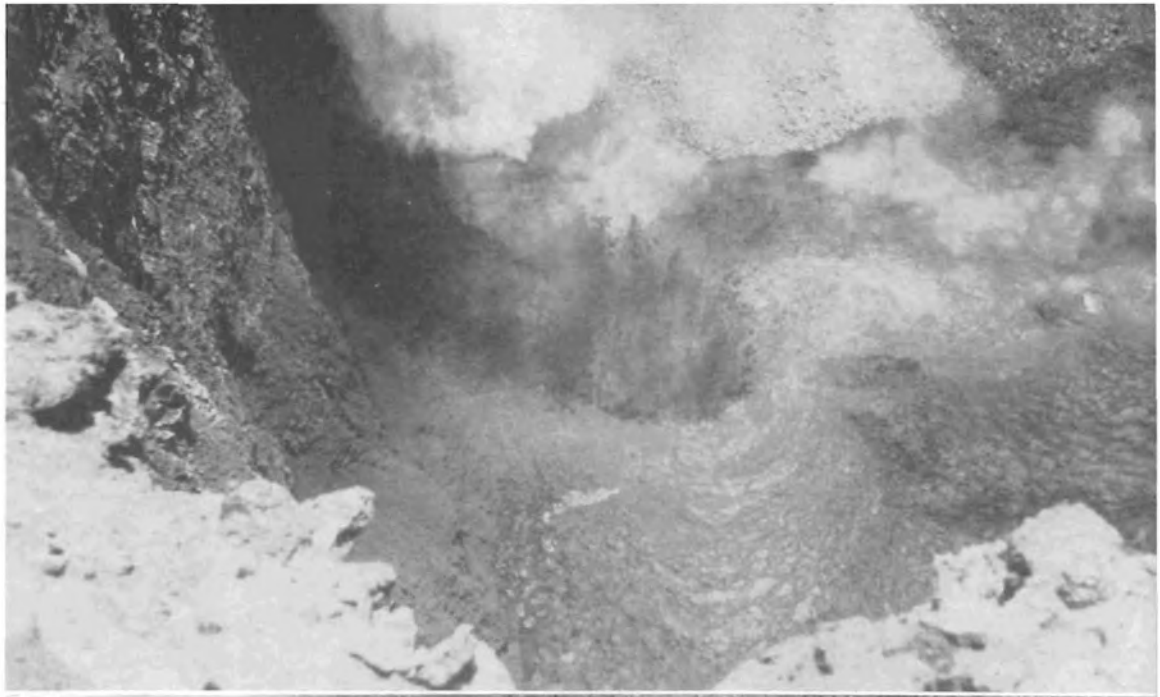

FIGURE 5. Lava fountain about 150 feet high at the southwestern edge of Halemaumau, at 11:15 A.M., July 2.

FIGURE 6. Lava fountains and cinder cone in Halemaumau on July 22. Rivers of lava are pouring out through gaps in the cone. The marginal bench along the western side of the crater floor is visible in the background. The highest cone segments are about 50 feet high.

FIGURE 7. Small spatter and cinder cones and lava lake in the crater of the large cinder cone, on September 9, looking westward from the southeast rim of Halemaumau. Comparison of the western wall of the crater with that shown in Figure 6 gives some indication of the amount of rise of the floor during the interval between the two photographs.

The end of October brought a brief revival of activity. On the night of October 31, the upper portion of the northern conelet collapsed, decreasing the height of the conelet from 65 to 35 feet, and big lava fountains veneered the outer slopes of the conelet with a thin layer of liquid spatter. On the next night, a further collapse of the conelet reduced its height to about 25 feet and broadened its wide-open crater to a diameter of about 90 feet. Lava overflowed the crater rim, completely covering the outer slopes of the conelet and extending thin flows to a point just beyond the northern edge of the cinder cone. On the south side of the conelet the flow spilled into the lava lake. With the reopening of the vent the gas cloud became thin and bluish again. As throughout much of the eruption, heat from the crater caused a convectional rise of the air above it, and condensation formed an often conspicuous cap of cumulus cloud two or three thousand feet above the crater rim.

Another overflow of the conelet, similar to that of November 1, occurred at about 10 P.M. on November 6. Within a few minutes a thin sheet of lava had covered the slopes of the conelet and the immediately adjacent region. The area of the overflow was estimated by C. K. Wentworth to be approximately 5 acres. Through early November, a small lava fountain was visible in the crater of the conelet. The fountain was generally only 15 or 20 feet in height, but it threw spasmodic bursts to heights as great as 150 feet.

The last activity of the lava lake was observed on November 9, and the last fountain activity on the morning of November 10.

Considering the eruption to have ended on November 10, its duration was 136 days. Glowing spots continued to be visible in the lava lake and north conelet until November 11, and at the south conelet and at solfataras on the crater floor northwest and south of the big cinder cone until November 18. At the end of 1952, moderate amounts of pale bluish-gray fume were still issuing at these solfataras.

THE LAVA

The total volume of the new lava fill in Halemaumau is approximately 64,000,000 cubic yards, and its average thickness is approximately 310 feet. The average depth to the crater floor from the visitors' observation area at the southeast rim of the crater is 460 feet. Figure 8 shows progressive stages in the filling of Halemaumau.

The only specimens of the erupted lava recovered are pumice. The latter has not yet been analyzed chemically, but it is basaltic in character, the refractive index of the glass being 1.598 ($\pm$.003).

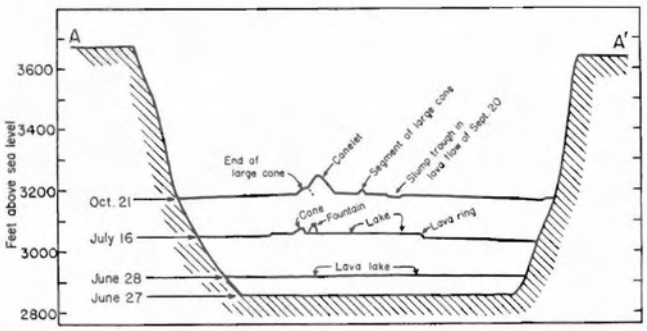

FIGURE 8. Profile across Halemaumau along line A-A′ in figure 1-A, showing successive levels of the crater floor just preceding and during the 1952 eruption. The vertical scale is twice the horizontal.

The temperature of the lava fountains was measured repeatedly with an optical pyrometer of the disappearing dot type. The reading on the hot core of the big fountains during the first month of the eruption ranged from 1030° to 1055° C., depending at least partly on the distance of the observer from the fountain. To these readings should be added a correction of about 20° for light absorption by the lava and, probably, a correction of 10° to 30° because of the fairly large distance from which readings were obtained. The actual temperature of the fountains appears, therefore, to have been in the vicinity of 1080° C. Early in August, the temperature of the fountains started to decrease. By mid-August, the corrected temperature had dropped to about 1050° C. and, by late August, to 1040°. Corrected temperature readings on active lava flows ranged from about 1030° to 920°.

The radioactivity of the erupted lava appears to have been low. Two samples of pumice ejected respectively during the first night of the eruption and at 6 A.M. on July 3, analyzed by the U. S. Geological Survey in Washington, D. C., each contained less than 5 parts per million of uranium equivalent.

ACKNOWLEDGMENTS

Many persons have contributed information on the eruption. It is impossible to mention all by name, but to all we extend our sincere thanks. Without their help it would not have been possible for the small staff of the Volcano Observatory to obtain so complete a record of the eruption. The staff of Hawaii National Park was especially helpful.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR OCTOBER–DECEMBER, 1952

By GORDON A. MACDONALD

VOLCANOLOGY

October

Kilauea Volcano continued active throughout the month of October. An account of the activity has been given in the foregoing pages.

Mauna Loa continued somewhat restless throughout October. During the month seismograph stations at the rim of Kilauea Caldera recorded 77 earthquakes, and the Mauna Loa seismograph recorded a total of 187. On October 24 and 25 the Mauna Loa instrument recorded 165 very small earthquakes originating on the northeast rift zone. Northeastward tilting of the ground at the seismograph station on the northeastern rim of Kilauea Caldera was at a rate somewhat greater than the normal, suggesting some increase of pressure beneath Kilauea and, probably, also beneath Mauna Loa.

November

The last visible lava activity in Halemaumau was on November 10. Small glowing spots continued to be visible on the crater floor until November 18. For the remainder of the month there were no signs of molten lava, and the only activity was the quiet liberation of pale bluish-gray fume at spots on the floor just south, west, and northwest of the big cinder cone. Steam issues from the talus banks at the foot of the eastern and southwestern walls of the crater, and at the top of the 1919 fissure in the southwestern wall.

Throughout November, tilting of the ground at the northeastern rim of Kilauea Caldera was northeastward at a rate approximately normal for that season of the year. This appears to indicate that there was little or no withdrawal of the molten lava, with an accompanying decrease of pressure, beneath Kilauea. Brief periods of volcanic tremor on November 19 and 29 are interpreted as indicating movement of the lava beneath the caldera. The liquid level probably still stands at a high level beneath Halemaumau, and, so long as this condition persists, lava activity may return to Halemaumau at any time with little or no warning.

Most of the earthquakes recorded during November had their origins in Kilauea Volcano. The uneasiness manifested by Mauna Loa during October did not continue. Seismographs at Kilauea Caldera recorded 56 earthquakes during the month, while the Mauna Loa seismograph recorded only 23. Several earthquakes originated in central Kona, probably on the Kealakekua fault near Napoopoo, and a few of them were felt by some persons in Kona. At 22:13 on November 27, a slight earthquake originated just west of the summit of Mauna Loa.

December

Hawaiian volcanoes were quiet throughout the month of December. Vents on the floor of Halemaumau continue to liberate moderate amounts of pale bluish-gray fume. On the morning of December 11, Ernest Morton, manager of the Kahuku Ranch, reported large clouds of steam in the vicinity of the vents of the 1950 lava flows at about 10,000 feet altitude on the southwest rift of Mauna Loa. The unusually prominent steam clouds probably resulted from unusually good visibility and high atmospheric humidity and low temperature, causing condensation.

Seismographs at Kilauea Caldera recorded 47 small earthquakes during December, and the Mauna Loa seismograph recorded 22. Several earthquakes originated in central Kona, probably on the Kealakekua fault. A few of these, together with the quake of November 27, appear to have had their foci along a line extending westward from the summit of Mauna Loa toward Kealakekua Bay and may have been caused by some shifting along the fracture along which occurred the eruption of 1877.

On December 10, at 18:01, a small earthquake was felt at Naalehu. This quake originated near the summit of Mauna Loa. On December 12, a quake, felt at 9:09 both in Naalehu and the Volcano district, originated on the Kaoiki fault about 9 miles southwest of Kilauea Caldera. A moderate earthquake, at 1:21 on December 28, appears to have had its origin beneath the summit of Hualalai.

Through most of December the ground surface at the northeastern rim of Kilauea Caldera tilted gently southwestward. The change from northeastward to southwestward tilting took place about a month earlier than usual. However, the time of reversal is rather variable from year to year, and the rate of tilting through December was about normal for the period following the usual seasonal reversal. Thus, there still appears to be little or no indication of decrease of volcanic pressure beneath Kilauea.

SEISMOLOGY

Earthquake Data, October–December, 1952

(Based on Bosch-Omori seismograph on northeast rim of Kilauea Caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms
Oct. 5	†	12	0	0	0	0	6.0	0
12	†	8	0	0	0	0	4.0	0
19	†	6	1	0	0	0	4.0	0
26	†	7	0	0	0	0	3.5	0
Nov. 2	†	6	0	0	0	0	3.0	1
9	8	3	0	1	0	0	5.5	0

14	8	2	0	0	0	0	3.0	0
21	4	1	0	0	0	0	1.5	0
28	9	3	1	0	0	0	4.75	0

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

† Continuous tremor.

Table of Tilt at Seismograph Vaults on Rim of Kilauea Caldera

Week Beginning	Whitney Vault (Northeast rim)		Uwekahuna Vault (West rim)	
	Amount	Direction	Amount	Direction

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori horizontal or Sprengnether vertical seismograms, in Hawaiian Standard time.

Nov. 4, 07:07, very strong. Near southern end of Kamchatka Peninsula. Accompanied by a tsunami that did moderate damage in the Hawaiian Islands.

Nov. 29, 14:03, slight. Off southern coast of Alaska Peninsula, at 56° N., 155° W.

Local Earthquakes

The data for the following local earthquakes were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The times given are arrival times at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea Caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

2128. Oct. 2, 10:04, very feeble.
2129. Oct. 3, 12:12, feeble (Mauna Loa, slight). Felt at Naalehu and Kapapala.
2130. Oct. 4, 02:56, very feeble.
2131. Oct. 4, 18:32, very feeble.
2132. Oct. 5, 14:29, very feeble.
2133. Oct. 5, 16:14, very feeble.
2134. Oct. 7, 11:40, very feeble.
2135. Oct. 7, 11:54, very feeble.
2136. Oct. 8, 00:04, very feeble.
2137. Oct. 8, 05:20, very feeble.
2138. Oct. 8, 14:40, very feeble (Mauna Loa, feeble).
2139. Oct. 8, 18:59, very feeble.
2140. Oct. 9, 15:35, no record at Kilauea (Hilo, feeble).
2141. Oct. 9, 17:46, very feeble.
2142. Oct. 10, 14:14, very feeble.
2143. Oct. 11, 05:14, very feeble.
2144. Oct. 11, 19:42, very feeble.
2145. Oct. 12, 13:42, very feeble.
2146. Oct. 13, 21:53, no record at Kilauea (Mauna Loa, very feeble).
2147. Oct. 13, 23:36, very feeble.
2148. Oct. 14, 07:30, very feeble.
2149. Oct. 14, 11:52, no record at Kilauea (Mauna Loa, very feeble).
2150. Oct. 14, 21:58, no record at Kilauea (Kona, very feeble). Central Kona.
2151. Oct. 15, 06:55, very feeble.
2152. Oct. 16, 14:31, very feeble.
2153. Oct. 16, 15:37, very feeble.
2154. Oct. 18, 02:47, very feeble.
2155. Oct. 18, 17:02, very feeble. Felt at Kapapala. Kaoiki fault near Wood Valley (?).
2156. Oct. 18, 21:17, very feeble.
2157. Oct. 20, 11:25, very feeble.
2158. Oct. 21, 07:23, very feeble.
2159. Oct. 22, 01:45, no record at Kilauea (Kona, feeble).
2160. Oct. 22, 10:10, very feeble.
2161. Oct. 22, 16:39, feeble. Kaoiki fault near Bird Park (?).
2162. Oct. 23, 14:11, very feeble. Kilauea.
2163. Oct. 24, 15:00, very feeble.
2164. Oct. 25, 09:25, very feeble (Kona, slight). Felt in Kona. Central Kona.
2165. Oct. 25, 14:30, tremor (Mauna Loa, very feeble).
2166. Oct. 25, 14:44, tremor (Mauna Loa, very feeble).
2167-2175. Oct. 25, very feeble earthquakes at Mauna Loa; at other stations tremors or no record.
2176-2184. Oct. 26, same.
2185-2186. Oct. 27, same.
2187. Oct. 29, 13:39, very feeble.
2188. Oct. 30, 05:15, no record at Kilauea (Kona, very feeble).
2189. Nov. 1, 01:23, very feeble.
2190. Nov. 1, 14:11, very feeble.
2191. Nov. 2, 02:57, very feeble.
2192. Nov. 5, 12:49, very feeble. Southwest rift of Kilauea (?).
2193. Nov. 7, 22:21, very feeble.
2194. Nov. 8, 18:33, very feeble.
2195. Nov. 9, 16:56, very feeble.
2196. Nov. 10, 21:42, very feeble (Kona, moderate). Felt in Kona. Central Kona.
2197. Nov. 12, 08:05, very feeble.
2198. Nov. 12, 10:43, very feeble.
2199. Nov. 12, 17:43, very feeble.
2200. Nov. 13, 12:28, slight. Off south coast.
2201. Nov. 13, 12:54, no record at Kilauea (Kona, feeble). Central Kona.
2202. Nov. 13, 14:57, tremor (Kona, very feeble).
2203. Nov. 16, 02:40, very feeble.
2204. Nov. 16, 02:41, slight. Off south coast.
2205. Nov. 16, 09:49, very feeble.
2206. Nov. 18, 00:39, no record at Kilauea (Kona, very feeble).
2207. Nov. 19, 03:27, very feeble.
2208. Nov. 20, 10:19, very feeble. Kilauea.
2209. Nov. 22, 01:08, slight. East rift of Kilauea near Alae Crater, depth about 13 miles.
2210. Nov. 23, 18:31, very feeble.
2211. Nov. 27, 16:35, very feeble (Kona, feeble). Felt in Kona. Central Kona.
2212. Nov. 27, 22:14, slight. Felt in Kona. Near summit of Mauna Loa, 4 miles west of North Bay; 19° 29′ N., 155° 38′ W.
2213. Dec. 1, 00:30, very feeble.
2214. Dec. 1, 01:22, very feeble. Off south coast (?).
2215. Dec. 3, 01:12, tremor (Kona, feeble). Felt in Kona. West slope of Mauna Loa.
2216. Dec. 3, 09:10, no record at Kilauea (Kona, very feeble). Central Kona.
2217. Dec. 3, 20:03, no record at Kilauea (Kona, very feeble). Felt in central Kona.
2218. Dec. 5, 17:59, very feeble. Off south coast; 19° 06′ N., 155° 19′ W.
2219. Dec. 6, 09:45, very feeble. Kilauea.
2220. Dec. 7, 02:26, very feeble. West slope of Mauna Loa; at about 19° 28′ N., 155° 43′ W.
2221. Dec. 7, 11:12, very feeble.
2222. Dec. 8, 17:30, very feeble.
2223. Dec. 10, 18:01, very feeble. Felt at Naalehu. Near summit of Mauna Loa.
2224. Dec. 11, 01:06, very feeble.
2225. Dec. 12, 09:09, feeble. Felt at Naalehu and Volcano district. Kaoiki fault, south of Ainapo.
2226. Dec. 15, 18:47, very feeble. East rift of Kilauea near Puu Huluhulu, shallow.
2227. Dec. 15, 18:57, very feeble. Kilauea Caldera, 28 miles deep (?).
2228. Dec. 15, 21:11, very feeble.
2229. Dec. 17, 03:00, no record at Kilauea (Kona, very feeble).
2230. Dec. 21, 12:12, no record at Kilauea (Kona, very feeble). Central Kona.
2231. Dec. 22, 01:18, no record at Kilauea (Kona, very feeble).
2232. Dec. 23, 03:46, tremor (Kona, very feeble).
2233. Dec. 25, 00:10, very feeble. Felt in central Kona.
2234. Dec. 28, 01:22, very feeble (Kona, moderate). Felt in Kona. Beneath summit of Hualalai.
2235. Dec. 29, 20:55, no record at Kilauea (Kona, very feeble).
2236. Dec. 31, 16:00, tremor (Kona, very feeble). Central Kona.

THE TSUNAMI OF NOVEMBER 4

On November 4, 1952, a strong earthquake occurred off the southeastern coast of Kamchatka. The notice of Preliminary Determination of Epicenter issued by the U. S. Coast and Geodetic Survey gives the point of origin as 52½° N., 159° E., and the origin time as 16:58:20 Greenwich Civil time (6:58:20 Hawaiian Standard time).

The earthquake was recording on the Bosch-Omori seismograph when the record was changed at 7:45 A.M. The amplitude of the record produced was among the largest recorded at the Volcano Observatory. Quick inspection of the record indicated that it probably originated beneath the Pacific Ocean, or very close to its border, and, consequently, that it might be accompanied by a tsunami. The large size of the earthquake suggested that the tsunami might also be big.

At about 8 A.M. the Director of the Volcano Observatory notified the Hawaii Police Department in Hilo that the earthquake had occurred and suggested that they be alert for a possible "tidal wave" warning that would be issued by the Seismic Sea Wave Warning System of the Coast and Geodetic Survey. The statement was also made that it would be at least three hours from that time before the "tidal wave," if there was one, would reach Hilo.

By 9 A.M. further study of the local records and comparison of arrival times at mainland stations, received by wire from the Hilo Tribune-Herald, made it apparent that the quake had originated in the Kamchatka area and that, if a tsunami had been generated, it should reach Hilo about 13:30. Shortly afterward the actual wave warning was issued by the Coast and Geodetic Survey, based on reports of actual observed water waves.

The tsunami reached Hilo at approximately 13:30, as predicted. The record of the tide gage at Kuhio wharf shows that a rise of approximately 4 feet began at 13:32, bringing the water level to approximately 7 feet above mean lower low tide at 13:49. This was followed by a trough, bringing the water level to one foot below mean lower low tide at about 14:05. These extreme oscillations were followed by a series of diminishing oscillations, with an average period of about 17 minutes, that continued for the next several days. The dominant period of 17 minutes in these oscillations probably is approximately that of the harbor seiche.

Heights reached by the water on the Island of Hawaii were very much less than in the Aleutian tsunami of 1946. At Hilo the greatest heights measured were at Kuhio wharf, in Reeds Bay, and on Cocoanut Island. Water swept over the wharf to a depth of 11.5 feet above mean lower low tide. Near the head of Reeds Bay the high water mark ranged from 9 to 11 feet above the same datum, and on Cocoanut Island the greatest height was approximately 12 feet. Near the mouths of the Wailuku and Wailoa rivers the water reached a height of about 9 feet.

Both northward and eastward from Hilo the height reached by the water decreased rapidly, and east of Keaukaha estuary the rise was so small that it is not certain any occurred. The same condition prevailed along the southeastern, southern, and northeastern coasts of the island. Along the western coast the rise at most places ranged from 2 to 4 feet. On Hawaii, damage was restricted to the Hilo area.

Damage at Hilo included beaching of several sampans and rolling over of another on the ways in a boat-building yard; damage to buildings on Cocoanut Island and near the head of Reeds Bay; destruction of one span of the bridge to Cocoanut Island; flood damage at the Naniloa Hotel, at the wharf, and along the shore between the wharf and Reeds Bay; and destruction of a boat landing at the wharf.

Practically all of the damage observed in Hilo appeared to be the result of gentle flooding. No signs of violent impact, such as occurred in 1946, were seen. No sharp crest, or "bore" front, was reported in Hilo Bay, although an 18-inch bore was reported in the Wailoa estuary.

The boat landing, a house on a bar in Reeds Bay, and the span of the Cocoanut Island bridge appear to have merely been floated from their foundations. At least in part, the flooding from the wharf to the Wailoa River appears to have resulted from entrance of water to the portion of the bay confined by the breakwater both through the channel west of the end of the breakwater and also by flooding over the breakwater during crests of the tsunami faster than it could drain out again during troughs.

Large differences in pattern of the effects around the Island of Hawaii between the 1946 and 1952 tsunamis illustrate well the individuality of such waves, resulting from disturbances of different sizes, centering at different distances and in different directions. Such individuality makes extremely difficult prediction of the nature and size of the effects at any given locality, even when measurements are available from other areas nearer the point of origin of the waves. Many more observations, over a period of many years, will be necessary before accurate local predictions can be made, although the generally excellent operation of the Seismic Sea Wave Warning System in November, 1952, demonstrates that prediction of the general fact of the occurrence of a "tidal wave" of distant origin is now well in hand.

VOLCANO NOTES AND NEWS

DR. THOMAS A. JAGGAR

It is our sad duty to report the death of Dr. Thomas A. Jaggar, on January 17, 1953, just a week before his 82nd birthday. His loss will be keenly felt by the staff of the Volcano Observatory, and by the volcanological profession generally. Dr. Jaggar was the last of the great pioneers of volcanology as a true science. A future issue of the Volcano Letter will be devoted to a review of his work at the Hawaiian Volcano Observatory.

MYOJIN REEF

In mid-September, 1952, a volcanic eruption began in the southern Izu Islands a few miles north of the Bayonnaise Rocks and about 250 miles south of Tokyo. The following information on the eruption has been supplied by Dr. T. Minakami of the Earthquake Research Institute of Tokyo University, Drs. S. K. Neuschel and Helen L. Foster of the U. S. Geological Survey, and Dr. H. Niino of the Tokyo College of Fisheries.

The new islet, named Myojin Reef, is at 31° 56.8′ N. latitude and 139° 59.5′ E. longitude. The eruption was first observed by the crew of the fishing boat Myojin Maru on September 17. When the eruption was seen by Dr. Minakami, on September 18, explosions were occurring every few seconds in the main crater and several smaller craters, ejecting incandescent bombs, scoriae, and ash, together with heavy vapor. The island was estimated to be several hundred yards in diameter and to rise about 60 feet above sea level. Soon after that explosions and erosion by sea waves greatly reduced the area of the island above sea level, but when it was visited by Drs. Foster and Neuschel, on September 22, part of the mass still projected above sea level. A streak of yellow-colored water that extended many miles southward is believed probably to have been caused by finely comminuted rock debris.

On September 23, the Maritime Safety Board survey vessel No. 5, the Kaiyo Maru, was dispatched with a party of scientists to study the eruption. Radio contact with the ship was lost on the same night, and the ship disappeared, presumably destroyed by an explosion of the volcano, or one of the tsunamis that accompanied the explosions. Floating wreckage was found near the volcano. The Asahi Shimbun for December 24 reports that the conclusion of the investigating committee is that an explosion occurred beneath the starboard side of the vessel at about 12:20 on September 24, largely destroying the starboard side of the superstructure and causing the vessel to sink immediately. Thirty-one persons were lost. The nine scientists included two geologists, Dr. R. Tayama of the Maritime Safety Board and Prof. K. Kawada of Tokyo Education University. Dr. Tayama was well known for his work on the geology of the former Japanese Mandated Islands.

The violent explosions of September 23 and 24 largely destroyed the portion of the volcanic peak above sea level. Photographs taken by Dr. Niino on September 23, show dense cauliflower explosion clouds rising within 8 minutes to a height of about 20,000 feet. By late December, however, the island had rebuilt to a height of 150 or 200 feet. It appears probably to be a dome of viscous dacite.

Volcanic activity is not new in the general area of Myojin Reef and Bayonnaise Rocks. Sapper (Vulkankunde, p. 318) reports pumice ejection at 31° 59′ N., 140° 07′ E., in early April, 1905. According to R. Mita, in Hydrographic Bulletin No. 12, 1949, the Okinawa Maru reported a "smoke" column about 300 feet in diameter and up to 1,000 feet high in April, 1906. Submarine eruptions near the Bayonnaise Rocks were reported by the Totomi Maru in April and June, 1915. Early in February, 1946, an island about 650 feet long and 500 feet wide appeared at 31° 57′ N., 140° 01′ E., close to the location of the present Myojin Reef. In April, several spine-like islands as much as 120 feet high were reported, and, in October, the island was reported

to be 300 feet in height. It appears to have been a volcanic dome. By December, 1946, the island had been reduced to a low reef, probably by explosions and the crumbling away that characteristically takes place on volcanic domes, as well as by wave erosion.

NORTHERN MARIANAS ISLANDS

In late October, 1952, the captain of a Japanese fishing boat reported volcanic explosions sending clouds of "smoke" to a height of 1,400 feet on the island of Uracas (Farallon de Pajaros). Dr. Joshua I. Tracy, Jr., writes that Lt. G. W. Watson, U.S.N., flew over Uracas on November 22, and reported that the volcano was much more active than he had seen it during a dozen previous flights. He circled the crater for about 10 minutes and observed four or five large puffs of brown "smoke." With each puff large rock fragments were blown about 50 feet above the rim of the crater.

Dr. Tracy and Dr. J. A. Stark, both of the U. S. Geological Survey, visited Pagan Island during early November. There appears to have been no activity there since 1925, but a cinder cone 100 feet high, in the center of the crater, was fuming slightly.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
Elizabeth G. Eklund, Secretary, part-time

Seismograph Station Operators:

Hilo Station:
Sister M. Thecla, St. Joseph's School

Kona Station:
Howard M. Tatsuno, Konawaena School

University of Hawaii:
T. A. Jaggar, Geophysicist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION
In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcanoes in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THOMAS AUGUSTUS JAGGAR

THOMAS AUGUSTUS JAGGAR

Photo by R. H. Post, Honolulu

In Philadelphia, on January 24, 1871, Thomas Augustus Jaggar, Jr., was born to a long life of scientific adventure terminated only by his death in Honolulu on January 17, 1953. The son of a bishop of the Episcopal Church, he was educated in public and private schools in Cincinnati, Montreux, and Philadelphia. He entered Harvard University in 1889 and in 1893 graduated with the A.B. degree in geology. He received his Master of Arts degree from Harvard in 1894 and spent most of the next 2 years in Europe, studying mineralogy under Professor Paul Groth at Munich and petrography under Professor Harry Rosenbusch at Heidelberg. Returning to Harvard, he completed his work for the Doctorate of Philosophy under Professor John E. Wolff in 1897, with a dual thesis on the microscopic determination of the hardness of minerals and the geologic evidence derived from certain inclusions in dikes in the Boston area.

From 1895 to 1903, Jaggar held the position of Instructor in Geology at Harvard, and from 1903 to 1906 he was an Assistant Professor in the same department. During these years he was also a member of the United States Geological Survey, working under S. F. Emmons in the region of the Black Hills, South Dakota, and under Arnold Hague in the Yellowstone region. The work in South Dakota and adjacent parts of Wyoming led to the publication, in 1901, of his first big work, an important study of

the laccoliths of the Black Hills. A report on the petrography of the Absaroka Range was prepared for the never-published first volume of the Geological Survey's memoir on Yellowstone National Park. In 1900 and 1901, he was engaged with Charles Palache on a study of the Bradshaw Mountains in Arizona. In 1906, Jaggar was appointed Professor and Head of the Department of Geology in the Massachusetts Institute of Technology.

Dr. Jaggar's approach to geology was a dynamic one. Beginning in his student days, geological processes were his major interest. He was, of course, interested also in the results of the processes, but largely for what they could tell him of how they came about. Fired by Daubree's *Géologie expérimentale,* he set about applying the experimental methods of physics and chemistry to geology. The results of laboratory experiments on stream erosion and sedimentation appeared in print in 1908. However, he was much more interested in applying similar methods in the field, in an attempt to measure and analyze geologic processes actually in operation. The most dynamic aspects of dynamic geology are seismology and volcanology, and to Jaggar the attraction of earthquakes and volcanoes was irresistible.

In 1902, Dr. Jaggar was one of the geologists on the expedition of the S.S. "Dixie" to the Antilles to study the results of the catastrophic eruptions of Mont Pelée and La Soufrière. It was this expedition that decided him definitely on adopting the field study of geophysics as his life work. It is noteworthy that the catastrophe at St. Pierre was the factor that guided into volcanologic work the two greatest American volcanologists of the early twentieth century, Thomas Augustus Jaggar and Frank Alvord Perret.

In 1906, Dr. Jaggar visited Italy to study the eruption of Vesuvius and the damage caused by it. There he found Perret already working as a volunteer assistant to Professor Raffaele Matteucci, director of the Vesuvius Observatory. In 1907, Jaggar was the leader of the Technology Expedition to the Aleutian Islands, during which Makushin and Bogoslof volcanoes received special study. In 1909, Professor Jaggar and his colleague Professor R. A. Daly visited the Hawaiian volcanoes, and Dr. Jaggar went on to Japan to visit the laboratories and stations of the Imperial Earthquake Investigation Committee. At that time a long friendship and mutual admiration began between him and Professor F. Omori, the great leader of seismology in Japan. In 1910, Jaggar and Charles M. Spofford, Professor of Civil Engineering at M.I.T., visited Central America for the purpose of studying the volcanoes of Costa Rica and the results of the great Cartago earthquake of that year, and Jamaica to examine the work being done there in enforcing earthquake-proof construction.

These excursions served to convince Professor Jaggar of the inadequacy of the expeditionary method of studying volcanoes and earthquakes and of the necessity for permanent observatories to keep constant record, every day, year in and year out, of volcanic and seismic activity. He was impressed also by the small amount of knowledge possessed by men of science regarding the prediction or alleviation of natural disasters and by the small amount of effort being expended in the attempt to acquire that knowledge. On January 7, 1909, following the Messina earthquake disaster, he wrote in *The Nation:* "The *highest* development of geology is the unravelling of the history of the past. We haven't time to go into prediction and humanistic geology." The blame did not lie, he added, with the geologist, but with the haphazard growth of the science and the very proximity of the earth which made terrestrial observation and measurement difficult. The time had come, however, when such studies could no longer be neglected. Instruments existed for the study of the earth processes, and others could be developed. The gravest difficulty lay in the fact that the new program would call for the establishment of permanent observatories in many lands. The goals of the program should be the prediction of volcanic eruptions and earthquakes and the development of engineering and types of construction to help alleviate the consequences of such cataclysms.

On July 1, 1909, the trustees of the estates of Edward and Caroline Whitney of Boston gave $25,000 to the Massachusetts Institute of Technology to be used for research or teaching in geophysics, including seismology, with a view to the protection of human life and property. It was decided to use these funds for the establishment of a laboratory at Kilauea, Hawaii, for the study of the activity of that volcano and its earthquakes and of waves traveling through the earth from distant earthquakes. Thus did Dr. Jaggar enter upon his true life's work—the establishment and operation of the Hawaiian Volcano Observatory.

Actually, it did not fall to Dr. Jaggar's lot to perform the first work of the new program at Kilauea. During 1910 and 1911, none of the professors at M.I.T. could be spared to go to Hawaii. In the meantime, part of the Whitney Fund had been used for the construction, under the direction of Dr. A. L. Day and Dr. E. S. Shepherd of the Geophysical Laboratory of the Carnegie Institution of Washington, of special resistance thermometers for the measurement of the temperature of molten lava at Kilauea. A cableway had been designed at M.I.T. for spanning Halemaumau Crater in order to lower the thermometers into the lava lake. Dr. Shepherd's services had already been secured for the summer of 1911 to make the temperature measurements. Because Dr. Jaggar could not accompany Shepherd to Kilauea, arrangements were made with the Volcanic Research Society of Springfield, Massachusetts, for the loan of the services of Frank A. Perret, volcanologist of that society, who had been engaged in studies of the Italian volcanoes. Perret and Shepherd reached Kilauea on July 2, 1911, built an observation station at the rim of Halemaumau, and, after much difficulty, succeeded in obtaining a measurement of the temperature of the lava (1000°C.). Perret began the series of systematic records and reports on Kilauea activity that still continues. Dr. Jaggar was granted leave of absence from the Massachusetts Institute of Technology in December, 1911, and reached Kilauea on January 17, 1912.

Establishment of the Hawaiian Volcano Observatory would not have been possible without the enthusiastic aid of the people of Hawaii. The Whitney Fund provided only $3,450 per year for 5 years. During his visit in 1909, Dr. Jaggar enlisted the support of the Honolulu Chamber of Commerce and some of Hawaii's leading citizens. On October 5, 1911, L. A. Thurston gave a luncheon at the University Club in Honolulu for the purpose of organizing a Hawaiian Volcano Research Association. This association subscribed an additional

$5,000 a year, over and above the amount from the Whitney Fund, for the operation of the Volcano Observatory. The College of Hawaii, through its president, J. W. Gilmore, pledged its interest and support. Hilo people also were eager to help, and through the efforts of Demosthenes Lycurgus $1,785 was quickly gathered for the construction of the Observatory building. On March 6, Dr. Jaggar was recalled to Boston, leaving the work at Kilauea temporarily in the hands of F. B. Dodge. But on June 13 he was back again, accompanied by Dr. Harry O. Wood, who became the first seismologist of the Volcano Observatory.

From that time on, the Hawaiian Volcano Observatory was the focal point of Dr. Jaggar's interest and efforts. Financially, things were seldom easy and often extremely difficult. There were times when Dr. Jaggar served wholly without any regular salary. There were still more times when Observatory funds were inadequate to buy even the most essential materials for the work, and he had to pay for them personally out of his own slim savings or appeal again for help from such loyal friends as Frank C. Atherton and Walter F. Dillingham. To such friends Dr. Jaggar was ever grateful, not only for their help to himself, but more particularly for their aid to the growth of the new science of volcanology. It is a fine tribute to Dr. Jaggar's determination and singleness of purpose that even in the hardest and most discouraging of times he did not falter, but somehow kept the program going. After responsibility for the operation of the Volcano Observatory was assumed by the United States Government in 1919, desperately lean periods were less frequent, and there were occasional times of relative opulence. Never, however, was Dr. Jaggar content with progress. Always, over the hills and valleys of varying prosperity, he was striving for greater things for the Observatory and for the science as a whole.

Work at Kilauea was diversified. To routine seismology and the continuous record of activity of Kilauea and Mauna Loa were added observations on the rise and fall of the level of molten lava in Halemaumau, measurements of the temperature of the melt, soundings of the depth of the lava lake, experiments on the viscosity of the lava, collections of volcanic gases for chemical analysis, borings to ascertain the nature of the crater floor and the distribution of temperature in the rocks underlying it, measurements of the shifting and tilting of the ground surface both laterally and vertically, study of the different types of lavas and how they form, and petrographic studies of the rocks. No phase or feature of the volcanoes remained uninvestigated if means could be found for Jaggar or his associates to attack it. In the field of distant earthquakes, a special study was made of tsunamis, the destructive ocean waves that sometimes accompany submarine earthquakes, and possible means of predicting them.

Hawaiian work did not preclude work elsewhere. Expeditions were made to Japan in 1914 and 1923 to study the eruption of Sakurajima and the great Yokohama-Tokyo earthquake. Seeking always to expand the continuous, observatory-type study of volcanoes, Jaggar visited New Zealand in 1920, at a time when the New Zealand Government was considering the establishment of a volcano observatory. In 1924 he visited Howland and Baker Islands with the "Whippoorwill" Expedition, sponsored by the Bishop Museum and the U. S. Navy. In 1927 he was engaged in field work in the Aleutian Islands, and in 1928 he conducted the Pavlof Expedition of the National Geographic Society to the Alaska Peninsula. In 1930 he was a member of the U. S. Naval Observatory's Eclipse Expedition to Niuafo'ou Island.

In 1924 the operation of the Hawaiian Volcano Observatory passed from the U. S. Weather Bureau to the Geological Survey. In 1926 the Survey established a Section of Volcanology, with Jaggar as its Chief. Stations were established at Lassen Volcano in California and at Dutch Harbor, Alaska. Investigations of Aleutian volcanoes were begun by Jaggar in 1927 and continued by R. H. Finch, volcanologist in charge of the Lassen Observatory, in 1931 and 1932. These investigations were resumed by the Geological Survey during World War II and are now being pursued on a systematic basis under the direction of Howard A. Powers, formerly geologist for the Hawaiian Volcano Observatory.

Dr. Jaggar was one of the early advocates of a national park to include the crater areas of Kilauea and Mauna Loa, and in 1915 he made a trip to Washington for the prime purpose of pleading for its establishment. He felt that the wonders of the great Hawaiian volcanoes and the surrounding tropical beauty, which he himself loved so much, should be the property of all the American people. The vision was consummated in the establishment of Hawaii National Park the next year. In 1935 the Volcano Observatory was transferred to the National Park Service, and Jaggar became an official of the park he had helped to establish. He remained such until his retirement in 1940. After his retirement from government service, Dr. Jaggar became research associate in geophysics at the University of Hawaii and retained that position until his death.

For many years Dr. Jaggar was intensely interested in the sea bottom. This 72 per cent of the earth's surface, concealed from man's view by deep water, was a challenge to his imagination and curiosity. He advocated its exploration by any means available and was especially interested in the possibility of drilling into it from great, floating seadromes. He recognized the technical difficulties of such a procedure but was confident they could be overcome if the results would be worth it—and he was firmly convinced that they would be.

Even all this activity could not absorb all the energy of Jaggar's restless mind. He loved to work with his hands and spent much time in his machine shop. New types of seismographs and seismometers were usually under design and construction, as he carried on a constant search for instruments that could be built and installed cheaply and yet yield valuable results. Such instruments would make possible the great expansion of seismic studies that he envisioned. When Aleutian field work presented difficulties in transportation, he invented an amphibian automobile, used successfully during the Pavlof Expedition, for which he received the 1945 Franklin L. Burr Prize of the National Geographic Society. Interest in boats led to interest in navigation and the design of instruments for locating the geographical position of a ship or airplane through observation of stars at the zenith.

After his retirement he returned to one of his earliest interests, the precise measurement of hardness of minerals and other substances, and he designed and built a new instrument for hardness testing. He was interested in astronomy and spent many evenings at his telescope observing heavenly objects, especially the moon, in whose craters he saw an analogy to the great volcanic craters of the earth. He even entered the fields of philosophy and religion with essays on Jesus; the origin of the earth, life, and man; evolution; and trends of science. He was a staunch church member. While he was still at Harvard and M.I.T., he became deeply interested in the problems and methods of education. In his later life this interest was expressed through his service on the governing board of Iolani School in Honolulu.

It is difficult to evaluate properly the importance of Dr. Jaggar's work in volcanology. We are still too close to it. It is abundantly obvious, however, that its importance is very great. At the time Jaggar founded the Hawaiian Volcano Observatory, the science of volcanology was in its infancy. It has now entered a stage of adolescence where some concrete results are beginning to appear from the great amount of work put into it. Unreservedly, Jaggar may be said to have been one of the very few principal contributors to this progress.

Early results of the work at Kilauea related largely to the dual nature of the lava lake, the shallowness of the pool of pyromagma, the temperature distribution in the lake, and the composition of gases given off by it. These were important in building a picture of the physical nature of the magma column feeding the volcano. Later work added somewhat to that picture, demonstrated the swelling and shrinking of the entire volcanic edifice related apparently to changes of magmatic pressure beneath it, showed the occasional occurrence of great collapses and related thereto occasional violent steam explosions due to cracking of the surrounding rocks and entrance of ground water to the hot volcanic conduit, and built a partial picture of the earthquake activity associated with volcanic changes. Tentative correlations of volcanic events with astrophysical forces and possible cycles in time have been made and are undergoing testing. The work is far from ended, but good progress has been made.

The work has not all been done by Jaggar, of course. Contributions have been made by a whole succession of capable scientific associates, among whom may be mentioned H. O. Wood, Arnold Romberg, E. G. Wingate, A. E. Jones, H. A. Powers, and Jaggar's long-time associate and successor as director of the Volcano Observatory, R. H. Finch. And certainly he would want included among his most valuable co-workers his wife, Isabel, who shared with him the disappointments, the joys of discovery, and much of the physical work. It has been Jaggar's vision and enthusiasm, however, that has guided the work and integrated it, and a very large proportion of it actually was done by him personally.

Possibly the greatest of all Dr. Jaggar's contributions are his ideas for the protection from lava flows of cities, harbors, or other important areas, through aerial bombardment or the construction of barriers to deflect the flows. Bombing has been tried, and the general method has proved feasible and effective. There is little question that the barriers also would do their job well. These things constitute a long step toward fulfillment of the motto adopted at the founding of the Hawaiian Volcano Research Association: "Ne plus haustae aut obrutae urbes"—no more shall the cities be destroyed!

Dr. Jaggar's dream was that some day the work on Hawaiian and other Pacific volcanoes might be combined with other types of geophysical studies in a great Institute of Terrestrial Research centered in Hawaii. It is a grand dream, which may, like so many of his dreams, someday materialize.

All of us who have been associated with Tom Jaggar mourn his passing. But at the same time we are grateful, as he would have us be, for his long and full life, profitably spent, and for memories of his superb intellect combined with a gentle and modest spirit whose greatest concern was with the well-being of the rest of mankind.

—G. A. MACDONALD.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JANUARY–MARCH, 1953

By GORDON A. MACDONALD

VOLCANOLOGY

January

Hawaiian volcanoes remained fairly quiet through the month of January. Seismographs at Kilauea Crater recorded 41 earthquakes during the month, and the Mauna Loa seismograph recorded 33. This is about the usual number recorded during times of volcanic quiet. However, some of the quakes were larger than usual.

Several earthquakes were felt in Kona during the month. Most of them originated locally, on the Kealakekua fault or at sources between central Kona and the summit of Mauna Loa. A small earthquake felt at Naalehu and Kapapala at 9:08 A.M. on January 9 originated beneath the southeast slope of Mauna Loa about 8 miles northwest of Kapapala, and another at 9:10 P.M. on the same day had its epicenter about 1.5 miles closer to the summit of the mountain. The latter quake was felt quite strongly all over the southern part of the island and less strongly at least as far north as Kukuihaele.

At 2:04 A.M. on January 15 a strong earthquake originated beneath the southeast slope of Mauna Loa near the Kapapala Ranch headquarters. Objects were upset and knocked from shelves as far away as Hilo. Residents of the southern part of the island of Hawaii were generally awakened, and the quake was felt as far away as Oahu. In its epicentral area the intensity of the quake is estimated to have been about 5 on the modified Mercalli scale.

Tilting of the ground at the Volcano House was in general slightly southward during the month, at a rate about normal for this season of the year. From January 1 to 15 there was an accumulation of a little more than 1 second of eastward tilting, suggesting a small increase of pressure beneath Mauna Loa associated with the Mauna Loa earthquake activity during the early part of the month. During late January, however, the eastward tilting and, presumably, the increase of pressure beneath Mauna Loa ceased. Late in January a slight northward tilting commenced.

February

Seismic activity on the island of Hawaii during the month of February was relatively slight. Seismographs at Kilauea Crater recorded only 18 earthquakes, the smallest number since January, 1951. The Mauna Loa seismograph recorded 25 quakes during the month. Some of these originated on the west slope of Mauna Loa and others on the northeast rift zone.

At 6:44 A.M. on February 12 an earthquake with an intensity of 4 on the modified Mercalli intensity scale was felt strongly at Kapapala. Its origin was close to Kapapala, probably on the Kaoiki fault, which parallels the highway between Kilauea Crater and Pahala.

The earthquake that occurred at 1:40 A.M. (Hawaiian time) on February 26 about 650 miles north of New Caledonia, near the Santa Cruz Islands, produced only a slight record on seismographs at Kilauea.

During the month there was a small accumulation of northward tilting of the ground at the seismograph station beneath the Volcano House. There was essentially no accumulation of tilt in the east-west direction. During this season of the year tilting at the Volcano House usually is south-southwest. Therefore, the slight northward tilting and absence of westward tilting indicate some increase of volcanic pressure beneath Kilauea Crater and, possibly, also under Mauna Loa.

Late in the afternoon of February 28, the seismographs recorded 18 minutes of continuous volcanic tremor, indicating movement of magma beneath the surface at Kilauea.

March

Seismographs of the Hawaiian Volcano Observatory recorded a total of 75 earthquakes during March. Many of these were too small to be recorded at more than one station. For example, the seismograph at Konawaena School recorded four very feeble earthquakes of nearby origin that were too small to be recorded at Kilauea Crater. During the month the seismographs at Kilauea recorded 45 earthquakes, and the Mauna Loa seismograph recorded 51. The number of earthquakes at any single station was approximately normal. Although the total number of quakes was somewhat greater than normal, such a large proportion of the quakes were very small that the total seismic activity also was only about normal in amount.

On March 6, at 7:48 A.M., a slight earthquake was felt in central Kona. Its origin apparently was on the Kealakekua fault, probably near Kealia. At 2:26 P.M. on the same day an earthquake was felt throughout much of Kona and Kau. Its origin lay at a depth of about 30 miles beneath the summit area of Hualalai.

At 6:19 P.M. on March 25 a moderately strong earthquake occurred, with its epicenter on the south slope of Mauna Loa, 10 miles N 25° W of Naalehu. It was felt strongly at Naalehu, where it had an intensity of about 4 in the modified Mercalli scale. At Kapapala its intensity was 2 to 3. The quake was felt slightly over most of the island. At 1:40 A.M. on March 26 a smaller earthquake was felt quite strongly at Naalehu, where its intensity was estimated as about 2, and less strongly over much of the southwest portion of the island. Its epicenter also lay on the south slope of Mauna Loa, about 5 miles north of Naalehu.

During March, tilting of the ground surface at the Volcano House was southwestward, both the direction and the aggregate amount being approximately normal for that season of the year. Temperatures of steam at vents in the vicinity of Kilauea Crater remained unchanged. General conditions at Halemaumau also remained unaltered, with no visible activity other than steam vents and a weakly active vent liberating sulphurous fume on the floor of Halemaumau Crater northwest of the large cones of the recent eruption. During recent weeks there has been a marked increase in the volume of steam visible at the northeast wall of Puhimau Crater.

On March 14 continuous tremor was recorded on the seismographs for 16 minutes, apparently indicating movement of magma beneath Kilauea. Again on March 29 there were recorded 13 minutes of continuous tremor, possibly a succession of very small earthquakes, but appearing more probably to be volcanic tremor of the sort that accompanies magma movement. Thus far there has been no sign of abnormal tilting such as would indicate any marked decrease of pressure beneath either Mauna Loa or Kilauea. Although there has been no marked restlessness to indicate imminent eruption of either volcano, it is entirely possible that if magma stands high in the conduits, as is suggested by the evidence, eruption might occur with little or no warning.

SEISMOLOGY

Distant Earthquakes

Only one distant earthquake was recorded during the quarter. It was recorded on February 26, at 01:59 H.S.T., and produced only a slight record on the Bosch-Omori seismograph. The notice of Preliminary Determination of Epicenter issued by the U. S. Coast and Geodetic Survey places the origin of the quake in the region of the Santa Cruz Islands, at 11° S., 164.5° E., about 650 miles north of New Caledonia. Its origin time was 11:42:26 G.C.T.

Earthquake Data, January–March, 1953

(Based on Bosch-Omori seismograph on northeast rim of Kilauea Caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms

29	11	1	0	0	0	0	3.25	0

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to an earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Vaults on Rim of Kilauea Caldera

Week Beginning	Whitney Vault (Northeast rim)		Uwekahuna Vault (West rim)

Local Earthquakes

The data for the following local earthquakes were determined from seismographs operated on the island of Hawaii by the Hawaiian Volcano Observatory. Locations given are epicenters. The times given are arrival times at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea Caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

1. Jan. 2, 03:32, very feeble. Near summit of Mauna Loa (?).
2. Jan. 2, 23:34, no record at Kilauea (Kona, very feeble).
3. Jan. 3, 11:31, feeble (Kona, strong). Felt strongly in Kona. Central Kona, on Kealakekua fault near Keei. 19° 28′ N., 155° 52′ W.
4. Jan. 3, 11:34, very feeble (Kona, slight). Felt in Kona (Kona aftershock).
5. Jan. 4, 23:07, very feeble. Kilauea.

6. Jan. 7, 15:58, tremor (Kona, very feeble). Felt in Kona.
7. Jan. 7, 21:31, no record at Kilauea (Kona, very feeble). Central Kona.
8. Jan. 9, 09:09, very feeble. Felt at Kapapala, Naalehu, Kona, SE slope of Mauna Loa at about 19° 22′ N., 155° 31′ W.
9. Jan. 9, 09:22, very feeble.
10. Jan. 9, 16:05, very feeble. Felt at Kapapala.
11. Jan. 9, 16:42, no record at Kilauea (Kona, very feeble). Felt in Kona. Central Kona.
12. Jan. 9, 21:10, strong. Felt strongly at Kahuku and Naalehu, moderately at Kapapala, Volcano district, Hilo, and Kona, slightly at Kukuihaele. SE slope of Mauna Loa about 4 miles SE of South Pit, at about 19° 24′ N., 155° 33′ W., about 14 miles deep.
13. Jan. 10, 06:32, tremor (Kona, very feeble). Central Kona.
14. Jan. 12, 03:27, tremor (Kona, very feeble). Central Kona.
15. Jan. 13, 04:13, slight. Four miles S 45° E of Naalehu.
16. Jan. 13, 07:29, very feeble. Felt quite strongly at Kapapala.
17. Jan. 14, 05:38, very feeble. SW rift of Kilauea (?).
18. Jan. 15, 02:05, strong. Felt strongly all over southern half of island from Hilo to Kona, and slightly as far away as Oahu. SE slope of Mauna Loa about 3 miles NNE of Kapapala Ranch headquarters, 19° 19′ N., 155° 26′ W., about 15 miles deep.
19. Jan. 15, 07:30, tremor (Kona, slight). Felt in Kona. Central Kona.
20. Jan. 16, 13:01, very feeble.
21. Jan. 16, 21:54, very feeble.
22. Jan. 17, 05:09, very feeble.
23. Jan. 17, 17:40, very feeble.
24. Jan. 18, 09:33, feeble. On SE slope of Mauna Loa near Ohaikea.
25. Jan. 21, 12:58, very feeble.
26. Jan. 23, 14:18, no record at Kilauea (Kona, very feeble). Felt in Kona. Central Kona.
27. Jan. 24, 11:14, no record at Kilauea (Kona, very feeble). Central Kona.
28. Jan. 25, 03:17, very feeble.
29. Jan. 27, 03:00, very feeble. Kilauea.
30. Jan. 29, 00:17, tremor (Kona, very feeble).
31. Jan. 30, 08:06, very feeble.
32. Jan. 30, 10:53, tremor (Kona, very feeble).
33. Feb. 3, 07:28, no record at Kilauea (Mauna Loa, tremor; Kona, feeble). Central Kona.
34. Feb. 6, 20:21, no record at Kilauea (Kona, very feeble). Central Kona.
35. Feb. 8, 18:48, tremor (Kona, very feeble).
36. Feb. 9, 22:47, very feeble (Kona, feeble). Near summit of Mauna Loa.
37. Feb. 11, 21:19, no record at Kilauea (Kona, very feeble). Central Kona.
38. Feb. 12, 04:38, no record at Kilauea (Kona, very feeble).
39. Feb. 12, 06:45, very feeble. Felt strongly at Kapapala, intensity about 4 (modified Mercalli). Kaoiki fault near Kapapala, at about 19° 17′ N., 155° 27′ W.; shallow focus.
40. Feb. 12, 14:06, no record at Kilauea (Kona, very feeble).
41. Feb. 13, 04:49, very feeble.
42. Feb. 13, 04:51, very feeble.
43. Feb. 13, 04:51, very feeble.
44. Feb. 15, 22:10, very feeble.
45. Feb. 16, 11:21, very feeble. Kaoiki fault, about 4.6 miles SW of Uwekahuna station, at about 19° 24′ N., 155° 22′ W.
46. Feb. 16, 20:20, no record at Kilauea (Kona, very feeble). Central Kona.
47. Feb. 18, 02:26, no record at Kilauea (Mauna Loa, tremor; Kona, very feeble). West flank of Mauna Loa.
48. Feb. 18, 02:30, no record at Kilauea (Mauna Loa, tremor; Kona, very feeble). West flank of Mauna Loa.
49. Feb. 20, 06:14, no record at Kilauea (Kona, very feeble). Central Kona.
50. Feb. 20, 06:16, no record at Kilauea (Kona, very feeble). Central Kona.
51. Feb. 21, 22:44, no record at Kilauea (Kona, very feeble). West slope of Mauna Loa.
52. Feb. 22, 02:40, slight. Felt in Volcano district. Kaoiki fault between Bird Park and Ohaikea.
53. Feb. 25, 15:30, very feeble.
54. Mar. 1, 22:42, very feeble. Off south shore at about 19° 00′ N., 155° 24′ W.
55. Mar. 3, 19:32, no record at Kilauea (Kona, very feeble). Central Kona.
56. Mar. 6, 04:39, feeble. Off south coast at about 19° 04′ N., 155° 25′ W.
57. Mar. 6, 06:06, very feeble.
58. Mar. 6, 07:48, very feeble (Kona, slight). Felt in central Kona. Kealakekua fault, near Kealia (?).
59. Mar. 6, 14:26, very feeble (Kona, feeble). Felt in central Kona, Naalehu, and Kapapala. Beneath summit area of Hualalai Volcano, about 30 miles deep.
60. Mar. 9, 19:27, feeble. Kilauea.
61. Mar. 10, 06:31, very feeble. North slope of Mauna Loa about 3 miles NW of Kokoolau cone, at about 19° 39′ N., 155° 37′ W.
62. Mar. 12, 18:58, tremor at Whitney Laboratory, very feeble at Uwekahuna. Kilauea.
63. Mar. 17, 03:20, no record at Kilauea (Kona, very feeble). Central Kona.
64. Mar. 18, 11:12, very feeble.
65. Mar. 18, 23:40, very feeble. Moderate distance.
66. Mar. 19, 06:45, no record at Kilauea (Kona, very feeble). Central Kona.
67. Mar. 19, 20:01, very feeble.
68. Mar. 23, 19:30, tremor (Mauna Loa and Kona, very feeble).
69. Mar. 23, 21:19, very feeble. Felt in south Kona. West slope of Mauna Loa.
70. Mar. 25, 10:50, very feeble (Mauna Loa, slight). Near summit of Mauna Loa, probably on NE rift zone.
71. Mar. 25, 18:19, moderate. Felt strongly at Naalehu and Kapapala and slightly over most of the island. South slope of Mauna Loa, at about 19° 12′ N., 155° 39′ W.
72. Mar. 26, 01:40, very feeble (Mauna Loa, feeble). Felt moderately at Naalehu and slightly as far as central Kona. South slope of Mauna Loa, at about 19° 08′ N., 155° 35′ W.
73. Mar. 27, 22:30, no record at Kilauea (Kona, very feeble). Felt in Kona. Central Kona.
74. Mar. 31, 03:54, very feeble.

VOLCANO NOTES AND NEWS

CONTINUED VOLCANIC ACTIVITY AT SAN BENEDICTO ISLAND, MEXICO

By Adrian F. Richards

Initial activity of Boqueron Volcano on San Benedicto Island, Mexico, has been described by Howel Williams in Volcano Letter 517. (The name Boqueron, meaning "Big Mouth," was suggested by Dr. Williams.)

On November 15, 1952, J. M. Snodgrass, D. L. Inman, and the writer, all of the Scripps Institution of Oceanography, flew to Boqueron Volcano in a U. S. Navy PBM. The small conical mass of lava that had plugged the conduit of the 700-foot-deep crater was observed to have increased greatly in size so that the crater had become half filled with a biscuit-shaped mass of block lava. This extrusion of lava probably took place about November 12, at which time the master of the tuna clipper "Constitution" reported to the Scripps Institution that intermittent smoke with flames shooting above the crater had been visible during the night at a distance of 40 miles from the island. No incandescence was seen on November 15. On November 19, the master of the clipper "Paramount" reported to the writer that he had seen glowing boulders hurled 200 feet above the crater at night. Based on observations of December 10, additional block lava was probably added to the crater at that time. On December 8, according to M. Silva of the "Star of the Sea," lava escaped from the flank of Boqueron Volcano at the eastern base of the cone, 60 feet above sea level.

Lewis Walker and the writer reached San Benedicto Island on December 9 for a stay of 4 days. The fissure, through which the blocky lava welled, lengthened upslope to 192 feet altitude by December 11. The temperature at the throat of the fissure was estimated by the writer to be approximately 1300°C., based on the orange-white incandescence. This lava extrusion advanced out to sea 900 feet in 2 days, during which time it grew laterally to 1,200 feet in the shape of a lobate delta. When last observed, the lava was advancing seaward at the rate of 150 feet per day.

Based on identical readings of aircraft altimeters on flights over Boqueron on November 15 and December 11, the elevation of the top of the cone of Boqueron Volcano was determined to be 1,250 feet. This figure is 250 feet less than that reported by Dr. Williams on the September 20 flight. Comparisons of September, November, and December photographs show no apparent change in the height of the rim; consequently, the 1,250-foot value is probably more nearly correct. On December 9, at intervals of approximately 1 hour, dense cauliflower clouds of steam and ash were observed to rise to 3,000 feet. On December 10, the crater rim was observed to be half a mile wide. Red incandescence of the crater lava was occasionally seen in broad daylight. On the morning of December 12, the volcanic activity increased to a continuous eruption of steam and ash from the crater. This eruption continued through December 13, when the island was seen by tuna fishermen. On January 5, Paul Lynn, master of the "Cape Beverly," reported rumbling sounds heard at a distance up to 1 mile from Boqueron, coincident with gas eruptions from the crater.

ERUPTION OF TRIDENT VOLCANO, ALASKA

Mount Trident, in Mount Katmai National Monument, erupted on February 15, 1953. Mount Trident is located near the base of the Alaska Peninsula, 110 miles northwest of Kodiak and 5 miles west-southwest of Katmai Volcano, which erupted violently in 1912. There is no previous record of activity of Trident Volcano during historic times.

On February 15 and 16, pilots of commercial and military planes reported a cloud of "smoke" rising about 30,000 feet into the air. Visibility was too poor, however, to permit precise determination of the type and place of activity. On February 18, the vent was finally located on the south slope of Trident Peak. Earlier reports that Katmai and Novarupta volcanoes were active proved false.

On February 21, seismologist Richard McDonald of the U. S. Geological Survey identified a lava flow issuing from a fissure about 1 mile southwest of the old crater of Trident Volcano. The flow was still active and was about 800 feet wide at its toe and 1,500 feet long. It had advanced about 1,000 feet since it was photographed on February 18. The eruption column rose to a height of about 11,000 feet, and a thin deposit of ash was observed over the surrounding area. The crater lake of Katmai Volcano was not frozen. Light steam rose from two craters on nearby Mageik Volcano, and steam was rising from a vent on the southeast flank of Mount Trident, about 1.5 miles east of the lava vent.

On March 11, geologist George Snyder of the U. S. Geological Survey reported Trident Volcano still active, with slow lava extrusion. Ash blanketed the area within a radius of 20 miles south and east of the volcano.

MYOJIN REEF, JAPAN

Dr. Helen Foster of the U. S. Geological Survey's office in Tokyo writes that Dr. H. Niino of the Tokyo College of Fisheries visited the area of Myojin Reef on February 1. He reported an island estimated to have a maximum diameter of 226 meters and a minimum diameter of 158 meters, in a northwest-southeast direction. The highest point was a black spine 94 meters high. There was also a grayish-white dome 54 meters high. Steam was being emitted from the spine, but there was no other sign of activity. The previous growth of the island was described in Volcano Letter 518.

The March 19 edition of the newspaper *Hawaii Hochi* reported three explosions at Myojin Reef on March 18. The eruption column was stated to reach a height of 1,000 feet.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
Elizabeth G. Eklund, Secretary, part-time

Seismograph Station Operators:

Hilo Station:

Sister M. Thecla, St. Joseph's School

Kona Station:

Howard M. Tatsuno, Konawaena School

University of Hawaii:

T. A. Jaggar, Geophysicist

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcances in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations. Dr. T. A. Jaggar is their geophysicist resident at Kilauea.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

THE VOLCANO LETTER

No. 520 **U. S. Geological Survey** **April–June, 1953**

PUBLISHED BY THE UNIVERSITY OF HAWAII

NOTES ON THE 1880–81 LAVA FLOW FROM MAUNA LOA

By E. D. BALDWIN[1]

At Honolulu in November, 1880, we were under a strict smallpox quarantine, no one being allowed to leave the Island of Oahu for fear of carrying the disease to the other islands. It was then that we received word that at 9 P.M. on November 5 a great lava flow had broken out on the top of the Mauna Loa divide about a mile above Puu Ulaula. One branch of the lava flow was heading northward toward Mauna Kea. The main branch was advancing rapidly down the mountainside south of the 1855 lava flow. It had often been remarked at Hilo that, if a great lava stream should flow down on the Puna (south) side of the 1855 lava flow, Hilo would be doomed. Here was a massive aa lava stream that in a few days had flowed with great speed down the steep part of the Mauna Loa slopes and then made a turn toward Hilo, on the Puna side of the 1855 lava flow.

A third flow started southward into Kau at 8 P.M. on November 9.

The great lava flows of Mauna Loa commonly are aa at first, changing to pahoehoe after a period of 2 or 3 weeks if the flow continues that long.[2] This fact was well known to all our old Hilo settlers. With the rapid advance of this great aa flow and the knowledge that at any moment the more rapid pahoehoe flow might start, one can easily imagine the nervous excitement of the Hilo residents. They appealed to the authorities at Honolulu for advice and suggested that Professor W. D. Alexander, Surveyor General of the Kingdom of Hawaii, be sent to Hilo to report on the lava flow. The Government acted immediately and passed Professor Alexander through the quarantine and on to the Island of Hawaii.

The writer was then a young man, living in Professor Alexander's home and just beginning his apprenticeship in the Government Survey. Consequently, after Professor Alexander's return from Hilo, the writer had the pleasure of listening to his brilliant account of the lava flow.

One of Hilo's greatest mountaineers, Judge D. H. Hitchcock, was assigned to guide Professor Alexander to the flow. The party started on horseback at daybreak on November 29, spent the night at Hitchcock's Kipuka Ahina camp, then continued to the lava flow on foot the next day. They first visited the western branch of the flow, which Professor Alexander stated was a red-hot stream of aa, then turned back downslope and visited the Hilo branch of the flow. The latter, he stated, was running liquid aa, with its front near the Mawae corner of the Piihonua land division.

Professor Alexander described the lava flow as appearing very liquid at its front, but so viscous that they were unable to drive a stick into it or get any of the molten lava on a stick to shape it into souvenirs, as they

[1] Mr. E. D. Baldwin, for 28 years surveyor and civil engineer in the Hawaiian Government Survey, under the Kingdom, the Republic, and the Territory, had a life-long interest in Hawaiian volcanoes. The present article was written in 1933, after his retirement and shortly before his death. His daughter, Mrs. Jessie Baldwin Hardy, referred it to K. P. Emory of Bernice P. Bishop Museum who in turn referred it to T. A. Jaggar and G. A. Macdonald. The map accompanying the article was prepared by Macdonald.

The article contains much of interest that does not appear to have been published previously. The accounts of the two barriers to protect Hilo from the 1881 lava flow are of special interest in connection with recently proposed barriers. As Mr. Baldwin points out, the wall built to protect the Waiakea mill certainly would not have been effective, as the lava soon would have overtopped the wall and continued on its course. The great earthen embankment along the edge of the Alenaio Gulch, proposed but not constructed, might well have saved the center of Hilo if the flow had continued. It would not, however, have saved the harbor, and it would not be adequate to protect the much expanded Hilo of today.—G. A. M.

[2] It should be noted that this succession of pahoehoe following aa as the eruption progresses is the result of a change in condition of the lava being poured out at the vent, resulting in a new pahoehoe flow flooding over and beyond an earlier aa flow, and not an example of change of aa to pahoehoe in a single flow as it progresses down slope.—G. A. M.

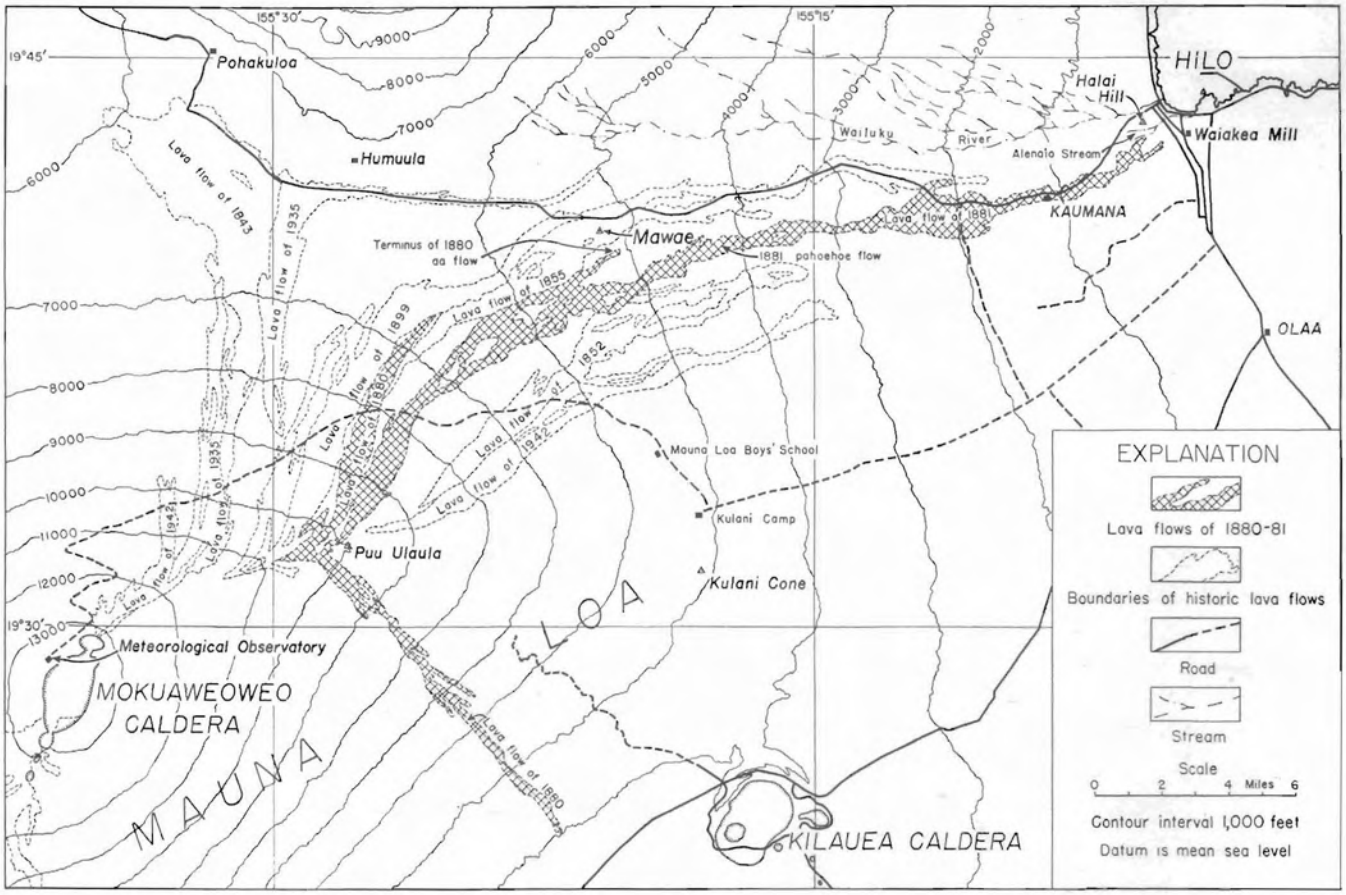

FIGURE 1. Map of the eastern portion of Mauna Loa, showing the 1880–81 lava flows.

were accustomed to do with molten pahoehoe. They cut a long pole from a tree and rushed with it against the most molten portion of the front of the flowing lava, but could make no impression on it.

Mr. Hitchcock has stated to the writer that he had visited the source of the flow a short time after it started and that it was aa all the way from its source to the point where Professor Alexander saw it. The aa flow continued for a short distance below that point, eventually stopping about 20 miles from Hilo. Shortly after Alexander's visit, however, the lava changed to pahoehoe at its source. According to Mr. Hitchcock, the pahoehoe flowed out of the same vent as the aa and flooded down over the aa, almost obliterating it.

For 7½ months the advance of the pahoehoe was slow, averaging only about ½ mile a month. Above Kaumana Woods the flow averaged about a mile wide. On June 30, 1881, the front of the flow was reported to be just above John Hall's house, near the upper edge of the woods about 5 miles from Hilo. As the flow moved through Kaumana Woods, it narrowed until it was hardly ¼ mile wide, and its speed increased greatly, to an average of about 4 miles a month. Almost before the Hilo people were aware of it, the lava suddenly appeared in a narrow stream coming down through the Kaumana lands at the seaward edge of the woods.

Finally the smallpox quarantine in Honolulu was lifted, and on July 12 the writer and a group of other boys took the first steamer for Hilo. The group included Willie and Arthur Alexander, sons of Professor Alexander; John Bishop, son of S. E. Bishop; Horace Chamberlain, son of Warren Chamberlain; and Henry Hyde, son of the Reverend Dr. Hyde. We reached Hilo on the morning of July 14, and as our steamer approached the port we had a fine view of the whole line of the flow, from its source to within a few miles of Hilo town. At the source two columns of dense smoke were rising.

We found the front of the flow about 3 miles from Hilo. When we first reached it, it appeared dead, and a stream of cold water was coming from under it. We traveled up along the flow looking for a suitable camping site and came to a place where it was in action. The pahoehoe lava was flowing into and burning a thick grove of sumach trees (called by the natives *neneleau*). We were new to a live lava flow and did not dare go near it. This amused us soon afterward, as we practically lived on the flow for 2 weeks.

On July 15 we camped at the Natural Bridge, about 4 miles from Hilo. Just below the Natural Bridge the flow had crossed the Alenaio Stream and formed a natural dam and reservoir in which one could enjoy any kind of bath, from cold to scalding hot. We cooked every meal on the lava flow. We found a place where the lava was oozing out in a small way and on this set our pots and fried our pancakes. Occasionally our fry-

ing pan floated down with the lava.

At several places there were openings in the top of the flow that exposed the tunnel of red-hot, flowing lava beneath. At one of these, on the steep slope near Kaumana, we threw stones on the flowing lava and timed their passage; we found that the stream of lava was traveling at an average rate of 40 miles an hour in its confining tunnel. This seemed astounding at first, but when one considers that the flow was then more than ½ mile wide at its advancing front, the lava would have to be traveling very fast in its narrow channels higher up to supply the broad spread of lava at the front of the flow.

The central supply tunnel was probably 20 to 50 feet wide, with numerous smaller branch tunnels extending from the main tunnel. Often these supply tunnels became blocked; then there would be a sudden outburst of lava, throwing great blocks of the cooled lava, with the molten lava, into the air.

After camping near the Natural Bridge for about a week, we went down to the front of the flow again and found it very active. On the side toward Hilo a great, red, molten stream was flowing down Alenaio Gulch. Another very active branch of the flow was pushing off toward Waiakea. We rounded the Alenaio flow and went over to the Waiakea branch. On returning, we found that the Alenaio flow had advanced so rapidly that we were cut off from our former trail. Our alternative was to break through a dense grove of hau trees or run across a tongue of lava about 30 feet wide and 1.5 feet thick that had flowed out only a few minutes before. The tongue was red hot, just beginning to turn black on top. After testing the tongue of new lava by throwing heavy stones on it and observing that the stones rolled over it as if it were solid, we sprang over it with as few steps as possible, only slightly scorching our shoes.

A pahoehoe lava flow in full motion is a very interesting sight. At the advancing front the lava seems to come out of its tunnel and flow in an open red river of fire as much as several hundred feet long. This then appears to clog up and cool on top, and the lava pushes out in great and small lobes, piling one over the other and eventually forming a new tunnel underneath for the molten lava. The latter will then again break out and go through the same process as before.

After 2 weeks we reluctantly packed up our camp and started on our return trip to Honolulu. As we passed down toward Hilo we could see the lava flow making a rapid advance toward the town and the Waiakea sugar mill. On passing upper Halai Hill we noticed Princess Ruth Keelikolani sitting on the brow of the hill with her retainers, all decked out in red bandanas. The report is that she broke a bottle of champagne and made other sacrifices to Pele. The natives give Princess Ruth credit for stopping the flow.

When we left Hilo, about July 29, the lava was approximately 1.5 miles from the main part of the town. Again the Hilo people appealed to the authorities at Honolulu for help. At that time Professor Alexander had in his employ Mr. W. R. Lawrence, a former military engineer and practical civil engineer. He sent Mr. Lawrence to Hilo to survey the front of the lava flow and suggest any method that might be used to prevent the flow from entering the main portion of the town.

It was evident that the main flow of molten lava, like water, was seeking the lowest level and following the bed of Alenaio Stream. Mr. Lawrence recommended building a massive embankment along the town side of Alenaio Gulch. At Honolulu, the writer had been loaned to the Interior Department to assist in reading proof of the 12 volumes of a new copy of the Land Commission Awards and was working in the telephone room of the Interior Office. There he had the pleasure of hearing Mr. H. A. P. Carter, Minister of Foreign Affairs, telephoning to a Honolulu business firm to order a thousand picks, shovels, hoes, wheelbarrows, etc. The Government was arranging to set 1,000 men to work building the embankment to protect Hilo. But the work was never actually started, as the next steamer brought word that the lava had stopped flowing on August 9.

The people of Waiakea Plantation had built an ordinary stone wall across the front of the Waiakea branch of the flow in an effort to protect the Waiakea mill and claimed that the Waiakea flow was stopped by that wall. The writer later visited the wall and found that a small tongue of lava had piled up a few feet along it. Fortunately the eruption ended just at that time, as in the opinion of the writer the stone wall could not have stopped the flow.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR APRIL–JUNE, 1953

By GORDON A. MACDONALD

VOLCANOLOGY

April

Hawaiian volcanoes were quiet throughout the month of April, and seismic activity was approximately normal in amount. Seismographs at the rim of Kilauea Caldera recorded 50 earthquakes during the month, and the Mauna Loa seismograph recorded 33. Thus, Kilauea showed somewhat more activity than Mauna Loa. The Kona seismograph recorded 19 small earthquakes not recorded at any other station. These originated in central Kona close to the station. Probably some or all of them resulted from small movements on the Kealakekua fault, which runs out to sea along the northern edge of Kealakekua Bay.

A feeble earthquake felt in the Volcano area at 11:09 A.M. on April 10 had its origin beneath the east slope of Mauna Loa. A quake at 2:20 A.M. on April 14 recorded as very feeble on the seismograph but was felt by several persons in central Kona. Another feeble quake originated beneath the southwest slope of Mauna Loa at 1:42 A.M. on April 24 and was felt in Kona and in the Volcano district. Moderate earthquakes at 8:50 and 11:03 A.M. on April 29 probably had their origin on the Kaoiki fault, which separates Kilauea and Mauna Loa west of Kilauea Crater.

Tilting of the ground surface at the northeast rim of Kilauea Caldera normally is toward the southwest throughout the month of April. This year, the southward component of tilting was approximately normal in amount, suggesting essentially no change in volcanic pressure beneath Kilauea. Westward tilting, however, was at a rate somewhat greater than normal, suggesting the possibility of some reduction of pressure beneath Mauna Loa.

May

During early May, Hawaiian volcanoes were fairly quiet. From May 1 to 17 ground tilting at the northeast rim of Kilauea Caldera was approximately normal, both in direction and

amount, for that season of the year. The number of earthquakes recorded was nearly twice the normal number, but most of them were very small.

On May 17 the ground surface at the northeast rim of the caldera began tilting rapidly northward, and northward tilting continued at a rate notably greater than normal throughout the rest of May. On May 20 the number of earthquakes recorded at Kilauea Crater increased greatly and through the rest of the month averaged about 20 per day, bringing the total number recorded during May to 259. Of these, about 90 percent had their origin beneath or near Kilauea Crater.

Several small earthquakes were felt in Kona during the month. All these except one originated in the Kona area, some of them probably on the Kealakekua fault. At 4:59 A.M. on May 29 a strong quake originated on the Kealakekua fault. This earthquake dismantled one component of the seismograph at Konawaena School. It was felt strongly in central Kona and weakly over much of the rest of the island.

At 2:44 A.M. on May 24 a moderate earthquake originating beneath the east flank of Mauna Loa was felt over much of the island. A sharp earthquake felt at Kapapala at 7:33 P.M. on May 27 probably had its origin on the Kaoiki fault.

June

Kilauea Volcano remained notably restless throughout the month of June. Of the 184 earthquakes recorded by seismographs at Kilauea Crater during the month, the great majority originated in Kilauea Volcano. The total number of earthquakes was more than four times the usual number recorded during times of volcanic quiet. Northward tilting of the ground surface at the northeast rim of Kilauea Crater during June amounted to 4 seconds of arc. This rate of tilting is about five times as rapid as the average for this season and demonstrates a distinct increase of volcanic pressure beneath Kilauea.

Several earthquakes originating beneath the slopes of Mauna Loa and along its northeast rift zone indicate some uneasiness of that volcano also. However, ground titling in the east-west azimuth at the northeast rim of Kilauea Crater was slightly westward at a rate approximately normal for this season of the year. This suggests a lack of any marked change of volcanic pressure beneath Mauna Loa.

A feeble earthquake felt in Hilo and the Volcano district at 8:38 P.M. on June 15 appears to have had its origin beneath the east flank of Mauna Loa, about 3 miles north-northeast of the Whitney Laboratory of Seismology. Another, felt in the same areas at 10:47 A.M. on June 27, originated beneath the east slope of Mauna Loa about 3 miles S60°E of Puu Kulua. A slight earthquake at 12:49 A.M. on June 9, felt in Hilo but not reported felt in the Volcano area, apparently had its origin beneath the crater region of Kilauea Volcano.

The seismograph at Konawaena School recorded 17 earthquakes during June. Most of them originated in central Kona close to the seismograph, probably on the Kealakekua fault.

LANDSLIDE ON THE HAMAKUA COAST

A small landslide took place on the sea cliff near the mouth of Manowaiopae Stream, just south of Laupahoehoe (Hamakua Coast), early on the morning of May 28. According to Joe Jose, who lives near the site of the slide, a small slip occurred at 3:00 A.M., followed by a larger one at 5:00 A.M. Seismographs on the Island of Hawaii recorded no earthquakes at those times, so the slides apparently were not set off by earthquakes. At the foot of the sea cliff the slides built a small peninsula; this was immediately attacked by waves which rapidly removed a large portion of it.

Such landslides are not uncommon along the sea cliffs of Hawaii, especially along the windward coast of Kohala. According to William Ellis (*Journal of a Tour around Hawaii*, Boston, 1825), similar landslides occurred late in 1822 or early in 1823 between Pololu and Honokane valleys and at a locality known as Laupahoehoe, about 1½ miles northwest of Waimanu Valley. Another landslide may have occurred at the latter locality during the violent earthquake of April 2, 1868. A large slide occurred on the sea cliff just east of the mouth of Honopue Valley during heavy rains in January, 1941 (Stearns and Macdonald, *Geology and Ground Water Resources of the Island of Hawaii*, 1946, p. 51). All these slides built debris fans at the base of the cliff, but only the Laupahoehoe fan was large enough to survive for long the attack of waves.

SEISMOLOGY

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the Island of Hawaii operated by the Hawaiian Volcano Observatory. Locations given are epicenters. The times given are arrival times at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea Caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

75. Apr. 2, 02:59, no record at Kilauea (Kona, very feeble). Central Kona.
76. Apr. 7, 23:37, tremor (Kona, very feeble).
77. Apr. 10, 11:09, feeble (Mauna Loa, slight). Felt in Volcano district. Northeast slope of Mauna Loa.
78. Apr. 13, 18:00, no record at Kilauea (Kona, very feeble).
79. Apr. 14, 02:20, tremor (Kona, very feeble). Felt in Kona. Central Kona.
80. Apr. 16, 14:36, no record at Kilauea (Kona, very feeble).
81. Apr. 17, 09:35, very feeble. Kilauea.
82. Apr. 22, 15:28, very feeble.
83. Apr. 24, 01:42, feeble. Felt in Volcano district, south Kona, and Kohala. Southwest slope of Mauna Loa, near 19°20′N., 155°47′W.
84. Apr. 24, 05:44, very feeble.
85. Apr. 29, 08:50, moderate. Southwest rift of Kilauea (?).
86. Apr. 29, 11:03, moderate. Kilauea.
87. Apr. 29, 13:00, slight. Southwest rift of Kilauea (?)
88. May 3, 23:50, no record at Kilauea (Kona, very feeble).
89. May 6, 17:59, tremor (Kona, very feeble).
90. May 7, 14:43, no record at Kilauea (Kona, very feeble).
91. May 8, 01:18, no record at Kilauea (Kona, very feeble).
92. May 8, 16:19, tremor (Kona, very feeble).
93. May 8, 17:53, tremor (Kona, very feeble).
94. May 11, 08:48, slight. Kilauea (east rift zone ?).
95. May 13, 08:25, very feeble.
96. May 13, 12:10, very feeble.
97. May 15, 13:31, very feeble.
98. May 16, 10:31, very feeble.
99. May 17, 09:30, no record at Kilauea (Kona, very feeble).
100. May 17, 13:48, very feeble.
101. May 18, 03:05, very feeble.
102. May 19, 18:02, tremor (Kona, very feeble). Felt in south Kona.
103. May 20, 13:05, very feeble.
104. May 21, 14:12, very feeble.
105. May 22, 23:22, very feeble (Kona, feeble). Felt in central Kona. Kealakekua fault (?).
106. May 24, 02:05, slight. Felt in Volcano district. Kilauea.
107. May 24, 02:12, very feeble. Kilauea.
108. May 24, 02:44, moderate. Felt over much of Hawaii Island as far north as Kukuihaele. East slope of Mauna Loa near 19°26′N., 155°27′W.
109. May 24, 13:15, tremor (Uwekahuna, very feeble).
110. May 25, 10:17, tremor (Kona, very feeble). Felt in south Kona.
111. May 26, 06:26, feeble. Felt at Naalehu.
112. May 27, 19:33, tremor. Felt at Kapapala.
113. May 29, 04:59, slight (Kona, strong). Felt in central and south Kona, Naalehu, and Volcano district. Kealakekua fault at north side of Kealakekua Bay, near 19°29′N., 155°56′W.
114. May 29, 05:08, tremor (Kona, very feeble). Central Kona.
115. May 29, 07:47, no record at Kilauea (Kona, very feeble). Central Kona.
116. May 29, 10:21, no record at Kilauea (Kona, very feeble). Central Kona.
117. May 30, 05:16, very feeble.
118. May 31, 04:13, very feeble.
119. June 4, 01:14, very feeble.
120. June 4, 17:01, very feeble.
121. June 4, 18:48, very feeble. Felt fairly strongly at Kapapala. Southeast slope of Mauna Loa near Kapapala.

122. June 5, 11:23, very feeble.
123. June 6, 04:48, very feeble. Kilauea.
124. June 8, 16:58, very feeble.
125. June 9, 00:44, very feeble.
126. June 9, 00:49, slight. Felt in Hilo. Kilauea (?).
127. June 10, 00:40, very feeble. Kilauea.
128. June 11, 21:27, no record at Kilauea (Kona, very feeble). Central Kona.
129. June 15, 03:24, no record at Kilauea (Kona, feeble). Central Kona.
130. June 15, 20:34, feeble. Felt in Hilo and Volcano district. Northeast slope of Mauna Loa about 3 miles N 30° E of Volcano House, near 19°29′N., 155°14′W.
131. June 16, 11:10, no record at Kilauea (Kona, very feeble). Central Kona.
132. June 17, 02:27, no record at Kilauea (Kona, very feeble). West slope of Mauna Loa.
133. June 18, 03:05, very feeble.
134. June 20, 20:55, tremor (Kona, very feeble).
135. June 21, 07:20, no record at Kilauea (Kona, very feeble).
136. June 23, 17:50, very feeble (Kona, slight). Central Kona.
137. June 23, 17:53, no record at Kilauea (Kona, very feeble).
138. June 26, 17:53, no record at Kilauea (Kona, very feeble).
139. June 26, 20:24, very feeble (Kona, feeble). Central Kona.
140. June 26, 20:54, tremor (Kona, very feeble).
141. June 27, 10:47, moderate. Felt in Volcano district. East slope of Mauna Loa about 3 miles S 60° E of Puu Kulua, near 19°31′N., 155°23′W.
142. June 27, 23:12, tremor (Kona, very feeble).
143. June 28, 20:20, very feeble.
144. June 30, 00:45, tremor (Kona, very feeble). Central Kona.
145. June 30, 06:37, tremor (Kona, very feeble). Central Kona.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori horizontal or Sprengnether vertical seismograms, in Hawaiian Standard time.

April 5, 14:48, slight. Banda Sea, at 7°S., 132°E.
April 18, 13:48, slight. Off south coast of Mexico, at 10°N., 102°W.
April 23, 06:34, slight. New Britain region, at 4°S., 154°E.
June 15, 08:05, slight. Near south coast of Kodiak Island, Alaska, at 56½°N., 154°W.

Earthquake Data, April–June, 1953

(Based on Bosch-Omori seismograph on northeast rim of Kilauea Caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms
April 5	6	0	1	0	0	0	2.5	1
12	5	1	0	0	0	0	1.75	1
19	12	0	1	0	0	0	4.0	1
26	17	0	0	1	2	0	9.25	0
May 3	11	0	0	0	0	0	2.75	0

June 7	30	3	0	1	0	0	11.0	0
14	48	1	1	0	0	0	13.5	1
21	58	2	0	0	1	0	18.5	0
28	15	2	0	0	0	0	4.75	0

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

Week Beginning	Whitney Station (Northeast rim)		Uwekahuna Station (West rim)	
	Amount	Direction	Amount	Direction
April 5	1.4″	S 38° W	0.6″	N
12	0.9″	N 56° E	1.3″	S 37° E

VOLCANO NOTES AND NEWS

VOLCANOLOGICAL SURVEY OF INDONESIA

The Volcanological Survey of Indonesia (Dinas Gunung Berapi Indonesia) is carrying on the work started by the Netherlands East Indies Volcanological Survey. Directly after the war the work was handicapped by a lack of funds and adequate personnel. Since 1950, however, rapid advances have been made in reconnaissance and mapping of volcanic districts, some of them previously unknown. Much of this has been made possible through the co-operation of the Air Force of the Republic of Indonesia. A summary account of the progress up to the end of 1952 is contained in *Berita Gunung Berapi (Communications of the Volcanological Survey of Indonesia)* 1 (1–2), Sept.–Dec., 1952.

Following the transfer of Sovereignty, Dr. G. A. deNeve became director of the Volcanological Survey, succeeding W. A. Petroeschevsky in September, 1950. It was decided that aerial reconnaissance offered the most expeditious way of obtaining a general view of the volcanic activity of the whole of Indonesia and determining which volcanoes are most urgently in need of more detailed examination. This reconnaissance was largely accomplished by mid-1951, and ground examinations and mapping had been carried on in some areas. As a result of this work 15 new active volcanic centers have been found on Sumatra, northern Celebes, and Flores, bringing the total number of active volcanoes and solfatara and fumarole fields in Indonesia to 167, in place of the 152 listed by C. H. Stehn in 1940.

Additional work was done during 1952 by teams of investigators transported to and from their respective areas of study in Catalina amphibian planes. Special studies have been carried out on Semeru to delineate the areas in danger from cold lahars (mud flows) and at Kelud for the restoration of the tunnels constructed to drain the crater lake.

This energetic resumption of work on Indonesian volcanoes is deserving of great praise, and it is to be hoped that the work can be continued in a similar manner and its scope increased still further.

ACTIVITY OF TRIDENT VOLCANO

Trident Volcano, in Alaska, continues in mild activity. The lava flow issuing about a mile southwest of the old crater of Trident continued to grow slowly until June 2. George Snyder, geologist of the U. S. Geological Survey, reports that between June 2 and June 17 the rate of growth of the flow increased markedly. He estimated the thickness of the flow in the vicinity of the vent to be about 1,000 feet on June 17. The rate of gas emission is much decreased over that during March. Snyder

reports there were two large explosions and constant gas liberation during an hour's observation on June 17. Steam is issuing from the crater of nearby Mageik Volcano. Robert R. Coats reports (U. S. Geological Survey Bulletin 974-B) that Mageik Volcano and the neighboring volcanoes Katmai, Martin, and Novarupta have been steaming almost constantly since 1912. A small cinder cone is reported to have been built on the southwest flank of Novarupta, in the Valley of Ten Thousand Smokes, in July, 1950 (Lowell Sumner, Sierra Club Bul. 37 (10) : 45, Dec., 1952). George Snyder states (Preliminary Report of Mt. Trident Eruption) that according to the *Kodiak Mirror* for Feb. 21, 1953, Mageik Volcano last erupted in 1951.

The accompanying photograph shows the lava flow on the southwest flank of Trident Volcano on February 21 and the cloud of ash and fume rising at the vent from which the flow is issuing.

Snyder estimates that from the beginning of the eruption until March 11 the volume of lava and ash liberated by Trident Volcano was between 2.2 and 4.5 billion cubic feet (0.015 to 0.03 cubic mile) and that between March 11 and June 17 from 1 to 2.5 billion cubic feet of additional lava was extruded. Compared with this, the volume of ash and other fragmental material produced by the great eruption of Katmai Volcano in 1912 has been estimated at 6 to 7 cubic miles.

R. E. Wilcox writes that the last significant ash eruption of Trident Volcano was on June 30.

ACTIVITY OF GREAT SITKIN VOLCANO

Richard McDonald, seismologist of the U. S. Geological Survey, reports that on May 11, 1953, the Coast and Geodetic Survey ship *Pioneer* observed a spectacular column of steam rising an estimated 5,000 feet above Great Sitkin Volcano, in the Aleutian Islands. The steam column lasted about an hour. An earthquake felt at Adak on May 12, with an intensity of 5 on the modified Mercalli scale, had its epicenter on a line passing through Great Sitkin. On the afternoon of May 14 a steam cloud was seen to rise about 4,000 feet above the crater rim of Great Sitkin, and during the evening another earthquake occurred, slightly less severe than that of May 12, with its epicenter on the same line. Both quakes apparently were more severe on Great Sitkin than on Adak. When next observed, on May 19, the steaming of Great Sitkin Volcano was much diminished but still greater than normal. Subsequent observations on May 23, June 5, and June 7 showed only weak emission of steam. No ash eruption was observed during the period from May 11 to June 7, nor did the form of the basalt dome in the crater of Great Sitkin change appreciably.

FIGURE 2. Trident Volcano, Mount Katmai National Monument, in eruption on February 21, 1953. The cloud of ash and fume is rising from a vent on the southwest slope of Trident, and a small lava flow also is issuing from the same vent. Knife Peak Volcano appears on the left of the view, and Katmai Volcano, with its summit caldera formed during the great eruption of 1912, is on the right. Official U. S. Navy photograph.

ACTIVITY IN THE MARIANA AND VOLCANO ISLANDS

Charles G. Johnson, of the U. S. Geological Survey's Military Geology Branch, has forwarded a report from the 54th Strategic Reconnaissance Squadron, USAF, on aerial reconnaissance of activity on Farallon de Pajaros, in the Mariana Islands, and submarine volcanic activity near Minami Iwo Jima, in the Volcano Islands.

During late March the Farallon de Pajaros volcano was in mild explosive activity. On March 25, Major J. F. Fagan reported small puffs of smoke from the crater at intervals of 2 to 3 minutes. On March 26, Lt. J. D. Long counted eight explosions in 11 minutes, during which rocks estimated to be as much as 3 feet in diameter were thrown an estimated 30 feet above the crater rim. On March 27, Capt. C. G. Cook observed only two belches of smoke containing only small fragments in a period of 20 minutes. On March 28, Capt. K. S. Durham observed puffs of smoke rising about 300 feet above the crater every 65 to 70 seconds. Similar activity was reported on March 30 and 31.

About 1.5 miles north-northeast of Minami Iwo Jima submarine volcanic activity produced a small area of very light green water.

ACTIVITY ON SAN BENEDICTO ISLAND

Adrian F. Richards, of the Scripps Institution of Oceanography, again visited the Revilla Gigedo Islands in March, 1953. At that time Boqueron Crater on San Benedicto Island was quiet. The lava in the crater was cool at the surface but gave vent to numerous active fumaroles. The delta of blocky lava at the eastern base of the cone was about three times as large as it had been during December, 1952, extending seaward about 2,100 feet beyond the old shoreline and providing a good small-boat harbor on its south side. Information from fishermen leads Richards to believe that the flow probably ceased its forward growth during January.

Richards also reports an area of active fumaroles covering nearly 2 acres near the peak on the north and northeast sides of Mount Evermann, on Socorro Island. Many small, boiling mud pots were observed.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
Elizabeth G. Eklund, Secretary, part-time

Seismograph Station Operators:

Hilo Station:
Sister M. Thecla, St. Joseph's School

Kona Station.
Howard M. Tatsuno, Konawaena School

HAWAIIAN VOLCANO RESEARCH ASSOCIATION

In cooperation with the UNIVERSITY OF HAWAII

The **Hawaiian Volcano Research Association** was founded in 1911 for the recording and study of volcances in the Hawaiian Islands and around the Pacific Ocean. Its equipment at Kilauea Volcano, Hawaii Island, has been transferred to the United States Geological Survey.

The **University of Hawaii** cooperates in maintaining a research laboratory at Kilauea. The Association and the University supplement the work of the government with research associates, instrumental equipment, and special investigations.

The **Volcano Letter**, a quarterly record of Hawaiian volcano observations, is published by the University of Hawaii and supplied to members of the Research Association and to exchange lists of the above establishments.

Although there are many volcanoes in Italy which have been active in very recent geologic time, the number which have been active in historic time is quite limited, even considering the fact that recorded history in this region goes back to around 800 B.C., when the first Greek colonies were established in the region. Today active vents are located in only three areas: (1) the Naples area, including Vesuvius and the Solfatara of Pozzouli, (2) the Eolian Islands, represented by Stromboli and Vulcano, and (3) Mt. Etna in Sicily.

The writer was privileged to spend most of 1952 in a study of the active and recently extinct volcanoes of Italy. The purpose of this brief paper is to set forth the state of activity during 1952 of the so-called active vents.

VESUVIUS

It should be kept in mind that Vesuvius is but one of a number of volcanoes in the Naples area which have been active in recent geologic time. Probably the oldest of these is Epomeo on the island of Ischia which last erupted in 1302. A very severe earthquake in 1883 at Casamiccola (Ischia) indicates that the volcanic energy is not entirely dead. In the Phlegrean Fields, on the shore of the Bay of Naples, there are no less than 19 separate craters, the last activity being the birth of the new crater, Monte Nuovo, in 1538. The Solfatara, one of the craters in the Phlegrean Fields, just west of Naples (Fig. 1), maintains a constant emission of hot gases from which the name "Solfatara" is derived. The activity of the Solfatara, with the exception of an eruption in 1198 in which lava poured, has been in about its present state since the earliest records.

The great eruption of Vesuvius in 79 A.D., in which Pompeii and Herculaneum were destroyed, blew away a large part of the old cone, and a new cone, the present Vesuvius, was built, its center being somewhat removed from the center of the old cone. The remnants of the old cone, which still partly encircle Vesuvius, are known as Monte Somma (Fig. 2).

Following the eruption of 79 A.D., the activity of Vesuvius appears to have been very irregular, with long

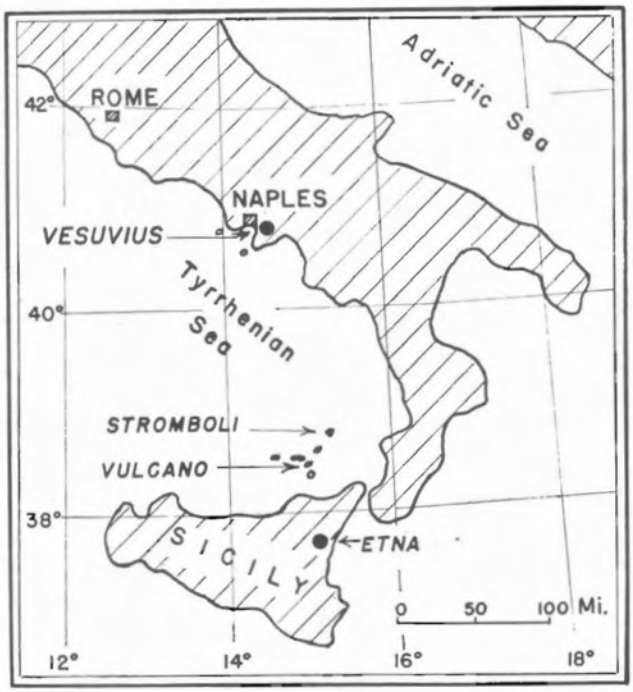

FIGURE 1. Map of southern Italy, showing the location of the principal volcanoes mentioned in the text.

intervals between eruptions, until the grand eruption of 1631. This eruption, one of the greatest in the entire history of Vesuvius, marks a new era in the activity of the volcano. Since 1631 Vesuvius has been in an almost constant state of activity. This activity, which may be described as cyclic, is marked by eruptive periods in which moderate activity is climaxed by a grand eruption which ends a cycle, the new cycle beginning with a repose period. Mercalli has published a list of 12 eruptive periods since 1700, each culminating with a paroxysm followed by a distinct interval of complete inactivity (repose period), the duration of which varied from 2 to 7 years. The repose period is marked by simple emanations of gaseous material. It is the period during

FIGURE 2. Vesuvius during 1952, with the Bay of Naples in the foreground. The present cone of Vesuvius is on the right. The peak at the left is a high portion of the encircling remnant of Monte Somma. Photo by author.

which the magma acquires a gas-saturated condition required for the next eruption.

The great eruption of 1906 closed a cycle, and the repose period which marked the beginning of the new cycle lasted until 1913 (some slight activity in 1911 is interpreted by some writers as marking the end of the repose phase), a period of 7 years. In the following years Vesuvius was in an almost continuous state of moderate activity until the grand eruption of 1944 which marked the end of the cycle. The 1944 eruption began on March 18 and lasted 11 days. Extensive lava flows covered the towns of Massa and San Sebastiano, as well as destroying a portion of the Vesuvius railway line. The new cycle was initiated by a repose phase which has continued to the present time. As the repose phase of Vesuvius has rarely exceeded 7 years, and it is now in its ninth year, it is obvious that a renewal of activity may be expected at any time.

At the end of the 1944 eruption the crater was an elliptical-shaped basin with a maximum depth of about 900 feet below the west rim. Since the 1944 eruption, the crater has been gradually filling by avalanches from the sides. Its depth in July, 1952, was estimated to be about 700 feet. As the sides avalanche, they not only fill up the bottom of the crater but also enlarge the upper rim. As some of the large avalanches crash into the crater, a great cloud of dust, resembling a cauliflower in appearance, boils out of the crater. Frequently, such clouds are reported in the press as eruptions.

The greatest thermal activity at present is on the eastern side, 200 to 300 feet below the rim on the outer slope. For the past year or so this has been a "hot" spot, and recent press reports list temperatures in excess of 650°C. Whether this indicates that the next outbreak will occur at this point cannot, of course, be determined, but it is at least suggestive. Numerous steam fumaroles rise from points on the interior walls of the crater. There is a considerable accumulation of sulphur around fumaroles on the inner slope of the northeast rim, which is the highest point on the crater.

If the renewal of activity at Vesuvius follows the pattern of the previous eruptive cycles, the first activity will begin with the opening of a *bocca* in the bottom of the crater and the development of a small cinder cone. Later, lava will appear as intercrater flows, perhaps filling the crater and overflowing the rim or issuing from cracks near the top as slow outpourings of lava.

STROMBOLI

The Eolian Islands (Lipari Islands), in the Mediterranean sea off the southern coast of Italy and directly north of Sicily, consist of a number of volcanoes, two of which (Stromboli and Vulcano) are considered active. Stromboli is a large volcano, rising from the floor of the Mediterranean Sea in water between 6,000 and 7,000 feet deep and reaching a height of approximately 3,000 feet above sea level. Its total height from its submarine base is 3,200 meters; by comparison, Mt. Etna reaches a height of only 2,900 meters. Thus Professor G. Ponte was not entirely incorrect when, in a recent paper, he described Stromboli as the highest active volcano in Europe.

Normally, the lava column stands very high in the conduit, and frequent gas explosions hurl quantities of red-hot scoria several hundred feet into the air. The explosions occur at intervals of 15 to 30 minutes, and at each outburst a red glow is reflected on the rising gas column, gradually dying out as the lava crusts over. This red glow, coming and going at more or less regular intervals, has given to this volcano the name, "Lighthouse of the Mediterranean." So characteristic of Stromboli is the throwing out of incandescent scoria that it has been selected as one of the types of volcanoes. Although the so-called Strombolian type of activity is characteristic of Stromboli, the volcano also exhibits rare but violent explosive eruptions accompanied by large *pino* (pine-tree shaped) clouds, which spread ash

FIGURE 3. Stromboli, from the north. The eccentric crater is about 600 feet below the summit. The talus-like slope extending from the crater to the sea is the Sciarra del Fuoco. Photo by the author.

and cinders widely. Effusive lava flows are also much more common than has been generally accredited, and because of this fact it must be recognized that Stromboli, like most volcanoes, exhibits various eruptive phases and is not limited to the so-called Strombolian type.

The writer made three visits to Stromboli in 1952: in June, again on December 1–3, and during the week of December 12–19. As one approaches Stromboli by ship (it is an overnight trip from Naples) in the early morning, the symmetrically shaped cone with a white vapor column rising from the crater can be seen for some time before the ship is close enough to enable one to distinguish the big scar on the side of the cone, known as the Sciarra del Fuoco (Fig. 3). On the first trip to Stromboli in June, 1952, numerous columns of white vapor were observed rising from the crater, and at infrequent intervals a dense, yellowish-brown gas issued. There was no noise, and no red glow was observed. The cone was climbed on June 21 and the activity observed from the top of the north peak, from which vantage point one is able to look down into the crater some 600 feet below. The first view into the crater is a thrilling sight.

The crater is a large, oval-shaped basin, about 500 feet in its longest dimension, about 600 feet below the summit of the mountain. It is separated into two sections by a low ridge of debris. Extending from the northwest edge of the crater to the sea is the Sciarra del Fuoco. In June, 1952, there were within the crater two active vents and possibly a third. The vent nearest the edge of the Sciarra del Fuoco was an oval-shaped crater, possibly 30 to 40 feet in diameter, from which issued a grayish gas and, at intervals, a dense white cauliflower cloud of steam. There was no noise associated with this vent.

At the opposite end of the oval-shaped crater was the most active vent. From it a grayish-white vapor issued which frequently filled the entire crater, obscuring everything. There was a continuous roar, more of a chugging or "sloushing" noise, comparable to that made by a locomotive when the engineer slides the wheels in starting, or to the unrhythmical exhaust of a pump station in an oil field. At intervals of 15 to 30 minutes this exhaust was interrupted by more violent outbursts (not an explosion but a tremendous outrush of gas) which hurled rocks (scoria) from 600 to 1,000 feet above the crater floor. They were not incandescent, and most of them fell back into the crater, the noise continuing until another outburst took place. There appeared to be a third vent, approximately midway between the two described. This vent could not be seen clearly from the vantage point, but a gas column was observed rising from this point from time to time. Active avalanching was taking place on the opposite wall of the crater. At irregular intervals avalanches slid from the wall, giving rise to dense, yellowish-brown cauliflower clouds which filled the crater and spread a rain of fine ash over the upper part of the cone.

Lava flow of June 6, 1952. This flow apparently began without any preliminary explosions or *pino* clouds which normally accompany an outflow, as the inhabitants of San Vincenzo were not aware of the flow until a tourist, arriving by ship, commented on the lava flowing down the Sciarra del Fuoco. The flow appears to have started on June 6 and to have continued for several days. The lava reached the sea at the base of the Sciarra del Fuoco, building out two small projections into the sea which were still steaming when visited by the writer on June 22.

The cone was not ascended on the December 1–3 visit to Stromboli because of bad weather conditions. However, from the deck of the ship, as the writer was leaving Stromboli for Naples late in the evening of December 3, a red glow was noted which faded and reappeared. Suddenly, with a brilliant glare, a tremendous explosion hurled fragments into the air which could be clearly distinguished even at a distance of a number of miles. The glare which illuminated the lower part of the cone was a whitish red, the upper part a

FIGURE 4. Vulcano, from Quattr'ochi, Lipari. The low rim encircling the highest cone is the remnant of an earlier cone. Photo by the author.

bright red. Two such explosions occurred during the hour the "Lighthouse of the Mediterranean" was watched from the deck of the ship before it disappeared over the horizon.

Two visits to the crater were made on the third trip to Stromboli in mid-December. On the first ascent (December 14) the conditions were generally the same as in June, except that the steam column was much denser (probably due to colder air temperature) and the visibility, as a result, much poorer. The west vent, as usual, was the most active and was accompanied by the chugging or exhaust noise as in June. When a second ascent was made on December 18, the conditions were somewhat different. From the west vent, at intervals of 20 to 30 minutes, showers of red-hot scoria were thrown to a height of around 600 feet. The outbursts, although definite explosions, were more like an exhaust with a hissing noise, or like the outrush of gas under high pressure. The scoria fragments were mostly flat and appeared to represent the thin crust from a bubble, which on bursting showered fragments into the air. All the scoria fell back into the cavity, none reaching the Sciarra del Fuoco. The chugging, so prominent on previous visits, was entirely absent, and between outbursts there was a silent emission of steam. The eastern vent (adjacent to Sciarra del Fuoco) continued to send up large quantities of steam, and at irregular intervals, probably 30 to 40 minutes, it exploded with a shrill, whistling noise. There was no apparent relationship between the activity of the two vents.

VULCANO

Vulcano is one of the Eolian Islands, immediately adjacent to Lipari, famous in classic mythology as the site of Vulcan's forge (Fig. 4). It was quite active in the early centuries of the Christian era but has been less active in recent times. The last eruption was in 1888–90. Since that time it has been in a solfataric state of activity. When the writer visited Vulcano in late November, 1952, it appeared to be in about the same state of activity as described in the literature of the past 10 to 20 years. Abundant fumaroles were active on the upper half of the inner slope of the west wall of the crater. Deposits of sulphur were abundant around all the openings. Strangely enough, no fumaroles occur on the floor of the crater, and there is no evidence in deposits to indicate that any ever were present.

Another active fumarole area is at the west base of the main cone, known as Faraglioni di Levante, or Porto di Levante. The mining of sulphur was carried on here for years, but no work is now being done. The sulphur occurs as impregnations in the porous tuffs. Active fumaroles occur along the beach and in the shallow water near shore, as well as on the land a few yards back of the beach. There are several active, boiling mud pits similar to those at the Solfatara of Pozzouli. Drilling is under way in this area in an effort to obtain natural steam for the generation of electricity.

MT. ETNA

Located on the east coast of Sicily, Mt. Etna is the greatest volcanic mass in Europe and one of the large volcanoes of the world. It has the shape of an enormous cone truncated at a height of 9,190 feet by a plateau on which stands the summit cone, which reaches a height of 10,742 feet. The regularity of the slope is marred by about 200 parasitic cones which mark the site of previous eruptions. On the east slope of the cone is the tremendous depression or valley known as the Valle del Bove.

Mt. Etna has been known as an active volcano from the earliest times. One of the greatest eruptions of Mt. Etna was in 1669, when the city of Catania was destroyed by a lava flow. From 1669 to 1951 there have been 35 eruptions, separated by an average interval of 8 years. The most recent eruptions were in 1923, 1928, 1942, and 1950–51.

The summit crater is a circular depression, some 2,000 feet in diameter. Numerous steam columns rise from

the floor and sides of the crater, but sublimate deposits are insignificant. Prior to 1942 the crater was a cone-shaped depression nearly 1,000 feet deep, with many steam vents and small cones on the floor. In 1942 there was an eruption within the crater, and it filled to its present level, which is about 300 feet below the rim. A low cinder cone, from which abundant steam issues, occupies a portion of the crater floor. On the northeast edge of the crater floor there is a circular depression (small-scale replica of Halemaumau on the floor of Kilauea) which was formed by subsidence of the crater floor in 1945. On the northeast edge of the summit crater and outside the rim is the Northeast Bocca (also known as the northeast subterminal crater). It is a cone formed during the eruption of 1911, partly merged with the present summit crater but some 200 feet below and on the outer slope. From this opening great volumes of steam and occasionally other gases issue. This is the vent which supplies the vapor column rising constantly from Mt. Etna. The vent can be well observed from a vantage point on the main crater rim. Large clouds of white steam boil out with a hissing noise, accompanied by a roar which resembles the continuous roll of thunder. The guide reported that the thunder-like noise is present only when the vapor is white (i.e., steam). If it is dark (ash-filled) there is no noise. A similar relationship between the composition of the eruption cloud and noise was noted at Paricutin Volcano, Mexico.

The last eruption of Mt. Etna began on November 25, 1950, preceded by intense activity at the northeast subterminal crater. Large quantities of fluid lava issued from the east base of the summit cone near the 9,000-foot level and flowed into Valle del Bove. This great expanse of fresh, black lava forms a striking floor in the Valle del Bove today.

A very sharp earthquake damaged a number of towns on the eastern slope of Mt. Etna on March 22, 1952. The greatest damage centered around San Venerina, where 400 families were left homeless. Whether this is to be the point of a future outbreak is, of course, not known, but it is interesting to point out the possibility of such being the case.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY–SEPTEMBER, 1953

By GORDON A. MACDONALD

VOLCANOLOGY

July

Seismographs of the Hawaiian Volcano Observatory recorded 82 earthquakes during July. Of these, 44 were recorded at Kilauea caldera and 58 at the Mauna Loa station. Many, of course, were recorded at both stations, but an unusually large proportion were too small to be recorded at any but the closest. The number of earthquakes was somewhat greater than usual, but only two were large enough to be felt. On July 26 at 1:52 P.M., a moderate quake was felt from central Kona to Hawi. It appears to have originated in the vicinity of Hualalai. At 10:24 P.M. on July 28, a quake felt lightly in central Kona probably was of nearby origin.

During the month, tilting of the ground at the northeast rim of Kilauea caldera was northward at a rate slightly greater than normal. There appears to have been little change of volcanic pressure at Kilauea. From July 22 to 31 there was a marked westward tilting. This, together with northwestward tilting at the Mauna Loa station, suggests a decrease of pressure beneath Mauna Loa, accompanied by some subsidence of the mountain.

August

Hawaiian volcanoes continued moderately uneasy throughout August. Observatory seismographs recorded 79 earthquakes during the month. Of these, 47 were recorded at the stations on the rim of Kilauea caldera, and 58 at the Mauna Loa station. Most of the quakes came from shallow foci on the northeast rift zone of Mauna Loa or in the vicinity of Kilauea Crater.

Earthquakes felt strongly at Kapapala and slightly from Naalehu to the Volcano district, at 6:48 A.M. on August 1, 5:20 P.M. on August 4, and 12:46 A.M. on August 6, originated on the southwest rift zone of Kilauea a short distance southwest of Mauna Iki. A quake felt strongly in central Kona at 3:00 A.M. on August 8 originated nearby, probably on the Kealakekua fault.

An earthquake felt all over the island of Hawaii and by many persons on Maui and Oahu, at 7:46 P.M. on August 21, appears to have originated beneath the north slope of Hualalai volcano in the vicinity of Puu Waawaa. This is the area from which came more than 6,000 earthquakes during September and October, 1929. Another earthquake, felt strongly in Kona and lightly over most of the rest of the island at 12:53 A.M. on August 23, originated beneath the southwest slope of Hualalai, east of Holualoa.

Through August the ground surface at the northeast rim of Kilauea Crater tilted northward at a rate somewhat greater than normal and westward in place of the eastward tilting normal during that season of the year. Some of this abnormal tilting may have been caused by the load imposed on the ground by the weight of the new addition to the Volcano House, then under construction. It appears probable, however, that much of it was of volcanic origin, resulting from a decrease of volcanic pressure beneath Mauna Loa and an increase beneath Kilauea.

September

Hawaiian volcanoes continued to be seismically restless during the month of September. A large number of very small earthquakes was recorded. Many of them apparently originated on or near the zone just south of the island from which came the great number of quakes during March and April, 1952, preceding the eruption of Kilauea. (See Volcano Letter 515.) Several other quakes had their origins along the Kaoiki fault zone near Ainapo and in central Kona. Two of the latter, at 3:00 P.M. on September 23 and 1:20 P.M. on September 27, were felt in Kona.

The ground surface at the northeast rim of Kilauea caldera tilted northward throughout the month at a rate slightly greater than normal for this season of the year. Eastward tilting was at approximately the normal seasonal rate. The possible small increase of volcanic pressure under Kilauea, suggested by the northward tilting, tends to be confirmed by the slight opening of cracks on the crater floor.

SEISMOLOGY

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the island of Hawaii operated by the Hawaiian Volcano Observatory. Locations given are epicenters. The times given are arrival times at the Whitney Laboratory of Seismology on the northeast rim of Kilauea caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

146. July 1, 15:14, tremor (Mauna Loa, very feeble). Northeast rift of Mauna Loa.
147. July 2, 00:12, very feeble.
148. July 2, 05:34, no record at Kilauea (Mauna Loa, very feeble). Northeast rift of Mauna Loa.
149. July 2, 07:09, tremor (Mauna Loa, very feeble). Northeast rift of Mauna Loa.
150. July 2, 11:58, no record at Kilauea (Mauna Loa, very feeble).
151. July 6, 02:51, very feeble, west slope of Mauna Loa.
152. July 6, 07:19, very feeble, northeast rift of Mauna Loa.
153. July 6, 15:07, tremor (Mauna Loa, very feeble).
154. July 6, 20:26, slight. Beneath southwest edge of Kilauea caldera.
155. July 6, 23:55, very feeble.
156. July 7, 15:59, tremor (Uwekahuna, very feeble).
157. July 7, 17:55, very feeble.
158. July 9, 09:21, tremor (Uwekahuna, very feeble).
159. July 10, 10:07, tremor (Mauna Loa, very feeble).
160. July 13, 15:56, very feeble.
161. July 14, 12:37, tremor (Mauna Loa, very feeble).
162. July 15, 04:59, very feeble. Felt at Kapapala.
163. July 19, 13:24, tremor (Mauna Loa, very feeble).
164. July 20, 18:07, very feeble (Mauna Loa, feeble). East slope of Mauna Loa.
165. July 21, 17:30, tremor (Mauna Loa, very feeble).
166. July 24, 02:29, tremor (Uwekahuna, very feeble).
167. July 26, 10:18, no record at Kilauea (Kona, very feeble). Felt in central Kona.
168. July 26, 13:52, tremor (Kona, very feeble). Felt in central Kona and at Hawi.
169. July 26, 21:47, tremor (Mauna Loa, very feeble).
170. July 26, 22:44, very feeble.
171. July 28, 22:24, tremor (Kona, feeble). Felt in central Kona. Central Kona.
172. July 30, 14:30, tremor (Mauna Loa, very feeble). Probably Kaoiki fault.
173. July 31, 13:07, very feeble.
174. July 31, 23:44, very feeble.
175. Aug. 1, 06:48, very feeble (Mauna Loa, feeble). Felt at Pahala. Southwest rift of Kilauea near 19° 20'N., 155°21'W.
176. Aug. 1, 08:13, 20'N., 155°21'W.
177. Aug. 1, 23:39, tremor (Mauna Loa, very feeble).
178. Aug. 2, 02:31, very feeble.
179. Aug. 4, 11:10, very feeble.
180. Aug. 4, 17:20, very feeble.
very feeble (Mauna Loa, feeble). Felt: Kapapala, strong; Volcano, Naalehu, slight. Southwest rift of Kilauea near 19°20'N., 155°23'W.
181. Aug. 5, 02:46, tremor (Mauna Loa, very feeble). Mauna Loa, northeast rift.
182. Aug. 6, 00:47, very feeble (Mauna Loa, slight). Felt at Kapapala. Southwest rift of Kilauea near 19°22'N., 155°21'W.
183. Aug. 6, 14:39, very feeble.
184. Aug. 6, 18:47, very feeble.
185. Aug. 6, 21:08, tremor (Mauna Loa, very feeble).
186. Aug. 7, 02:17, very feeble.
187. Aug. 7, 05:53, very feeble.
188. Aug. 8, 00:37, tremor (Mauna Loa, very feeble).
189. Aug. 8, 03:00, very feeble. Felt strongly in central Kona.
190. Aug. 11, 07:12, very feeble.
191. Aug. 11, 09:16, very feeble. Kilauea.
192. Aug. 11, 12:39, very feeble. Kilauea.
193. Aug. 12, 08:38, very feeble.
194. Aug. 13, 05:55, very feeble (Uwekahuna, feeble).
195. Aug. 14, 18:20, tremor (Mauna Loa, very feeble).
196. Aug. 14, 22:14, very feeble.
197. Aug. 15, 10:33, tremor (Mauna Loa, very feeble).
198. Aug. 15, 12:04, tremor (Mauna Loa, very feeble).
199. Aug. 15, 16:27, no record at Kilauea (Kona, very feeble). Kona.
200. Aug. 16, 20:53, no record at Kilauea (Kona, very feeble). Central Kona.
201. Aug. 18, 17:47, no record at Kilauea (Mauna Loa, very feeble).
202. Aug. 20, 12:56, tremor (Mauna Loa, very feeble).
203. Aug. 21, 19:47, slight (Mauna Loa, Kona, and Hilo, strong). Felt all over island of Hawaii and as far away as Honolulu. Felt on Maui, generally weakly, but strong in Haleakala Crater. North slope of Hualalai near Puu Waawaa.
204. Aug. 21, 21:07, very feeble. Felt in Kona.
205. Aug. 23, 00:53, strong. Felt: Kona strong; Naalehu and Kapapala, moderate; Volcano, slight. Beneath southwest slope of Hualalai about 3 miles east of Holualoa.
206. Aug. 24, 23:05, no record at Kilauea (Kona, very feeble). Felt slightly in central Kona. Central Kona.
207. Aug. 25, 14:54, tremor (Mauna Loa, very feeble).
208. Aug. 27, 09:44, tremor (Mauna Loa, very feeble).
209. Aug. 27, 10:49, tremor (Mauna Loa, very feeble).
210. Aug. 29, 06:16, tremor (Mauna Loa, very feeble).
211. Sept. 1, 04:07, very feeble.
212. Sept. 1, 15:31, very feeble (Mauna Loa, feeble).
213. Sept. 1, 15:36, tremor (Mauna Loa, very feeble).
214. Sept. 2, 06:24, tremor (Mauna Loa, very feeble).
215. Sept. 3, 04:42, very feeble. Felt at Hawaii National Park. Kilauea.
216. Sept. 4, 05:58, no record at Kilauea (Kona, very feeble).
217. Sept. 4, 15:40, no record at Kilauea (Mauna Loa, very feeble).
218. Sept. 10, 07:00, tremor (Mauna Loa, very feeble).
219. Sept. 10, 20:02, no record at Kilauea (Mauna Loa, very feeble).
220. Sept. 12, 01:58, very feeble.
221. Sept. 12, 06:57, very feeble.
222. Sept. 13, 07:16, very feeble.
223. Sept. 13, 16:35, tremor (Mauna Loa, very feeble).
224. Sept. 14, 14:03, tremor (Mauna Loa, very feeble).
225. Sept. 15, 02:37, no record at Kilauea (Kona, very feeble). Kona.
226. Sept. 15, 10:57, tremor (Mauna Loa, very feeble).
227. Sept. 16, 04:22, tremor (Mauna Loa, very feeble).
228. Sept. 17, 19:34, very feeble.
229. Sept. 23, 07:50, tremor (Mauna Loa, very feeble).
230. Sept. 23, 14:50, very feeble (Kona, slight). Felt in central Kona. Central Kona.
231. Sept. 24, 02:09, no record at Kilauea (Mauna Loa, very feeble).
232. Sept. 25, 09:40, tremor (Mauna Loa, very feeble).
233. Sept. 25, 11:46, tremor (Mauna Loa, very feeble).
234. Sept. 25, 12:00, tremor (Mauna Loa, very feeble).
235. Sept. 25, 12:19, tremor (Mauna Loa, very feeble).
236. Sept. 25, 13:10, tremor (Mauna Loa, very feeble).
237. Sept. 25, 16:33, tremor (Mauna Loa, very feeble).
238. Sept. 25, 17:13, tremor (Mauna Loa, very feeble).
239. Sept. 26, 11:04, no record at Kilauea (Mauna Loa, very feeble).
240. Sept. 26, 12:16, no record at Kilauea (Mauna Loa, very feeble).
241. Sept. 26, 12:57, no record at Kilauea (Mauna Loa, very feeble).
242. Sept. 26, 13:02, no record at Kilauea (Mauna Loa, very feeble).
243. Sept. 26, 13:43, tremor (Mauna Loa, very feeble).
244. Sept. 26, 17:25, no record at Kilauea (Mauna Loa, very feeble).
245. Sept. 26, 20:11, no record at Kilauea (Mauna Loa, very feeble).
246. Sept. 27, 06:08, very feeble. Probably Kaoiki fault.
247. Sept. 27, 13:20, no record at Kilauea (Kona, feeble). Felt in central Kona.

Earthquake Data, July–September, 1953

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms
July 5	10	4	0	1	0	0	4.5	0
12	7	2	0	0	0	0	2.75	0
19	6	1	0	0	0	0	2.0	0
26	6	5	0	0	0	0	4.0	0

27	8	2	0	0	0	0	3.0	2

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

New Seismographs

On June 26, 1953, the old Hawaiian-type seismograph at the Mauna Loa station was replaced by a new Loucks-Omori seismograph. The station had been out of operation for about 3 weeks during renovation of the vault and installation of the new instrument. The Loucks-Omori seismograph is an Omori-type seismograph developed at the Hawaiian Volcano Observatory as a result of gradual and long-continued modification of the Bosch-Omori instrument. Built by Burton J. Loucks and John C. Forbes in the Observatory's instrument shop, it consists of two heavy horizontal pendulums hung respectively north-south and east-west, operating at an undamped period of 3 seconds, with a static magnification of 200.

The seismograph station on Haleakala, island of Maui, had been out of operation since the early part of World War II. On August 20, 1953, a new Loucks-Omori seismograph was installed in the Haleakala station. Like the Mauna Loa instrument, it has a static magnification of 200 and is being operated at a period of 3 seconds. The station is situated in the headquarters area of the Haleakala Section of Hawaii National Park, at 20°45′57″N. and 156°14′58″W. It is operated by the National Park staff under the direction of Mr. Eugene Barton, Assistant Superintendent. Records are sent to the Hawaiian Volcano Observatory for interpretation.

New buildings for seismograph stations were completed during July on the grounds of the Waimea School at Kamuela, the Naalehu School at Naalehu, and the Pahoa School at Pahoa, island of Hawaii. These new stations will be operated in cooperation with the Territory of Hawaii Department of Public Instruction. It is expected that seismographs will be installed in them within the next few months.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori horizontal or Sprengnether vertical seismograms, in Hawaiian Standard time.

July 1, 21 : 05,	slight. New Hebrides Islands, 18½°S., 169°E.
Sept. 13, 14 : 46,	slight. Fiji Islands, 18½°S., 178½°E. Accompanied by a tsunami. Several persons killed, and extensive property damage.
Sept. 28, 15 : 46,	slight. Origin probably within a few hundred miles.
Sept. 30, 13 : 23,	moderate.

VOLCANO NOTES AND NEWS

ACTIVITY AT NGAURUHOE, NEW ZEALAND NOVEMBER, 1952, TO JULY, 1953

By J. Healy

(Published by permission of the Director, N. Z. Geological Survey)

On November 29, 1952, Ngauruhoe volcano erupted clouds of ash 6,000 feet into the air in what the manager of the Chateau, Mr. L. S. Dennis, described as the most intense activity for many months. The mountain had erupted at intervals of several months during the previous 2 years, but now activity mounted, and for a period of nearly 3 months it continued in violent eruption for most of the time. Unfortunately, the weather was not good and only spasmodic observations were possible.

The eruption of ash in billowing, cauliflower-shaped clouds characterized the eruptive activity, and was accompanied by thunderous explosions, frequently heard at the Chateau at a distance of 8 miles. Toward the end of January the climax was reached, and for several days windows and doors at the Chateau were rattled by the closely spaced detonations. Guests on the evening of January 23 watched white-hot blocks being thrown from the crater, fall beyond its rim, and roll down the mountain slopes, while the entire crest was illuminated by a bright red glow that dilated at short intervals as big "shots" went up. Considerable noise like thunder and drums was heard during this period. At this distance the visibility of discrete blocks being erupted through the air testified to their large size. The periodicity of large explosions at this stage was about 8 to 10 minutes, whereas earlier it had been up to a half hour. Later the periodicity again increased as the eruptive activity waned.

Strong activity continued until the middle of February, after which active periods became shorter and more widely spaced. On March 27 a single eruption of a black ash cloud to an estimated height of 20,000 feet was reported, but since that date eruptions have been few. One was reported on July 28.

The writer inspected the crater from the air on February 4, 1953, but clouds kept the plane at about the level of the west rim. Steam was on that occasion issuing from vents near that rim, but from a vent farther east a straight plume of light-brown ash was rising. A climber had previously reported on January 30 the emission of "brown, semi-transparent substance several hundred feet into the air" and had stated that this was falling back to build up the cone around the vent. He also reported the discharge of masses of molten, orange-colored lava, so it appears most likely that this light-brown emission consisted of red-hot ash and scoria.

Ngauruhoe is an andesite volcano with perfect conical symmetry, and the summit, which is a little over a quarter mile in diameter, was divided prior to 1949 into three units. The main crateral floor occupied the eastern half, with the precipitous east rim rising above it. On the western side were two contiguous subcraters—a smaller one on the north, and a larger active one on the south. The crater at that time and the eruptive activity of 1948 have been described by Allen (1). In the eruption of 1949, which has been described by Battey (2) and Cloud (3),

the active subcrater was filled with lava in the early stages but finally became a shallow pit floored with loose pyroclastic material. Its earlier rim, which separated it from the main crater floor on the east, was obliterated, and the foot of the east wall was buried.

The latest activity was similar to that described by Allen in the account of the 1948 eruption, and the crater now shows a return to the earlier conditions. The active subcrater on the southwest has again been deepened, and a rim of pyroclastic material has again been built up between it and the wide floor of the main eastern half of the summit. A difference has remained, however. The 1949 eruption apparently weakened the northwest rim and permitted small fumaroles to emerge on the outer slopes. During the winters since then a large patch outside the northwest rim has been observed to remain free of snow, due to the presence of warm ground.

ERUPTION OF MOUNT SPURR, ALASKA

By Ray E. Wilcox

Mount Spurr is the northeasternmost of a chain of many active volcanoes comprising the Aleutian volcanic arc. The explosive outbreak of Mount Spurr which took place early on July 9, 1953, was its first strong activity during the 200 years of recorded history of that area.

The eruption took place from an old ice-filled vent at an altitude of about 7,000 feet on the south shoulder of Mount Spurr. Reports of concurrent eruptions from other points on Mount Spurr and Mount Torbert appear to have been erroneous, as also do reports of eruption in the Lake Beluga-Mount Susitna area, 30 miles east of Mount Spurr, on July 10. The eruption was observed by Werner Juhle and Henry Coulter, of the U. S. Geological Survey, from July 11 to 14, and by the writer from July 12 to 27.

The earliest observations of the eruption were made by airplane pilots at 5:05 A.M., July 9, apparently only minutes after the initial outbreak. From a distance of 60 miles they noted the eruptive cloud rising through the overcast to a height of about 15,000 feet and a width of about ⅛ mile, growing rapidly. By 5:25 A.M. the cloud had risen to the 30,000-foot level and had begun to mushroom. At 5:40 A.M. the mushrooming portion extended from an altitude of 32,000 feet to 60,000 or 70,000 feet, with an estimated diameter of 30 miles. Its stalk was estimated to have a diameter of about a mile. Electrical discharges were seen at intervals of about 3 seconds throughout the mushroomed portion. By 6:00 A.M. falling ash obscured the area below the expanded portion of the cloud, and the stalk was lost from sight.

A report by a pilot at 9:00 A.M. indicated that the ash still was erupting in large quantities and that the radius of the mushroom cloud had increased to 40 to 60 miles at 27,000 feet altitude. At noon the activity was greatly diminished, but by 3:30 P.M. moderately strong eruption had resumed and, apparently, continued through the afternoon and evening. On the morning of July 10 the vent was steaming only, but at 3:30 P.M. an especially strong surge of ash-laden steam rose to 20,000 feet. From July 11 to 14 the activity consisted of the liberation of moderately large quantities of steam, with little or no ash. The intensity of the steam eruption in general diminished from day to day, with the exception of one stronger surge of steam and minor ash at 2:00 P.M. on July 13. This trend of gradually diminishing intensity continued through the rest of July.

No lava flows were produced during the eruption. Immense floods and mud flows did occur on July 9 or 10, however, the water for which no doubt stemmed from the melting of the ice in the crater and, possibly, from local torrential rains associated with the strong ash eruption. Thousands of cubic yards of debris of all sizes up to several yards in diameter were carried down the south flank of the mountain to pile up in the Chakachatna River and form a dam, behind which the water backed up for a distance of about 5 miles, nearly to Chakachamna Lake.

The huge ash cloud from the first surges of the eruption moved slowly eastward, and by 11:00 A.M. its leading edge had spread over Anchorage, 80 miles east of the volcano. Street lights in Anchorage came on automatically at 11:00 A.M., due to the increasing darkness, and by noon ash was falling abundantly, accompanied by a perceptible odor of gas. Complete darkness lasted from 1:00 to 3:00 P.M. Ash continued to fall through the remainder of the afternoon and evening, but by early morning on July 10 only a haze of dust hung over the area. No significant amount of new ash appears to have reached the Anchorage area after that. At Anchorage the measured thickness of ash ranged from ⅛ to ¼ inch. In the Beluga Lake area the ash deposit may have ranged from 1 inch to several inches in thickness, judging from the large number of trees and bushes bent down by the load. On the southeast slope of Mount Spurr, Juhle found only a couple of inches of coarse debris. Westward the ash deposit thinned rapidly, and little or no ash could be seen on the snow a mile or two west of the active vent.

[Sometime in the last week of August, Dr. R. Werner Juhle, who made some of the observations of activity of Mount Spurr presented above, lost his life in Knife Creek in (the Valley of Ten Thousand Smokes) Katmai National Monument, Alaska. He had gone out alone from the base camp on a traverse planned to take several days. When he failed to return at the appointed time, an exhaustive search by planes and by men on foot aided by bloodhounds (flown up from San Francisco for the search) discovered his footprints leading up to and disappearing on the bank of a narrow, deep rapids of Knife Creek. His pack and exposure meter were found on the oposite bank of the rapids but prolonged search failed to find any further trace. Dr. Juhle, one of the outstanding recent graduates in geology from Johns Hopkins University, had done his Doctor's thesis on Iliamna Volcano, Alaska, and was engaged during the 1953 field season in the study of Katmai Volcano and the Valley of Ten Thousand Smokes as part of the co-operative investigation of Katmai National Monument by the National Park Service, Geological Survey, and other organizations.—*H. A. Powers.*]

J. P. EATON JOINS HVO STAFF

On September 15, Dr. Jerry P. Eaton joined the staff of the Hawaiian Volcano Observatory as Seismologist. Dr. Eaton has just completed his work for the degree of Doctor of Philosophy at the University of California, with a thesis on "The Theory of the Electromagnetic Seismograph." The thesis deals in large part with the response characteristics of Sprengnether seismographs, one of which is being operated at the Observatory's Uwekahuna station. Dr. Eaton is assuming charge of the seismological work, and most other geophysical work, of the Volcano Observatory.

THE VOLCANO LETTER

No. 522 **U. S. Geological Survey** **October–December, 1953**

PUBLISHED BY THE UNIVERSITY OF HAWAII

A SUGGESTED EXPLANATION OF THE ALTERNATION OF ACTIVITY BETWEEN TWO VENTS AT KILAUEA VOLCANO

By CHESTER K. WENTWORTH

After the first month of the eruption of Kilauea in 1952 and for several weeks thereafter, visible outflow of lava took place from one or both of two vents somewhat southwest of the center of the Halemaumau pit. At first both vents were active centers of fountaining, with one or the other more active, but in late August and early September one or the other would remain crusted over and almost dead while the other would be quite vigorous and even spectacular in its action for several hours to a day or more. Then the inactive one would come to life and rival its twin while the latter in turn became quiet. Such alternations took place a number of times, were observed by many persons who were able to visit the eruption repeatedly, and came to be predicted confidently by various observers.

Such behavior, among the many other points of interest, aroused speculation as to its cause, and the following note offers a tentative explanation, after a brief additional description. The two vents, during the early part of the period under discussion, were the sources of fountains which bubbled through a common liquid pool of lava. With some variation, the centers were about 150 to 175 feet apart, and in the later stages there had been built two merged ring cones that generally were maintained some 50 or 60 feet above the central lake, and which together had roughly the shape of a figure eight. At various times this bilobate lake had as many as six outlet lava rivers which streamed through breaks in the ring cones and formed ever-changing and often merging fans on the low dome of the rising floor of Halemaumau. In later stages the outlet rivers were only three, two, or one in number. In the last case the lava output from both fountains, if any, passed out by the one outlet. With only slight differences, the liquid level was commonly about the same throughout the lake. Most of the features of the filling crater and the character of the fountains have been described elsewhere.[1] It is only necessary here to mention certain conditions which may bear on the alternation of activity.

[1] G. A. MACDONALD, THE 1952 ERUPTION OF KILAUEA, Volcano Letter 518: 1–10. 1952.

First, we must keep in mind that the two vents maintained their approximate positions during the last 100 feet or more of rise of the lava fill and were, as far as we can see, the same as two of the most prominent of the vents along the initial rift in the floor which survived after the sheet fountaining of the first few hours. Second, it is to be presumed from the evident circulation of liquid in the pool, the peripheral breaking and exposure of bright lava, and the rise of the chilled floor without change of pattern that the larger part of the lava fill had remained very hot but was far from a homogeneous liquid. It seems quite certain that the two vents were branches from the same source at no very great depth.

Essential to the postulated mechanism is recognition of two sorts of physical condition in and around a vent conduit. We assume that, when lava outflow from a given vent is continuous and active, there must be a heating of the surrounding solid rock and an injection of all openings near the conduit so that the whole column represents an active, live, bulb-like pressure and heat system which would quickly make a liquid response and invade any adjacent opening. The pressure of the liquid must be at least slightly in excess of that required by the level of the vent pool through which it issues.

If such a conduit becomes inactive, cooling will result, the liquid parts will become less mobile, and the whole will presently lose its capacity for a quick hydraulic response to an opening. On the other hand, cooling will result eventually in shrinking, possibly in the production of actual openings, and moreover, if stresses are transmitted, the response of the mass is likely to be by rupture rather than by flow. It is not a contradiction to suggest the possible growth of linear stresses while at the same time postulating shrinkage, because we have to consider the possibility of juxtaposition of two interconnected conduits in alternating phase.

Assume, for instance, that arm A of such a dual system for some reason commences to chill and becomes less fluid. It will gradually lose its capacity for liquid

pressure behavior and approach and enter the rupture stage. If arm B continues active, building slightly higher pressures as the pool rises and maintaining or raising the surrounding throat temperature and liquidity, it can be able at some common point to apply stress in the form of liquid pressure to a part of arm A which may be in the rupture state. The result could be a breaking through of liquid, rise of the column, and renewal of activity in vent A. If such breaking through into vent A saps the hydraulic and thermal activity of vent B sufficiently, it is plausible that conduit B might then, in time, cool toward the rupture state. If this takes place while vent A goes through its phase of fully injecting the rupture system adjacent to its main conduit, the time may come after some hours when the hot, swelling, hydraulic phase of conduit A will develop sufficient boundary stress to invade the rupturing realm of conduit B and bring that vent to a renewed phase of liquid activity, thus completing a cycle. The period of such a cycle would depend essentially on volumes and cooling rates.

It is not possible or necessary to define or describe what degree of solidity is reached in the rupture stage if it is once accepted that there can be a relative contrast between the mobile, liquid pressure of the hydraulic phase and the firm, or pasty but crackable, condition of the rupture phase. The contrast is one of response to stresses that operate over a few minutes or hours; it is one of rigidity rather than strength. The contrast is related to but not of the same dimensions as the well-known contrast between zones of flow and of rupture in the parlance of structural geologists.

It appears that the alternation is related to a rate of outflow of lava and heat which can maintain one active vent but probably not two and thus leads to waning of one when the other waxes. It seems also that the postulated tendency can operate in varying degrees from sharp, accurately timed alternation (though this would hardly be the normal) to a more irregular, somewhat diffuse, and not always completed alternation, perhaps with a considerable amount of overlapping. It should also be recognized that the pressure built in the liquid phase need not be strictly hydrostatic or uniform, merely that it be effectively continuous throughout the volume involved. Neither must it be measured exactly by the fluid level of the pool; it will obviously be higher in the active conduit than in the connected but recently inactivated conduit which was formerly feeding the same pool at a slightly lower level.

THE PHILIPPINE COMMISSION ON VOLCANOLOGY

During 1952, the Congress of the Republic of the Philippines established by legislative act a five-man Commission on Volcanology. The Commission is composed of Dr. Jose M. Feliciano, Head of the Department of Geology and Geography of the University of the Philippines, Chairman; Dr. Casimiro del Rosario, Director of the Weather Bureau; Mr. Benjamin Gozon, Director of the Bureau of Mines; Professor Ramon Abarquez, Chairman of the Section on Geology, Seismology, and Volcanology of the National Research Council; and Mr. Jose C. Quema, representative of the Philippine Geological Society. The purposes of the Commission are:

1. To conduct studies of all active Philippine volcanoes.
2. To establish necessary facilities in order to predict volcanic eruption if possible.
3. To formulate in advance and in detail specific plans of action and of relief in the event of eruption.
4. To recommend to the President of the Philippines such measures as may be necessary to protect life and property in areas which may be affected by volcanic eruptions, including the declaration of certain areas as closed to human habitation or subject to regulation.
5. To study the economic importance of Philippine volcanism.

A working staff has been established by the Commismission, with its headquarters at the University of the Philippines in Quezon City, near Manila. The staff consists of Mr. Arturo Alcaraz, Geologist-in-Charge; Mr. Gregorio A. Andal, Assistant Geologist; Mr. Benigno Yambao, Junior Geologist; Mr. Eugenio Omahoy, Volcanological Observer on Camiguin Island; and Miss Annie C. Aterrado, Secretary. A seismograph station is being operated at the town of Mambajao on Camiguin Island, close to the base of the volcano; field studies are in progress at both Hibok-Hibok and Taal volcanoes. Daily reports are received on volcanic conditions at Taal and Hibok-Hibok. A seismograph station at Taal volcano is being operated by the Weather Bureau, in close co-operation with the Commission on Volcanology. A bibliography on Philippine volcanoes and solfataric areas has been compiled and was presented to the Eighth Pacific Science Congress in November, 1953.

Detailed topographic and geologic mapping of all active Philippine volcanoes is planned, and it is hoped to establish additional seismograph and tilt-measuring stations in the near future. At present, a Loucks-Omori two-component horizontal seismograph, with static magnification of 200, is being operated at Hibok-Hibok volcano. The seismograph at Taal is a Wiechert inverted pendulum, also with a magnification of 200. Dr. Gordon A. Macdonald of the United States Geological Survey, Director of the Hawaiian Volcano Observatory, is spending approximately three months in the Philippine Islands, aiding in the work of the Commission on Volcanology. During the Eighth Pacific Science Congress very helpful advice was received by the Commission from Dr. G. A. de Nevé, Director of the Volcanological Survey of Indonesia; Mr. James Healy, Chief of volcanological investigations for the New Zealand Geological Survey; and Professor Howel Williams of the University of California.—G. A. MACDONALD.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR OCTOBER–DECEMBER, 1953

By JERRY P. EATON

VOLCANOLOGY

October

Seismic unrest at Mauna Loa and Kilauea continued through October. A series of sharp earthquakes on October 26, 27, and 28 caused some excitement at the Observatory. Four of these quakes, which originated under the east rift of Kilauea, were felt in the Volcano area at 1:07 A.M., 3:36 A.M., and 4:30 A.M. on the twenty-seventh, and at 10:58 P.M. on the twenty-eighth. A continuous watch was maintained at Halemaumau crater from 4:30 A.M. on October 27 until late in the afternoon of the same day, when it appeared that the seismic crisis had passed.

Of about 20 small to moderate earthquakes originating along the southwest rift of Kilauea and the Kaoiki fault, one was felt at Pahala on October 9 at 6:15 A.M., one was felt at Naalehu on October 27 at 8:02 A.M., and three were felt at the Kapapala Ranch on October 28 at 3:50 P.M., 5:03 P.M., and 9:15 P.M.

Thirteen earthquakes were centered in Kona. Of these, five were felt: October 2 at 10:06 P.M., October 8 at 9:22 A.M., October 15 at 5:10 P.M., October 19 at 2:33 A.M., and October 31 at 6:15 A.M. In addition, earthquakes felt at Pepeekeo on October 23 at 2:02 P.M. and at Kukuihaele, in Kohala, on October 9 at 6:15 A.M. were recorded by the Observatory's seismographs.

Although the number of earthquakes recorded during October was not unusually large, a surprising number of these were felt.

Northward tilting of the earth's surface at the Volcano House on the northeast rim of Kilauea Crater continued at a rate slightly greater than normal for this season of the year. Eastward tilting was at the normal seasonal rate. An increase of pressure under Kilauea indicated by this excessive northward tilting was not confirmed by the further opening of cracks in the floor of the crater.

November

Seismic activity centered at Kilauea during the month of November. Of the 44 earthquakes rated as very feeble or larger which were recorded during November, 21 originated on Kilauea, 8 originated on Mauna Loa, and 15 recorded too weakly to be located.

Twelve of the Kilauea earthquakes centered very near the Observatory, four being felt weakly in the Volcano area at 9:32 P.M. on November 22, at 3:38 P.M. on November 28, at 7:44 P.M. on November 29, and at 1:04 P.M. on November 30. The largest earthquake of the month was felt quite generally in the Puna and Hilo districts and weakly as far as Kealakekua, Kona, and Kukuihaele, North Hamakua. It occurred on November 29 at 8:43 P.M. and originated on the east rift of Kilauea 10 miles from the Observatory at a depth of about 10 miles.

A feeble earthquake recorded at 8:37 P.M. on November 8 was felt at Naalehu and probably centered along the coast south of Kilauea. Slight earthquakes were felt in Kealakekua at 8:35 P.M. on November 4 and in Kamuela at 9:45 A.M. on November 16, but neither was recorded at the Observatory.

Northward tilting of the ground at the Volcano House on the north rim of Kilauea Crater continued at a rate slightly greater than normal for this season of the year, indicating continuing high pressure under Kilauea.

December

Many small earthquakes originating under Kilauea and Mauna Loa during December indicated that the Hawaiian volcanoes remained in a state of unrest. Of 51 quakes rated as very feeble or larger recorded by the Observatory's seismographs during the month, 17 originated at Kilauea, 8 at Mauna Loa, 1 at Kohala, and 25 were recorded too feebly to be located.

Between November 30 and December 6 a large number of tremors was recorded by the Mauna Loa seismograph. One of the larger earthquakes accompanying this swarm of tremors was felt in Hilo at 1:56 A.M. on December 1. It is probable that the tremors stemmed from foci near the focus of this larger earthquake, deep under the northeast rift of Mauna Loa.

Two quakes originated on the southeast flank of Mauna Loa between its summit and the Kaoiki fault. Two of the five quakes occurring on the Kona side of Mauna Loa were felt, one in Kalihiki at 4:16 P.M. on December 14, the other in Captain Cook at 1:00 P.M. on December 16.

Seismic activity at Kilauea continued to center around the caldera. Twelve of the 17 quakes occurring on Kilauea originated within a few miles of the Observatory. In addition, two quakes proceeded from epicenters on the southwest rift of Kilauea, two others from epicenters along the coast south of Kilauea.

Earthquakes were felt in the Kohala district at 7:42 P.M. on December 11, 2:53 A.M. on December 12, and 7:11 P.M. on December 17. The second of these was not recorded on any of the Observatory's seismographs.

The rate of northward tilting of the earth's surface at the Volcano House on the northeast rim of Kilauea caldera decreased, as is usual at this time of the year. Eastward tilting, however, proceeded at the same moderate rate which had prevailed since mid-August. The failure of eastward tilting to slacken and reverse during December suggested an increase in pressure under Mauna Loa. No other evidence was available, however, to check this conclusion.

SEISMOLOGY

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. Locations given are epicenters. The times given are arrival times at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

248. Oct. 1, 09:23, tremor (Mauna Loa, slight). Kaoiki fault.
249. Oct. 1, 22:02, very feeble.
250. Oct. 2, 20:18, tremor (Mauna Loa, very feeble). Southwest rift of Kilauea 2 miles east of Kapapala Ranch.
251. Oct. 2, 20:36, tremor (Mauna Loa, very feeble). Kaoiki fault.
252. Oct. 2, 22:06, no record at Kilauea (Kona, very feeble). Felt in Capt. Cook. Central Kona.
253. Oct. 4, 22:27, tremor (Mauna Loa, very feeble).
254. Oct. 5, 01:20, very feeble.
255. Oct. 5, 11:21, very feeble. Kilauea.
256. Oct. 8, 09:22, feeble (Mauna Loa, moderate). Felt in central Kona. Nine miles east of Hainoa Crater on Hualalai.
257. Oct. 9, 06:16, very feeble. Felt at Kukuihaele. Kohala.
258. Oct. 9, 16:26, no record at Whitney Laboratory (Mauna Loa, very feeble).
259. Oct. 9, 16:28, no record at Whitney Laboratory (Mauna Loa, very feeble).
260. Oct. 9, 19:03, no record at Whitney Laboratory (Kona, very feeble). Central Kona.
261. Oct. 9, 21:11, tremor (Mauna Loa, very feeble).
262. Oct. 9, 21:53, tremor (Mauna Loa, very feeble). Felt at Pahala. Mauna Loa.
263. Oct. 10, 02:04, tremor (Mauna Loa, very feeble).
264. Oct. 10, 02:51, very feeble. East rift of Kilauea at Alae Crater.
265. Oct. 14, 17:23, tremor (Mauna Loa, very feeble). Kaoiki fault.
266. Oct. 14, 18:28, tremor (Mauna Loa, very feeble). Five miles east of Hainoa Crater on Hualalai.
267. Oct. 15, 07:11, very feeble. Kilauea.

268. Oct. 15, 17:10, very feeble (Kona, feeble). Felt in Capt. Cook. Central Kona.
269. Oct. 16, 00:33, very feeble. South flank of Mauna Loa near Anipeahi.
270. Oct. 17, 18:09, very feeble. South flank of Mauna Loa.
271. Oct. 18, 00:57, very feeble. Kilauea.
272. Oct. 18, 15:16, very feeble. East rift of Kilauea.
273. Oct. 19, 02:33, no record at Kilauea (Mauna Loa, very feeble). Central Kona.
274. Oct. 20, 06:15, tremor (Mauna Loa, very feeble). Kaoiki fault.
275. Oct. 22, 14:00, no record at Kilauea (Kona, very feeble).
276. Oct. 22, 14:02, very feeble (Mauna Loa, feeble). Felt at Pepeekeo. East flank of Mauna Kea.
277. Oct. 23, 14:49, no record at Whitney Laboratory (Mauna Loa, very feeble).
278. Oct. 25, 00:53, no record at Kilauea (Mauna Loa, very feeble).
279. Oct. 25, 01:23, very feeble.
280. Oct. 25, 04:17, very feeble. Makaopuhi Crater.
281. Oct. 25, 10:42, tremor (Uwekahuna, very feeble). East rift of Kilauea near Napau Crater.
282. Oct. 26, 14:13, very feeble. East rift of Kilauea near Napau Crater.
283. Oct. 26, 17:46, slight. East rift of Kilauea south of Alae Crater.
284. Oct. 26, 17:50, slight. East rift of Kilauea south of Alae Crater.
285. Oct. 26, 17:51, slight. East rift of Kilauea.
286. Oct. 26, 17:53, very feeble.
287. Oct. 27, 00:22, feeble.
288. Oct. 27, 01:07, strong. Felt at Volcano. East rift of Kilauea south of Aloi Crater near Ainahou.
289. Oct. 27, 01:10, very feeble.
290. Oct. 27, 01:38, slight.
291. Oct. 27, 03:37, strong. Felt at Volcano. East rift of Kilauea south of Makaopuhi Crater.
292. Oct. 27, 04:30, strong. Felt at Volcano. East rift of Kilauea near Alae Crater.
293. Oct. 27, 06:20, strong. East rift of Kilauea south of Napau Crater.
294. Oct. 27, 08:02, very feeble. Felt at Naalehu. Southwest rift of Mauna Loa near Alika Cone.
295. Oct. 27, 23:56, tremor (Uwekahuna, very feeble).
296. Oct. 28, 06:44, tremor (Uwekahuna, very feeble). Kaoiki fault near Halfway House.
297. Oct. 28, 07:21, very feeble. Kaoiki fault near Halfway House.
298. Oct. 28, 15:50, very feeble. Felt at Kapapala. Hilina Pali.
299. Oct. 28, 17:03, very feeble. Felt at Kapapala. Southwest rift of Kilauea near Ponohohoa Chasms.
300. Oct. 28, 21:15, very feeble. Felt at Kapapala. South flank of Mauna Loa.
301. Oct. 28, 22:58, very feeble. Felt at Volcano. East rift of Kilauea near Aloi Crater.
302. Oct. 29, 04:47, very feeble. Southwest flank of Kilauea.
303. Oct. 29, 05:40, very feeble.
304. Oct. 30, 08:16, tremor (Uwekahuna, very feeble). Kilauea caldera.
305. Oct. 31, 06:08, tremor (Kona, feeble). Felt in North Kona and North Kohala. North flank of Hualalai.
306. Oct. 31, 12:26, very feeble. Southwest flank of Kilauea.
307. Oct. 31, 13:22, very feeble. Southwest flank of Kilauea.
308. Nov. 1, 03:22, no record at Whitney Laboratory (Uwekahuna, very feeble).
309. Nov. 1, 14:42, very feeble. Southwest flank of Kilauea near Maunaiki.
310. Nov. 3, 10:14, tremor (Uwekahuna, very feeble). Southwest rift of Kilauea.
311. Nov. 5, 00:16, tremor (Mauna Loa, very feeble).
312. Nov. 5, 07:55, tremor (Mauna Loa, very feeble). Mauna Loa.
313. Nov. 5, 23:47, very feeble. Southwest rift of Mauna Loa.
314. Nov. 6, 02:30, feeble (Mauna Loa, slight). Mauna Loa, 3 miles south of the Mauna Loa seismograph.
315. Nov. 6, 11:24, tremor (Mauna Loa, very feeble).
316. Nov. 8, 18:14, very feeble.
317. Nov. 8, 20:37, very feeble. Coast south of Kilauea.
318. Nov. 10, 13:48, tremor (Uwekahuna, very feeble).
319. Nov. 12, 09:37, tremor (Mauna Loa, very feeble).
320. Nov. 14, 04:55, very feeble. Coast south of Kilauea.
321. Nov. 14, 05:12, very feeble. Coast south of Kilauea.
322. Nov. 19, 03:20, no record at Kilauea (Mauna Loa, very feeble).
323. Nov. 19, 05:36, tremor (Uwekahuna, very feeble).
324. Nov. 20, 05:10, tremor (Uwekahuna, very feeble).
325. Nov. 21, 11:26, very feeble (Mauna Loa, feeble). Red Hill.
326. Nov. 21, 15:23, very feeble (Uwekahuna, feeble). Kilauea.
327. Nov. 21, 16:11, very feeble. Mauna Loa.
328. Nov. 22, 21:32, moderate. Felt in Hawaii National Park and at Volcano. Kilauea caldera.
329. Nov. 23, 17:26, very feeble. Near Kilauea caldera.
330. Nov. 25, 07:07, no record at Whitney Laboratory (Uwekahuna, very feeble).
331. Nov. 25, 12:42, tremor (Uwekahuna, very feeble).
332. Nov. 26, 02:09, no record at Kilauea (Mauna Loa, very feeble).
333. Nov. 26, 03:09, very feeble.
334. Nov. 26, 05:52, very feeble (Mauna Loa, feeble). Red Hill.
335. Nov. 26, 13:54, very feeble (Uwekahuna, feeble). Near Kilauea caldera.
336. Nov. 26, 13:55, very feeble (Uwekahuna, feeble). Near Kilauea caldera.
337. Nov. 26, 16:58, very feeble. Near Kilauea caldera.
338. Nov. 27, 19:25, very feeble. Kilauea.
339. Nov. 28, 08:11, very feeble. Kilauea.
340. Nov. 28, 15:38, moderate. Felt in Hawaii National Park. Near Kilauea caldera.
341. Nov. 28, 20:46, no record at Kilauea (Mauna Loa, very feeble).
342. Nov. 29, 03:05, very feeble. Near Kilauea caldera.
343. Nov. 29, 03:49, no record at Kilauea (Kona, very feeble). Kona.
344. Nov. 29, 07:36, tremor (Uwekahuna, very feeble). Near Kilauea caldera.
345. Nov. 29, 19:44, moderate. Felt in Hawaii National Park. Near Kilauea caldera.
346. Nov. 29, 20:43, strong. Felt from Hawaii National Park to Hilo. East rift of Kilauea near Napau Crater.
347. Nov. 29, 21:18, very feeble.
348. Nov. 29, 23:18, no record at Whitney Laboratory (Uwekahuna, very feeble).
349. Nov. 30, 13:02, tremor (Uwekahuna, very feeble).
350. Nov. 30, 13:04, slight. Felt in Hawaii National Park. Near Kilauea caldera.
351. Nov. 30, 13:30, no record at Whitney Laboratory (Uwekahuna, very feeble).
352. Dec. 1, 01:56, tremor (Mauna Loa, very feeble). Felt in Hilo. Northeast rift of Mauna Loa.
353. Dec. 1, 02:01, no record at Kilauea (Mauna Loa, very feeble).
354. Dec. 1, 03:20, no record at Kilauea (Mauna Loa, very feeble).
355. Dec. 1, 03:21, no record at Kilauea (Mauna Loa, very feeble).
356. Dec. 1, 04:17, no record at Kilauea (Mauna Loa, very feeble).
357. Dec. 1, 04:20, tremor (Mauna Loa, very feeble).
358. Dec. 1, 04:24, tremor (Mauna Loa, very feeble).
359. Dec. 1, 08:46, no record at Kilauea (Mauna Loa, very feeble).
360. Dec. 1, 09:09, tremor (Mauna Loa, very feeble).
361. Dec. 1, 10:54, tremor (Mauna Loa, very feeble).
362. Dec. 1, 12:34, no record at Kilauea (Mauna Loa, very feeble).
363. Dec. 1, 12:43, tremor (Mauna Loa, very feeble).
364. Dec. 1, 12:45, tremor (Mauna Loa, very feeble).
365. Dec. 1, 13:13, tremor (Mauna Loa, very feeble).
366. Dec. 1, 13:20, no record at Kilauea (Mauna Loa, very feeble).
367. Dec. 1, 14:12, tremor (Uwekahuna, very feeble).
368. Dec. 1, 16:27, tremor (Mauna Loa, very feeble).
369. Dec. 1, 21:23, no record at Kilauea (Mauna Loa, very feeble).

370. Dec. 2, 23:19, tremor (Mauna Loa, very feeble).
371. Dec. 3, 01:54, no record at Whitney Laboratory (Mauna Loa, very feeble).
372. Dec. 3, 01:59, tremor (Mauna Loa, very feeble).
373. Dec. 6, 21:02, feeble. Near Halfway House on the south flank of Mauna Loa.
374. Dec. 8, 03:29, no record at Whitney Laboratory (Uwekahuna, very feeble). Near Kilauea caldera.
375. Dec. 8, 14:00, very feeble. Kilauea caldera.
376. Dec. 8, 23:59, very feeble. Kilauea caldera.
377. Dec. 9, 01:13, slight. Felt in Hawaii National Park. Kilauea caldera.
378. Dec. 9, 01:18, slight. Kilauea caldera.
379. Dec. 9, 01:56, slight. Kilauea caldera.
380. Dec. 9, 10:03, very feeble. Kilauea caldera.
381. Dec. 9, 10:43, very feeble. Kilauea caldera.
382. Dec. 11, 12:27, no record at Kilauea (Kona, very feeble).
383. Dec. 12, 08:56, very feeble. Southwest rift of Kilauea near the Ponohohoa Chasms.
384. Dec. 12, 15:15, tremor (Uwekahuna, very feeble). Near the coast south of Kilauea.
385. Dec. 13, 02:53, very feeble.
386. Dec. 14, 04:08, very feeble.
387. Dec. 14, 08:15, very feeble.
388. Dec. 14, 12:39, very feeble. Kilauea caldera.
389. Dec. 14, 14:54, very feeble.
390. Dec. 15, 21:08, no record at Kilauea (Kona, very feeble).
391. Dec. 16, 13:00, no record at Kilauea (Kona very feeble). Felt in Capt. Cook. Kona.
392. Dec. 16, 17:01, very feeble.
393. Dec. 17, 19:11, very feeble. Kohala.
394. Dec. 20, 04:11, very feeble (Uwekahuna, feeble). Southeast flank of Kilauea near Kalapana.
395. Dec. 21, 12:24, tremor (Mauna Loa, very feeble). East rift of Kilauea.
396. Dec. 21, 12:40, tremor (Uwekahuna, very feeble). Kilauea caldera.
397. Dec. 28, 22:24, no record at Whitney Laboratory (Uwekahuna, very feeble). Kilauea caldera.
398. Dec. 29, 06:01, tremor (Uwekahuna, very feeble). Kilauea caldera.
399. Dec. 30, 08:05, tremor (Uwekahuna, very feeble).
400. Dec. 31, 16:53, very feeble. Kilauea caldera.
401. Dec. 31, 19:54, very feeble.
402. Dec. 31, 20:50, no record at Kilauea (Kona, very feeble). Kona.
403. Dec. 31, 22:55, very feeble.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori horizontal or Sprengnether vertical seismograms, in Hawaiian Standard time.

Nov. 3, 17:59, slight. New Hebrides Islands, 12½°S., 166½°E.
Nov. 17, 03:55, slight. Near coast of Guatemala, 14°N., 92°W.
Nov. 25, 07:59, moderate. Near south coast of Honshu, Japan, 34°N., 141°E. Felt Honshu and Hokkaido. Seismic sea wave.
Dec. 4, 05:11, strong. Off coast of Vancouver Island, 49½°N., 129°W.
Dec. 12, 07:53, feeble. Near coast of Peru, 3½°S., 81°W. Several killed and heavy property damage in Tumbes and Corrales.

Earthquake Data, October–December, 1953

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning		Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms
Oct.	4	10	11	0	0	1	0	11.0	0
	11	21	5	1	0	0	0	8.75	0
	18	16	6	1	0	0	0	8.0	0
	25	40	19	3	4	0	4	46.5	0
Nov.	1	8	7	0	1	0	0	7.5	1

	13	42	9	0	0	0	0	15.0	0
	20	6	2	1	0	0	0	3.5	0
	27	9	7	0	0	0	0	5.75	0

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

VOLCANO NOTES AND NEWS

ERUPTIONS OF MIHARA-YAMA, O-SHIMA, AND ASAMA-YAMA, JAPAN

By Helen L. Foster

(From data supplied by Central Meteorological Observatory, Tokyo, Japan)

Mihara-yama, O-shima: October 5, 1953 to January 6, 1954. Mihara-yama, O-shima, erupted from July 16, 1950, to September 24, 1950. It was then quiescent until February 4, 1951, when eruption recommenced and lasted until June 28, although the activity in April, May, and June was intermittent. The volcano was again quiescent until October 5, 1953, when activity commenced again, heralded by minor earth tremors and rumbling sounds. The first explosion was heard at 8:32 A.M. on October 5. A new vent about 1.5 meters in diameter opened on the inner south wall of the larger cinder cone formed in the 1951 eruption. Lava fragments as large as 1 foot in diameter were hurled to a height of 50 or 60 meters above the vent. Explosions continued intermittently until October 13, when activity subsided after 7:30 P.M. Although emission of gas clouds occurred at intervals, no further explosions were recorded until November 10. On November 11 lava flows and fragments were emitted from two new vents in the crater of the 1951 cinder cone. Only steam and gases were emitted from the vent, which had been active in October. By November 14 a small cone about 3 meters high had formed around the active vents. The volcano was quiescent again during most of the remainder of November, although steam and other gas fumes were emitted.

On December 1 eruptions began again and continued intermittently until December 18, 1953. Gas, ash, and ejecta were emitted from the November vents and from a new vent which opened between those formed in October and November.

Observations on December 24 determined that in the vicinity of the vents which were active in October there was a crater 40 meters long, 20 meters wide, and 8 meters deep which had two vents. In the area of the vents active in November there was a crater 70 meters long and 40 meters wide, with two vents.

Eruption recommenced on December 29 at 3:27 A.M. Activity continued through December 31, 1953. Slight activity was again recorded on January 4, 5, and 6, 1954, when explosions hurled bombs 200 meters high and horizontal distances of 400 meters. Minor topographic changes were taking place in and around the old 1951 cinder cone as the result of collapse and the accumulation of new ejecta.

All the new activity of Mihara-yama in 1953 and 1954 has been on a small scale as compared with the eruptions of 1950 and 1951. Only small quantities of lava and ejecta have been emitted, all of which have been within the crater of the 1951 cinder cone, with the exception of a few pieces of ejecta which have been thrown beyond the 1951 cinder cone crater.

Asama-yama: December 27, 1953 to January 7, 1954. A series of small explosions of Asama-yama began on December 27, 1953. The volcano had been quiescent since June, 1952.

Explosions occurred on December 27 at 1:41 P.M. and 4:45 P.M. and on December 29 at 8:40 A.M. and 10:23 A.M., and on December 30 small ash falls from minor explosions occurred, beginning at 8:00 P.M.

Another explosion occurred on January 3, 1954, and a cloud, probably ash-laden, rose to a height of 600 meters.

On January 7 explosions occurred at 3:30 P.M. and 3:34 P.M., and an ash cloud rose to a height of 700 meters. These explosions were the largest of the series of about 10 which have occurred since December 27, 1953.

CURRENT ACTIVITY OF ALEUTIAN VOLCANOES

By H. A. Powers

There has been but slight activity at most Aleutian volcanoes during the fall of 1953. Observations are being made by members of the Armed Forces and by Austin Jones, Seismologist of the Geophysics Branch, U. S. Geological Survey.

Trident. During July and August a tongue of lava flowed as much as 3 miles, starting from the northwest side of the original vent and following the west margin of the June flows. It terminated in two broad lobes, one crossing the south-flowing stream from Katmai Pass where it dammed a small lake at about 2,000 feet altitude, the other extending a half mile farther south into the Pass drainage at a lower altitude. The new lava flow did not increase visibly in area during the fall months, but was still steaming in December. The vent is sporadically erupting small bursts of ash, and constantly fuming and steaming.

Spurr volcano has been steaming but has had no renewal of ash eruption since the July explosions.

Shishaldin erupted hot ash during the first week of October.

Pavlov was seen "glowing" on November 25 by the personnel of the *Penguin*, sailing from the Pribilof Islands.

Steam plumes but no new ash on the recent snows are reported at various December dates from Gareloi, Kanaga, Great Sitkin, Cleveland, and Makushin.

SECTION OF VOLCANOLOGY EIGHTH PACIFIC SCIENCE CONGRESS

A highly successful meeting of the section of volcanology of the Eighth Pacific Science Congress was held on November 17, 1953, at the University of the Philippines. The meeting opened with the presentation of the report of the Standing Committee on Volcanology of the Pacific Area, by J. Healy, Chairman of the Committee. The report was presented only in brief at the meeting, but the full report was distributed to those present, and copies were sent to contributors who were not present. The 33-page mimeographed report contains accounts of volcanic and thermal activity and investigations in Canada, Hawaii, Alaska, continental United States, Mexico, Guatemala, San Salvador, Nicaragua, South America, New Zealand, Australian territories, Philippines, Japan, Fiji, Solomon Islands, and Indonesia. A 22-page appendix contains a list of volcanological and allied research workers in all these countries. Mr. Healy deserves, and received, the sincere thanks of his fellow workers for his excellent report and organization of the meeting itself.

Following presentation of the Chairman's report, a symposium on Volcanology of the Pacific was convened by Mr. Healy. Chairmanship of the morning session, which was devoted to *nuées ardentes* and related phenomena, was turned over to Mr. Arturo Alcaraz of the Philippine Commission on Volcanology, with Mr. Jose C. Quema of the Philippine Bureau of Mines as secretary. Papers presented during the morning session were: Glowing Avalanche Deposits of Central America, by Howel Williams; Mount Katmai and the Valley of Ten Thousand Smokes, Alaska (a new interpretation of the great eruptions of 1912), by Howel Williams, Garniss Curtis, and Werner Juhle; An Outline of Mount Lamington Phenomena, by G. A. Taylor (presented by J. Thompson); Volcanic Activity of Catarman and Hibok-Hibok, by V. R. Pelaez; Recent Volcanicity at Taupo, New Zealand, by I. L. Baumgart and J. Healy; Some Problems of Welded-Lava and Welded-Tuff Related with the Sunken Calderas in Japan, by T. Matumoto, T. Isikawa, and M. Minato (presented by Howel Williams).

The afternoon session was devoted to descriptive volcanology, petrology of volcanic rocks, and geophysics, under the chairmanship of G. A. Macdonald of the U. S. Geological Survey. Fourteen papers were presented, as follows: The Didicas Submarine Volcano, by A. Alcaraz, L. F. Abad, and M. H. Tupas; Eruption on San Benedicto Island, Mexico, 1952, by R. S. Dietz and A. F. Richards; Combined Air- and Terrain-Reconnaissances Carried out by the Volcanological Survey in the Indonesian Archipelago, and Its Program for Future Research, by G. A. de Nevé; Seventy Years Krakatoa and Twenty-Five Years Anak Krakatoa, with a Communication Concerning the Latest Investigation in October, 1953, by G. A. de Nevé; Volcanic Activity in New Guinea, by J. G. Best (presented by J. Thompson); A Cluster of Little-Known Philippine Volcanoes, by A. Alvir; The Significance of Pillow Lavas in Pacific Islands, by H. T. Stearns (read by title only); The Difference of Chemical Composition between Japanese and Manchurian Volcanic Rocks, by I. Iwasaki and T. Katsura (presented by Y. Miyake); Preliminary Account of the Hydrothermal Condition at Wairakei, New Zealand, by J. Healy; Geochemical Investigation of Geysers in Japan, by K. Noguchi (presented by Y. Miyake); Volcanic Activities in Japan During 1949–1953, by T. Minakami and R. Morimoto (presented by G. A. Macdonald); Transpacific Detection by Underwater Sound of Myojin

Volcanic Explosions, by R. S. Dietz and M. J. Sheehy; The New Seismological Equipment for the Permanent Conservation-Posts of the Volcanological Survey of Indonesia, by G. A. de Nevé; Rehabilitation of the Guarding-System of the Volcanological Survey, by G. A. de Nevé.

A public lecture on Hawaiian volcanoes, illustrated with color movies of the 1949 and 1950 eruptions of Mauna Loa and 1952 eruption of Kilauea, was given by G. A. Macdonald on the evening of November 18, in the auditorium of the Philippine General Hospital.

On November 15, the delegates to the Division of Geology and Geophysics took part in a field trip to Taal volcano. Volcano Island, in the midst of Taal Lake, and the crater from which occurred the disastrous explosions of 1911 were visited. Further glimpses of Taal volcano and the structure of the surrounding region were obtained on a field trip to Tagaytay Ridge on November 19, under the auspices of the Philippine Geological Society and the Philippine Association of Mining, Metallurgical, and Geological Engineers. Following the meetings of the Congress, a group of 15 persons from the Division of Geology and Geophysics participated in a field trip to the southern part of the Philippines, during which both Hibok-Hibok and Mayon volcanoes were visited. Both volcanoes were fuming, but no other activity was visible.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Jerry P. Eaton, Seismologist
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
Elizabeth G. Eklund, Secretary, part-time

Seismograph Station Operators:

Hilo Station:
Sister M. Thecla, St. Joseph's School

THE VOLCANO LETTER

No. 523 **U. S. Geological Survey** **January–March, 1954**

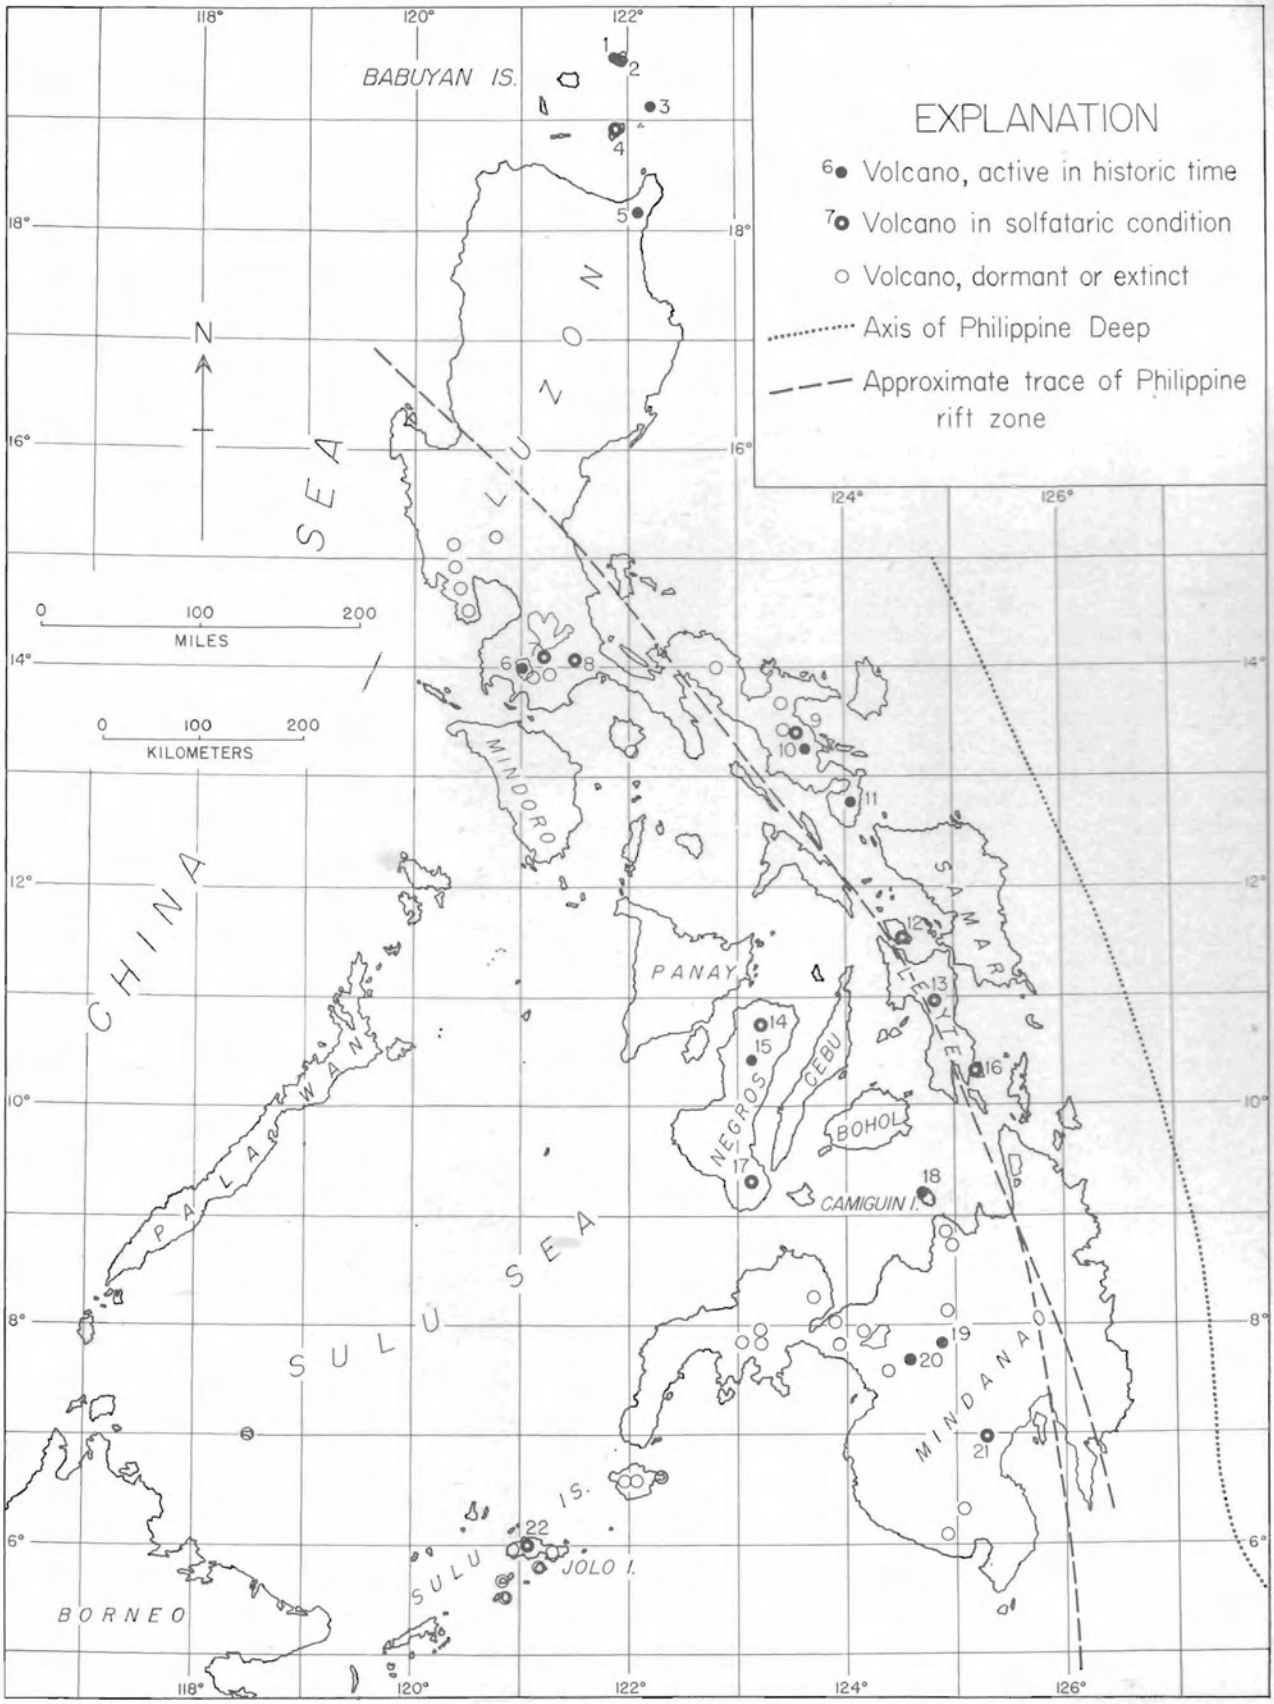
PUBLISHED BY THE UNIVERSITY OF HAWAII

PHILIPPINE VOLCANOES DURING 1953 AND EARLY 1954

By GORDON A. MACDONALD and ARTURO ALCARAZ

The work of the Philippine Commission on Volcanology, created in mid-1952, includes continuous watch over volcanoes that are in eruption or show indications of possible impending eruption, periodic examinations of other active volcanoes (not in eruption), and, as time permits, studies of the dormant and extinct volcanoes of the archipelago. During 1953 and early 1954 continuous observations were made at Hibok-Hibok and Taal volcanoes and short investigations at Didicas and Mayon volcanoes. Canlaon and Bulusan volcanoes were viewed from a distance.

Arturo Alcaraz has been in charge of the field operations of the Commission on Volcanology since December, 1952. Gordon A. Macdonald spent December, 1953, and January and early February, 1954, in the Philippines assisting in the work of the Commission. We wish to express our thanks to the members of the Commission and to the U. S. Geological Survey for making our respective work possible; and to our coworkers, Gregorio A. Andal, Benigno Yambao, and Eugenio Omahoy, for much assistance and pleasant companionship in the field.



Throughout the known part of geologic time, volcanoes have played an important part in the development of the Philippine Archipelago. Volcanic rocks of uncertain age appear among the metamorphosed basement rocks in the Northwestern Cordillera, Mountain Provinces, and Sierra Madre of Luzon Island; on Marinduque and Masbate islands; on the islands of the Palawan group; on Panay, Cebu, Bohol, Samar, and Mindanao islands; and on islands of the Sulu group (Irving, 1951). Volcanic rocks known or believed to be of Tertiary age are exposed at various places from central Luzon to Zamboanga (Irving, 1953). But it is with the volcanoes of Pleistocene and Recent age that we are principally concerned.

The new geologic map of the Philippines (Irving, 1953) shows numerous areas of Quaternary volcanic rocks, scattered all the way from the Babuyan Islands, north of Luzon, to the Sulu Islands, south of Mindanao. Of the major islands in the archipelago, only Palawan, Panay, Cebu, Bohol, Masbate, and Samar lack Quaternary volcanics. Many of the cones, probably of Pleistocene age, are moderately dissected by erosion. Examples of these include Mariveles Mountain on the Bataan Peninsula, Mount Arayat in the central plain of Luzon, Mount Macolod at the southeastern edge of Lake Taal in Batangas Province, Mounts Isarog and Iriga in Camarines Sur Province, the small cone at the southern end of Marinduque Island, Mount Mambajao on Camiguin Island, and many others. In the vicinity of the city of San Pablo, in the area between Mounts Banahaw and Malepunyo, there are many small depressions, several of them occupied by crater lakes. These appear to be diatremes, formed by short-lived volcanic explosions with or without accompanying collapse, perforating the plateau of Quaternary tuff.

Eleven Philippine volcanoes have erupted during historic times. Thirteen others show solfataric activity. These active and solfataric volcanoes are listed in the accompanying table and shown on the map (Fig. 1). Data concerning historic eruptions have been assembled by Andal and Yambao (1953).

Mount Santo Tomas, or Tonglon, near the city of Baguio, has in the past been listed as a volcano in solfataric condition, or even as having erupted in 1641 (Musper and Neumann van Padang, 1937; Andal and Yambao, 1953). These reports must, however, refer to some other locality, because examination of Mount Santo Tomas during February, 1954, showed it to consist of ancient, interstratified volcanic and sedimentary rocks of probable Tertiary age.

Didicas volcano, in the Babuyan Islands north of Luzon, resumed eruption in March, 1952, after a period of quiescence lasting nearly a century. Eruptive activity between 1856 and 1860 had built a mountain that rose some 700 feet above sea level, but subsequent wave action had reduced it to three small rock masses 200 to 270 feet high. Relatively quiet eruption resulted in the building of a blocky dome, from which escaped large volumes of steam and sulfurous gases. The new Didicas dome covered the former rock masses, and by late 1953 the top of the dome was about 830 feet above sea level (Alcaraz, Abad, and Tupas, 1953). Mild vulcanian explosions at the summit of the dome were reported during the early stages of the activity. Ash fell on Calayan Island, 25 miles to the north, but in quantities

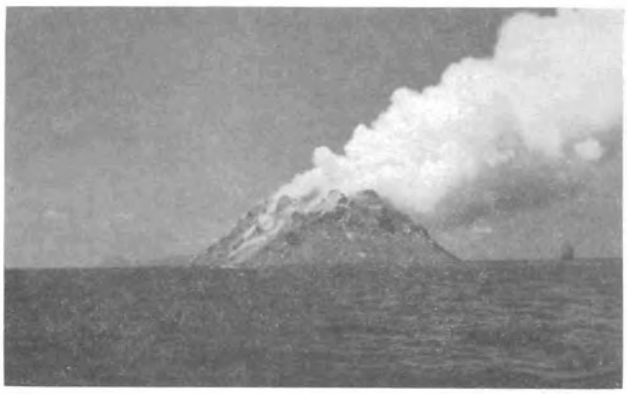

FIGURE 2. Didicas volcano from a point 0.25 mile to the east-northeast, on March 30, 1952. The blocky character of the dome and the banks of crumble breccia on its flanks are clearly visible. One of the old Didicas Rocks can be seen at the right. Photo by Arturo Alcaraz.

too small to cause damage (Andal and Yambao, 1953). In June, 1953, G. A. Andal and L. F. Abad were able to land on the dome and reported that the activity had subsided appreciably.

After its catastrophic eruption in 1911, Taal volcano remained entirely quiet until early 1953. During February, 1953, reports were received of signs of renewed activity, but examinations of the volcano on February 12 and 19 revealed no sign of change from the conditions observed during a survey of the volcano in February, 1949. The temperature of the water of the crater lake was found to be 32°C. In May, 1953, steam vents and hot springs became active in a zone about 100 meters long at and near the southwestern shore of the crater lake. Some sulfur gas is present in the steam. On May 19 the temperature of the steam was 98°C., and the temperature of the crater lake had risen to 36°C. By mid-June the temperature of the steam had increased to 101°C., but since then it has remained stable, with occasional decreases to about 100°C. During the remainder of 1953 the volume of steam fluctuated, but generally it was somewhat less than during May and June. There was a slight northwestward shifting of the active area. In early 1954 there has again been some increase in the apparent volume of steam, which in early March was about twice that observed in May, 1953.

The renewal and gradual increase of solfataric activity at Taal volcano seems unquestionably to indicate a rise of magma at depth or some other change in subsurface conditions resulting in a greater supply of heat to the volcanic vent. No other signs of impending eruption have been observed, and people are still being permitted to reside on Volcano Island, though some have left voluntarily. Close watch is being kept for increased earthquake activity or other signs of eruption; residents of Volcano Island have been informed of the possibility of eruption, and a plan for possible evacuation of the island and areas along the shore of Taal Lake has been prepared.

Mayon volcano, in Albay Province, is the most frequently active volcano in the Philippines and is believed to have the most perfectly symmetrical cone in the world. Since 1800, Mayon has had 31 recorded eruptions, with an average interval of one each 4.9 years. The actual interval has varied, however, from less than 1 to 26 years. The 1928 and earlier eruptions have been described by Faustino (1929). Since that time, eruptions have occurred in 1938, 1939 (a single brief explosion), 1943, and 1947. During late 1953 and early 1954 Mayon volcano was fuming quietly. Most of the fume rose from fissures in and around the small, blocky mass of 1947 lava in the small crater.

Mayon volcano is a composite strato-volcano, composed dominantly of pyroclastics but with numerous interbedded lava flows. The flows are of block-lava type, transitional toward aa. Pyroclastic beds on the northern slope of the volcano above the Mayon resthouse consist largely of Strombolian cinder. Abundant mudflows have formed a broad apron completely around the base of the cone and have been responsible for most of the damage to life and property during historic times.

Bulusan volcano, in Sorsogon Province, has not erupted in recent years. The last eruptive period began on January 18, 1916, and continued intermittently until 1922. During that period there were 17 separate mild explosions, each lasting only a few minutes. Ash fell on towns west, southwest, and south of the volcano, but not in sufficient amount to cause damage. Maso (1928: 765) describes what appears to have been a block-lava flow in the crater during November and December, 1918. The flow pushed its snout out through a breach in the crater rim, and from the snout fragments rolled down the ravine below the breach, black by day but exhibiting dull red incandescence at night. He also describes what

FIGURE 1. Map of the Philippine Islands, showing the location of volcanoes active in historic time, those in solfataric condition but not historically active, and known volcanoes of probable Quaternary age that have shown neither eruptive nor solfataric activity during historic times. The latter are taken from the new geologic map of the Philippines (Irving, 1953). The active and solfataric volcanoes are numbered on the map as follows: 1, Smith; 2, Babuyan Claro; 3, Didicas; 4, Camiguin de Babuyanes; 5, Cagua; 6, Taal; 7, Maquiling; 8, Banahaw; 9, Malinao; 10, Mayon; 11, Bulusan; 12, Biliran; 13, Burauen area; 14, Silay; 15, Canlaon; 16, Cabalian; 17, Magaso; 18, Catarman (Hibok-Hibok); 19, Calayo; 20, Ragang; 21, Apo; 22, Bud Dajo.

FIGURE 4. The dome of Hibok-Hibok volcano seen from the top of the 1948 lava flow, December 19, 1953. Part of the old crater wall is visible on the left skyline. The dome is nearly buried by its long slopes of talus (crumble breccia). Photo by G. A. Macdonald.

appear to have been small, avalanche-type *nuées ardentes*. In his own words, "Sometimes instead of rocks a mass not unlike mud detached itself from the said hot base and showed a great effervescence while sliding down the ravine and raised a white yellowish cloud which had a great ascensional force. After the effervescence had ceased the bottom of the ravine and the vegetation on its sides was seen covered with white dust. . . ."

The last known eruption of Canlaon volcano, on Negros Island, occurred during 1906. The volcano was viewed from the air on January 22, 1954. The mountain has two principal peaks. The northern peak is vegetated to its top, is moderately eroded, and does not appear to have been recently active. The southern peak appears to be a rounded cinder cone, little vegetated and entirely uneroded, sitting on a forested and moderately eroded base which is probably a composite cone. A prominent crater is present in the southern peak. No fumarolic activity was visible.

Calayo and Ragang volcanoes, on Mindanao Island, were not visited during 1953 or early 1954. The last recorded eruption of the former was in 1887 (Andal and Yambao, 1953: 22), while the latter was reported to be active in 1915 (Smith, 1924: 216). Makaturing volcano, also in Mindanao, has been listed by several writers as active. However, there is serious doubt that it ever was active within historic times. Maso (1922: 142) wrote, "Considering the different actual conditions of the Makaturing and of the Ragang one is inclined to believe that all the historic eruptions attributed to the former occurred in the latter. Writers give the years 1834, 1840, 1858, 1871 and 1873, but nearly all these dates are somewhat doubtful because of the lack of reliable particulars and of the fact that the writers are at variance about the same."

Hibok-Hibok volcano, on the northern end of Camiguin Island, just north of Mindanao, was in eruption from 1948 to early 1953. During that period two block-lava flows were extruded on the eastern flank of the mountain, mudflows devastated an area on the northern slope, a dome was built in the summit crater partly overlapping onto the flanks of the mountain, and destructive *nuées ardentes* took the lives of about 500 persons in the sector northeast of the summit (Alcaraz, Abad, and Quema, 1952). As a result of this, the zone around the volcano was closed to public occupation by Presidential order, until such time as the danger from the volcano should subside.

Three visits were made to Hibok-Hibok during December, 1953, and January, 1954. Records from a new, more sensitive seismograph installed in the town of Mambajao, near the base of the volcano, indicated that very few earthquakes were originating beneath the volcano. There had been no ash eruptions since July 14, and no large avalanches from the dome had been reported since May. Eugenio Omahoy, the volcanological observer stationed in Mambajao, had detected no changes in the size or outline of the dome since May, except for the collapse of one prominent spine. In December the dome was examined from the upper part of the valley down which had rushed the *nuées ardentes* of December, 1951, and many smaller, later avalanches. In January the dome itself was climbed and examined at close hand. The dome was fuming quite strongly, but there was no sign of present or recent active growth. Talus banks extended far up the flanks of the dome, in places nearly to its summit. Except in small local areas, the rock ribs between the talus banks had been reduced by crumbling to a slope of stability. Several small spines were present on the dome, and at the summit there was a narrow spine, about 100 feet high, that appeared from some angles to be curved like the dorsal fin of a shark. Some of the spines, including the eastern end of the large spine at the summit, appeared about to collapse. These collapses undoubtedly will cause small avalanches, but it is unlikely that the avalanches will travel far enough to cause damage to inhabited areas. Deposits of recent avalanches are all small and extend little beyond the edge of the dome itself.

Therefore, it appears that, barring renewal of eruptive activity, danger from the dome is over. On that basis, it was recommended that the ban on occupation of the town of Mambajao and the agricultural lands

FIGURE 5. The summit of the Hibok-Hibok dome, seen from the southeast, January 26, 1954. The spine at the top of the dome is badly fissured. The mass in the left foreground was formed in an early stage of the dome growth. Later, activity shifted slightly northeastward and produced the more recently active mass in the background. Photo by G. A. Macdonald.

around the foot of the volcano be abolished, but a new, smaller restricted zone with a radius of 3 kilometers be established around the summit of the volcano, in which no residence would be permitted. These recommendations have been acted upon. At the same time, the dangers of residing upon an active volcano were pointed out to the local populace. A close watch is being kept on the volcano for any signs of renewal of eruptive activity.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JANUARY–MARCH, 1954

By JERRY P. EATON

VOLCANOLOGY

January

January was a quiet month for Hawaiian volcanoes. Only 27 earthquakes were recorded by seismographs of the Hawaiian Volcano Observatory. Seven of them originated under Kilauea, 12 under Mauna Loa, and 8 recorded too weakly to be located.

An earthquake at 9:39 P.M. on January 20, issuing from a focus 10 miles deep under Red Hill on the northeast rift of Mauna Loa, was felt in the Volcano district, Hilo, Pepeekeo, Kukuihaele, and Papaloa, Kona. Two smaller earthquakes from foci under the east rift of Kilauea were felt in Hilo; the first at 4:36 A.M. on January 24 and the second at 11:48 A.M. on January 31. At 2:27 A.M. on January 17 a slight earthquake was felt at Kalahiki, Kona.

Tilting of the earth's surface measured at the Volcano House on the northeast rim of Kilauea caldera was southwestward at a rate which is normal for this season of the year. Measurements of cracks in the floor of Kilauea do not show any significant change in the volcanic pressure under the volcano.

February

Hawaiian volcanoes remained quiet during February. Only 3 of the 27 earthquakes recorded by the Hawaiian Volcano Observatory seismographs were felt. Fourteen earthquakes originated on Mauna Loa, including those at 3:59 P.M. on February 6, 3:15 A.M. on February 16, and 5:32 P.M. on February 22, which were felt in Kona. Kilauea was shaken by six earthquakes, none of which was felt. Seven of the recorded earthquakes were too feeble to be located.

Tilting of the earth's surface at the northeast rim of Kilauea caldera proceeded in a southwesterly direction at a rate approximately normal for this season of the year.

March

Thirty-six earthquakes were recorded by seismographs of the Hawaiian Volcano Observatory during March. During most of the month seismic activity remained at the low level established during January and February; only 15 earthquakes were recorded from March 1 to March 29. Nine of them originated at Kilauea. The remaining six, including the earthquake at 4:19 P.M. on March 16, which was felt in Captain Cook, issued from Mauna Loa.

A series of small tremors felt in Hawi at about 8:30 P.M. on March 23 was not recorded on any of the Observatory's seismographs.

Two strong earthquakes, which originated at a depth of about 15 miles on the east rift zone of Kilauea or the eastward extension of the Hilina fault system between the rift zone and the south shore in the vicinity of Kalapana, rocked the Island of Hawaii early on the morning of March 30. The first shock was recorded on the seismographs at the Volcano Observatory at 6:40:07 A.M.; the second at 8:42:01 A.M.

Both earthquakes were felt over the entire Island of Hawaii, and at least the second, which was the larger of the two, was felt on parts of Maui. Extensive, but mostly moderate, damage was caused in the Hilo and Puna districts. Although the shaking was most intense in the Puna district, where water tanks were thrown down and stone fences were damaged, the most spectacular damage occurred in and near Hilo, where many windows were broken and portions of a few houses were deranged or thrown down.

On March 30 and 31 a total of 16 aftershocks, several of which were felt in Puna and Hilo, stemmed from the same region as the two large quakes. The largest of these occurred at 6:57 A.M. on March 30 and at 3:04 P.M. and 4:00 P.M. on March 31. The

aftershock sequence extended into April, with small earthquakes at 3:57 P.M. on April 1 and 2:05 P.M. on April 8.

Concurrent with the large earthquakes in Puna and the associated aftershocks, seismic activity increased near Kilauea caldera. Four quakes originated in this region on March 30 and 31, and two more occurred on April 1. Of these six earthquakes, those at 11:19 A.M. on March 30 and 6:35 A.M. on April 1 were felt in the Volcano area.

The normal seasonal southwestward tilting at the Volcano House on the northeast rim of Kilauea caldera reversed for about 1 week at the time of the Puna earthquakes. Subsequently, southwestward tilting normal for this season has been re-established.

No general change in the width of cracks in Kilauea caldera, which might indicate changing pressure under the volcano, accompanied the Puna earthquakes.

SEISMOLOGY

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

Week Beginning	Whitney Station (Northeast rim)		Uwekahuna Station (West rim)	
	Amount	Direction	Amount	Direction
January 3	0.5″	E 14° S	1.3″	S 14° W
10	1.2″	S 6° E	1.2″	S 34° W

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. Locations given are epicenters. The times given are arrival times at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea caldera. They are stated to the closest minute in Hawaiian Standard time, which is 10 hours slower than Greenwich Civil time. The number preceding each earthquake is the serial number for the current year. The intensity rating (Feeble, Moderate, etc.) given is that for the Whitney Laboratory. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

1. Jan. 3, 03:06, very feeble. Kilauea caldera.
2. Jan. 6, 09:11, very feeble.
3. Jan. 9, 03:17, very feeble (Mauna Loa, feeble). Southeast flank of Mauna Loa 3 miles west of Halfway House.
4. Jan. 9, 13:57, very feeble. Southeast flank of Mauna Loa 5 miles southeast of Halfway House.
5. Jan. 10, 00:19, very feeble.
6. Jan. 12, 08:01, very feeble (Mauna Loa, feeble). Southeast flank of Mauna Loa.
7. Jan. 13, 04:30, tremor (Mauna Loa, very feeble). Southeast flank of Mauna Loa near Halfway House.
8. Jan. 13, 22:48, very feeble.
9. Jan. 14, 17:28, not recorded at Kilauea (Mauna Loa, very feeble).
10. Jan. 14, 03:04, very feeble.
11. Jan. 15, 13:17, tremor (Uwekahuna, very feeble). Kilauea caldera.
12. Jan. 16, 12:49, not recorded at Kilauea (Kona, very feeble). Kona.
13. Jan. 17, 02:27, tremor (Uwekahuna, very feeble). Felt in Kalihiki, Kona. Kona.
14. Jan. 17, 05:29, very feeble.
15. Jan. 17, 15:39, Kilauea.
16. Jan. 17, 17:17, not recorded at Kilauea (Kona, very feeble). Kona.
17. Jan. 19, 12:11, tremor (Mauna Loa, very feeble). Southeast flank of Mauna Loa.
18. Jan. 20, 21:39, tremor (Uwekahuna, very feeble). Hilina Pali.
19. Jan. 20, 21:39, feeble (Mauna Loa, slight). Felt in Papaloa, Kona; Hawaii National Park; and Kukuihaele, North Hamakua. Ten miles deep under Red Hill on the northeast rift of Mauna Loa.
20. Jan. 20, 21:40, very feeble.
21. Jan. 22, 03:13, tremor (Uwekahuna, very feeble).
22. Jan. 24, 04:36, slight. Felt in Hilo. Twelve miles deep under Alae crater on the east rift of Kilauea.
23. Jan. 26, 06:48, tremor (Mauna Loa, very feeble).
24. Jan. 28, 13:15, not recorded at Kilauea (Kona, very feeble). Kona.
25. Jan. 29, 22:54, very feeble. Kaoiki fault.
26. Jan. 30, 08:31, very feeble. Southwest rift of Kilauea near the coast.
27. Jan. 31, 11:48, slight. Felt in Hilo. East rift of Kilauea about 6 miles from the Observatory.
28. Feb. 6, 15:59, tremor (Mauna Loa, very feeble). Felt in Kalihiki, Kona. Kona.
29. Feb. 6, 20:41, tremor (Mauna Loa, very feeble). Southeast flank of Mauna Loa.
30. Feb. 7, 14:15, tremor (Mauna Loa, very feeble). Deep under the summit of Mauna Loa.
31. Feb. 7, 19:50, tremor (Uwekahuna, very feeble). Kilauea caldera.
32. Feb. 10, 22:14, very feeble (Mauna Loa, feeble). Southeast flank of Mauna Loa.
33. Feb. 12, 03:24, tremor (Uwekahuna, very feeble).
34. Feb. 12, 03:51, very feeble. Kilauea.
35. Feb. 12, 13:10, not recorded at Kilauea (Kona, very feeble). Kona.
36. Feb. 12, 15:30, not recorded at Kilauea (Hilo, very feeble). Near Hilo.
37. Feb. 13, 13:01, tremor (Uwekahuna, very feeble).
38. Feb. 13, 23:44, very feeble. Kilauea.
39. Feb. 16, 03:15, not recorded at Kilauea (Kona, feeble). Felt in Captain Cook. Kona.
40. Feb. 16, 08:31, not recorded at Kilauea (Mauna Loa, very feeble). Northeast rift of Mauna Loa.
41. Feb. 18, 14:39, not recorded at the Whitney Laboratory (Mauna Loa, very feeble).

42. Feb. 19, 06:31, not recorded at the Whitney Laboratory (Uwekahuna, very feeble). Southwest rift of Kilauea.
43. Feb. 19, 21:27, not recorded at Kilauea (Mauna Loa, very feeble). Mauna Loa.
44. Feb. 20, 02:33, not recorded at the Whitney Laboratory (Mauna Loa, very feeble). Summit of Mauna Loa.
45. Feb. 22, 17:32, not recorded at the Whitney Laboratory (Mauna Loa, very feeble). Felt at Kalihiki, Kona. Kona.
46. Feb. 23, 16:50, not recorded at the Whitney Laboratory (Mauna Loa, very feeble). Southeast flank of Mauna Loa.
47. Feb. 24, 01:04, tremor (Uwekahuna, very feeble).
48. Feb. 24, 03:36, not recorded at the Whitney Laboratory (Mauna Loa, very feeble).
49. Feb. 25, 15:38, not recorded at the Whitney Laboratory (Mauna Loa, very feeble). Southeast flank of Mauna Loa.
50. Feb. 26, 09:50, not recorded at Kilauea (Mauna Loa, very feeble).
51. Feb. 26, 14:15, tremor (Mauna Loa, very feeble). Mauna Loa.
52. Feb. 26, 14:16, not recorded at Kilauea (Mauna Loa, very feeble). Mauna Loa.
53. Feb. 27, 14:53, tremor (Uwekahuna, very feeble). Kilauea.
54. Mar. 3, 23:30, not recorded at the Whitney Laboratory (Uwekahuna, very feeble). Kilauea.
55. Mar. 6, 02:35, very feeble. East rift of Kilauea.
56. Mar. 6, 21:49, very feeble. Kilauea.
57. Mar. 9, 02:51, very feeble. Kilauea caldera.
58. Mar. 9, 03:22, very feeble. Kilauea caldera.
59. Mar. 12, 15:32, not recorded at the Whitney Laboratory (Hilo, very feeble). Near Hilo.
60. Mar. 15, 06:50, very feeble. Kilauea caldera.
61. Mar. 16, 16:19, tremor (Kona, feeble). Kealakekua fault.
62. Mar. 19, 00:23, tremor (Mauna Loa, very feeble). Southeast flank of Mauna Loa.
63. Mar. 24, 07:25, very feeble. East rift of Kilauea near Alae Crater.
64. Mar. 26, 00:28, very feeble. Southwest rift of Kilauea 4 miles southeast of Kapapala Ranch.
65. Mar. 26, 03:08, not recorded at the Whitney Laboratory (Mauna Loa, very feeble). Southeast flank of Mauna Loa.
66. Mar. 26, 15:02, not recorded at the Whitney Laboratory (Uwekahuna, very feeble). Kilauea caldera.
67. Mar. 26, 16:07, not recorded at the Whitney Laboratory (Mauna Loa, feeble). Northeast rift of Mauna Loa near the Mauna Loa seismograph.
68. Mar. 29, 19:31, tremor (Mauna Loa, very feeble). Deep under the northeast rift of Mauna Loa.
69. Mar. 30, 06:40, strong. About 15 miles deep between the east rift of Kilauea and the sea near Kalapana.
70. Mar. 30, 06:57, slight. Aftershock of No. 69.
71. Mar. 30, 07:02, tremor (Uwekahuna, very feeble). Kilauea caldera.
72. Mar. 30, 07:38, very feeble. Aftershock of No. 69.
73. Mar. 30, 08:42, strong. About 15 miles deep between the east rift of Kilauea and the sea near Kalapana.
74. Mar. 30, 09:08, very feeble. Aftershock of No. 73.
75. Mar. 30, 10:08, tremor (Uwekahuna, very feeble). Aftershock of No. 73.
76. Mar. 30, 10:17, very feeble. Aftershock of No. 73.
77. Mar. 30, 10:26, very feeble. East rift of Kilauea.
78. Mar. 30, 11:19, strong. Felt in Hawaii National Park. Kilauea caldera.
79. Mar. 30, 12:13, tremor (Mauna Loa, very feeble). Aftershock of No. 73.
80. Mar. 30, 13:31, tremor (Uwekahuna, very feeble). Aftershock of No. 73.
81. Mar. 30, 14:44, tremor (Mauna Loa, very feeble). Aftershock of No. 73.
82. Mar. 30, 15:42, very feeble. Aftershock of No. 73.
83. Mar. 30, 18:15, very feeble. Aftershock of No. 73.
84. Mar. 31, 00:30, very feeble. Aftershock of No. 73.
85. Mar. 31, 01:09, tremor (Uwekahuna, very feeble). Aftershock of No. 73.
86. Mar. 31, 01:30, very feeble. Kilauea caldera.
87. Mar. 31, 05:46, very feeble. Kilauea caldera.
88. Mar. 31, 15:04, feeble. Aftershock of No. 73.
89. Mar. 31, 15:48, very feeble. Aftershock of No. 73.
90. Mar. 31, 16:00, moderate. Aftershock of No. 73.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters and the magnitudes are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Bosch-Omori horizontal or Sprengnether vertical seismograms, in Hawaiian Standard time.

Jan. 19, 18:40:00. Pacific Ocean south of Mexico, 8½°N., 103½°W., magnitude 6.

Jan. 31, 15:16:40. Volcano Islands, 24½°N., 142½°E., magnitude 7¼.

Feb. 4, 23:29:31. Off coast of New Britain, 4½°S., 153°E., magnitude 6¼–7.

Feb. 6, 14:28:01.

Feb. 6, 20:24:15. New Hebrides Islands, 15°S., 167½°E., magnitude 6–6½.

Feb. 10, 14:43:07. Ningsia Province, China, 39½°N., 101°E., magnitude 7–7½.

Feb. 18, 14:51:22. Off coast of Nicaragua, 11½° N., 87½°W., magnitude 6¾–7.

Feb. 19, 09:17:17. Kermadec Islands, 30°S., 178°W., magnitude 7–7½.

Feb. 19, 11:45:33. Coast of Nicaragua, 12½°N., 87½°W., magnitude 6¾–7. Felt at Managua.

Feb. 20, 08:46:36. Flores Sea, 7°S., 124½°E., magnitude 6½–6¾.

Mar. 2, 20:13:50. New Guinea, 5½°S., 142½°E., magnitude 7–7¼.

Mar. 19, 00:12:00. Santa Rosa Mountains, California, 33.3°N., 116.1°W., magnitude 6–6¼. Slight property damage.

Mar. 21, 13:55:34. Northwestern Burma, 24½°N., 95°E., magnitude 7–7¼. Felt in Eastern India.

Mar. 28, 10:44:04. Rat Islands, Aleutian Islands, 52°N., 176°E., magnitude 6½.

Mar. 28, 18:13:13. Near north coast of Luzon Island, Philippine Islands, 19½°N., 121½°E.

Mar. 28, 20:34:45. Near south coast of Spain, 37°N., 3½°W., magnitude 7¼–7½. Extensive property damage at Granada and Malaga.

VOLCANO NOTES AND NEWS

RABAUL OBSERVATORY

The following notes are abstracted from an account of the Volcanological Observatory at Rabaul and its operations, prepared by Mr. J. G. Best, volcanologist at the Observatory, and forwarded through the kindness of Dr. N. H. Fisher, Chief Geologist of the Bureau of Mineral Resources, Commonwealth of Australia.

The Volcanological Observatory at Rabaul is built on the northern rim of the Blanche Bay caldera, 600 feet above sea level. The site overlooks the township of Rabaul and affords an excellent view of the various craters within Blanche Bay.

The Observatory was completed shortly before the capture of Rabaul by the Japanese in early 1942. Subsequently, however, the upper portion of the building, together with all records, was destroyed, and all instruments and fittings removed from the instrument cellar. In December, 1951, work was commenced on reconstruction of the Observatory. The upper portion of the building was restored and now contains a laboratory, records room, and office, as well as temporary housing for the staff.

Upon the erection of permanent housing for the staff, these living quarters will be converted for use as a museum, photographic dark room, and workshop.

The instrument cellar is beneath the office building. It is 25 feet long, 15 feet wide, and 9 feet deep, and is concrete lined. Four concrete instrument piers are set well below the floor of the cellar and are based on the surface of a lava flow which lies 8 feet below the cellar floor. A 3-inch gap, loosely filled with soil and covered with tarred paper, is left between the piers and the cellar floor.

Three Benioff seismometers, a Benioff recorder, and two tiltmeters have been installed in the instrument cellar. The start of recording with the Benioff instruments has been held up through lack of accessories.

At Rapindik, 3¼ miles southeast of the Observatory, an Omori-type seismograph with low magnification and mechanical recording was installed in May, 1950. It is so placed to detect seismic activity of volcanic origin at the active centers in Blanche Bay.

The two tiltmeters at the Observatory are normally read daily and the readings plotted graphically. Temperatures of hot springs, wells, fumaroles, and solfataras at 51 points in the Blanche Bay area are taken weekly and recorded graphically. In the event of an upward trend in temperature, the frequency of the readings would be increased. Analysis of volcanic exhalations is to become routine, being done jointly with the weekly temperature readings. Photographic records of selected fumaroles and other thermal points also are to become a routine feature. The Commonwealth Department of Public Works operates a Stevens continuous-recording water gauge in Simpson Harbour and the volcanological staff have access to this instrument for any information required. In addition, tide poles are installed at selected points around Blanche Bay and are read weekly, so that changes in the level of the strandline can be detected.

A systematic investigation is to be made of all volcanic areas in the Territory of Papua and New Guinea, and eventually regular inspections will be made of the more active areas. Preliminary investigations of several areas have already been made.

To keep in touch with events at other centers, a system of reporting seismic and volcanic phenomena has been introduced. This involves the reporting by radio of all important earthquakes and changes in volcanic activity. Monthly reports of all relevant information from outside areas are forwarded to the Observatory by government stations through the Territory.

ACTIVITY OF MOUNT ASAMA

By T. Minakami

Asama volcano resumed activity on December 27, 1953, after a complete quiescence of 38 months. The usual Asama eruptions are Vulcanian in type and of explosive character, with furious detonations lasting several minutes throwing up abundant ejecta including numerous lava blocks and bombs. The interval between successive eruptions is usually several days, even during such markedly active periods as 1935–38. The present activity differs from this in that each explosion is on an extremely small scale compared with the usual ones and occur very frequently. During the period from the beginning of the eruption to the end of February, 1954, the number of separate explosions observed has ranged from 0 to 10 per day, and because observation is not possible during hours of darkness the total number of explosions probably is about 30 per cent greater than this. The kinetic energies of individual explosions during the present activity are estimated to range from 10^{14} to 10^{16} ergs, whereas those of the ordinary explosions of Asama are estimated to be nearly 10^{19} ergs. The explosions have ejected volcanic ash and pumice-like gravel. No serious damage has resulted, although ice skating at rinks at Karuizawa, near the southeastern foot of the volcano, was disturbed by the fall of fine ash.

Highly sensitive seismographs at the Asama Volcano Observatory indicated an increase in frequency and amplitude of microearthquakes originating from Asama volcano during the late summer and autumn of 1953. On August 2 and 3 a swarm of at least 200 microearthquakes originated in the neighborhood of the summit crater. After that, the emission of vapor (including volcanic gases such as SO_2) from the crater became very irregular in quantity. At times the gas was very abundant, and at other times it was very sparse. This is a common occurrence at Asama preceding and during eruption. On November 5, when the summit of the mountain was visited by a party including the writer and Dr. G. A. Macdonald of the Hawaiian Volcano Observatory, vapor was so abundant that the crater floor was invisible. Rumblings from the crater were heard at the Volcano Observatory on December 20, a week before the outbreak.

ACTIVITY OF OTHER JAPANESE VOLCANOES

Early in February newspapers reported a submarine disturbance observed by crews of MATS aircraft in the vicinity of Minami Iwo Jima, about 30 miles south-southeast of Iwo Jima in the Volcano Islands group. The surface of the ocean was reported to be boiling and steaming, presumably as a result of volcanic eruption in the ocean. Activity in the same general area was reported in March, 1953 (Volcano Letter 520: 7).

Charles G. Johnson, of the U. S. Geological Survey, Pacific Geological Surveys, reports that volcanic explosions began on Suwanose Island in the northern Ryukyu group at about 12:30 P.M. on February 22. Ash fell as far as 20 nautical miles south-southwest of the island.

Mr. Johnson also reports that the activity of O-shima volcano, which began on December 29, 1953 (Volcano Letter 522: 6), ceased, at least temporarily, about February 15. The last strong activity was on January 27, when bombs were reported hurled 1,000 feet into the air, and a small lava flow covered part of the crater floor. This violent activity subsided about 4:30 P.M. on January 27. Small explosions occurred for about 6 minutes on January 31 and intermittently for about 2 hours on February 1, followed by intermittent small-scale activity until February 15.

ERUPTION OF MERAPI VOLCANO

Merapi volcano, in east-central Java, probably is the most dangerous volcano in Indonesia, partly because of the type of its activity, and partly because of the concentration of a dense agricultural population of some 3 million persons in the area close around its base. For several months the Volcanological Survey of Indonesia had been calling attention to the restlessness of the volcano, and warning that it might erupt. The eruption came on January 18. Scant newspaper reports state that the outbreak came in the form of a violent explosion, and that it was preceded by two perceptible earthquakes. The press descriptions suggest that *nuées ardentes* may have formed on the flanks of the mountain. On January 20 the reported casualties were 68 known dead and 145 injured. Many thousands of people were being evacuated from danger areas.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Jerry P. Eaton, Seismologist
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
Elizabeth G. Eklund, Secretary, part-time

Seismograph Station Operators:

Hilo Station:

THE VOLCANO LETTER

No. 524 **U. S. Geological Survey** **April–June, 1954**

PUBLISHED BY THE UNIVERSITY OF HAWAII

THE ERUPTION OF KILAUEA VOLCANO IN MAY, 1954

By GORDON A. MACDONALD and JERRY P. EATON

INTRODUCTION

Kilauea Volcano erupted early on the morning of May 31, 1954, after a dormancy of 18½ months. Although it could not be specifically predicted, the eruption was not unexpected. The termination of activity at Kilauea in November, 1952, was neither accompanied nor followed by any abnormal tilting that would suggest reduction of volcanic pressure beneath the volcano. On the contrary, during 1953 there was an accumulation of approximately 12 seconds of northward tilting at the Whitney Laboratory of Seismology on the northeastern rim of Kilauea caldera, in excess of the usual seasonal tilting. This suggested an actual increase of volcanic pressure beneath the caldera, resulting in a tumescence of Kilauea Volcano. Short periods of volcanic tremor during February and March, 1953, indicated subsurface movement of lava at Kilauea. All indications were that molten lava continued to stand at a high level within the conduit. In the report on activity of Hawaiian volcanoes during 1953 (Macdonald and Eaton, in preparation), submitted to the U. S. Geological Survey in mid-May, 1954, it was stated: "Under such conditions, eruption might come with very little forewarning."

Kilauea continued restless through the early months of 1954, but although eruption remained a possibility at any time, there was no evidence that appeared adequate for the basis of a prediction of an outbreak at any specific time.

NARRATIVE OF THE ERUPTION

Numerous small earthquakes occurred during the night of May 30–31. Slight earthquakes were recorded at 3:42 and 3:47 A.M. These wakened many persons, including the writers, in the region near Kilauea caldera. Shortly afterward Macdonald became conscious of a faint, persistent low-pitched roaring, almost a felt vibration rather than a recognizable sound, somewhat resembling the vibration caused by a heavy truck in low gear climbing a distant hill. The sensation continued as long as the observer remained motionless. A moderate earthquake occurred at 3:51 A.M., followed by a strong quake at 3:54 A.M. The latter was violent enough to dismantle the Bosch-Omori seismograph, and immediately both of us went to the Whitney Laboratory of Seismology to restore the instrument to operation.

Halemaumau had been visited at approximately 3:30 A.M. by G. H. Ruhle, Naturalist of Hawaii National Park, who reports that complete darkness reigned and everything appeared as usual. When we reached the seismograph vault, at approximately 4:03 A.M., there still was no sign of glow at Halemaumau. The seismograph was restored to operation, and a drum bearing a new record sheet placed on the instrument at 4:08 A.M. At 4:09 A.M. we observed the beginning of registration of volcanic tremor on the seismograph. Rushing from the vault, we observed (at approximately 4:10 A.M.) a bright glow at Halemaumau, reflected on a rising cloud of gas that already had reached a height of about 2,000 feet above the crater rim. The fume cloud continued to expand upward. About daylight the pilot of a plane inbound to Hilo reported it to have reached a height of 30,000 feet, where it was spreading out like a great mushroom.

We reached the Volcano Observatory at about 4:20 A.M. Half a mile away, a dense column of fume was rising from the northeastern part of Halemaumau Crater, nearly hiding the top of a giant lava fountain that appeared from time to time, with its top about 100 feet above the rim of the crater. This fountain rose from the crater floor, 470 feet below the rim. Thus, its total height was between 550 and 600 feet. Thin fume rose from the entire area of the crater, and a second principal fume column rose near the southwestern edge. These columns of fume rose nearly vertically above the crater. There was little low-lying fume, such as made approach to the lee side of the crater almost impossible in June, 1952.

At 4:27 A.M. the eruptive activity was entirely confined to Halemaumau Crater. Between 4:30 and 4:35

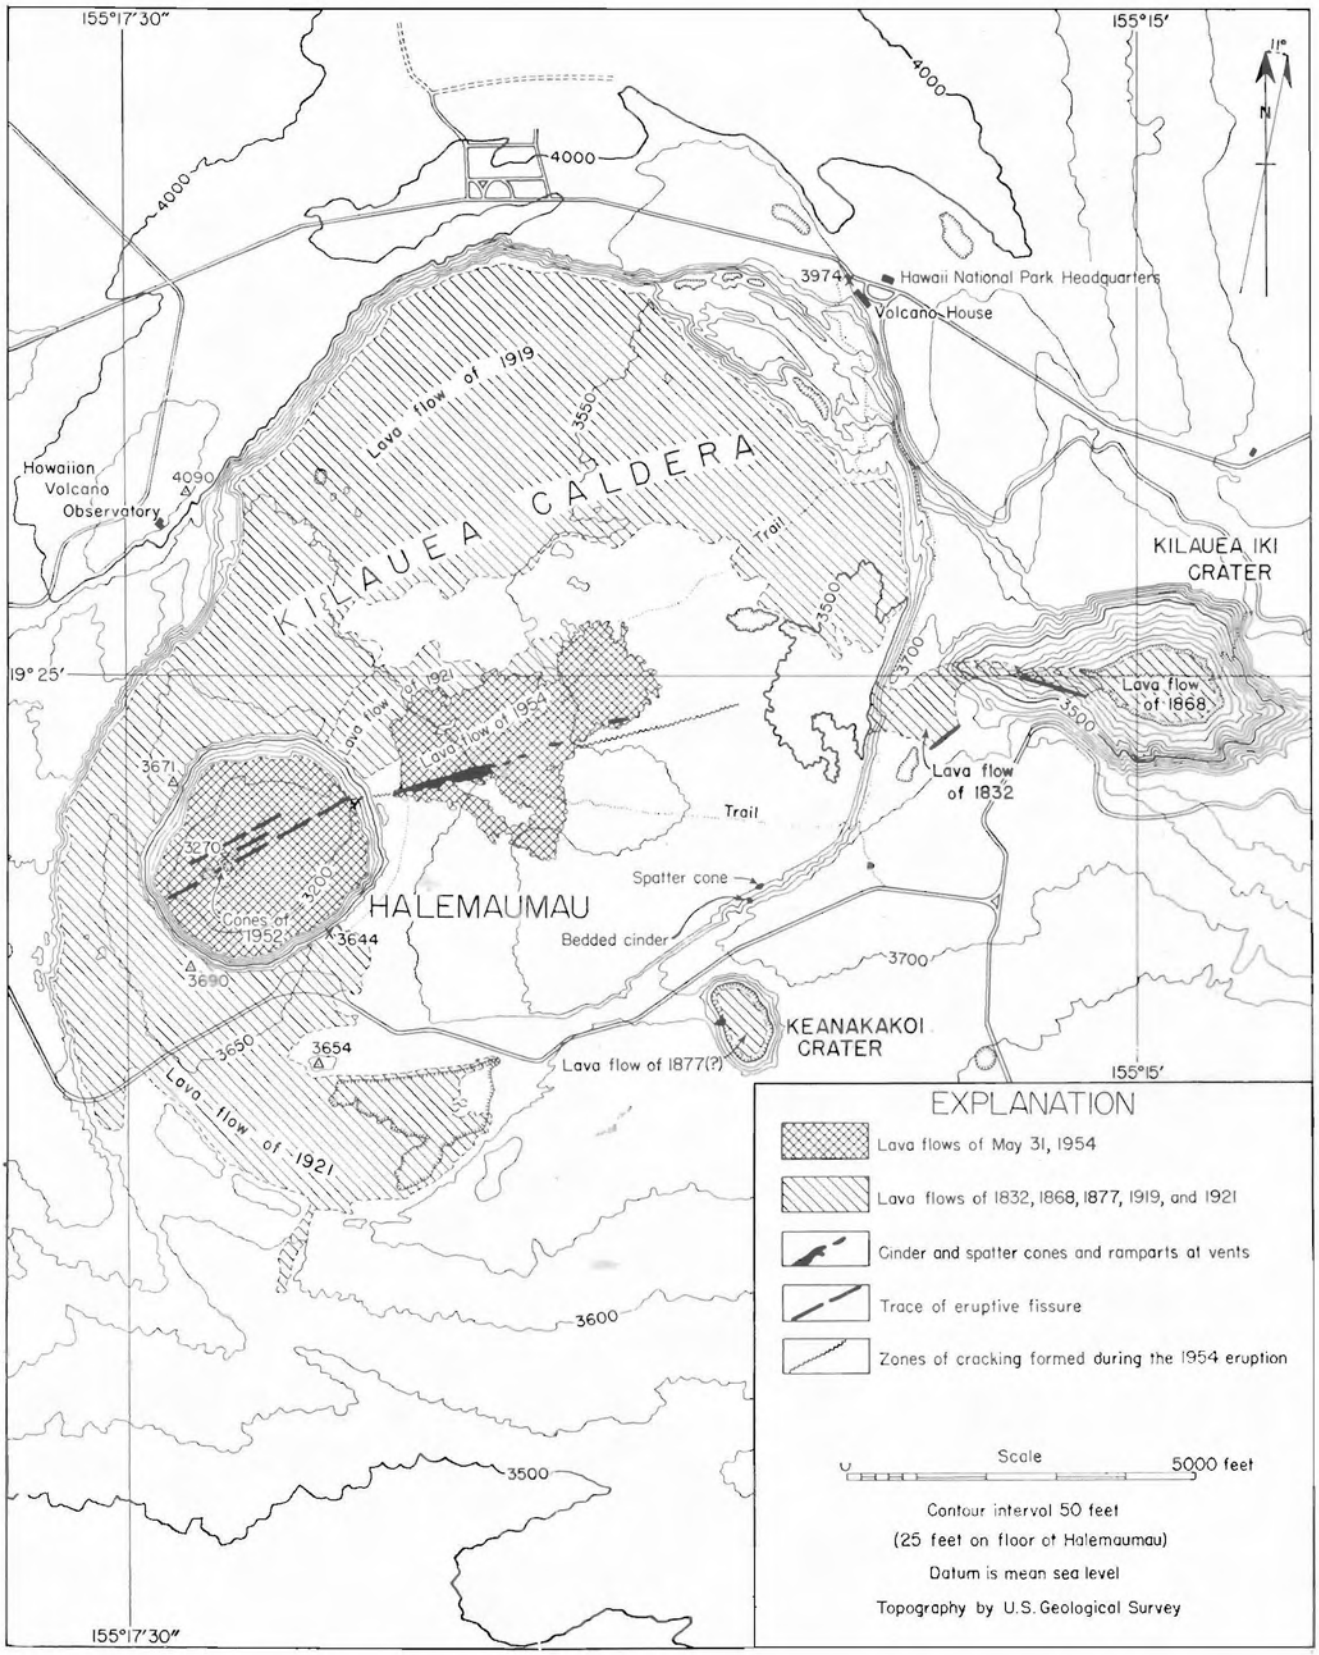

FIGURE 1. Map of Kilauea caldera, showing the location of the eruptive fissures and lava flows of the 1954 eruption, and some older flows outside Halemaumau.

A.M. lava issued from a fissure on the floor of Kilauea caldera northeast of Halemaumau. Ranger D. J. Tobin, Jr., of Hawaii National Park, viewed this event from a point near Kilauea Iki, nearly in line with the opening fissure. He states that at first the incandescent lava welled out gently, with little or no fountaining, followed by a gradual waxing of the fountains to a height of 50 to 100 feet. Because of the cloud of fume rising from Halemaumau immediately behind the new outbreak, he was unable to tell whether the arrival of lava at the surface was preceded by an outburst of fume from the fissure outside Halemaumau.

At 4:35 A.M. the line of fountains on the caldera floor northeast of Halemaumau was estimated to be 300 feet long, with its western end about 300 feet from the rim of Halemaumau. During the next few minutes the fountain chain spread rapidly, mostly eastward but also slightly toward the west. By 4:50 A.M. the principal chain was 1,400 feet long. Three other shorter chains were active farther east-northeast (Figs. 1 & 2). Very active flows of pahoehoe were spreading from the base of the fountains, and had already reached lengths as great as 1,000 feet.

We reached the rim of Halemaumau Crater at approximately 4:55 A.M. The entire crater floor was covered with a pond of incandescent lava. Across the floor diagonally from east-northeast to west-southwest, approximately along the line of the eruptive fissure of 1952, stretched a row of lava fountains from a few feet to more than 100 feet high (Fig. 1). The fissure bisected the cones left by the 1952 eruption, and lava poured from the cones into the surrounding pool. At the southwestern end of the line, approximately in the position occupied by the principal fountain during the early days of the 1952 eruption (Macdonald, 1952), was a fountain 250 to 300 feet high (Fig. 3). At the northeastern end the huge fountain visible earlier from the Volcano Observatory continued to play to a height at least 100 feet above the observers' heads (Fig. 4). Between these two end fountains the row of smaller fountains was nearly continuous.

Northwest of the principal row of fountains lay another shorter row, parallel to the first, and extending just northwest of the 1952 cones. Between these two rows of fountains was a third short row of three fountains, just northeast of the 1952 cones (Fig. 1). All of the fountains of the second and third rows were small. Few of them exceeded 10 feet, and none exceeded 25 feet in height.

Possibly the most spectacular feature of the eruption was the cascade of brilliant, orange-yellow lava that poured from the eruptive fissure 300 feet above the floor, on the northeastern wall of the crater (Fig. 4). Plunging down the wall, this "fire-fall" of incandescent liquid joined the turbulent pool around the base of the northeastern fountain. The lava issued at the head of the cascade quietly, with little spattering and no fountaining, as though it were poor in gas. At the base of the cascade a row of small fountains issued from the eruptive fissure, merging southward with the big northeast fountain.

Spreading out from the rows of source fountains, the lava was quickly covered with a thin black crust that was rifted apart by movement to reveal in a network of cracks the bright orange liquid beneath. Distinct waves, set up by surging at the fountains, swept outward across the surface of the lake. At the foot of the crater walls, the surging liquid alternately covered and revealed a bright band 5 to 10 feet in height. Locally, foundering of fragments of the crust resulted in small secondary fountains, apparently caused by release of air and other gases carried down by the sinking crusts. Many of the secondary fountains were evanescent, and shifting in position. Others, however, occurred persistently along certain lines, apparently determined by the boundaries of flow units. The most prominent line of that sort extended from the southeast to northwest edges of the lake, passing just northeast of the 1952 cones, and apparently marked the boundary between two principal convective cells surrounding the southwest and northeast fountains respectively.

A gap of 200 feet separated the westernmost fountains on the caldera floor from the rim of Halemaumau Crater (Fig. 1). By 5:40 A.M., lava liberation had nearly ceased along the westernmost 100 feet of the fountain chain, and activity at those vents consisted largely of roaring gas release, accompanied by showers of incandescent ejecta. The preponderance of gas at these vents, together with the gas-poor character of the lava forming the cascade on the adjacent wall of Halemaumau, suggests that in the section of the fissure near Halemaumau there was a partial separation of the gas and liquid phases, the gas-rich portion rising nearly vertically to feed the westernmost vents of the fountain chain on the caldera floor, and the liquid largely draining into Halemaumau, forming the cascade.

No conspicuous crack was visible on the wall of Halemaumau above the head of the cascade, or between the rim of Halemaumau and the end of the fountain chain to the east. In the latter gap there were many cracks in a zone about 50 feet wide along the projected course of the eruptive fissure farther east, but none of them were continuous for more than a few feet, or were more than 2 or 3 mm. wide.

Eastward, the principal line of fountains was approximately 1,400 feet long, and essentially continuous. The fountains forming this "curtain of fire" were a few feet to about 100 feet high, and the accumulation of ejecta from them was rapidly building a spatter rampart. Fragments of ejected pumice were drifted southwestward by the trade wind, partly mantling the southern slope of the spatter rampart and the adjacent lava. Along its southwestern part the rampart was breached, and several flow units were escaping northwestward, merging into a single, very active flow of pahoehoe. A smaller flow moved southeastward on the southern side of the rampart. A large river issued from the fountain pit at the eastern end of the spatter rampart and moved southeastward, spreading out to form a broad flow that merged with the lava flowing eastward north of the spatter rampart and with other lava from vents farther east.

Three other short rows of small fountains, less than 20 feet high, lay respectively 200, 400, and 900 feet east of the principal fountain chain. These also built small ramparts and cones of spatter, and liberated small flows. A somewhat more conspicuous row of fountains, 300 feet long, lay 1,800 feet east of the principal fountain chain.

All of these short rows of fountains were essentially parallel to the principal chain, but were offset en echelon from it. West of the easternmost row, a zone of narrow, diagonal cracks extends across an embayment in the new flow toward the next group of vents. Another zone of narrow cracks extends eastward for about 900 feet beyond the new lava, as a prolongation of the line of the principal fountain-chain (Fig. 1).

By 6:45 A.M. new lava had accumulated to a depth of more than 50 feet in Halemaumau Crater, nearly burying the cones of the 1952 eruption. Dense, bluish-white fume filled the crater, nearly obscuring the floor. Two principal fume columns rose from the northeast and southwest fountains. Strong winds, which were directed centripetally entirely around the crater, blew these fume columns inward, causing them to meet a few hundred feet above the crater rim. Above that level the fume cloud rose nearly vertically. No doubt the violent centripetal winds were caused by the strong convective rise of warm air and fume above the crater. Small, violent whirlwinds caused dust-devils around the edge of the crater, and swept across the crater floor, carrying off whirling fragments of the thin crust of the lava lake.

At 7:10 A.M. a good view of the northeastern portion of the crater floor was obtained by Eaton from the northern rim. The northeast fountain consisted of a surging, dense, domical core rising about 200 feet above the crater floor, with frequent bursts of scattered incandescent ejecta as high as the crater rim. The main outward flowage from the base of the fountain was southward. Concentric lobe-shaped markings on the crust of the new lava developed around the base of the fountain. These were stretched outward as the current spread from the fountain source at a velocity of 5 to 10 miles per hour. The circulation appeared to move in a circle and return toward the northwest base of the fountain, but dense fume caused poor visibility of that part of the floor.

At 7:30 A.M. fountain activity, both in Halemaumau and on the caldera floor to the northeast, was decreasing. The largest fountains northeast of Halemaumau were only about 75 feet high, and the westernmost 200 feet of the eruptive fissure was almost dead. The southwest fountain in Halemaumau was about 150 feet high, with occasional bursts reaching 200 feet. The northeast fountain was about 450 feet high. Other small fountains, 10 to 50 feet high, were active in the central part of the floor. The cascade had dwindled to a mere trickle, and by 8:00 A.M. it was entirely inactive.

Between 8:00 and 9:00 A.M. the flow on the caldera floor was still advancing slowly, but had reached nearly its full extent. The three segments of eruptive fissure east of the principal cone chain were nearly inactive, and at the fourth (easternmost) segment activity was very weak. At the latter the repetitive pattern of behavior consisted of a few seconds of quiet followed by loud hissing, culminating in a dull, hissing explosion that threw fragments of pasty lava 15 feet in the air. Along the main section of the active fissure lava fountains still played to heights of 50 to 75 feet.

Between 10:00 and 11:00 A.M. activity within Halemaumau was restricted largely to the northeast and southwest fountains. A prominent sinkhole was active from time to time near the northeastern end of the 1952 cones. Many small avalanches were occurring on the crater walls. Striking the fluid lava of the lake, these caused violent splashing and sank quickly out of sight, to be followed for several minutes by a group of small, secondary fountains. The lava fountains northeast of Halemaumau continued to decrease in size, and by 11:00 A.M. were essentially inactive. By 1:00 P.M. the southwest fountain in Halemaumau had decreased to a height of only 50 feet, and the northeast fountain was throwing only occasional showers of spatter to heights of less than 25 feet. A slump scarp was starting to form around the edge of the crater floor.

At 1:30 P.M. fountains along the central part of the chain northeast of Halemaumau again became weakly active, throwing sporadic showers of incandescent ejecta to heights as great as 25 feet. This revival was brief. By 4:00 P.M., the fountain activity outside Halemaumau was completely ended except for occasional very weak flings and weak, whistling gas release. A little sluggish movement continued in the flow until evening, and glow was visible in the throats of the cones until the night of June 1.

By 3:00 P.M. the northeast fountain in Halemaumau was completely inactive, and the southwest fountain was throwing weak, sporadic bursts of ejecta to heights up to

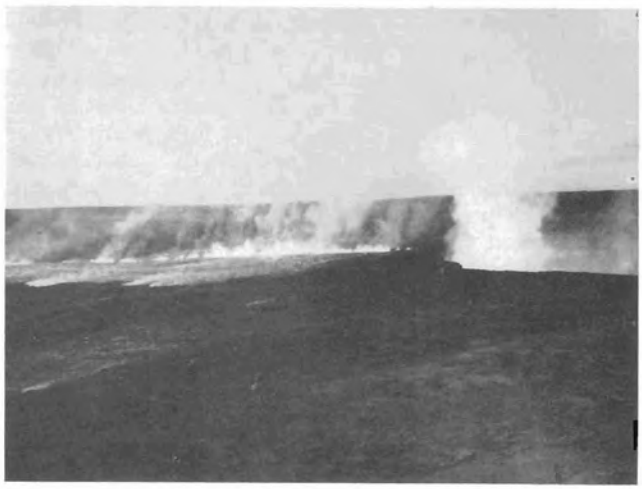

FIGURE 2. Lava fountains along the fissure northeast of Halemaumau and flow spreading from them. At the right, fume rises from the northeastern edge of Halemaumau. Photo from Uwekahuna about 6 A.M., by Ralph T. Kanemori, Modern Camera Center, Hilo.

25 feet. Similar, but smaller fountains were active in the pit of the principal 1952 cone and just northeast of the 1952 cone group. The slump scarp around the edge of the floor continued to grow in height. By 4:00 P.M. it averaged about 25 feet high, and by the morning of June 1 its height was estimated at 40 feet.

During the evening of May 31 occasional small showers of red-hot cinders were being thrown from the throat of the 1952 cone, but the principal activity was at a vent about 500 feet northeast of the 1952 cones (Fig. 1). At intervals of a few minutes noisy, semi-explosive bursts from that vent threw showers of incandescent ejecta to heights of about 100 feet. The ejecta falling and accumulating around the vent were building a small cone. The vent continued in similar activity until the

afternoon of June 3. During daylight hours each blast was seen to be accompanied by a puff of bluish-white fume.

On the morning of June 1 two small flows were active near the northeast and east-northeast edges of the floor of Halemaumau, and occasional weak lava movement was visible near the southwestern edge. This condition continued throughout the day. During the afternoon a tiny lava fountain, about two feet high, was visible at the head of the east-northeast flow. On June 2 the southwest and east-northeast flows had ceased, but the northeast flow continued active and was developing into a small lava lake. This lake was approximately 300 feet long and 100 feet wide, and was situated on the course of the eruptive fissure. Slow circulation in it, from east to west, was accompanied by occasional disintegration and foundering of the crust and small secondary fountains. No primary fountaining was visible. The lake became inactive about 3:00 A.M. on June 3. The last weak blasts from the semi-explosive central vent were observed at about 6:00 P.M., June 3. Thus, the duration of the eruption was approximately three and one-half days.

Gradual shrinkage of the new lava fill in Halemaumau continued through the eruption and for several days thereafter. Old features, such as the 1952 cones and the prominent fault scarp running northwestward from them, temporarily buried by the new lava, reappeared. The slump scarp around the edge of the crater floor eventually reached a height of approximately 45 feet.

FIGURE 3. Southwest fountain in Halemaumau, seen from the east rim about 6:30 A.M., May 31. To the right small fountains are playing along fissures that cross the 1952 cones. The bright lines on the crater floor are cracks in the dark lava crust, revealing the incandescent material beneath. Photo by Ralph T. Kanemori, Modern Camera Center, Hilo.

THE LAVA

The lava poured out onto the caldera floor northeast of Halemaumau is basalt containing only 1 to 2 per cent olivine. The olivine is present both as scattered phenocrysts up to about 2 mm. across, and as microlites visible only under the microscope.

The flow consists almost entirely of pahoehoe. Aa is present in small patches only locally. A particularly interesting feature is the development of typical clinkery aa in narrow bands, generally less than a foot wide, along the lines of principal shear near and parallel to the margins of lava streams. Part of the pahoehoe, especially that liberated late in the eruption, is dense, but much of it is very vesicular and shelly. Many toes near the edge of the flow are hollow, consisting of a thin crust 2 to 6 inches thick, covering a central opening as much as 2 feet in diameter. These toes appear to have been inflated by gas, like balloons.

An upper layer of vesicular pahoehoe crust, generally 1 to 3 inches thick, appears to have been essentially isolated from the underlying flow by a layer of gas bubbles. This crust behaved semi-independently from the flow beneath it, being dragged along by movement of the underlying liquid, folded and rolled into ropy forms, and locally fractured and tilted. At the edges of the flow this crust was in places thrust out as much as 3 or 4 feet over the adjacent rocks.

The area covered by the flow northeast of Halemaumau is approximately 139 acres, and the volume of the flow is approximately 1.5 million cubic yards.

The rapid gush of liquid lava into Halemaumau during the first eight hours of the eruption produced a fill averaging 63 feet in thickness, with a volume of approximately 15 million cubic yards. Most of the lava was extruded during the first two hours. About noon on May 31, there began a rapid sinking of the lava level over the entire floor of Halemaumau, leaving a narrow band of congealed lava clinging to the crater walls. By the evening of May 31 the slump scarp thus produced around the edge of the floor was about 25 feet in height, and by the end of the eruption the scarp had increased to an average of 32 feet. Thus the permanent fill of new lava in Halemaumau had an average thickness of 31 feet, and a volume of approximately 7 million cubic yards.

In Hawaii, shrinkage of ponded lavas on cooling and loss of gas commonly produces slump scarps, indicating a decrease of volume of as much as 20 per cent (Macdonald, 1954). However, the decrease of volume of the new fill in Halemaumau was approximately 52 per cent. This proportion appears to be far too great to have resulted from shrinkage due to loss of gas and cooling. Furthermore, the major part of the sinking of the new lava surface was too rapid to have resulted from those causes. The conclusion appears inescapable that some of the new lava disappeared downward, presumably draining back into the fissures through which it had previously risen. The slower sinking, of approximately 7 feet, after the evening of May 31, may have resulted partly from additional draining away of the liquid, but unquestionably also in part from loss of gas and cooling.

RADIOACTIVITY

An attempt to determine the degree of radioactivity of the fume was only partly successful. An hour after the outbreak of the eruption Macdonald took a Geiger-Muller counter into the fume cloud at the southwestern edge of Halemaumau. The fume was rising almost directly upward, however, and only occasionally did moderately dense clouds blow momentarily over the ground at the rim. At no time was it possible to keep the counter

tube in dense fume for long periods. Two counts for periods of only one minute each were obtained. A third count was made in fume rising from a crack several feet away from the crater rim. All of these counts were within the range normally obtained in the Kilauea area at times of no surface volcanic activity, and counts made on the caldera floor away from the crater rim on the morning of May 31. Thus, the counts obtained give no evidence of any concentration of radioactive material in the fume cloud, just as earlier counts have revealed no concentration in active flows or pumice ejected by the lava fountains (Macdonald and Orr, 1950, p. 24; Finch and Macdonald, 1953, p. 76).

EARTHQUAKES ASSOCIATED WITH THE ERUPTION

Following the cessation of the last eruption of Kilauea in November 1952, seismic activity remained at a low level for about five months. On April 29, 1953, three moderate earthquakes originating on the southwest rift of Kilauea initiated a mild resurgence of seismic activity which continued through May, June, and July. August, September, and most of October were extremely quiet months at Kilauea.

A sequence of moderate to strong earthquakes on October 26 and 27 stemming from the upper part of Kilauea's east rift was the first major seismic event at the volcano following the 1952 eruption. After another three weeks of quiet there began a series of frequent, small earthquakes originating at Kilauea caldera which continued until the end of the year.

The first three months of 1954 were very quiet. Coincident with the occurrence of two large earthquakes

FIGURE 4. Northeast fountain in Halemaumau, seen from the east rim about 6:30 A.M., May 31. The cascade on the crater wall is visible just to the right of the fountain. The crater wall to the right is approximately 400 feet high. Photo by Ralph T. Kanemori, Modern Camera Center, Hilo.

along the east rift of Kilauea between Pahoa and Kalapana on March 30, the series of frequent, small to moderate quakes stemming from Kilauea caldera began again. This series continued until the outbreak of the eruption on May 31.

The majority of these earthquakes were of shallow origin, not more than three to five miles deep, although between May 13 and 18 four quakes originated under the caldera region at depths of 15 to 25 miles. Predominantly, these quakes were small, only eight being felt in spite of the shallow focal depths. From March 30 through May 31 about 90 quakes were large enough to be identified as being of Kilauean origin, while almost 900 quakes, too small to locate but apparently from Kilauea, were recorded at the Uwekahuna station. Like the larger members of the same group these small quakes appear to have been predominantly of shallow origin. Two characteristic types occurred. One had very sharp preliminary phases and an S-P interval of between 0.2 and 1.5 seconds. The other had no identifiable phases; it consisted only of a train of very irregular waves. Both types were recorded only by instruments around Kilauea caldera and, undoubtedly, were of local origin.

At 3:26 A.M. on May 31 intermittent, high-frequency spasmodic tremor began recording on the Sprengnether vertical seismograph at Uwekahuna. About 3:37 A.M. a series of small, sharp quakes began recording at a rate of about one per minute, the records of the quakes superimposed on the now continuous spasmodic tremor. After 3:42 A.M. these frequent quakes and the continuous spasmodic tremor became so large that the Sprengnether record was unreadable.

Between 3:37 A.M. and the beginning of harmonic tremor at 4:09 A.M., 33 quakes, several of which were felt, were recorded on seismographs around Kilauea caldera. The large quake at 3:54 A.M., which originated at a shallow depth just east of Halemaumau, awakened people generally in the vicinity of the caldera.

It appears probable that the spasmodic tremor and earthquake sequence immediately preceding the eruption were caused by the splitting open of the eruptive fissure and the intrusive rise of the fluid lava through the opening fissure at moderate to shallow depths in the volcano. When the lava reached the surface and the sporadic rise through the opening fissure gave way to a free and voluminous outflow of lava at the surface, harmonic tremor with approximately 10 times the amplitude of the preceding spasmodic tremor suddenly appeared on the seismographs.

Less than one minute after the sharp beginning of strong harmonic tremor on the Bosch-Omori seismograph, the authors rushed from the seismograph vault and found Kilauea already in eruption. This sharp beginning of harmonic tremor and its coincidence in time with the beginning of the eruption is a further check on the long-standing belief that harmonic tremor is generated by the movement of magma through fissures feeding the eruption. The intensity of harmonic tremor recorded by instruments around the caldera correlated closely with the rate of outpouring of lava by the volcano. Continuous harmonic tremor ceased when lava fountaining died out about 2:00 P.M. on May 31. Following the cessation of lava fountaining in Halemaumau and along the rift on the caldera floor, several small vents on the floor of Halemaumau continued in mild gas and cinder activity. One of these continued to throw up occasional showers of cinders until the afternoon of June 3. Associated with the mild explosions from these vents frequent packets of harmonic waves, each about 15 seconds in duration and closely resembling harmonic

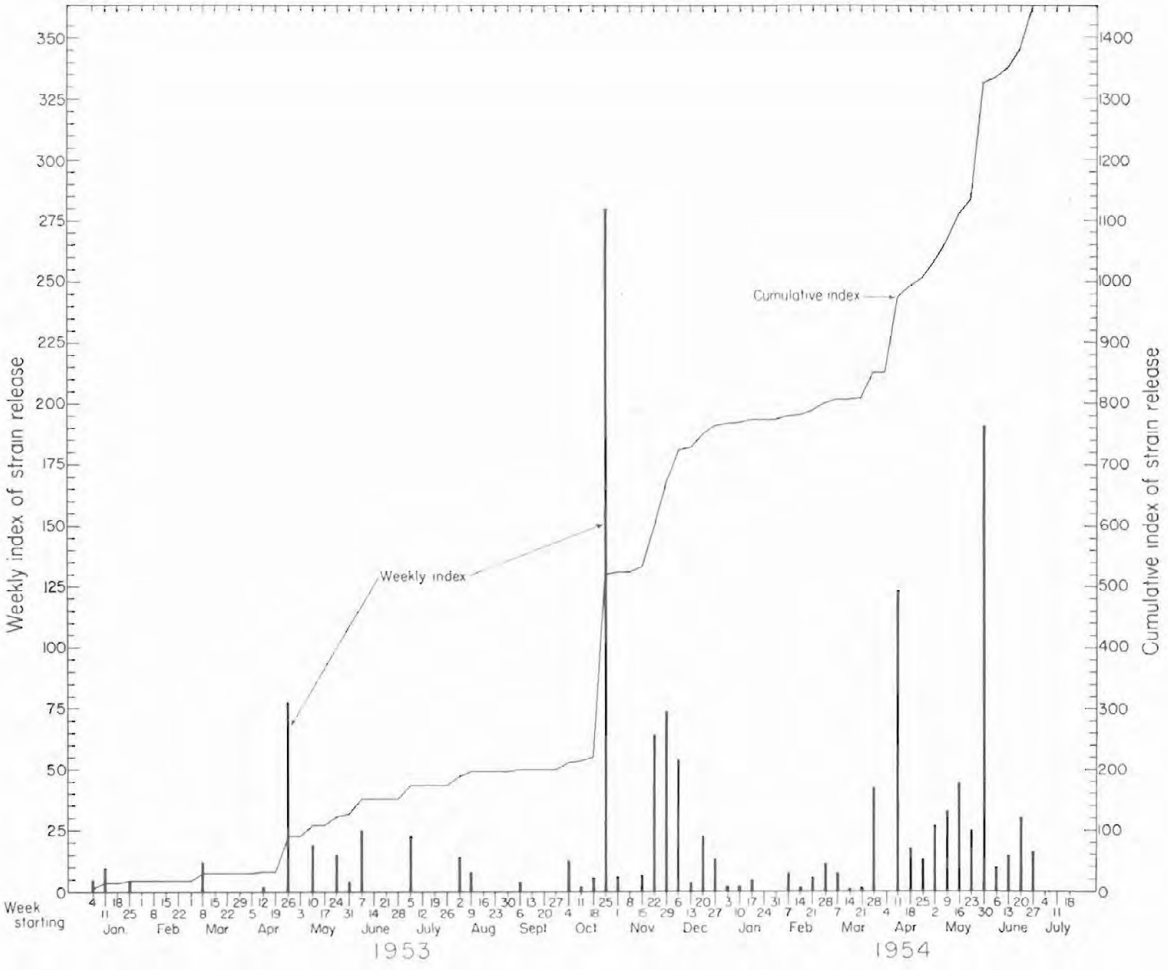

FIGURE 5. Graph showing weekly strain release index (vertical bars) and cumulative strain release index (continuous curve) for the Kilauea caldera region from January 1953 to mid-July 1954. An increase in steepness of rise of the cumulative curve represents an increase in rate of strain release through earthquakes.

tremor, were recorded by the Sprengnether vertical seismograph. These packets, about 3,700 in all, increased and decreased in frequency of occurrence in rather close correspondence to the frequency of explosions at the cinder vents although no coincidence in time between vent explosion and recorded packet could be demonstrated.

STRAIN-RELEASE INDEX

Benioff (1954) has pointed out that, under certain simplifying assumptions, if a uniformly strained body be released suddenly from its strained state by faulting, a fraction of the energy so released radiating outward as seismic waves, the amount of strain released is proportional to the square root of the energy released. If magnitudes of the earthquakes considered are available this energy can be obtained from the Gutenberg-Richter (1942) magnitude-energy formula. To date, determination of magnitudes of local Hawaiian earthquakes has been impeded by proximity of recording stations to the epicenters and variable focal depths. Pending a solution of this problem an approach somewhat different from Benioff's will be followed.

Supposing that we are dealing with regular, sinusoidal, body waves in a homogeneous medium, at any distance from the focus the S-P interval multiplied by the amplitude of the largest wave is constant and is proportional to the square root of the energy in the earthquake. For earthquakes of moderate range in size recorded at small epicentral distances the above relationship permits us to calculate a quantity proportional to the strain release without knowing the earthquake's magnitude.

Dealing only with local earthquakes, we can adopt one instrument as standard and avoid the reduction of recorded amplitudes to earth amplitudes. Thus, the product (S-P) x A, where S-P and A are, respectively, the S-P interval and the maximum amplitude of a given earthquake recorded on the Sprengnether vertical seismograph at Uwekahuna, is a measure of the strain release or the faulting or fracturing which generated the earthquake.

Because of the extreme difference between the energy released by a large earthquake and that released by a small one, (S-P) x A shows a great variation from large to small earthquakes. Since the many small earth-

quakes which precede eruptions of Hawaiian volcanoes and which appear to be a significant premonitory symptom of eruption are dwarfed relative to the infrequent, much larger earthquakes occurring at times remote from eruptions, an additional weighting device is employed. The strain release index of a given earthquake is defined as: S-R Index $= \sqrt{(S\text{-}P)}\ A$, where S-P and A are as defined above.

To obtain geologic units small enough that its rocks may be considered to be acted upon by a single system of forces it is necessary to divide the volcanoes into units, guided insofar as possible by the known geology. For the present purpose the Kilauean unit is taken as the volcano Kilauea minus the eastern half of its long east rift zone. S-R Indices for earthquakes larger than tremors originating in this unit were computed for 1953 and the first half of 1954. When records from the standard instrument, the Sprengnether vertical seismograph at Uwekahuna, were not available records from other instruments located around Kilauea caldera were used. In such cases, empirically determined amplitude correction factors were applied to obtain S-R Indices corresponding to those from the Sprengnether seismograph.

In Figure 5 are plotted weekly S-R Indices (the sum of the S-R Indices of earthquakes occurring during a given week) and cumulative weekly S-R Indices. The slope, not the height, of the latter curve is significant: it is a measure of the rate of strain release in the volcano.

CONCLUSION

The 1954 eruption of Kilauea is one of the shortest on record, being exceeded in brevity during recent years only by that of February, 1929, which lasted two days. The total final volume of lava left in Halemaumau and on the caldera floor was only about one-twelfth that extruded during 1952, but the rate of lava output during the first few hours of the eruption was very high, approximately equal to that during the corresponding part of the 1952 eruption.

The fissure eruption on the caldera floor east-northeast of Halemaumau appears to have been unique in the recent history of Kilauea caldera. A search of the literature reveals no record of similar activity at least since 1877. Before that, the records are too incomplete to constitute any good basis for comparison. The eruptive fissure extends almost directly toward the vents of the eruptions of 1832 and 1868. Neither of these eruptions was on the caldera floor. The eruption of 1832 occurred on the Byron Ledge, spilling lava both into the caldera and into Kilauea Iki Crater. That of 1868 occurred on the wall of Kilauea Iki and sent no lava into the caldera proper. Both, however, were intimately associated with caldera activity, and the alignment of the 1954 fissure with these earlier vents suggests that this is an important zone of weakness across the caldera floor.

On or about May 4, 1877, an eruption occurred along a fissure at the southeastern edge of Kilauea caldera. An entry by Thomas E. Cook in the Volcano House record book, under the date of May 21, 1877, states that the fissure from which the flow of lava took place commenced at the caldera wall and extended up to within 20 or 30 feet of the top of the wall (Brigham, 1909, p. 132). Under the date of May 6, 1877, Sanford B. Dole states, also in the Volcano House record book, that the lava spouted from the fissure to heights of 50 to 150 feet (Brigham, 1909, p. 131). Activity appears to have lasted only a few hours, but lava covered several acres of the caldera floor. The eruption was accompanied by draining of Halemaumau, leaving a fuming pit about 250 feet deep. The large size of the fountains and the location of the fissure indicate quite certainly that the eruption came from a primary, deep-seated vent, and was not merely an overflow from Halemaumau.

Eruption may have occurred in Keanakakoi Crater at about the same time. There appears, however, to be considerable doubt regarding the date of the lava that forms the floor of Keanakakoi (Stearns and Clark, 1930, p. 79).

The location of the eruptive fissure of 1877 is not known with certainty. H. A. Powers suggests (personal communication) that the small spatter cone at the southeast edge of Kilauea caldera just north of Keanakakoi (Fig. 1) may have been formed at that time. The suggestion is highly plausible, but cannot be confirmed. Both the spatter cone and a 2-foot bed of cinder on the caldera wall south of it, 150 feet above the caldera floor, may have been formed during the 1877 eruption.

None of the lava outpourings on the caldera floor between 1877 and 1954 appear to have been from primary, deep-seated vents. In 1884 and 1885 lava flowed northeastward from Halemaumau to the caldera wall near Kilauea Iki, building a small cone, known as Little Beggar, near its point of emergence. Little Beggar was a well-known landmark on the floor of Kilauea caldera until it was buried by the 1954 eruption. It was a "rootless" driblet cone (Wentworth and Macdonald, 1953, p. 52) built by spatter from an opening in the roof of a lava tube. L. A. Thurston believed that overflows during 1894 destroyed the original Little Beggar cone, and built another in its place (Stearns and Clark, 1930, p. 79). However, comparison of a photograph of Little Beggar in 1889 published by Brigham (1909, p. 157), with others taken during recent years indicate that it probably was the same cone. If there were two Little Beggars they were very closely similar in form and identical in origin. It appears probable that the 1884–85 flow was simply a drainage from the Halemaumau lake, through fissures in the edge of the broad, shield-shaped Halemaumau cone. Certainly no strong lava fountaining occurred at the 1884 vent. The 1894 lava flooding in the same general area undoubtedly was merely an overflow from the Halemaumau lake.

The outpourings of 1918 and 1919 also were obviously merely overflows from the Halemaumau lake, even though the latter sent a big stream of lava all the way to the northern wall of the caldera. The 1921 flow, over the southern portion of the caldera, issued from cracks southwest of Halemaumau formed at the time of the 1919–20 outbreak in the Kau Desert. Two prominent conelets were formed at the points of issue of the lava. However, the fountains at these vents were low and poor in gas, and photographs of the conelets show them to have been driblet cones. Almost surely, the eruption of 1921, like those of 1884, 1894, 1918, and 1919, was merely an overflow from the Halemaumau lake.

Persons familiar with the behavior of Kilauea previous to the great collapse in 1924 have remarked on the dis-

tinct change in character of its behavior during the 1952 and 1954 eruptions (Isabel P. Jaggar, personal communication). Unquestionably, these last two eruptions have resembled much more closely the eruptive habit of Mauna Loa than that of Kilauea during the 19th, and early part of the 20th centuries. Probably, however, the change does not represent any fundamental alteration in the eruptive habit of Kilauea, but rather merely reflects the absence of an open vent between eruptions (or lava overflows). The open conduit, marked by the presence of the active lava lake most of the time from 1823 to 1924, prevented the accumulation of any large "head" of gas on the magma column, and consequently the formation of large gas-rich fountains such as have characterized the activity of Mauna Loa and the 1952 and 1954 eruptions of Kilauea. There is no good reason to believe, however, that the "permanent" lava lake and open conduit have been characteristic of Kilauea volcano throughout its period of growth. Its geologic structure and the formations at prehistoric vents indicate, on the contrary, that throughout most of its growth it has closely resembled Mauna Loa. The century of nearly constant lava lake activity, which ushered in our knowledge of Kilauea, may well have been an unusual period in the long-term history of the volcano.

REPORT OF THE HAWAIIAN VOLCANO OBSERVATORY FOR APRIL–JUNE, 1954

By GORDON A. MACDONALD

April

Seismic activity on the island of Hawaii was appreciably greater than normal during the month of April. A total of 69 earthquakes larger than tremors was recorded on seismographs operated by the Volcano Observatory on the island of Hawaii. Of these, 44 originated in Kilauea Volcano, 19 of them in or near the crater area, and most of the rest along the east rift zone, which extends from the crater eastward through Puna to Cape Kumukahi. Three of these earthquakes were felt in the Volcano district on April 15, and one each on April 1 and 22. The quake felt in Hilo on April 8 was an aftershock of the large quakes that originated in Puna on March 30. Another, felt in Hilo on April 26, had its focus on the east rift zone of Kilauea near Napau Crater.

Only six earthquakes were definitely related to Mauna Loa, although the origins of 14 others could not be located with certainty. On April 23 and 24, three small quakes originated beneath the western slope of Hualalai Volcano.

Tilting of the ground surface at the northeastern rim of Kilauea caldera was southwestward, but at a rate somewhat less than normal. This apparently represented a slight increase of volcanic pressure beneath Kilauea.

Although Kilauea Volcano was definitely restless, there was as yet no indication of imminent eruption.

A new seismograph station at Pahoa, in eastern Puna, was put into operation on April 1. The station is situated on the grounds of the Pahoa school, through a cooperative agreement with the School Department of the County of Hawaii. The station is equipped with a Loucks-Omori two-component horizontal seismograph, with static magnification of 250, recording on smoked paper with a recorder speed of 60 mm. per minute. Time marks on the record originate from an I.B.M. master clock in the station. The clock time is corrected by means of the Bureau of Standards time signal, broadcast over station WWV, and marked directly on the record by means of a device constructed by Jerry P. Eaton. The station operator is Kongo Kimura.

May

The outstanding event of the month was the outbreak of Kilauea on May 31, described in preceding pages.

Earthquake activity at Kilauea remained greater than usual throughout May. Both the total number of quakes recorded and the weekly seismicity index ranged from two to four times the normal. Thus the volcano was obviously uneasy, but no single event or pattern of events was recognized that would make possible a definite prediction of coming eruption. A large number of very small earthquakes recorded on the Sprengnether vertical seismograph at the Uwekahuna station may, on further analysis, prove to have characteristics that would aid prediction if similar swarms occur in the future. This is the first pre-eruption seismic activity recorded on seismographs of high sensitivity in Hawaii.

Ground tilting at the northeastern rim of Kilauea caldera was approximately normal during May. The seasonal reversal from southward to northward tilting took place a little earlier than usual, and as a result there was a slightly larger than usual accumulation of northward tilting during the month. It was, however, well within the limits of variation of non-eruption years. Thus there was little or no evidence of change of magmatic pressure beneath Kilauea during the months just preceding the eruption.

June

The eruption of Kilauea that began at 4:09 A.M., May 31, ended late in the afternoon of June 3. No eruptive activity occurred during the remainder of the month.

Seismic activity at Kilauea remained somewhat greater than normal through the month of June. The seismograph at the Whitney Laboratory of Seismology recorded a total of 65 earthquakes. Most of these came from a depth of several miles beneath the Kilauea crater area, and represented continued uneasiness of Kilauea volcano. Ground tilting was normal for this season of the year, indicating no marked change of volcanic pressure during or following the eruption.

From June 16 to 20 a swarm of small quakes originated apparently at a depth of about 25 miles in the vicinity of the Mauna Loa seismograph station. Many of these were felt at Umikoa, and some at other localities on the north and east flanks of Mauna Kea.

Several small quakes were felt in Kona during June. Two of these, on June 1 and 16, dismantled the seismograph at Konawaena school. The quakes originated in central Kona, probably on the Kealakekua fault.

Starting early on the morning of May 31, and continuing throughout June, a very large number of landslides occurred on the walls of Halemaumau Crater. More broken rock accumulated at the foot of the wall during the month of June than during the entire interval between the 1952 and 1954 eruptions. Several segments of the crater rim collapsed. One of these was almost directly in front of the visitors' overlook, but the greatest instability was on the northern wall. There, an average width of about 10 feet of the rim collapsed over a distance of several hundred feet, taking with it one benchmark and several other surveying stations used by the Volcano Observatory. Cracks near the northern rim show an aggregate opening of about one foot. Less-pronounced cracking occurred on the caldera floor southeast, south, and west of Halemaumau. The crack at station 40, west of the west tilt cellar, opened 9 mm. during June.

The summit region and northeast rift zone of Mauna Loa were examined on June 24 to 27. No signs of any unusual conditions were detected. There have been no apparent changes in Mokuaweoweo caldera since the end of the 1949 eruption.

A new seismograph station at Kamuela, on the northern part of the island of Hawaii, was put into operation on June 9. It is situated on the grounds of the Waimea school, and is equipped in the same manner as the Pahoa station (see above). The station operator is Thomas C. Mills.

SEISMOLOGY

Earthquake Data, April–June, 1954

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Local Seismicity*	Teleseisms
April 4	0	3	0	0	0	0	1.50	0
11	6	9	0	2	0	1	14.00	1
18	3	1	1	1	0	0	4.25	0
25	4	5	0	0	0	0	3.50	3
May 2	7	9	0	0	0	0	6.25	1
9	7	5	1	0	0	0	4.25	2
16	12	10	2	1	0	0	12.00	0
23	13	9	2	0	0	0	9.75	0
30	984	22	2	1	1	1	268.00	1
June 6	20	8	0	0	0	0	9.00	3
13	815	16	0	0	0	0	212.00	2
20	5	12	1	0	0	0	8.25	1
27	5	11	3	0	0	1	13.75	1

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

Week Beginning	Whitney Station (Northeast rim)		Uwekahuna Station (West rim)

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. The number preceding each quake is the serial number for the current year. Only earthquakes classed as feeble or larger are included in the list. Many very feeble quakes, to which serial numbers are assigned also, are omitted. Locations given are epicenters. Except where otherwise indicated, the times given are arrival times at the Uwekahuna station, on the western rim of Kilauea caldera. They are stated in Hawaiian standard time, which is 10 hours behind Greenwich civil time. The intensity rating (Feeble, Moderate, etc.) given is based on the Bosch-Omori seismograph at the Whitney Laboratory of Seismology. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney station.

92. Apr. 1, 06:34:49, strong. Felt in Hawaii National Park. Kilauea caldera.
93. Apr. 1, 15:56:42, slight. Felt in Puna. East Puna.
94. Apr. 1, 17:52:30, feeble. Kilauea caldera.
101. Apr. 11, 02:20, not recorded at the Whitney Laboratory (Pahoa, slight). East Puna.
116. Apr. 15, 06:27:11, very feeble (Uwekahuna, feeble). Kilauea caldera.
117. Apr. 15, 06:27:50, slight (Uwekahuna, moderate). Felt in Hawaii National Park. Kilauea caldera.
118. Apr. 15, 06:43:03, very feeble (Uwekahuna, feeble). Kilauea caldera.
119. Apr. 15, 07:01:11, slight (Uwekahuna, moderate). Felt in Hawaii National Park. Kilauea caldera.
120. Apr. 15, 07:15:00, strong. Felt in Hawaii National Park. Kilauea caldera.
123. Apr. 15, 19:19:53, not recorded at the Whitney Laboratory (Pahoa, feeble). East Puna.
131. Apr. 17, 17:25:34, very feeble (Uwekahuna, feeble). Kilauea caldera.
138. Apr. 22, 14:31:54, slight. Felt in Hawaii National Park. Kilauea caldera.
141. Apr. 23, 16:13:23, feeble. Kaoiki fault.
143. Apr. 23, 23:14, not recorded at the Whitney Laboratory (Kona, feeble). Kona.
149. Apr. 25, 11:22:17, not recorded at the Whitney Laboratory (Pahoa, feeble). East Puna.
177. May 6, 20:31:41, very feeble (Mauna Loa, feeble). Northeast rift of Mauna Loa near Puu Ulaula.
190. May 14, 07:53:19, not recorded at the Whitney Laboratory (Pahoa, feeble). East Puna.
192. May 15, 01:45:36, feeble. Three miles south of Uwekahuna at a depth of 15 miles.
197. May 18, 03:34:34, feeble. Kilauea caldera.
198. May 18, 10:36:40, feeble. Six miles south of Uwekahuna at a depth of 20 miles.
199. May 18, 16:56:48, very feeble (Kona, strong). Felt in Kealakekua and Capt. Cook, Kona. Kona.

203. May 20, 20 : 40 : 03, slight. Kilauea caldera.
212. May 24, 09 : 11 : 56, feeble (Uwekahuna, slight). Kilauea caldera.
218. May 26, 16 : 39 : 42, feeble (Mauna Loa, strong). Kaoiki fault near Halfway House at a depth of 6 miles.
233. May 31, 03 : 42 : 32, slight (Uwekahuna, moderate). Kilauea caldera.
236. May 31, 03 : 46 : 57, very feeble (Uwekahuna, feeble). Kilauea caldera.
237. May 31, 03 : 47 : 38, very feeble (Uwekahuna, feeble). Kilauea caldera.
238. May 31, 03 : 48 : 06, very feeble (Uwekahuna, feeble). Kilauea caldera.
239. May 31, 03 : 48 : 16, feeble. Kilauea caldera.
246. May 31, 03 : 50 : 44, moderate (Uwekahuna, strong). Felt in Hawaii National Park. Kilauea caldera.
247. May 31, 03 : 50 : 59, very feeble (Uwekahuna, feeble). Kilauea caldera.
253. May 31, 03 : 54 : 05, strong. Felt in Hawaii National Park. Kilauea caldera just east of Halemaumau.
258. May 31, 14 : 45 : 40, very feeble (Uwekahuna, feeble). Kilauea caldera.
266. June 1, 20 : 42 : 53, very feeble (Kona, strong). Felt in Kona. Kona.
267. June 2, 00 : 03 : 03, feeble. Kilauea caldera.
289. June 16, 09 : 42 : 28, very feeble (Pahoa, feeble). East rift of Kilauea.
299. June 18, 03 : 00 : 03, very feeble (Mauna Loa, feeble). Approximately under the Mauna Loa seismograph station at a depth of about 25 miles. This is one of the largest of a series of more than 100 very feeble quakes and innumerable tremors originating from this focus on June 18, 19, 20, and 21. Many of these quakes were felt at Umikoa on the northeast flank of Mauna Kea, and several were felt at Kamuela and Hilo.
429. June 23, 02 : 03 : 09, feeble. Kilauea caldera.
445. June 29, 02 : 35 : 27, very feeble (Mauna Loa, slight). Same epicenter as No. 299.
456. June 30, 17 : 20 : 11, feeble. Kilauea caldera.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters and the magnitudes are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Sprengnether vertical seismograms, in Hawaiian standard time.

Apr. 2, eP 05 : 07 : 35, 28½° S., 177° W. Kermadec Islands.
Apr. 17, iP 10 : 17 : 51.4, 51½° N., 179° W. Andreanof Islands, Aleutian Islands. Felt on Adak. Magnitude 6¾–7.
Apr. 26, eP 10 : 33 : 29.4, 51° N., 158½° E. Off southeast coast of Kamchatka. Magnitude 6½–6¾.

June 6, eP 07 : 02 : 04, 3½° S., 136½° E. Western New Guinea. Magnitude 7.
June 7, eP 00 : 24 : 37.5, 3½° S., 152° E. New Britain Region. Depth 450 km. Magnitude 6¾.
June 11, iP 19 : 42 : 34.4, 18° S., 179° W. Fiji Islands. Depth 550 km. Magnitude 6½.
June 15, eP 03 : 41 : 02.6, 5° S., 77° W. Northern Peru. Magnitude 6½–7.
June 16, iP 15 : 49 : 31.5, 56° N., 159½° W. Off south coast of Kodiak Island. Magnitude 6½.
June 23, eP 22 : 07 : 28.2, 18½° N., 145½° E. Marianas Islands.

VOLCANO NOTES AND NEWS

TANGIWAI RAILWAY DISASTER

Christmas Eve of 1953, and the visit of Queen Elizabeth to New Zealand, were marred by disaster. Shortly after 10:20 P.M. on December 24, the Wellington-Auckland express train plunged into the gorge of the Whangaehu River near Tangiwai station. Casualties numbered 151, of which 131 are known dead, and 20 are missing. The immediate cause of the catastrophe was the destruction of the railway bridge by a large mudflow (lahar) originating on Ruapehu volcano and rushing down the Whangaehu River. The following account of the causes of the catastrophe is derived largely from a report by James Healy, Supervising Geologist of the Geological Survey Branch, New Zealand Department of Scientific and Industrial Research. The report is contained in a longer report of the Board of Inquiry into the Tangiwai Railway Disaster (Government Printer, Wellington, 31 pp., 1954).

Ruapehu is a composite volcanic cone south of Lake Taupo, in the central part of the North Island of New Zealand. At its summit is a broad crater, a mile long and half a mile wide, within which is an inner cone with a crater containing a small lake. The central cone is surrounded on three sides by fields of snow and ice, occupying the larger crater. On the east, however, the central cone slopes directly down to the Whangaehu Glacier, on the outer flank of the mountain. The crater lake is generally unfrozen, being warmed by rising volcanic steam. The water of the lake may rise until it spills out through the lowest notch in the crater rim, melts a channel beneath the adjacent ice field, and finally emerges to form a branch of the Whangaehu River. Recent activity of Ruapehu has been restricted largely to the inner cone. During the last eruption a dome of lava grew in the crater during March and April, 1945, followed by explosions that continued until early 1946. The explosions left a crater 1,000 feet deep, and covered the summit of the mountain with loose ash and larger ejecta.

In prehistoric times large mudflows buried much of the region around the base of Ruapehu. Mudflows down the Whangaehu River occurred on four previous occasions during the past century. Those of 1889 and 1895 resulted from eruptions in the crater lake; those of 1861 and 1925 were cold mudflows result-

ing from release of the water of the lake below the glacier. None appears to have equaled in size that of 1953.

After the end of explosive activity in 1946, the crater began to refill with water, and by August 1953 the lake level had again stabilized and the outlet tunnel under the glacier had been re-established. The new lake level was 20 to 25 feet higher than before 1945. Water appears to have been seeping through a barrier of ash and scoria alongside the outlet tunnel, to form another channel beneath the ice at a lower level.

No new volcanic activity appears to have contributed to the origin of the 1953 mudflow. The cause of the sudden release of water from the crater lake, which resulted in the disastrous mudflow, appears to have been fissuring, and collapse of the barrier of ash at one side of the entrance of the outlet tunnel. Collapse of the barrier may have resulted partly from erosion by the stream of water in the hidden channel beneath the ice, and partly from weakening of the barrier by seepage of water through it (Healy, 1954). The lake level dropped 26 feet, and the rate of discharge is believed to have reached 30,000 cubic feet per second. As the flood moved down the Whangaehu Valley it brought with it huge quantities of loose ash and boulders, together with blocks of ice from the glacier. At the lower end of the Whangaehu Gorge the flood, at its maximum, filled a channel 105 feet wide to a depth of 22 feet (as compared to the river flow on December 28, which occupied a channel only 20 feet wide and 1.5 feet deep).

Mudflows, both hot and cold, are a common cause of disaster in volcanic regions, and methods for warning and control of mudflows are one of the most pressing problems in practical volcanology. During the past few months two persons were killed by mudflows on the slopes of Hibok-Hibok volcano in the Philippines. These mudflows resulted from torrential typhoon rains falling on the loose debris left on the upper slopes of the volcano by the recent eruptions. On January 23, 1954, A. Alcaraz and G. A. Macdonald warned the municipal council of Mambajao of the possibility of such mudflows, and advised that local people should not live within a few feet of stream courses.

UNITED NATIONS TRAINEE IN VOLCANOLOGY

Gregorio A. Andal, assistant geologist of the Philippine Commission on Volcanology, arrived at the Hawaiian Volcano Observatory on June 7 for a stay of nearly two months. Mr. Andal's visit is under the auspices of the United Nations Technical Training Program. He will spend his time in Hawaii studying Hawaiian volcanoes and volcano observatory methods. On his departure from Hawaii, early in August, he plans to spend an additional two months on similar study in Japan.

VOLCANIC ERUPTIONS OF 1953 AND 1948 ON ISABELA ISLAND, GALAPAGOS ISLANDS, ECUADOR[1]

By ADRIAN F. RICHARDS[2]

1953 FLANK ERUPTION OF SIERRA NEGRA (Volcan Grande)

On August 27, 1953, the northern flank of Sierra Negra (Volcan Grande), situated on southern Isabela (Albemarle) Island, the largest of the Galapagos Islands, was reported in a state of eruption. The reports were contained in radio messages sent by the captains of several tuna clippers to the Scripps Institution of Oceanography, University of California, and the U. S. Hydrographic Office (Notice to shipmasters, volcanic activity, Pacific Ocean: U. S. Hydrog. Office, Hydrographic Bul. No. 36, Sept. 5, 1953). Joe Marques, Master, and Robert Robbins, Navigator and Radio Operator, of the "Normandie," and Captain George Zeluff of the "Paramount" have furnished the writer with their observations of the beginning of this eruption.

During the afternoon of August 27 a presumedly new lateral fissure, believed to trend northeast-southwest and estimated to be two miles long, opened about three-fourths of the way up the northern side of Sierra Negra, at an approximate altitude of 3,700 feet. The beginning of the eruption was witnessed from the "Paramount," located in Bolivar Canal nearly 30 nautical miles north of the fissure site. A very large, light-colored eruption column was observed to ascend to a height of more than 30,000 feet, and voluminous flows of lava started to issue from the ends of the fissure and flow north towards Elizabeth Bay.

During the night of August 28 a bright red reflection in the sky was observed from the "Normandie," which was then off the west end of San Cristobal (Chatham) Island, approximately 90 miles east of the volcano. On the 29th the eruption was viewed from the "Normandie" in Elizabeth Bay, about 20 miles from the fissure. Unfortunately much "smoke"—slightly darker than the fog—and haze obscured the site of the eruption. However, at night visibility improved, and cherry-red lava could be seen flowing down the northern side of Sierra Negra. Lava from the north end of the fissure appeared to flow due north, to the shore of Elizabeth Bay, about 5 miles from the fissure. It is not known whether or not the lava flowed into the bay. From the southern end of the fissure the lava stream apparently divided and flowed toward both sides of Point Moreno, which is located approximately 10 miles northwest of the fissure. "Red eruptions," probably lava fountains or showers of incandescent cinder, ascended an estimated 400 feet (as seen from 20 miles away) above the fissure at intervals of seven to eight minutes. Most of the visible activity appeared at the northern extremity of the fissure.

On August 31 a bright reddish glow, reflected from low clouds, was seen from James Bay on the western side of San Salvador or Santiago (James) Island, nearly 40 miles north-northeast of the volcano. On September 10 the "Normandie" was near Webb Cove, about 15 miles west of the fissure. Volcanic activity, if present, was not observed, due to heavy fog, mist, and clouds which obscured the island from view.

Ray Maderis, Navigator of the "Equator," has informed the writer that on October 7 volcanic activity on southern Isabela Island was observed from Baltra Island, about 60 miles to the northeast.

At the end of January, 1954, the "Paramount" again visited Isabela Island. Visibility from Elizabeth Bay was

[1] Contribution from Scripps Institution of Oceanography, New Series, No. 741.

[2] Scripps Institution of Oceanography, La Jolla, California. The writer wishes to express his appreciation to all of the men of the tuna fishing fleet who have contributed the information which has made this report possible. The assistance of Professors F. P. Shepard and Chas. H. Behre, Jr., who have critically read the manuscript, is also appreciated. Professor Behre has also aided the writer with the nomenclature of the Isabela Island volcanoes.

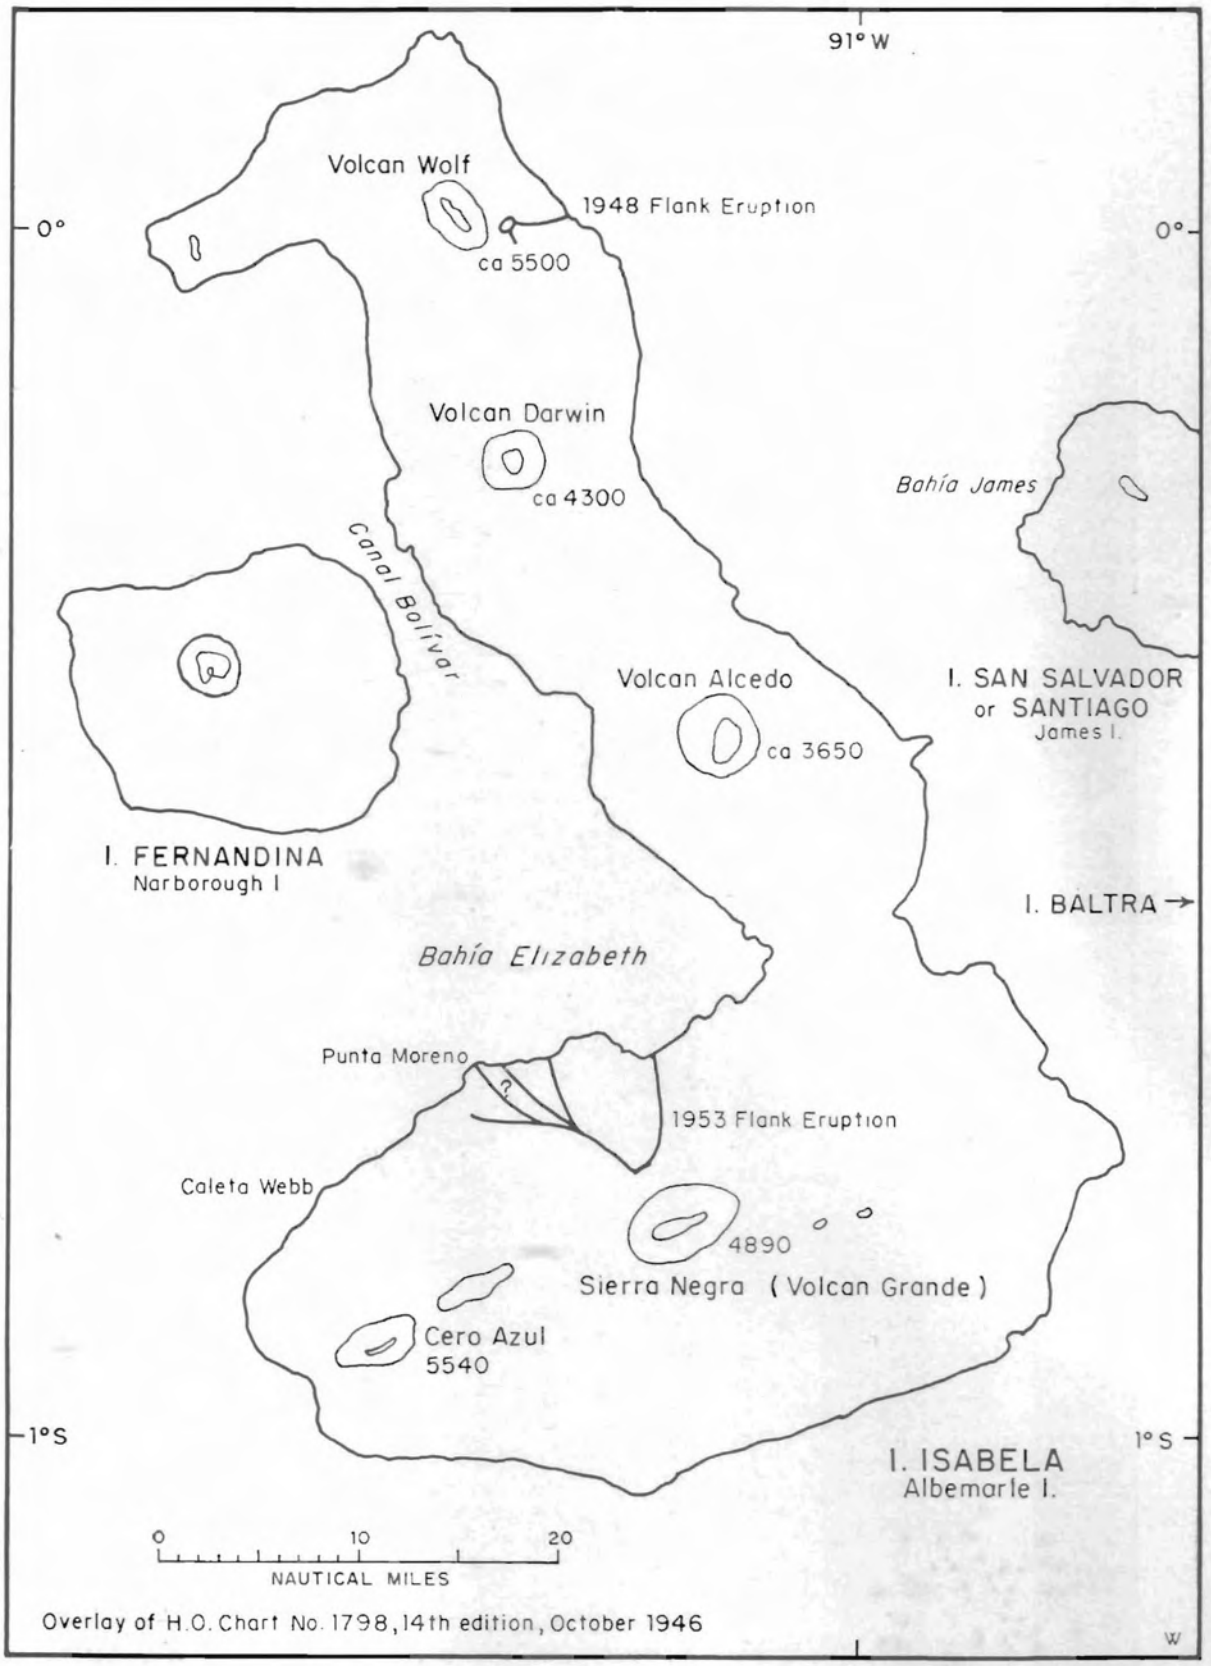

FIGURE 1. Location of the 1948 and 1953 flank eruptions on Isabela Island.

excellent and Captain Zeluff reported that he observed the lava flows to be located approximately as shown in Figure 1. No cone was seen at the site of the fissure, where fumarolic activity was observed. The violent phase of the eruption ceased between October 7 and the end of January, 1954. The exact date is unknown.

1948 FLANK ERUPTION OF VOLCAN WOLF

According to notations made in the log book of the "Paramount," and information obtained from Joseph Madruga, Master of the "Paramount" at that time, an eruption occurred on January 24, 1948, from a new peripheral vent near the east summit of Volcan Wolf on northern Isabela Island. To the writer's knowledge this eruption has not been previously recorded in the literature.

At the beginning of the eruption Volcan Wolf was observed from Banks Bay, about 11 nautical miles southwest of the volcano. A light-colored eruption column originating from the new vent was observed to ascend more than 10,000 feet above sea level. Throughout the time that the "Paramount" was in the vicinity of the volcano, an intermittent rumbling noise was heard. At night red incandescent bombs were seen ejected an estimated 200 to 300 feet above the vent, and Banks Bay was illuminated by the volcanic activity as brightly as during a night with a full moon.

On the 25th Madruga was flown near the eruption site in the fish-spotting Piper Cub belonging to the "Paramount." A small cone, estimated to be about 100 feet high, was seen forming on the southeastern side of the volcano near the peak, at an altitude of approximately 4,000 feet. The crater of the cone glowed cherry-red, and lava appeared to be flowing over the rim. However, the base of the cone could not be clearly seen, and consequently it is possible that the lava could have been emerging from a fissure in the cone instead of flowing over the rim. Large bombs or blocks of lava were also seen shooting skyward.

A single stream of lava from the crater of the parasitic cone was observed flowing very slowly down the flank of the volcano. Several days later, according to Madruga, other fishermen noticed that steam was rising from the shore, and it appears probable that the lava had reached the sea, about 3.5 miles from the cone. On the day of the flight a small second stream of lava was observed flowing a short distance south from the cone. The approximate position of the cone and two flows, based on the data given by Madruga, are shown in Figure 1.

The violent phase of the activity continued for at least four or five days before the "Paramount" left Isabela Island. At the end of January, or early in February, the ship was at Wolf (Wenman) Island, 85 miles north of the volcano, and a red glow from the eruption was clearly visible at night. The date of the end of the eruptive activity is not known to the writer.

A METHOD FOR RECORDING RADIO TIME SIGNALS ON SEISMOGRAMS

By JERRY P. EATON

One of the most exacting requirements in seismology is the accurate timing of seismic events. For earthquake work the precision in timing currently sought is one-tenth of a second. To attain this precision an accurate time base must be provided on the seismogram. The usual procedure is to maintain a station clock, capable of running at a very uniform rate, which is equipped with contacts for marking minutes and hours on the seismogram. Time indicated by this clock is then checked periodically against the accurate radio time signals broadcast by the National Bureau of Standards Stations WWV or WWVH; by one of the U. S. Naval Radio Stations NSS, NPG, NPM, or NBA; or by similar institutions abroad.

Granted that a reliable station clock is available, the accuracy of the seismogram time base is limited by the accuracy of the radio time signal and the accuracy of the comparison of clock and radio time. Of the American stations, WWV, WWVH, and NSS broadcast time signals accurate at least to a few hundredths of a second. Signals broadcast by NPM and NPG appear to be accurate to within about one-tenth of a second. Thus, any of these stations provides time precise enough for the needs of earthquake seismology.

The most satisfactory method for comparing radio and clock time is to record the radio time signal directly on the seismogram, permitting a clock correction to be measured with at least as great a precision as that attainable in measuring individual seismic events on the seismogram. Special receivers built to close a relay in the seismograph timing circuit in response to the make-break continuous wave signals sent out by the Naval Radio Stations are usually employed for this purpose.

At the Hawaiian Volcano Observatory the need arose to adapt a small commercial communications receiver (Hallicrafters S-38C) to the task of closing a relay in response either to the NPM (Oahu) continuous wave signal or to the WWVH (Maui) modulated signal. A diagram of the rather simple and inexpensive solution to this problem is given in Figure 2. The audio frequency emf appearing across the speaker transformer primary, *T*, is rectified in a voltage-doubling circuit employing two germanium diodes, *D*. The output of this system is applied to the coil of a plate circuit relay, *Rel*. With the

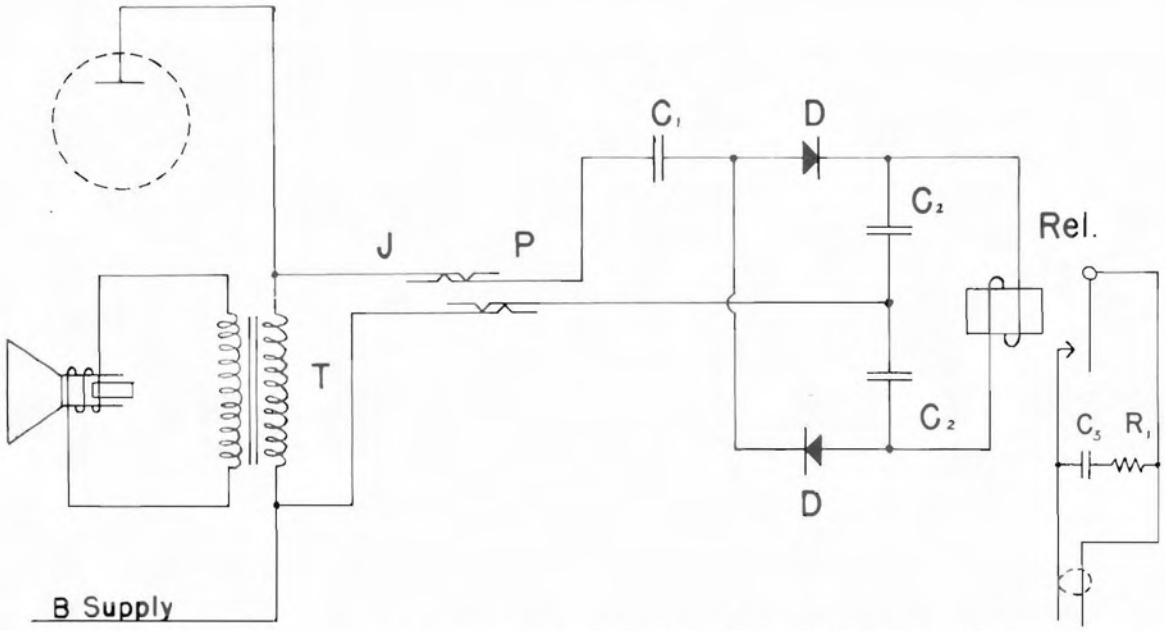

FIGURE 2. Radio adapter for recording time signals. T—Speaker transformer, J—Phone jack, P—Phone plug, C_1—2μF capacitor, C_2—1μF capacitor, C_3—0.25μF capacitor, D—Germanium diode (G.E.1N91 or 1N34A), Rel.—Plate circuit relay (Potter-Brumfield LS-5, 5000Ω coil), R_1—20 to 50Ω 1 watt carbon resistor. The 1μF and 2μF capacitors preferably should be pyranol, but electrolytic capacitors are satisfactory if polarization is maintained.

circuit components used the relay closes on about 10 volts, whereas a good, strong signal develops up to 60 volts across the relay. Since this recording device requires no operating power supply, the relay, two diodes, four condensers, and one resistor required in its construction are simply mounted on a 1 × 4 × 10 inch wooden block. The device is attached to the radio circuit by means of a phone plug and jack so that it need not interfere with other use of the receiver.

Signals broadcast on any frequency which can be tuned by the receiver can be used provided the structure of the signal is suitable for recording. At the Volcano Observatory the signal from WWVH has proved to be most useful. Beginning on the hour, WWV broadcasts a 600 cps audio frequency and a one cps modulation consisting of five 1000 cps pulses at the beginning of each second. This one cps modulation, or "tick," as it sounds on the receiver, is omitted on the 59th second of each minute. During the fourth minute of the hour the audio frequency is omitted; code, voice announcements, and the one cps modulation are broadcast during this minute. At exactly five minutes after the hour a 440 cps audio frequency comes on. This frequency and the one cps modulation continue for four minutes, then the 440 cps tone goes off and another minute of code, voice announcements, and "ticks" follows. The foregoing 10-minute cycle is repeated six times per hour and continues day and night. Except for minor periodic interruptions, the WWVH signal is the same as that of WWV. The adapter described above closes the relay during period of audio frequency, code, voice announcements, and, with moderate signal strength, at each of the one cps "ticks." The timing event most clearly recordable is the return of the audio frequency after the one minute of audio frequency silence.

If photographic recording is employed the adapter relay contacts can be placed in parallel with the clock relay contacts to permit the radio time signal to be re-

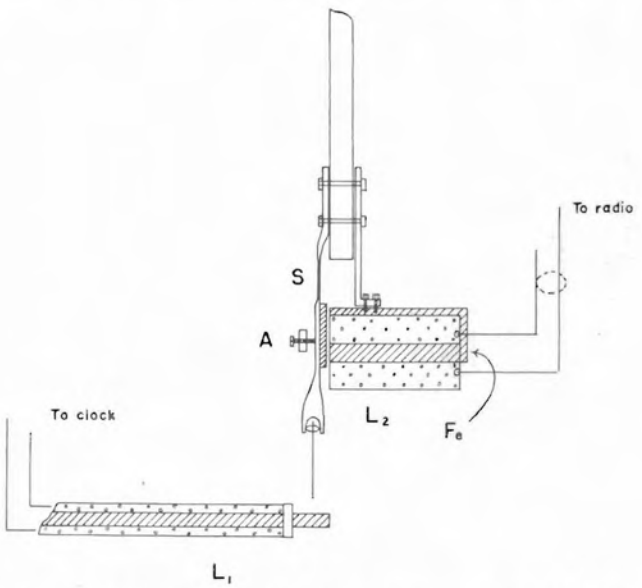

FIGURE 3. Radio time-signal marking pen for mechanical recorder. L_1—Pen lift magnet, L_2—Pen deflector magnet, Fe—Iron core and armature, A—Amplitude adjustment screw, S—Flexible pen arm.

corded by the minute-mark deflector system. If mechanical recording is used and the writing points are lifted to record time marks, it is convenient to record the radio time signal by a separate writing point which is deflected horizontally by the radio signal and is lifted from the paper by the clock signal. In practice the clock correction is obtained once a day when the record is changed. The operator drops the timing needle onto the drum and tunes the radio to record the signal. After the signal has been recorded he lifts the timing pen to avoid interference with the seismograph pens during the registration of earthquakes.

Figure 3 is a diagram of the time marker used with the mechanically recording Loucks-Omori seismographs built at the Observatory. The pen is lifted by the regular pen-lift magnet used to record clock time. In addition the pen is carried on a flexible arm which is deflected horizontally by another electromagnet controlled by the radio.

One difficulty encountered in the use of this time-marking system originated in the "feedback" through the receiver of the static generated at the relay contacts. This difficulty was overcome by employing a half-wave doublet antenna with a twin-line lead-in to the receiver; by placing a simple capacity-resistance filter across the relay contacts and near each heavy inductance in the time-signal marking circuit; and by using shielded conductors in this circuit.

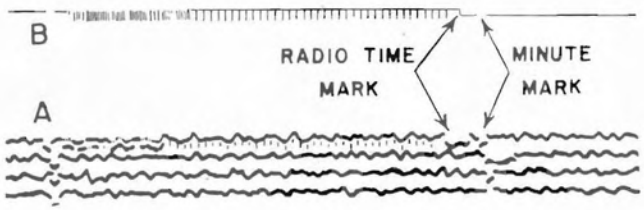

FIGURE 4. WWVH time signals recorded on an optical (A) and mechanical (B) seismograph.

Figure 4 illustrates WWVH time signals recorded on the photographic record of the Sprengnether and on the smoked-paper record of the Loucks-Omori.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY-SEPTEMBER, 1954

By GORDON A. MACDONALD and JERRY P. EATON

VOLCANOLOGY

July

Earthquake activity on the island of Hawaii continued somewhat greater than usual throughout July. The seismograph at the Whitney Laboratory of Seismology, on the northeast rim of Kilauea caldera, recorded 58 quakes during the month. This is approximately twice the number usual during times of volcanic quiet. The more sensitive Sprengnether seismograph at Uwekahuna recorded a much larger number of very small earthquakes.

Most of the quakes originated within a few miles of the Whitney and Uwekahuna stations, probably beneath Kilauea caldera and the east rift zone near the caldera. On July 3, at 11:53 A.M., a strong earthquake was widely felt over the southern part of the island, and did minor damage in Hilo. Its epicenter was about a mile north of Alae Crater, five miles southeast of the caldera. J. B. Wosky, Superintendent of Hawaii National Park, reported that during and after the quake numerous heavy rock falls occurred on the seaward face of Puu Kapukapu, in the vicinity of Halape, at the coast south of Kilauea caldera. Other small shocks of this group were felt lightly in the Volcano district on July 25 and 26.

Several small earthquakes, originating farther east on the Kilauea rift zone, were recorded at the Pahoa station. A light quake, probably of local origin, was felt in central Kona on July 29.

Tilting of the ground surface at the northeastern edge of Kilauea caldera was northward at a rate only slightly greater than usual at that time of year. There did not appear to be any marked change in volcanic pressure, indicated by ground tilting.

Occasional rock falls continued on the walls of Halemaumau Crater, but their frequency during the latter half of July was somewhat less than during June. Fresh cracking of the ground surface was observed near the west, southeast, and north rims of Halemaumau.

August

Kilauea Volcano continued somewhat uneasy during August. The seismograph at the Whitney Laboratory of Seismology recorded 46 earthquakes during the month. This is somewhat more than the number normally recorded in times of volcanic quiet. Most of the quakes originated beneath or near Kilauea caldera. Tilting of the ground at the northeastern rim of the caldera was northward at a rate slightly greater than usual at that season. There was no indication of any decrease of volcanic pressure beneath Kilauea.

A sharp earthquake was felt in Kona at 11:27 P.M. on August 1. Its origin was within a few miles of the seismograph station at Konawaena school, probably on the Kealakekua fault near the northern edge of Kealakekua Bay. At 2:27 P.M. on August 7 a strong quake originated beneath Kilauea caldera. It was felt by many persons in the Volcano area, and by some in Hilo and Kona. A moderate quake at 11:16 P.M. on August 30, felt by residents of the Volcano area, also originated beneath Kilauea caldera.

September

The seismograph at the Whitney Laboratory of Seismology recorded 94 earthquakes during the month, approximately three times the number recorded during normal times of volcanic quiet. During the week starting September 12 alone, 56 quakes were recorded. Most of the earthquakes appear to have originated beneath the Kilauea caldera area or the adjacent part of the east rift zone. Several during mid-September appeared to originate at depths of 25 to 30 miles beneath the caldera or the nearby slope of Mauna Loa. One at 2:43 A.M. on September 13 was felt in Hilo.

Several quakes were felt in Kona during early September. These originated on the western slope of Mauna Loa, probably on the Kealakekua fault. No other signs of uneasiness of Mauna Loa were noted.

Tilting of the ground at the northeast rim of Kilauea caldera was approximately normal in direction and amount for that season of the year. Thus no marked change in volcanic pressure beneath Kilauea was indicated.

Neither during the May-June eruption of Kilauea, nor in the four months following the eruption, has there been any indication of reduction of volcanic pressure beneath Kilauea Volcano. Magma appears probably to be still standing at a high level in the conduit. Under such conditions, eruption may occur with little or no warning other than the numerous earthquakes that indicate continued uneasiness of the volcano.

SEISMOLOGY

Local Earthquake Data, July-September, 1954

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Total	Local Seismicity*
July 4	2	4	0	0	0	0	6	2.50
11	10	15	2	0	0	0	27	12.00
18	6	6	1	0	0	0	13	5.50
25	1	9	0	2	0	0	12	8.75
Aug. 1	1	9	0	1	0	0	11	6.75
8	6	6	0	0	0	2	14	12.50
15	1	4	0	0	0	0	5	2.25
22	3	5	2	2	0	0	12	9.25
29	7	7	0	0	1	0	15	8.25
Sept. 5	3	4	1	0	0	0	8	3.75
12	32	19	3	2	0	0	56	21.00
19	9	9	0	1	0	0	19	8.75
26	5	8	1	0	0	0	14	6.25

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

Week Beginning	Whitney Station (Northeast rim)		Uwekahuna Station (West rim)	
	Amount	Direction	Amount	Direction
July 4	0.4″	S 56° W	1.8″	S 31° E
11	1.0″	N	1.3″	S

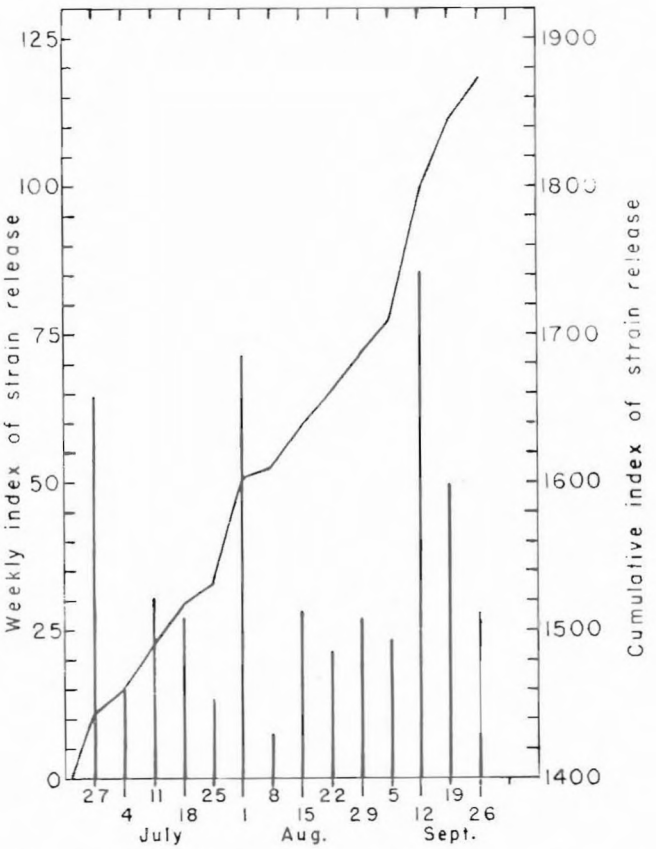

FIGURE 5. Graph showing weekly strain release index (vertical bars) and cumulative strain release index (continuous curve) for the Kilauea caldera region from late June through September, 1954. An increase in steepness of rise of the cumulative curve represents an increase in rate of strain release through earthquakes.

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. The number preceding each quake is the serial number for the current year. Only earthquakes classed as feeble or larger are included in the list. Many very feeble quakes, to which serial numbers are assigned also, are omitted. Locations given are epicenters. Except where otherwise indicated, the times given are arrival times at the Uwekahuna station, on the western rim of Kilauea caldera. They are stated in Hawaiian standard time, which is 10 hours behind Greenwich civil time. The intensity rating (Feeble, Moderate, etc.) given is based on the Bosch-Omori seismograph at the Whitney Laboratory of Seismology. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney Station.

461. July 1, 09:06, feeble (Mauna Loa, moderate). Felt in Hawaii National Park. About 10 km deep under Kilauea caldera.
462. July 2, 06:00, feeble. Kilauea caldera.
465. July 3, 11:52:35, strong. Felt quite generally over southern half of Hawaii. About 12 km deep under Alae Crater on the east rift of Kilauea.
476. July 11, 12:07:26, feeble. East rift of Kilauea near Napau Crater.
486. July 15, 17:10:07, feeble. Kilauea caldera.
500. July 22, 13:35 (Pahoa), not recorded at Kilauea (Pahoa, feeble). East rift of Kilauea near Pahoa.

501. July 22, 15 : 38 (Pahoa), not recorded at Kilauea (Pahoa, feeble). East rift of Kilauea near Pahoa.
502. July 22, 20 : 36 : 50, feeble. Kilauea caldera.
506. July 25, 18 : 17 : 55, slight. Felt in Hawaii National Park. Near Mauna Loa seismograph station about 10 km deep.
508. July 26, 00 : 51 : 44, slight. Felt in Hawaii National Park and in central Kona. Along the Kaoiki fault west of the Observatory at a depth of 10 km.
520. Aug. 1, 23 : 27 : 48, not recorded at the Whitney Laboratory (Kona, feeble). Felt in central Kona. Central Kona.
521. Aug. 2, 13 : 40 : 33, strong. Felt in Volcano area. About 15 km deep under Alae Crater on the east rift of Kilauea.
523. Aug. 7, 14 : 26 : 17, strong. Felt generally over central Hawaii. 25 km deep under Kilauea caldera.
536. Aug. 16, 04 : 45 : 33 (Pahoa), not recorded at Kilauea (Pahoa, feeble). East rift of Kilauea near Pahoa.
540. Aug. 18, 07 : 13 : 56, slight. Kilauea caldera.
542. Aug. 20, 01 : 58 : 54, feeble. East rift of Kilauea near Makaopuhi Crater.
559. Aug. 30, 23 : 17 : 04, moderate. Felt in Volcano area. 20 km deep under Makaopuhi Crater.
564. Sept. 1, 15 : 17 : 49, not recorded at the Whitney Laboratory (Kona, slight). Felt in central Kona. Central Kona.
570. Sept. 7, 14 : 48 : 36, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
576. Sept. 8, 23 : 03 : 52, feeble. Kilauea caldera.
588. Sept. 12, 21 : 58 : 59, slight. Under Kilauea caldera at a depth of 20 km.
590. Sept. 12, 23 : 08 : 26, tremor (Mauna Loa, very feeble). This very feeble earthquake is included in the list because it is typical of about 250 earthquakes (tremor and very feeble in strength) which originated on Sept. 12 and Sept. 13 at a depth of about 45 km below the southeast flank of Mauna Loa between the Mauna Loa seismograph station and the Volcano Observatory.
595. Sept. 13, 02 : 42 : 53, feeble. Felt in Hilo. 5 km east of Puu Kapukapu along south coast of Kilauea at a depth of about 15 km.
598. Sept. 13, 18 : 22 : 05, feeble. 20 km deep under east rift of Kilauea near Makaopuhi Crater.
602. Sept. 15, 01 : 23 : 06, feeble. Kilauea caldera.
604. Sept. 16, 08 : 15 : 04, slight. Kilauea caldera.
622. Sept. 22, 00 : 19 : 35, slight. Kilauea caldera, 15 km deep.
630. Sept. 25, 21 : 12 : 07, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs of the Hawaiian Volcano Observatory. Locations of the epicenters and the magnitudes are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey. The time given is that of the first detectable emergence of the quake on the Sprengnether vertical seismograms, in Hawaiian standard time.

July 1, eP 16 : 51, 13½° N., 123½° E. Southeastern Luzon, P. I. Many casualties and extensive property damage. Mag. 6¾–7¼.

VOLCANO NOTES AND NEWS

ERUPTION OF NGAURUHOE

Ngauruhoe Volcano, on the North Island of New Zealand, broke into violent eruption on June 4. The volcano is a conical mountain 7,515 feet in altitude, 175 miles southeast of Auckland. The following information was furnished by James Healy, New Zealand Government volcanologist, and Brenda Bishop, Secretary of the Pacific Science Council.

The volcano had been in activity for some time, sending big ash clouds high into the air. On the morning of June 4 the entire top of the mountain was reported to be aglow even in daylight. Flying over the volcano, Healy found the crater full of lava, with spurts of orange-red lava going some 500 feet into the air, and two lava flows moving down the slopes of the mountain. One flow came down directly on top of the lava flow

of 1949, and the other a little farther south. Very little ash was being liberated. The lava flows were visited on June 5. They had nearly come to rest, but large blocks were rolling down the mountainside following numerous explosions at the crater. On June 6 activity was more explosive and more ash was being liberated. The explosive phase continued for several days, but on a lesser scale than in 1949.

Another increase of activity occurred on the night of June 9. Spectacular flows of lava were visible from Chateau Tongariro during the evening, but by 3 A.M. on June 10 the spurt of activity was nearly over. The lava flow is reported to be of aa type, and in places to exceed 70 feet in thickness. A cinder cone built in the crater of the volcano was reported to have reached a height of 200 feet on June 9, and to be breached toward the west where the lava flows escaped.

In September Ngauruhoe was still active. Strong explosions took place on the night of September 2. Several lava flows have been reported on the flanks of the cone during June, July, and August. One of the largest occurred on August 18.

Ruapehu Volcano, 12 miles southwest of Ngauruhoe, was reported steaming in early October. Healy flew over the crater on October 8, and reported that the steam was thick enough to obscure part of the crater lake. Ruapehu Volcano erupted in 1895. Another eruption in 1945 caused the temporary drying up of the crater lake. During that eruption a small lava dome was built in the crater.

THE VOLCANO LETTER

No. 526 **U. S. Geological Survey** **October-December, 1954**

PUBLISHED BY THE UNIVERSITY OF HAWAII

KAUAI, AN ANCIENT HAWAIIAN VOLCANO

By G. A. MACDONALD[1], D. A. DAVIS[1], and D. C. COX[2]

Kauai is one of the oldest, and structurally the most complicated of the Hawaiian Islands. Like the others, it consists principally of a huge dome-shaped shield volcano, built up from the sea floor by many thousands of thin flows of basaltic lava. The volume of this great shield was on the order of 7,000 cubic miles. Through much of its growth it must have resembled rather closely the presently active shield volcano Mauna Loa, on the island of Hawaii. When the Kauai volcano started its growth is not known with certainty. It is believed that activity started late in the Tertiary period of geologic time, possibly in the early or middle part of the Pliocene epoch, some 8 to 10 million years ago. Growth of the shield was rapid in the geological sense, and probably was completed before the end of the Pliocene epoch.

Toward the end of the growth of the shield, its summit collapsed to form a broad caldera, the largest that has been found in the Hawaiian Islands. Like the calderas of Kilauea and Mauna Loa, that of Kauai had boundaries which were rather indefinite in part. The principal central depression was bordered by less depressed fault blocks, some of which merged imperceptibly with the outer slopes of the volcano. Elsewhere the caldera rim was low, and flows spilled over it onto the outer slopes. The well-defined central depression of the major Kauai caldera was approximately 10 to 12 miles across.

At about the same time as the formation of the major caldera, another smaller caldera was formed by collapse around a minor eruptive center on the southeastern side of the Kauai shield. Lavas accumulated in the calderas, gradually filling them, and burying talus that formed along the foot of the boundary cliffs. These lava flows differed from those that built the major portion of the shield in being much thicker and more massive, as a result of ponding in the depressions. The petrographic types are for the most part the same throughout. Both the flank flows that built most of the shield, and the flows that filled the calderas, are predominantly olivine basalt. Picrite-basalt (oceanite), with very abundant large phenocrysts of olivine, and basalt containing little or no olivine are present, but together comprise less than 10 percent of the whole. Late in the period of filling of the major caldera a small amount of basaltic andesine andesite was extruded.

Near the end of the period of filling of the major caldera further collapse occurred, forming a large triangular graben (down-faulted trough) on the southwestern side of the shield. Lava flows erupted within the caldera poured southwestward over the cliff bounding the graben and spread over the gently sloping graben floor. Other flows were erupted along the fault forming the northeast edge of the graben. Near the present Waimea Canyon their advance was obstructed by the fault scarp at the western edge of the graben. The cliff along the northeastern edge of the graben eventually was buried by lava flows from within the caldera, but that along the western edge continued to stand above the level of the flows in the graben. The flows accumulated in the graben are of the same types as those that filled the caldera, and like them are mostly thick and massive because of ponding and the gentle slopes over which they spread.

The rocks of the major Kauai shield volcano are known as the Waimea Canyon volcanic series. The thin flows that accumulated on the flanks of the shield, and that comprise the major portion of the volcanic edifice,

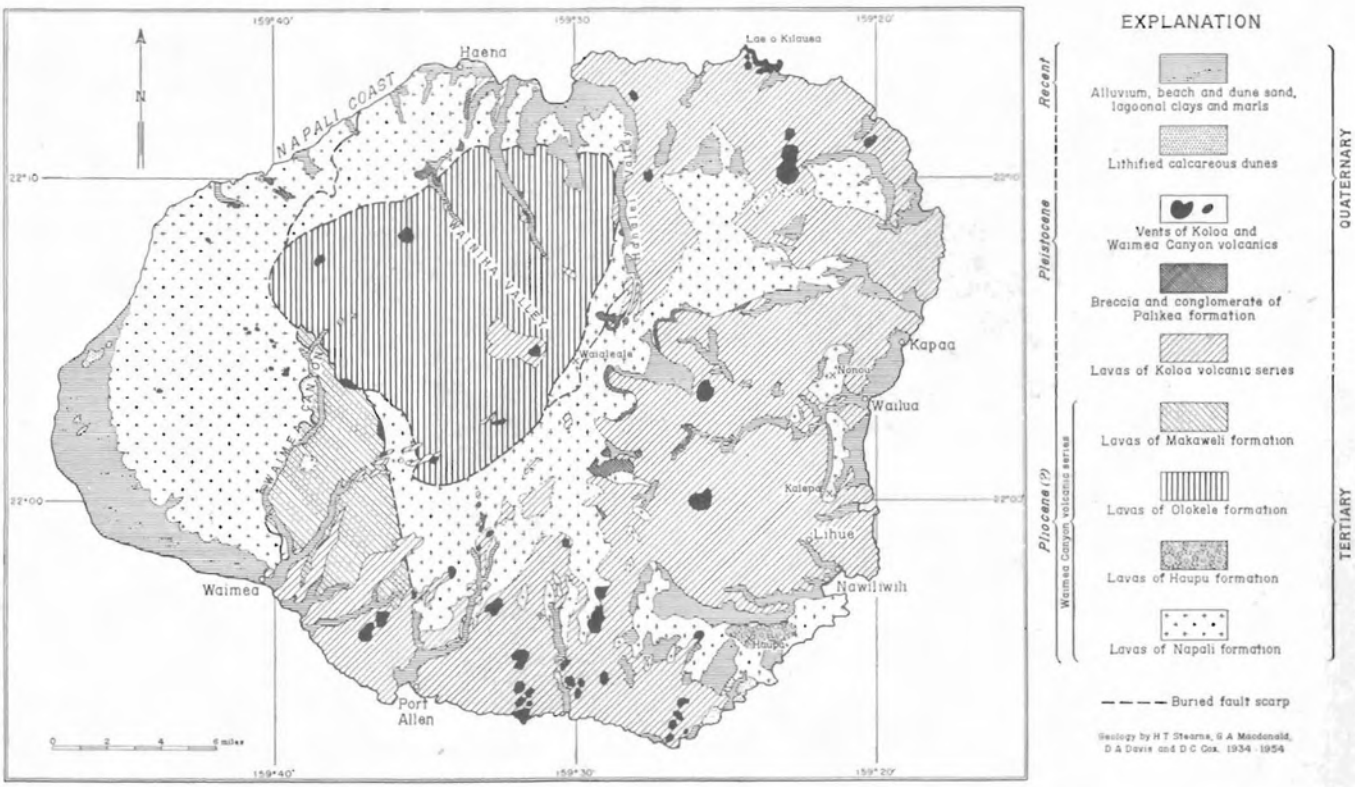

FIGURE 1. Generalized geologic map of the island of Kauai.

are named the Olokele formation, and those that filled the small caldera are named the Napali formation. The rocks that accumulated in the big summit caldera on the southeastern slope of the shield are named the Haupu formation. The volcanic rocks accumulated in the graben on the southwestern side of the shield are named the Makaweli formation, and sedimentary rocks interbedded with them are known as the Mokuone formation. These formations are formally defined and described in detail in the forthcoming Bulletin 13 of the Hawaii Division of Hydrography. The relationships of the rock units are shown in generalized fashion in (Fig. 1).

About the end of eruption of the Waimea Canyon volcanic series, or shortly afterward, another great collapse took place on the eastern flank of the volcano. A subcircular graben 6 or 7 miles across sank several thousand feet, forming a broad depression between the Waialeale massif on the west and Kalepa and Nonou ridges on the east. This collapsed structure cannot be demonstrated as clearly as the Makaweli graben, on the southwest side of the shield, because its walls have been greatly eroded and its floor is deeply buried by lavas of the later Koloa volcanic series. It appears, however, to be the most reasonable explanation of the physiography of the eastern side of the island (Fig. 2).

Following the building of the great Kauai shield came a long period of volcanic quiescence in which erosion carved deeply into the island. Waves cut high sea cliffs, and streams cut grand canyons as much as 3,000 feet deep. The course of the most magnificent of these, Waimea Canyon, was governed by the partly buried eroded fault scarp along the western edge of the Makaweli graben. The massive caldera-filling lavas were more resistant to erosion than the thinner flank flows, and the caldera fills stand in relief above the eroded flanks of the volcano. The Haupu mass is a prominent landmark from both the Lihue and Koloa areas, and along the northern side of the island the eroded edge of the caldera fill forms an imposing escarpment culminating in Puu Iliahi, Mamalahoa, and Hihimanu peaks.

During this period of erosion sea level was several hundred feet below the present level. Test holes have passed through younger rocks to more than 200 feet below sea level on the south side of the island, and more than 300 feet below sea level on the east side of the island, without entering rocks of the Waimea Canyon volcanic series. Probably this early sea level on Kauai was as far below the present sea level as the minus-1200-foot shoreline recognized on Oahu. The later rocks of the Koloa volcanic series probably rest in part on a platform formed by wave erosion during this early low stand of the sea.

After a period of quiescence long enough for deep soil to form over much of the mountain and erosion to carve the shield nearly to its present degree of dissection, volcanism was renewed. Eruption occurred from a series of minor vents arranged in nearly north-south and

northeast-southwest lines across the eastern two-thirds of the island. The lavas, cinder cones, and ash beds of this period of volcanism are known as the Koloa volcanic series. The Koloa lavas include olivine basalt, picrite-basalt of mimosite type with few phenocrysts of olivine, basanite, nepheline basalt, melilite-nepheline basalt, and ankaratrite (nepheline basalt very rich in pyroxene and olivine). Inclusions of dunite, composed almost entirely of olivine, are common in the Koloa flows. Just before and during the eruption of the Koloa volcanics, voluminous landslides and mudflows brought down a large amount of rock debris and soil from the steep slopes of the mountainous central upland and deposited it as breccias at the foot of the steep slopes in valley heads and along the border of the marginal lowland. Streams distributed part of the material across the lowland. The breccias and conglomerates thus formed, and later buried by Koloa lavas, are named the Palikea formation.

The structures formed at Koloa vents include cinder cones, one tuff cone, and lava cones. The latter are miniature shields resembling the major Kauai shield volcano, and like it formed by repeated outpourings of fluid lava. The tuff cone, at Lae o Kilauea, was formed by phreatomagmatic explosions caused by rising magma coming in contact with water-saturated rocks. It resembles Diamond Head and Punchbowl cones on the island of Oahu.

Koloa volcanism continued for a long period. It was not, however, continuous over the entire eastern part of the island. Locally long periods of quiet occurred, allowing streams to re-excavate some of the canyons filled by earlier Koloa lavas, and weathering to form deep soils later buried by new Koloa flows. Some of the canyons formed by erosion between Koloa eruptions were several hundred feet deep. Koloa eruptions probably continued through the Pleistocene and into the Recent epoch. The latest Koloa flow appears very recent. The lava is essentially unweathered and the surface features of the flow are well preserved. It overlies lithified calcareous sand dunes formed during a low stand of the sea, probably at the time of the last advance of the Pleistocene glaciers.

At times during the Pleistocene epoch lowered sea levels permitted erosion of stream valleys and sea cliffs to more than 200 feet below present sea level. Coral reefs were formed during some of these low stands of the sea and calcareous beaches accumulated. A test boring about 1.5 miles north of Kapaa penetrated a calcareous beach buried 240 feet below present sea level beneath Koloa lavas. Calcareous sand dunes also were formed, and now stand with their bases submerged in the ocean. The tuff cone at Lae o Kilauea was formed by phreatomagmatic explosions caused by rising hot magma encountering water-saturated rocks. The explosions threw up fragments of reef limestone. Much of the apron of Koloa lavas around the northeast side of the island probably rests on a platform formed below present sea level by wave erosion and the growth of coral reef.

At other times during the Pleistocene the sea stood higher than at present. Some stream terraces may be graded to a stand of the sea as high as 260 feet above present sea level, but no positive evidence for stands higher than 40 feet have been found. Well-preserved shorelines are recognized approximately 40, 25, and 5 feet above sea level. Some of the present coral reef probably was formed when the sea stood about 5 feet higher than now, and has been planed down to its present level by solution and wave erosion.

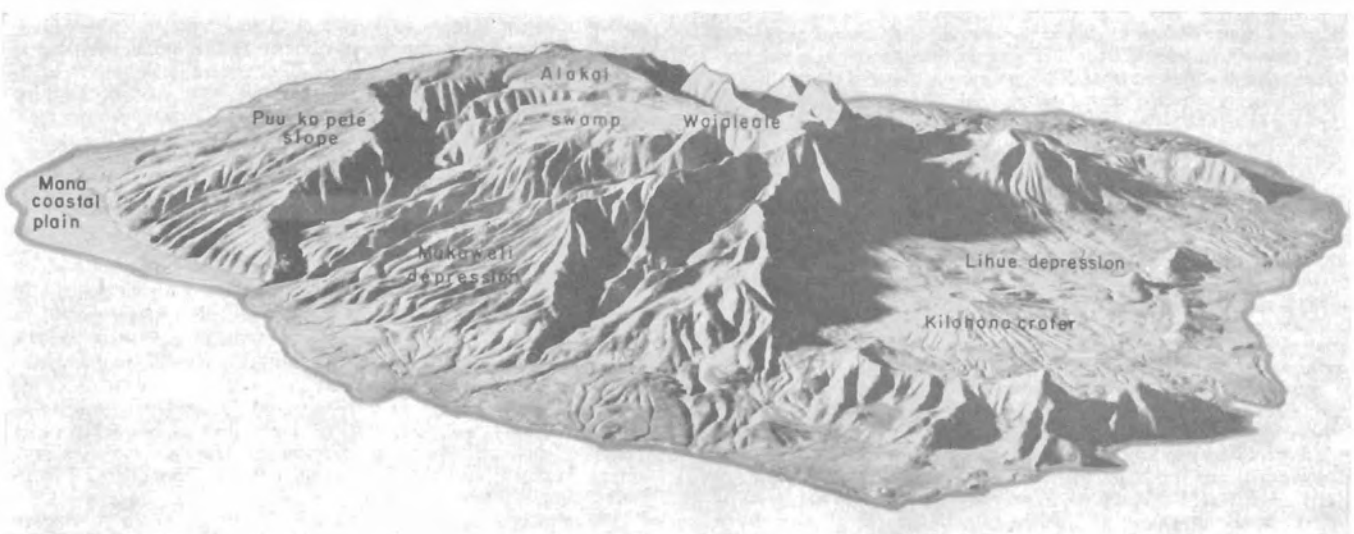

FIGURE 2. Photograph of a topographic model of Kauai, at the University of Hawaii. The model is viewed from the south, and shows at the right the Lihue basin, on the eastern side of the island. In the left center is the Makaweli graben, with Waimea Canyon at its western edge.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR OCTOBER-DECEMBER, 1954

By GORDON A. MACDONALD and JERRY P. EATON

VOLCANOLOGY

October

Kilauea volcano remained in a restless condition during October. About two-thirds of the 70 earthquakes recorded on the seismograph at the Whitney Laboratory of Seismology stemmed from the region of Kilauea caldera and the adjacent portion of the east rift zone. None of these earthquakes was reported felt.

Approximately one-third of the earthquakes recorded during the month originated beneath Mauna Loa. Among these were the four earthquakes reported felt on Hawaii during October. At 8:50 P.M. on October 7 the southern part of the island was shaken by an earthquake from an epicenter about 10 miles north of Naalehu. The largest quake of the month, which occurred near Hookena at 6:26 A.M. on October 11, was felt over most of the island. Two aftershocks, the first at 6:39 A.M. and the second at 6:52 A.M. on October 11, were felt in South Kona.

Tilting of the ground at the northeast rim of Kilauea caldera was approximately normal in direction and amount for this season of the year.

November

Kilauea volcano continued moderately uneasy through November. The seismograph at the Whitney Laboratory of Seismology recorded 72 earthquakes during the month. The more sensitive seismograph at the Uwekahuna station recorded approximately 385 quakes. Both the total number of earthquakes and the amount of energy released in earthquakes, which is represented in a general way by the seismicity index, were approximately three times as great as during periods of volcanic quiet.

Most of the earthquakes that could be located came from points of origin near Kilauea caldera. Two of these, at 11:09 P.M. on November 23 and 11:34 A.M. on November 26, were felt in Hawaii National Park. Two other quakes, felt at Kamuela at 10:56 A.M. on November 19 and 3:02 P.M. on November 20, appear to have come from a depth of about 20 miles beneath the northwest flank of Mauna Kea, 10 miles southeast of Kamuela. On November 21, a small quake came from a shallow focus 3 miles south-southeast of the summit of Mauna Loa.

Tilting of the ground at the northeastern rim of Kilauea caldera was approximately normal during most of the month. However, from November 27 to 30 it was northeastward at a rate decidedly greater than normal. This may have been related to heavy rains rather than to changes of volcanic pressure.

December

Kilauea volcano continued uneasy through the month of December. The seismograph at the Whitney Laboratory recorded 91 earthquakes during the month, more than twice the number normally recorded during times of volcanic quiet. The local seismicity, which is a rough indication of the amount of energy released by the earthquakes, was more than three times as great as that normally experienced during quiet periods. The more sensitive seismograph at the Uwekahuna station recorded 353 earthquakes during December. Most of the quakes originated at or close to Kilauea caldera. Several interesting quakes came from foci approximately 28 miles deep beneath the caldera. Others were of exceedingly shallow origin.

Many earthquakes originated also along the east rift zone of Kilauea volcano both in the vicinity of the Chain of Craters Road in Hawaii National Park, and in east Puna. A large number of small quakes, and a few fairly large ones, came from foci only about 5 miles from the Pahoa seismograph station. The Pahoa seismograph was dismantled by these quakes several times during the month. Two of the quakes, at 11:00 A.M. and 4:02 P.M. on December 14, were felt quite strongly 4.5 miles east-southeast of Pahoa.

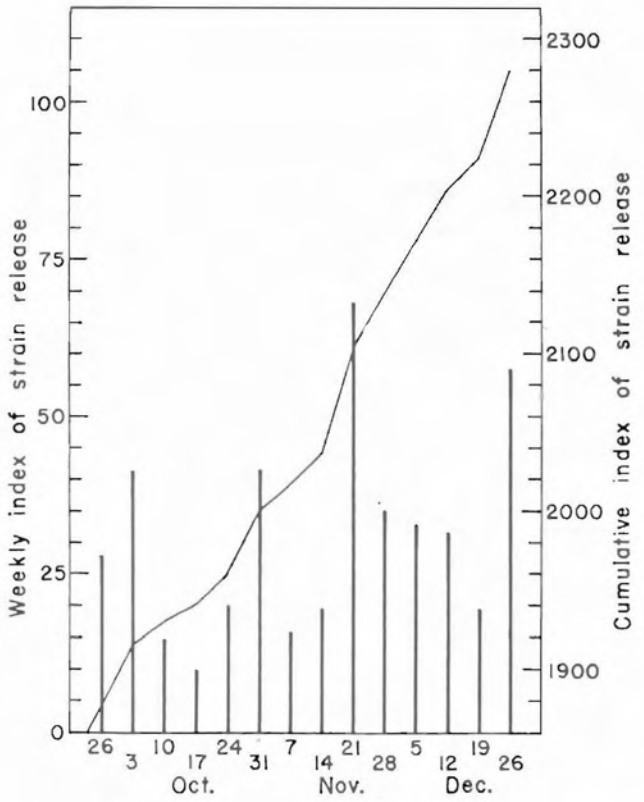

FIGURE 3. Graph showing weekly strain release index (vertical bars) and cumulative strain release index (continuous curve) for the Kilauea caldera region from October through December, 1954. An increase in steepness of rise of the cumulative curve represents an increase in rate of strain release through earthquakes. Earthquakes on the Kilauea rift zone east of Kalalua Crater and on the Hilina and Kaoiki fault zones are not included.

An earthquake at 2:30 P.M. on December 4, felt by some persons from Hilo to Pahala, originated at a depth of about 10 miles beneath the south flank of Kilauea just south of the caldera. A quake felt slightly at Captain Cook and Pahala at 8:59 P.M. on December 5, and another felt in the Volcano district at 10:26 P.M. on December 14, originated beneath the Kilauea caldera area. Another, felt in the Volcano district at 8:49 A.M. on the 28th, appears to have stemmed from the Kaoiki fault, which separates Kilauea and Mauna Loa.

Quakes felt in Kona at 7:15 P.M. on December 6, 6:00 P.M. on December 11, and 9:10 P.M. on December 24, probably came from foci beneath the western flank of Mauna Loa. A quake felt in Kamuela and Hawi at 12:46 P.M. on December 23, originated near Kamuela.

Particularly noteworthy volcanologically, although they were felt by no one, were several periods of almost continuous small earthquakes recorded at the Mauna Loa and Uwekahuna stations. The longest of these periods extended from 2:00 P.M. on December 3 to 9:45 A.M. on December 4. Other shorter periods of this continuous spasmodic tremor, from 10 minutes

to more than one-half hour in duration, occurred at intervals from November 30 to December 5, and on December 21. These quakes appear to have come from a depth of 25 to 30 miles beneath the Kilauea caldera area.

Tilting of the ground surface at the northeastern edge of Kilauea caldera was slightly southwestward during the month. Because the normal tilting at this season is slightly northeastward, this suggests the possibility of a slight decrease in volcanic pressure beneath Kilauea. However, the reversal to southwestward tilting normally takes place in January, and exceptionally heavy rains during December may have had enough effect on the temperature of the rocks near the seismograph station to cause the reversal to southwestward tilting to occur a little earlier than usual, independently of any volcanic effect. Tiltmeters at Uwekahuna and on the caldera floor showed no marked centripetal tilting.

Although Kilauea volcano shows definite signs of uneasiness, there is at the end of December no definite evidence that eruption is imminent. However, conditions somewhat resemble those preceding the eruption on May 31, and there is little or no evidence of any reduction in pressure since before the May eruption. Molten lava may still be standing at high levels in the conduit of the volcano, and it is not unlikely that eruption might again occur with little or no additional forewarning.

SEISMOLOGY

Local Earthquake Data, October-December, 1954

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Total	Local Seismicity*

* For definition of local seismicity see Volcano Letter 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. The number preceding each quake is the serial number for the current year. Only earthquakes classed as feeble or larger are included in the list. Many very feeble quakes, to which serial numbers are assigned also, are omitted. Locations given are epicenters. Except where otherwise indicated, the times given are arrival times at the Uwekahuna station, on the western rim of Kilauea caldera. They are stated in Hawaiian standard time, which is 10 hours behind Greenwich civil time. The intensity rating (Feeble, Moderate, etc.) given is based on the Bosch-Omori seismograph at the Whitney Laboratory of Seismology. If the intensity was greater at one of the other stations, the name of that station and the intensity rating there are given in parentheses after the rating at the Whitney Station.

641. Oct. 1, 14:49:57, feeble. East rift of Kilauea near Kilauea caldera.
648. Oct. 2, 22:22:54, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
649. Oct. 3, 11:09:02, feeble. Near Kilauea caldera at a depth of 20 km.
653. Oct. 5, 12:23:54, very feeble (Mauna Loa, feeble). Felt in Hawaii National Park. Northeast rift of Mauna Loa near Puu Ulaula.
658. Oct. 6, 13:42:46, feeble. Near Kilauea caldera.
661. Oct. 7, 18:43:22, moderate. East rift of Kilauea near Pauahi Crater at a depth of about 10 km.
662. Oct. 7, 20:56:25, moderate (Naalehu, strong). Felt Kalahiki, Capt. Cook, and Hawaii National Park. Southeast flank of Mauna Loa about 20 km. north of Naalehu.
664. Oct. 8, 11:56:39, very feeble (Mauna Loa, feeble). Southeast flank of Mauna Loa near the Mauna Loa seismograph station.
665. Oct. 9, 04:20, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
666. Oct. 11, 01:18:41, feeble. Near Kilauea caldera.
667. Oct. 11, 06:26:33, strong. Felt in Kalahiki, Capt. Cook, Kamuela, Hawaii National Park, Hilo, and Honokohau. West shore of Mauna Loa near Hookena.
677. Oct. 15, 23:16:50, feeble. Near Kilauea caldera.
679. Oct. 16, 06:16:32, not recorded at the Whitney Laboratory (Pahoa, feeble).
684. Oct. 18, 23:07:05, tremor (Kamuela, feeble). West flank of Mauna Kea.
686. Oct. 19, 01:25:41, feeble. Near Kilauea caldera.
698. Oct. 27, 13:30:14, feeble. Near Kilauea caldera.
708. Nov. 4, 04:49:21, moderate. Near Napau Crater on the east rift of Kilauea at a depth of about 10 km.
714. Nov. 6, 16:04:36, moderate. Felt in Hawaii National Park. Near Kilauea caldera at a depth of about 20 km.
723. Nov. 11, 01:53:43, slight. Near Kilauea caldera at a depth of about 15 km.
737. Nov. 17, 04:30:48, feeble. Near Kilauea caldera.
738. Nov. 18, 19:30:39, not recorded at the Whitney Laboratory (Naalehu, feeble). Near the summit of Mauna Loa.
743. Nov. 19, 10:55:34, feeble (Kamuela, strong). Felt in Kamuela. Fifteen km. southeast of Kamuela at a depth of about 35 km.
745. Nov. 20, 15:02:51, very feeble (Mauna Loa, slight). Felt in Kamuela. Ten km. west of Pohakuloa at a depth of about 30 km.
748. Nov. 21, 19:32:55, very feeble (Mauna Loa, feeble). Ten km. southeast of Mokuaweoweo at a depth of 10 km.

753. Nov. 23, 07 : 47 : 54, not recorded at the Whitney Laboratory (Pahoa, moderate). East rift of Kilauea near Pahoa.
756. Nov. 23, 08 : 21 : 25, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
763. Nov. 23, 23 : 08 : 35, slight. Kilauea caldera.
771. Nov. 26, 02 : 20 : 19, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
773. Nov. 26, 02 : 30, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
776. Nov. 26, 05 : 50 : 24, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
779. Nov. 26, 11 : 34 : 05, feeble. Felt in Hawaii National Park. East rift of Kilauea near Kilauea caldera.
786. Nov. 26, 15 : 37 : 59, feeble. Near Kilauea caldera.
789. Nov. 27, 08 : 04 : 58, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
797. Dec. 1, 17 : 27 : 34, feeble. Near Kilauea caldera.
811. Dec. 4, 06 : 35 : 56, not recorded at the Whitney Laboratory (Mauna Loa, feeble). About 45 km. deep in the vicinity of Kilauea caldera.
815. Dec. 4, 08 : 49, not recorded at the Whitney Laboratory (Mauna Loa, feeble). About 45 km. deep in the vicinity of Kilauea caldera.
818. Dec. 4, 14 : 29 : 36, slight. Felt in Hilo and Pahala. Hilina Pali.
833. Dec. 5, 10 : 46 : 42, feeble. East rift of Kilauea near Napau Crater.
837. Dec. 5, 20 : 59 : 15, tremor (Pahoa, feeble; Kona and Mauna Loa, very feeble). Felt in Capt. Cook and Pahala. About 45 km. deep in the vicinity of Kilauea caldera. This is the largest of a swarm of more than 200 small earthquakes originating at about the same place on Dec. 4 and 5.
840. Dec. 6, 08 : 55 : 07, not recorded at the Whitney Laboratory (Kona, feeble). Offshore west of Hualalai.
841. Dec. 6, 19 : 15, not recorded at the Whitney Laboratory (Kona, feeble). Felt in Capt. Cook.
848. Dec. 9, 16 : 02 : 18, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
863. Dec. 14, 11 : 01 : 04, not recorded at the Whitney Laboratory (Pahoa, moderate). East rift of Kilauea near Pahoa.
866. Dec. 14, 17 : 35 : 26, very feeble (Kamuela, feeble). Between Mauna Loa and Hualalai at a depth of about 15 km.
867. Dec. 14, 22 : 25 : 52, moderate. Felt in the Volcano area. Kilauea caldera.
868. Dec. 15, 11 : 21 : 30, feeble. Near Kilauea caldera.
887. Dec. 22, 02 : 50 : 52, not recorded at the Whitney Laboratory (Pahoa, feeble). East rift of Kilauea near Pahoa.
889. Dec. 23, 12 : 45 : 54, not recorded at the Whitney Laboratory (Kamuela, moderate). Felt at Kamuela and Hawi. About 25 km. deep near Kamuela.
899. Dec. 27, 03 : 19 : 30, tremor (Pahoa, feeble). East rift of Kilauea near Pahoa.
904. Dec. 28, 03 : 06 : 36, moderate. Just south of Kilauea caldera. Shallow.
905. Dec. 28, 03 : 31 : 26, slight. Just south of Kilauea caldera. Shallow.
906. Dec. 28, 07 : 26 : 22, slight. Just south of Kilauea caldera. Shallow.
907. Dec. 28, 08 : 49 : 17, feeble (Mauna Loa, slight). Felt in the Volcano area. Kaoiki fault near Halfway House at a depth of 15 km.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs at the Hawaiian Volcano Observatory (19° 25.4′ N. latitude, 155° 17.7′ W. longitude). Beginnings of phases are given in Hawaiian standard time, which is 10 hours slower than Greenwich civil time. Locations of epicenters, magnitudes, and depths of focus are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey.

Oct. 2, eP 16 : 56 : 10.9, 10° S., 166° E. Santa Cruz Islands. Magnitude 6¾–7.
Oct. 3, iP 01 : 26 : 28.2, 60° N., 151° W. Kenai Peninsula, Alaska. Minor damage at Anchorage, Seward, Valdez and Homer. Magnitude 6½–7. Depth about 100 km.
Oct. 3, eP 13 : 33 : 53.4, ½° S., 127° E. Molucca Islands.
Oct. 17, eL 13 : 13, 13½° N., 116½° W. Lower California. Felt in San Diego and Imperial Valley, California. Magnitude 6.
Oct. 20, eP 21 : 02 : 05, 14° N., 90½° W. Guatemala. Magnitude 6½.
Nov. 1, eP 18 : 13 : 42
Nov. 1, eP 22 : 36 : 16.7, 7½° S., 119° E. Sumbawa Island region. Magnitude 6½–6¾.
Nov. 12, eP 02 : 34 : 06, 31½° N., 116° W. Lower California. Felt in San Diego and El Centro, California. Magnitude 6–6½.
Nov. 12, eP 11 : 56 : 15, 15½° S., 174° W. Tonga Islands.
Nov. 15, iP 06 : 36 : 01.5, 19½° N., 145½° E. Marianas Islands. Magnitude 6½–6¾. Depth 200 km.
Nov. 18, eP 20 : 05 : 49.1, 41° N., 131½° E. Sea of Japan. Magnitude 6½–6¾. Depth about 600 km.
Nov. 25, iP 01 : 23 : 12.9, 40½° N., 126° W. Off Cape Mendocino, California.
eT 01 : 55 : 40, Felt in Northern California. Magnitude 6¼–6½.
Nov. 25, iP 11 : 41 : 20.5, 21½° S., 179° E. Fiji Islands region. Magnitude 6½. Depth about 650 km.
Dec. 16, iP 01 : 14 : 32.0, 39½° N., 118° W. Near Fallon, Nevada. Moderate property damage. Magnitude 6¾–7¼.
Dec. 21, iP 10 : 03 : 14.7, 41° N., 124° W. Humboldt County, California.
eT 10 : 38 : 26, Several injured and extensive property damage. Magnitude 6¼–6¾.
Dec. 26, eP 19 : 40 : 15.2, 19° S., 178° W. Fiji Islands. Depth about 500 km.
Dec. 26, eP 20 : 59 : 26.2, 4½° S., 130° E. Banda Sea.
Dec. 27, eP 15 : 10 : 28.8, 5° S., 152½° E. New Britain region.
Dec. 30, eP 01 : 39 : 10.1, 53° N., 168° W. Fox Islands, Aleutian Islands. Felt on Unalaska. Magnitude 6½–6¾. Depth about 60 km.

VOLCANO NOTES AND NEWS

VOLCANIC ACTIVITY IN JAPAN

By Helen L. Foster

(From personal observations and data supplied by Central Meteorological Observatory, Tokyo.)

Mihara-yama, O-shima.—Mihara-yama, on O-shima, has been quiescent since February, 1954, although steam and other gases have been emitted continuously from various parts of the crater in varying amounts. At times steam and gas emission has been quite heavy with billowing clouds rising 100 to 300 meters into the air.

Volcanic tremors were recorded at intervals in April, June, and on September 25. At 4:25 P.M. on September 24 an earthquake originated beneath O-shima which, on the island, had an intensity of II on the scale of VII used by Central Meteorological Observatory, Japan.

On November 2, 1954 at 5:45 A.M. volcanic tremors were recorded for periods of about 12 minutes at 30-minute intervals. On November 6 and 7 when the crater was visited volcanic tremors were continuing, and steam and gas emission had increased considerably. At times, steam clouds rose to a height of 500 meters. Ground temperatures in the crater area seemed higher than in previous months. Sublimates were being deposited in increased amounts in many places in the crater. Numerous new fissures, particularly in the remnants of the 1951 cinder cone, were observed. Some old fissures had opened wider and were emitting steam. A small cone formed in January, 1954, was considerably broken, partly by fissures which opened in August and partly by new collapses.

On November 9 the volcanic tremors again ceased and steam and gas emission decreased.

1954 Eruptions of Asama-yama.—The 1953 and January and February, 1954, activity of Asama-yama was reported in Nos. 522 and 523 of the *Volcano Letter*. Since then small explosions have continued. The Karuizawa Weather Station recorded about 50 small explosions in January, about 70 in February, 31 in March, 17 in April, 19 in May, 4 in June, 6 in the latter part of July, 4 in August, and 2 on September 6 including quite a large explosion at 5:58 P.M.

After an inactive period in September and October a small explosion occurred at 1:45 P.M. on November 2 and another at 1:50 P.M. on November 4. A small amount of ash was ejected on November 4.

Volcanic ash has been ejected during many of the explosions, but no serious damage has been reported. All of the explosions have been comparatively small.

Submarine Eruption of Myojin-sho.—Myojin-sho is a rock bank in the Beyoneisu-retsugan (Bayonnaise Rocks), about 50 kilometers south of Aoga-shima, Izu Islands. It was the site of violent volcanic eruptions in 1952 and 1953 and became especially well known because of the loss of the Kaiyo-maru, a patrol ship of the Japanese Hydrographic Office, in an eruption on September 24, 1952. (See *Volcano Letter* No. 518.)

Renewed eruption at Myojin-sho has been reported by a fishing boat, the Eikichi-maru. Members of the crew witnessed two explosions between 2:00 and 3:00 P.M. on November 4, 1954. The eruptions were not recorded on the seismograph or wave-recorded at Aoga-shima and no steam cloud was seen from there.

The Tori-shima Weather Station, about 160 kilometers south of Myojin-sho, reported several ocean swells during a 3-hour period on November 5 which might have been caused by eruptions at Myojin-sho.

CATALOGUE OF PHILIPPINE VOLCANOES

Late in 1953 appeared Part II of the *Catalogue of the active volcanoes of the world, including solfatara fields. Part II, Philippine Islands and Cochin China*, by M. Neumann van Padang, closely follows the plan of Part I. (See *Volcano Letter* No. 516.) In 49 pages, it lists and briefly describes 41 volcanoes and solfatara fields in the Philippine Archipelago, and 2 in Cochin China. Of the Philippine volcanoes, 16 have had historic activity, 12 are in a solfataric and fumarolic state, and 3 are solfatara and fumarole fields not belonging to any well-defined volcano. Both the Cochin China volcanoes have been active in historic time. Like Part I, this new section of the Catalogue will be of great value as a reference work.

The Catalogue is being published by the International Volcanological Association, part of the cost of printing of Parts I and II being borne by a grant-in-aid from UNESCO. A limited number of copies of Part II are available from Professor Francesco Signore, General Secretary of the Association, Via Tasso 199, Napoli, Italy, for $3.60 (U.S.).

ERUPTION IN THE GALAPAGOS ISLANDS

Alcedo Volcano, in the central part of Isabela (Albermarle) Island, erupted on November 9. According to Adrian Richards, of the Scripps Institution of Oceanography, fume rose from the crater and from numerous fissures on the east flank of the cone. The eruptive activity of Alcedo on the first day was reported to be less intense than that of Sierra Negra (Volcan Grande), on the south end of Isabela Island, during 1953 (see *Volcano Letter* No. 525). Later (exact date unknown) a small flow of lava was reported high on the north-northwest side of the cone, and shimmering heat waves were observed above the crater during daylight and a bright glow from the crater at night.

Richards states that the eruption of Alcedo was preceded in late 1953 or early 1954 by upheaval of the shore in the vicinity of Bahia Urvina and for three miles southward. The upheaval raised the reef surface as much as 15 feet, and caused the shoreline to migrate about 2,400 feet seaward. The raised area is on the western flank of the Alcedo cone.

This appears to be the first recorded eruption of Alcedo volcano, although eruptions elsewhere on the island occurred in 1797, 1800, 1813, and 1847. An eruption in the northern part of Isabela Island in April, 1925, was recorded by William Beebe; and eruptions occurred at Wolf volcano in 1948 and at Sierra Negra volcano in 1953. The latter two eruptions, in the northern and southern parts of Isabela Island, respectively, are described by Richards in *Volcano Letter* No. 525.

FRENCH BIBLIOGRAPHICAL DIGEST

Just received is the third issue of the second series of the French Bibliographical Digest, devoted to Geology. This series is intended to make French scientific work better known in the United States, and numbers are sent free of charge upon request. Correspondents are asked to specify the subjects in which they are interested. Requests should be addressed to the Cultural Division of the French Embassy, 972 Fifth Avenue, New York 21, N. Y. The present number of the Digest contains 102 pages, and lists approximately 500 titles, most of them accompanied by brief abstracts. One of the several sections deals with volcanology and paleovolcanology. Another volume in preparation will include papers on geophysics.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

THE VOLCANO LETTER

No. 527 **U. S. Geological Survey** **January–March, 1955**

PUBLISHED BY THE UNIVERSITY OF HAWAII

RECENT VOLCANIC ACTIVITY IN CENTRAL AMERICA

By A. R. McBIRNEY

Although the years 1952, 1953, and 1954 have seen little primary activity in the Central American volcanoes, there have been several interesting events that merit recording. In general, activity through this period has been characterized by low temperature steam and gas emissions often of violent nature, and little if any juvenile material has been erupted. The locations of the volcanoes are shown in Figure 1.

Starting in the northernmost extremity of the Central American volcanic chain, in Guatemala conditions have remained more or less unchanged during the last five years. Tacaná, which erupted in 1950, is quiet and shows not even fumarolic activity. Santa Maria continues to give off a respectable amount of steam and gas, but there is no sign of significant growth in the protrusive spine. Fuego has been quiet, and aside from a steady mild fuming around the circumference of the summit crater, has given off nothing of note. Fumaroles are reported active on Zuñil, Pacaya, Atitlán, and Acatenango.

In El Salvador, Izalco has been the only volcano to show activity. During 1953 and early 1954 it erupted with remarkable regularity, blowing off puffs of steam and dust at intervals of 20 to 90 minutes, but this declined around the middle of 1954 and finally stopped. Early in 1955 (probably in February) Izalco again became active, with strong explosive discharges of gas and incandescent bombs every 5 to 10 minutes. Other recently active volcanoes in El Salvador have shown only fumarolic activity.

Nicaragua still has the greatest concentration of active vents along the chain. Old Telica continues to send up a steady cloud of gases of considerable volume, although no ash or lava has been given off for several years. Cerro Negro has been quiet since the spectacular outburst of 1950, but when I visited it last around the end of August, 1954, I noticed several active fumarolic vents on the summit and along a set of parallel north-south lines on the north side of the cone. Las Pilas has developed into a vent of major importance. It opened on the 23rd of October, 1952, with a fissure approximately a kilometer in length running north-south across the top and down both flanks. Steam, gas, and lithic dust from wall rocks were blown out along the entire length of the fissure, but soon the activity became centralized on the south side of the peak. Apart from a short period of quiet between December, 1952, and February, 1953, the volume of gases has continued to increase and the centralized vent has been widened. Following a period of very heavy rainfall, it erupted a considerable amount of ash (accessory wall rock material) for three days starting the 31st of October, 1954, and blanketed the town of Leon, 23 kilometers to the west, with a thin layer of dust.

Momotombo continues to steam quietly, as it has since the last important eruption of cinders and lava in 1905. The Santiago vent of Masaya, which probably has given off more steam and gas during the last eight years than any other volcano of the world, has increased its rate of gas emission. I made a descent into the 680-foot deep crater during the first week of October, 1954, and found that the concentric faulting around the floor close to the vertical walls has reached a maximum downthrow of

16 feet. A new collapse appears to be imminent. The activity of the volcano Concepcion on the island of Ometepe resembles that of Izalco in El Salvador. It sends up large puffs of steam and dust at intervals varying from seven minutes to several hours, and for nearly three years its spectacular performance has delighted travelers on the air plane flights south of Managua.

In Costa Rica, Poás has been the only volcano to show much activity. The present cycle started in February of 1953 when eruptions under the crater lake finally vaporized the water and began, in March of that year, to hurl incandescent bombs in Strombolian fashion nearly a thousand feet into the air. When I visited it in September, 1953, the strength of the steam blast was very impressive, and the roar from the vents could be heard for several miles down the mountain side. It began building a small cinder cone in the bottom of the crater, and Fred M. Bullard, who visited it in August of 1954, told me that the cone had been well formed around a single vent, which still gives off large quantities of steam. The remaining active volcanoes in Costa Rica—Rincon de la Vieja, Irazú, and Turrialba, have not shown more than fumarolic activity.

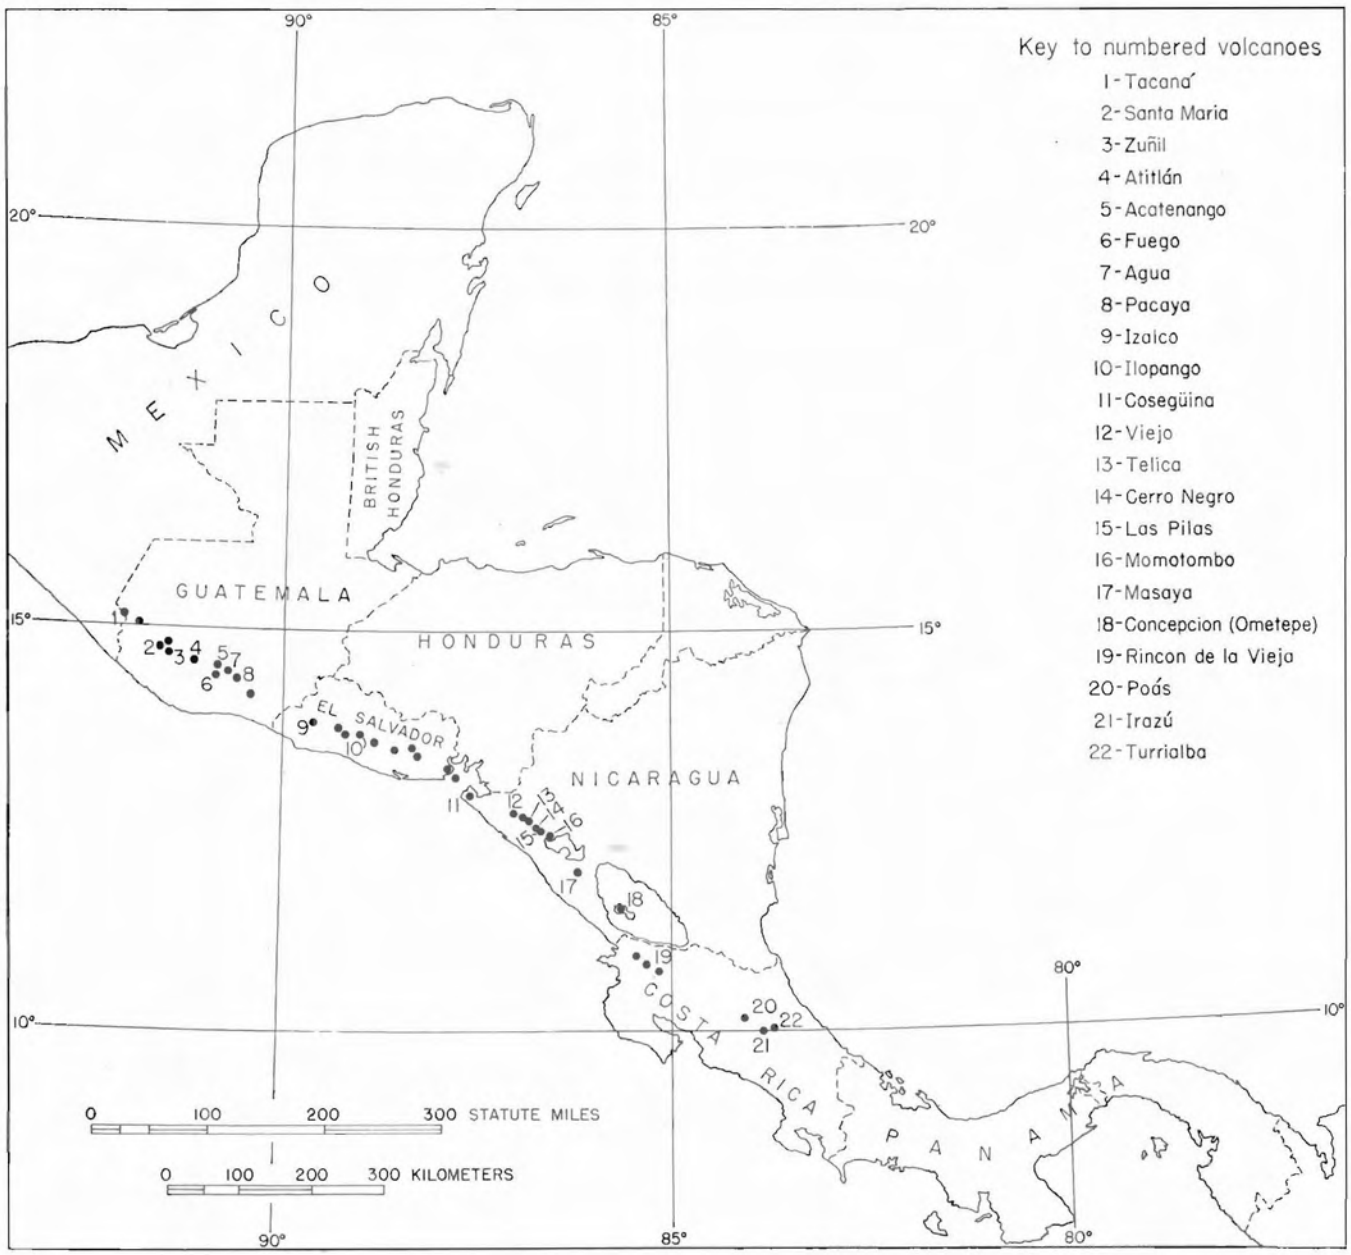

FIGURE 1. Map of Central America showing the location of volcanoes mentioned in the text. Black dots indicate volcanoes that have been active in historic time.

A NEW DATE IN KILAUEA'S HISTORY

By HOWARD A. POWERS

An old fern forest growing on the northeast rim of Kilauea was killed and buried under a layer of hot pumice and Pele's hair about 2,500 years ago. Much charcoal from this old forest has been found in excavations in the vicinity of the Volcano House since the original Hawaiian Volcano Observatory buildings were erected in 1912, and the date of the death of the forest has been found by measuring the amount of carbon 14 isotope in the charcoal.

Carbon 14 is a radioactive form of carbon that is present in small quantities compared to the inert form, carbon 12. The proportion of these two sorts of carbon remains the same so long as the plant or animal is living. At the death of the organism, the carbon 14 begins to break down to carbon 12 at a known rate, and if the amount of radioactive carbon 14 in a sample of dead carbon is measured, the number of years that the carbon has been dead can be determined with reasonable accuracy. This important detective tool was discovered and made useful by W. F. Libbey of the University of Chicago, and has been employed to determine the age of many events in both human and geological history that occurred between about 25,000 B.C. and the beginning of written history.

This carbon date at Kilauea makes it possible to extend backward the history of volcanic activity with considerable certainty. The high spots probably were about as follows:

Kilauea was exceedingly active several thousand years before the birth of Christ and overflowed its crater frequently, building the broad dome of the volcano. Activity slowed down and a caldera formed. (The Volcano House is on the rim of that caldera.) A steam blast eruption, perhaps similar to the one of 1924, plastered the rim with a layer of mud and boulders, on which later a fern forest grew while activity in the crater remained moderately quiet.

About 500 B.C., lava returned to form a lava lake with fountaining that probably rarely has been equalled since. The Pele's hair and pumice fell over the countryside forming a deposit several inches thick a mile away from the crater on the windward rim, killing the forest. Downwind, in the Kau desert, pumice and glassy ash piled up more than 30 feet thick. Several small overflows of the crater rim took place.

At the time of Hawaiian occupation overflows were continuing, according to information given by Hawaiians to Ellis in 1823. He said: ". . . it had been burning from time immemorial . . . and had overflowed some part of the (adjacent) country during the reign of every king that had governed Hawaii." (Ellis, W. 1917. *A narrative of a tour through Hawaii.* P. 184. Honolulu.)

A change of activity from overflow to collapse with many explosive eruptions is recorded in the rock record and also by Hawaiian verbal history. Ellis goes on to say (p. 184): ". . . for many kings' reigns past, it had kept below the level of the surrounding plain, continually extending its surface and increasing its depth, and occasionally throwing up, with violent explosion, huge rocks or red-hot stones." In the rock section, this change in nature of activity is well marked, and it is quite possible that datable charcoal may be found also among the buried remains of the forest that was killed by these later explosive eruptions.

This period of collapse and explosive activity probably culminated in the explosion of 1790, vividly described by the Hawaiians. Since that time, Kilauea has changed again to a stage of voluminous lava eruption that has filled the greater crater up to a point where overflows to the desert again are possible.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JANUARY–MARCH, 1955

By GORDON A. MACDONALD and JERRY P. EATON

VOLCANOLOGY

January

Kilauea volcano continued markedly uneasy through most of January. The Bosch-Omori seismograph at the Whitney Laboratory of Seismology, on the northeastern rim of Kilauea caldera, recorded 94 earthquakes during the month. This is nearly the same number as recorded in December, 1954, and between two and three times the number normally recorded during times of volcanic quiet. The local seismicity was more than four times as great as that normally experienced during quiet periods. The more sensitive Sprengnether seismograph at the Uwekahuna station recorded 316 earthquakes during January, a few less than during December. Most of the quakes originated in or very close to the Kilauea caldera region, probably on the east rift zone or the zone of faults that extends westward from it 2 to 4 miles south of the caldera.

Even greater restlessness was displayed by the Pahoa station, where 140 quakes were recorded on the Loucks-Omori seismo-

graph as compared to 127 during December. Most of the quakes originated on the east rift zone of Kilauea within 6 miles of the station.

Tilting of the ground surface at the northeast rim of Kilauea caldera was south-southwestward at a rate normal for that season of the year.

February

The uneasiness of the east rift zone of Kilauea volcano increased throughout February. From February 1 to 23, the Pahoa seismograph recorded an average of 6 earthquakes a day, excluding swarms on February 12 and 17. On February 12 a swarm of 50 small quakes was recorded, and on the 17th a swarm of 173. On February 24 the instrument recorded 130 quakes. On subsequent days the number increased rapidly to 350 on the 25th, 600 on the 26th, and 700 on the 27th. The last three numbers are estimates because the seismograph was dismantled for several short periods. Most of the earthquakes originated within 10 miles of the station.

The seismic uneasiness of the east rift zone began in November, 1954, and continued with general slight increase through December, January, and February. It was accompanied by similar uneasiness in the caldera region. This uneasiness was pointed out in press releases in November, December, January, and early February, and in *Volcano Letter* 526 (pp. 4-5). Early on the morning of February 28, it was culminated by eruption of the volcano on the east rift near the southern base of Puu Honuaula, 6 miles west-southwest of Cape Kumukahi (East Cape). The eruption will be described in detail in a later issue of the *Volcano Letter*.

Throughout most of February tilting of the ground surface at the northeastern rim of Kilauea caldera was south-southwestward at a rate approximately normal for that season of the year. Beginning about February 20, however, the rate of southwestward tilting increased markedly, indicating a decrease of volcanic pressure beneath the caldera region.

Neither tilting nor earthquakes gave any indication of uneasiness of Mauna Loa associated with that of Kilauea.

March

The lava extrusion that began near Puu Honuaula on the morning of February 28 ceased abruptly just after noon of March 1. It was followed during the next few hours by voluminous steam liberation accompanied by small phreatic explosions.

On March 2, cracks started to open in the ground farther northeast, in the area between Puu Honuaula and Kapoho. The cracks closely followed the zone of cracking of the 1924 disturbance. Sharp earthquakes of very shallow origin accompanied the formation of small fault scarps. Early on the afternoon of March 2 lava broke out along a fissure near the south base of Kaholua o Kahawali hill, 4.5 miles west-southwest of Cape Kumukahi. During that afternoon and night, and through March 3, the eruptive fissures spread both southwestward and northeastward, and on the evening of March 3 lava fountains broke out in the outskirts of Kapoho village. The evacuation of Kapoho had already been recommended on March 1, and by afternoon of March 3 it was essentially completed.

Activity in the zone between Kapoho and Puu Honuaula continued strong until March 6, but by evening of that day lava eruption had ceased. On March 7 earthquakes again became very numerous on the Pahoa seismograms, with a total of 326 recorded in 24 hours. On March 8 the number increased to 596, and on March 9 to 1,392. Most of these quakes originated along the rift zone from 8 to 16 miles west-southwest of Cape Kumukahi, and it became apparent that eruption probably would occur somewhere in that region. Early on the morning of March 12 cracks appeared in the Kalapana road 3 to 3.5 miles south of Pahoa, and in the late afternoon fume, followed by lava fountains, appeared near the south base of Puu Kaliu. The next morning lava broke out in the vicinity of the Kalapana road. On March 14 a large lava fountain developed between Puu Kaliu and the Kalapana road, and on March 16 the lava flow reached the ocean 1.5 miles southwest of Opihikao. At 2 P.M. on March 16, a lava outbreak occurred east of the old Iilewa Crater, about 3,000 feet southwest of the Kalapana road outbreaks. On March 19 another outbreak occurred about 1.3 miles farther southwest. The vent near Iilewa Crater continued active until March 27, and on March 26 another vent became active about a quarter of a mile farther southwest. Flows from this new vent reached the ocean on March 28 and April 2. At the end of March the lava fountains at the vent about 0.6 mile south of old Iilewa Crater were still very active.

South-southeastward tilting at the northeastern rim of Kilauea caldera continued from late February into March, and on March 7 the rate of tilting became very much accelerated. Throughout the remainder of the month the ground tilting was rapid, indicating a sinking of the floor of Kilauea caldera. Apparently there occurred a withdrawal of magma from beneath the caldera to compensate for the extrusion of lava 20 miles to the eastward. The tilting at the Whitney Laboratory totaled 34 seconds of arc between February 20 and April 10, and during the same period tilting of 30 seconds of arc occurred at the Uwekahuna station. Using the azimuths of tilting determined at those two stations, the point of maximum subsidence on the caldera floor is found to lie approximately 4,700 feet N. 77° E. of the center of Halemaumau, and assuming uniform tilting from the stations to that point the amount of sinking is calculated to have been approximately 1.2 feet. The point of maximum subsidence is close to that indicated by tilting at the same two stations during the subsidence of December 1950, and is in the same general region as the zone of maximum subsidence in 1924 as determined by R. M. Wilson by differential leveling.

The sinking was accompanied by very numerous earthquakes. During the week starting March 20, the Bosch-Omori seismograph at the Whitney Laboratory recorded approximately 2,667 earthquakes, and during the following week approximately 778. An even greater number was recorded on the more sensitive seismographs. At 4 P.M. on March 27, an earthquake of about intensity 5 broke water lines and cracked houses in the residence area of Hawaii National Park, and opened cracks across the Mamalahoa Highway about 1,000 feet east of Park Headquarters.

Assuming the cone of depression to have had the same area as that of 1924, as delineated by Wilson, and using the ratio of the maximum subsidence to that of 1924 in the same region, the volume of the subsidence has been calculated to be of the order of 220 million cubic yards. This is of the same order of magnitude as the volume of lava extruded in east Puna during the eruption.

Over the rest of the island seismic activity was low during March. Mauna Loa continued to show no signs of uneasiness.

SEISMOLOGY

Local Earthquake Data, January–March, 1955

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Total	Local Seismicity*
Jan. 2	10	8	0	1	0	0	19	8.5
9	0	5	0	0	0	0	5	2.5
16	7	29	5	3	0	0	44	27.25
23	4	11	2	1	0	0	18	10.5
30	9	8	0	0	0	0	17	6.25
Feb. 6	13	9	1	0	0	0	23	8.75
13	14	6	0	0	0	0	20	6.5
20	53	13	1	4	0	0	71	28.75
27	128	0	1	0	0	2	131	41.0
Mar. 6	15	8	4	2	1	2	31	26.75
13	38	42	6	1	5	0	92	53.5
20	**2600±	55	5	5	2	0	2667±	698.5±
27	** 700±	69	6	0	1	2	778±	220.5±

* For definition of local seismicity see *Volcano Letter* 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor ("harmonic tremor") is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

** Number of tremors partly estimated.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

Week Beginning	Whitney Station (Northeast rim)		Uwekahuna Station (West rim)

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. Except for smaller earthquakes of special interest, only earthquakes classed as slight or larger were included in the list. The intensity ratings assigned are based on the Bosch-Omori seismograph at the Whitney Laboratory. This intensity scale has been extended empirically to permit its use with the Loucks-Omori and Sprengnether seismographs. The entries for a given earthquake are: date, time of arrival at the nearest station (Hawaiian standard time), intensity at the nearest station, name of the nearest station, epicenter, and general remarks.

A large fraction of the earthquakes occurring on the east rift of Kilauea near Pahoa were felt in the epicentral area. The number felt was so large that no attempt was made to keep an accurate record of those felt. It may be assumed that all of the quakes from the Pahoa area which are listed below either were felt or could have been felt by a favorably situated observer.

Jan. 5, 00:16:43, slight at Pahoa. East rift of Kilauea near Pahoa.
Jan. 6, 15:44:07, slight at Uwekahuna. East rift of Kilauea near Napau Crater.
Jan. 6, 18:33:55, slight at Pahoa. East rift of Kilauea near Heiheiahulu at a depth of about 5 km.
Jan. 8, 17:33:33, slight at Pahoa. East rift of Kilauea southeast of Pahoa.
Jan. 8, 18:20:03, Ditto
Jan. 11, 11:03:27, Ditto
Jan. 17, 03:49:16, slight at Mauna Loa. Kaoiki fault near Halfway House at a depth of about 15 km.
Jan. 18, 13:33:55, slight at Kamuela. Near Kamuela at a depth of about 20 km.
Jan. 21, 02:54:09, slight at Uwekahuna. East rift of Kilauea near Kalalua Crater.
Jan. 21, 07:56:01, slight at Uwekahuna. East rift of Kilauea near Napau Crater.
Jan. 21, 22:00:41, slight at Uwekahuna. East rift of Kilauea near Kalalua Crater.
Jan. 22, 09:01:02, moderate at Pahoa. East rift of Kilauea southeast of Pahoa.
Jan. 25, 05:08:10, slight at Pahoa. East rift of Kilauea near Pahoa.
Jan. 27, 06:18:43, slight at Uwekahuna. East rift of Kilauea near Napau Crater at a depth of about 5 km.
Feb. 21, 19:17:45, slight at Uwekahuna. East of Puu Kapukapu at a depth of about 5 km. Felt in the Volcano area.
Feb. 23, 13:58:49, slight at Uwekahuna (slight at Mauna Loa and Pahoa, very feeble at Hilo, Naalehu, and Kamuela). East rift of Kilauea near Makaopuhi Crater at a depth of about 25 km. Felt in Hawaii National Park, the Volcano area, and Pepeekeo.
Feb. 24, 15:06:17, slight at Pahoa. East rift of Kilauea southeast of Pahoa.
Feb. 24, 18:46:22, moderate at Pahoa. East rift of Kilauea near Puu Honuaula at a depth of about 5 km.
Feb. 24, 21:23:28, slight at Pahoa. East rift of Kilauea southeast of Pahoa.
Feb. 25, 01:34:43, Ditto
Feb. 25, 05:50:34, Ditto
Feb. 25, 06:11:25, moderate at Pahoa. East rift of Kilauea southeast of Pahoa.
Feb. 25, 13:19:21, slight at Pahoa. East rift of Kilauea near Pahoa.
Feb. 25, 15:19:56, slight at Pahoa. East rift of Kilauea near Pahoa.
Feb. 25, 22:01:50, moderate at Pahoa. East rift of Kilauea near Pahoa.
Feb. 26, 07:30:43, slight at Pahoa. East rift of Kilauea near Pahoa.
Feb. 26, 08:47, Ditto
Feb. 26, 10:37:13, slight at Uwekahuna (Pahoa seismograph out of operation. Estimated moderate at Pahoa). East rift of Kilauea near Puu Kepaka.
Feb. 26, 12:22:05, slight at Pahoa. East rift of Kilauea near Pahoa.
Feb. 26, 15:40:18, Ditto

Mar. 1, 09:06:43, Ditto
Mar. 1, 14:21:30, strong at Pahoa. East rift of Kilauea near Kalalua Crater. Felt in the Volcano area.
Mar. 4, 14:32, slight at Uwekahuna. East rift of Kilauea near Kilauea caldera.
Mar. 5, At 12:30 a series of earthquakes which was recorded at all stations on the islands of Hawaii and Maui began. These earthquakes originated at a shallow depth on the east rift of Kilauea between Napau Crater and Kalalua Crater. For the first hour and a half the seismograms at Uwekahuna and the Whitney Laboratory were so disturbed by spasmodic tremor that arrival times of individual earthquakes could not be determined. During this interval, arrival times and intensities recorded at the Pahoa station will be given although Uwekahuna might be a few km. closer to the epicenters of some of the earthquakes.
Mar. 5, 12:39:08, strong at Pahoa. Four km. east of Napau Crater. Felt in Hilo.
Mar. 5, 12:46:53, moderate at Pahoa. Near Kalalua Crater.
Mar. 5, 12:48:37, Ditto
Mar. 5, 12:53:21, slight at Pahoa. Near Kalalua Crater.
Mar. 5, 12:53:44, strong at Pahoa. Near Kalalua Crater.
Mar. 5, 12:54:43, moderate at Pahoa. Near Kalalua Crater.
Mar. 5, 12:58:26, strong at Pahoa. Four km. west of Kalalua Crater. Largest earthquake of series.
Mar. 5, 14:13:51, moderate at Pahoa. Near Kalalua Crater.
Mar. 5, 14:22:08, strong at Pahoa. Near Kalalua Crater.
Mar. 5, 14:56:57, slight at Uwekahuna. Near Kalalua Crater.
Mar. 5, 15:19:04, Ditto
Mar. 5, 15:29:40, slight at Uwekahuna. Near Kalalua Crater.

Mar. 25, 20 : 17 : 00, very feeble at Mauna Loa. About 10 km. north of Kilauea caldera at a depth of about 40 km. This earthquake and the next are representative of a large number of small earthquakes originating in this region on March 25, March 26, and March 27.
Mar. 26, 06 : 34 : 08, very feeble at Mauna Loa. About 10 km. north of Kilauea caldera at a depth of about 50 km.
Mar. 27, 09 : 23 : 43, strong at the Whitney Laboratory. Kilauea caldera. Felt in Hawaii National Park.
Mar. 27, 16 : 02 : 20, strong at the Whitney Laboratory. Kilauea caldera. Felt strongly in Hawaii National Park. Water lines broken and roads cracked in Hawaii National Park.
Mar. 28, 20 : 39 : 00, slight at Uwekahuna. Kilauea caldera.
Mar. 30, 13 : 41 : 31, moderate at Naalehu. Southwest rift of Mauna Loa about 15 km. northeast of Puu Keokeo.
Mar. 30, 16 : 57 : 23, Moderate at the Whitney Laboratory. Kilauea caldera.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs at the Hawaiian Volcano Observatory (19° 25.4′ N. latitude, 155° 17.7′ W. longitude). Beginnings of phases are given in Greenwich civil time, which is 10 hours faster than Hawaiian standard time. Locations of epicenters, magnitudes, and depths of focus are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey.

Jan. 5, eP 01 : 02 : 19.6, 50° S., 162½° E. Off coast of South Island, New Zealand. Magnitude 6½–6¾.
Jan. 5, eP 17 : 57 : 51.0, 16° S., 167½° E. New Hebrides Islands. Magnitude 6¾.
Jan. 5, eP 23 : 51 : 13.5, 16° S., 167½° E. New Hebrides Islands. Damage at Malekula. Magnitude 6¾–7.
Jan. 8, eP 07 : 42 : 29.3, 11½° S., 166½° E. Santa Cruz Islands. Depth about 60 km. Magnitude 6¾–7.
Jan. 13, eP 02 : 10 : 37.5, 53° N., 167½° W. Fox Islands, Aleutian Islands. Felt on Unalaska.
eT 03 : 00 : 44,
Jan. 13, eP 02 : 42 : 38.8, Fox Islands aftershock.
eT 03 : 34 : 02,
Jan. 31, eP 16 : 11 : 05.7, 46½° N., 153° E. Kurile Islands. Magnitude 6¼–6½.
Feb. 27, iP 20 : 52 : 30.6, 27½° S., 176° W. Kermadec Islands region. Magnitude 7¾–8.
Mar. 14, iP 13 : 19 : 01.8, 52½° N., 173½° W. Andreanof Islands, Aleutian Islands. Magnitude 6¾–7. Depth about 100 km.
Mar. 18, eP 00 : 15 : 28.4, 54½° N., 161° E. Near east coast of Kamchatka.
Mar. 31, eP 18 : 29 : 08.2, 8° N., 124° E. Near northwest coast of Mindanao, P. I. About 425 killed. Magnitude 7½.
Mar. 31, iP 21 : 04 : 54.7, 8° N., 124½° E. Mindanao aftershock. Felt.

VOLCANO NOTES AND NEWS

ERUPTION OF STROMBOLI

Following a series of strong earthquakes in its vicinity, Stromboli volcano erupted in late December, 1954. On December 29, United Press reported a stream of lava entering the sea near the village of Ginostra, and ash falls over other parts of the island. The earthquakes caused a large amount of damage on the island of Salina, 20 miles from Stromboli. It was stated that no house was left habitable on Salina Island, and many of the inhabitants were evacuated. Etna also was reported fuming heavily.

ASSOCIATION OF PHYSICAL VOLCANOLOGY OF JAPAN

Letters from Akira Suwa, Chief of the Volcanological Subsection of the Central Meteorological Observatory, and Prof. Sakuma of Hokkaido University announce the formation of an Association of Physical Volcanology. At the end of December the Association had about 240 members. Chairman of the committee for the Association is Prof. T. Minakami, of the Earthquake Research Institute of Tokyo University.

SUBMARINE ERUPTION IN THE CELEBES SEA

On February 13 the crew of a Japanese fishing boat reported a submarine eruption south of the Philippine Islands. Black "smoke," probably an ash-laden cloud of fume and steam, at first rose from the sea to a height of 200 to 300 meters. Five minutes later the cloud became white, probably largely steam. The cloud rose from an area of about 1,800 square meters of sea surface.

According to Mr. Arturo Alcaraz, Geologist in Charge, Philippine Commission on Volcanology, the eruption probably took place at or near a known submarine volcano that lies about 130 kilometers west-northwest of Great Sangihe Island in the northern part of the Celebes Archipelago, about 250 kilometers southwest of the Davao Peninsula on the island of Mindanao, Philippines. (Lat. 3° 58′ N., Long. 124° 10′ E.) The volcano, which last erupted early in 1922, is unnamed. It bears the serial number 6,7-5 in M. Neumann van Padang's *Catalogue of the Active Volcanoes of Indonesia.*

DISTRIBUTION OF AREAS OF PNEUMATOLYTIC DEPOSITION ON THE FLOOR OF KILAUEA CALDERA

By GORDON A. MACDONALD

Gases rising through innumerable fissures in the lavas that floor Kilauea caldera have formed white deposits on the surface of the lava. These deposits are not distributed uniformly over the caldera floor, but are concentrated in narrow bands and irregular patches. For the most part, the active steam vents are confined to the same areas. With certain qualities of lighting, the areas of deposition show up clearly to the eye in the field, from the caldera rim, and in aerial photographs. I commenced the mapping of these areas by plane table in 1951, but the mapping was interrupted by the heavy earthquake of August 21, in Kona. The mapping was completed in January 1955, by use of a photo-mosaic compiled by E. K. Field, former chief ranger of Hawaii National Park, from aerial photographs taken in 1944. Thanks are extended to Elroy Bohlin, acting chief ranger, for permission to use the mosaic.

Gases issuing at the two solfataras, known respectively as Sulphur Bank and Southeast Sulphur Bank (Fig. 1), contain sulphur dioxide and carbon dioxide. In those two areas of acid gas release the rocks are much altered to iron oxides and clay minerals, and leached to form pseudomorphs of opaline silica (Macdonald, G. A. 1944. Solfataric alteration of rocks at Kilauea volcano. *Amer. Jour. Sci.* 242: 496-505). For the most part, however, the fumarole gases in and near Kilauea caldera consist largely or entirely of steam and air. Gas was collected by Kazuji Terada from a vent on the eruptive fissure of the 1954 lava flow on June 23, and from a vent on the northern part of the caldera floor on July 16, 1954. The latter vent (A, Fig. 1) is at or near the site of the former prominent conelet known as the Perret cone, buried by the lava flow of 1919. The gases were analyzed by Terada for the Geological Survey, and found to contain only water vapor and air. Gas from a vent on the flat above the Steaming Bluffs, 0.4 mile southwest of Sulphur Bank, contained a very small amount of carbon dioxide, possibly as a result of contamination by vegetable matter along the fissure (Terada, K. Unpublished report to U. S. Geological Survey, 1954).

Along the source fissure of the 1954 lava flow on the caldera floor northeast of Halemaumau (Fig. 1) small deposits of thenardite (Na_2SO_4) are found, associated with a little opal. These resemble deposits along eruptive fissures on Mauna Loa (Macdonald, G. A., and C. K. Wentworth. 1954. Hawaiian volcanoes during 1951. *U. S. Geol. Survey, Bul. 996d*: 180). At other areas within Kilauea caldera the deposits appear to be entirely opal. The opal is white and powdery, and forms thin crusts commonly in mammilary, botryoidal, and stalagmitic forms, and rarely miniature conelets resembling geyser cones but less than a centimeter high. Below the crust the lava rocks are generally partly altered to clay minerals and iron oxides for thicknesses of a few millimeters or a few centimeters. Generally the line of demarcation between the altered rock and the overlying crust is very sharp. The silica has clearly been transported and deposited by the rising steam, though it probably was derived by leaching of the altered rocks along the walls of the channel rather than from any deep-seated magmatic source.

Most of the areas of pneumatolytic deposition on the caldera floor show a strikingly arcuate arrangement (Fig. 1). With little question, these arcuate traces mark the buried margins of the sunken central basins that existed in the caldera during the nineteenth century. The buried scarps that bounded the basins, and the faults beneath them on which the sinking took place, still constitute pathways that guide the rise of steam from greater depths.

Comparison with Figure 2 demonstrates that trace 1 (Fig. 1) coincides approximately with the margin of the inner basin of 1840. Trace 2 nearly corresponds with the ridge of talus pushed up by bodily elevation of the

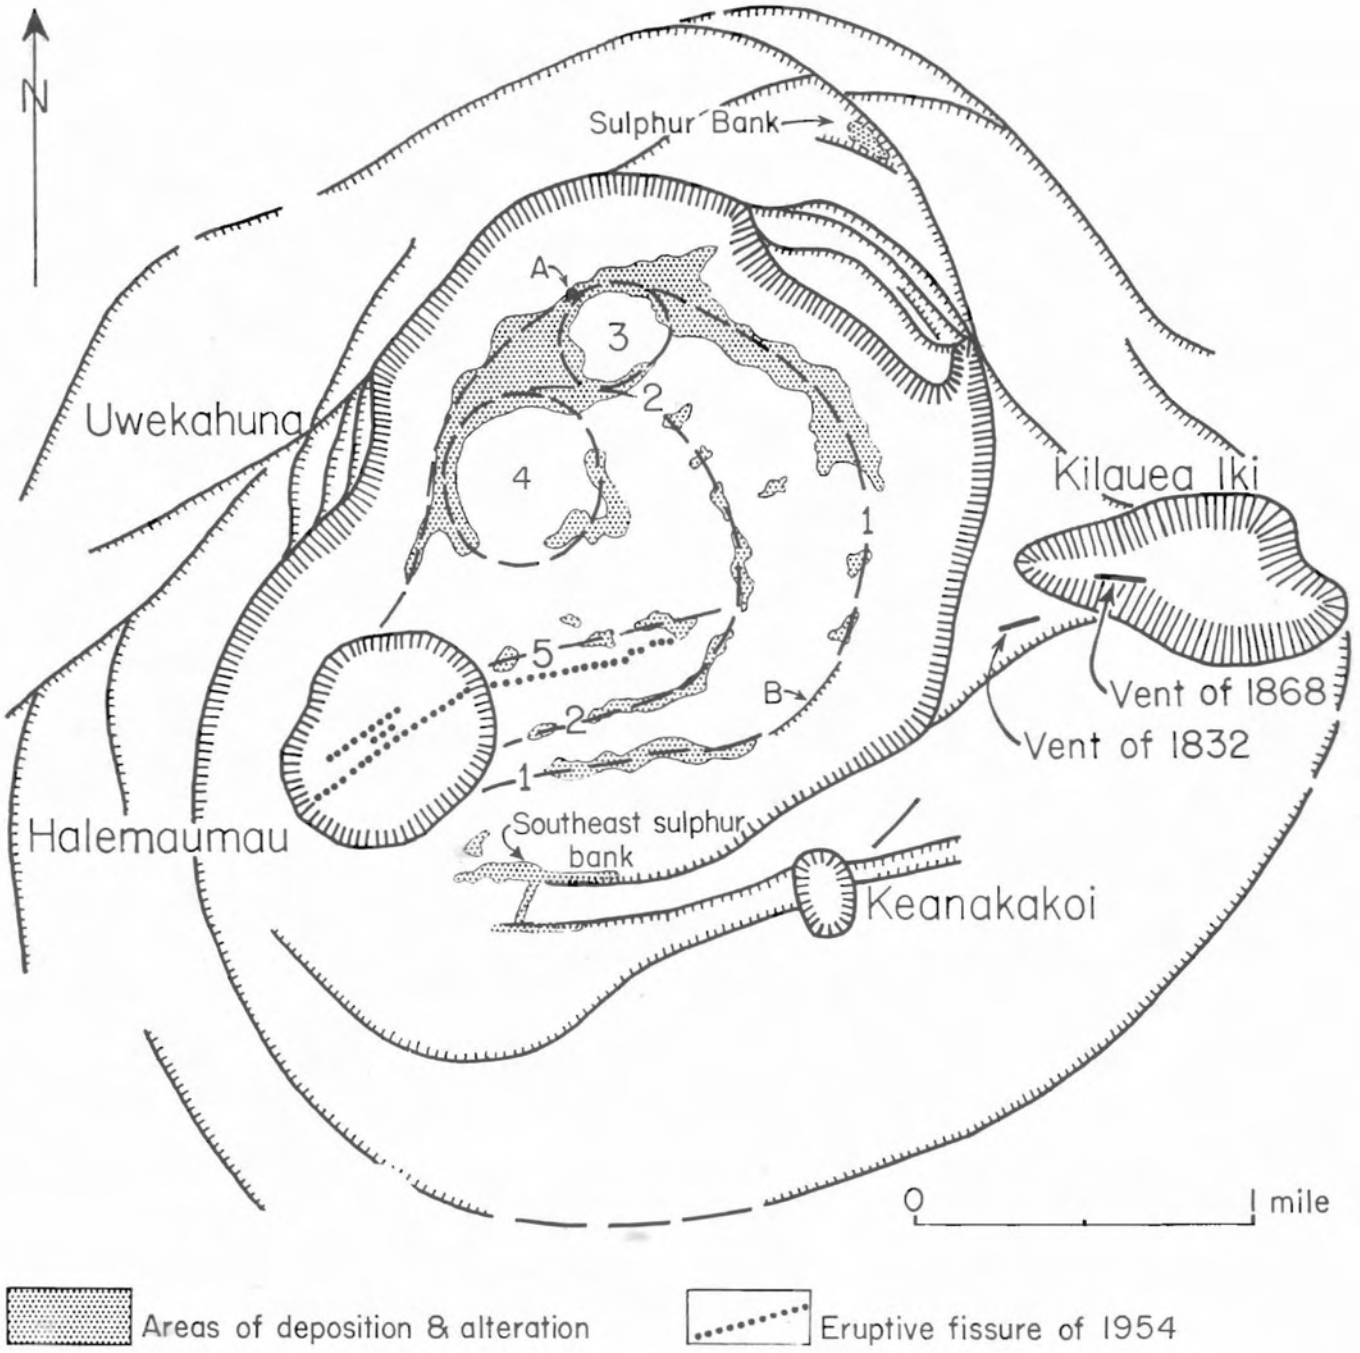

FIGURE 1. Map of Kilauea caldera, showing areas of deposition and alteration, the Perret steam vent (A), and a small monoclinal scarp (B) on one of the arcuate lineaments marked by the areas of deposition.

central part of the caldera floor in 1845 and 1846, and may correspond with the central basin of 1868. Trace 3 coincides in position with the embayment at the north edge of the inner basin in 1825 (Fig. 2), and 1841 (Wilkes, Charles. 1845. *Narrative of United States Exploring Expedition During the Years 1838-1842*. Vol. 4. Map facing p. 165). Trace 4 appears probably to reflect the position of another small pit, possibly the lake shown north of Halemaumau in Malden's map of 1825, and the sketch by Captains Parker and Chase in 1838 (Brigham, W. T. 1909. The volcanoes of Kilauea and Mauna Loa. *Bernice P. Bishop Mus., Mem.* 2(4) : 45-48), and the embayment on the west side of the central basin shown in Wilkes' map of 1841.

Along trace 1, in the southeastern part of the caldera, a scarp (B, Fig. 1) as much as 10 feet high formed

principally by flexing of the lavas, with cracking and minor faulting, has resulted from uplift of the central portion of the crater floor in relation to the margin. This uplift probably took place since 1884, because the lavas covering that portion of the floor probably are of that date.

Trace 5 appears to be essentially straight, rather than arcuate. It coincides closely in direction, and very nearly in position, with the eruptive fissure of the 1954 lava flow, and probably represents the northeast rift zone crossing the caldera floor. The eruptions of 1832 and 1868 no doubt represent activity on this rift zone.

Strikingly linear also is the arrangement of the three small circular structures, pits 3 and 4 and Halemaumau. The trend of this lineament departs somewhat from that of the southwest rift zone, and even more from that of the northeast rift. It is, however, approximately the same as that of two dikes cropping out in the caldera wall west of the fault blocks at the northeastern edge of the caldera. These dikes are the only ones exposed in the walls of Kilauea caldera other than those in Halemaumau.

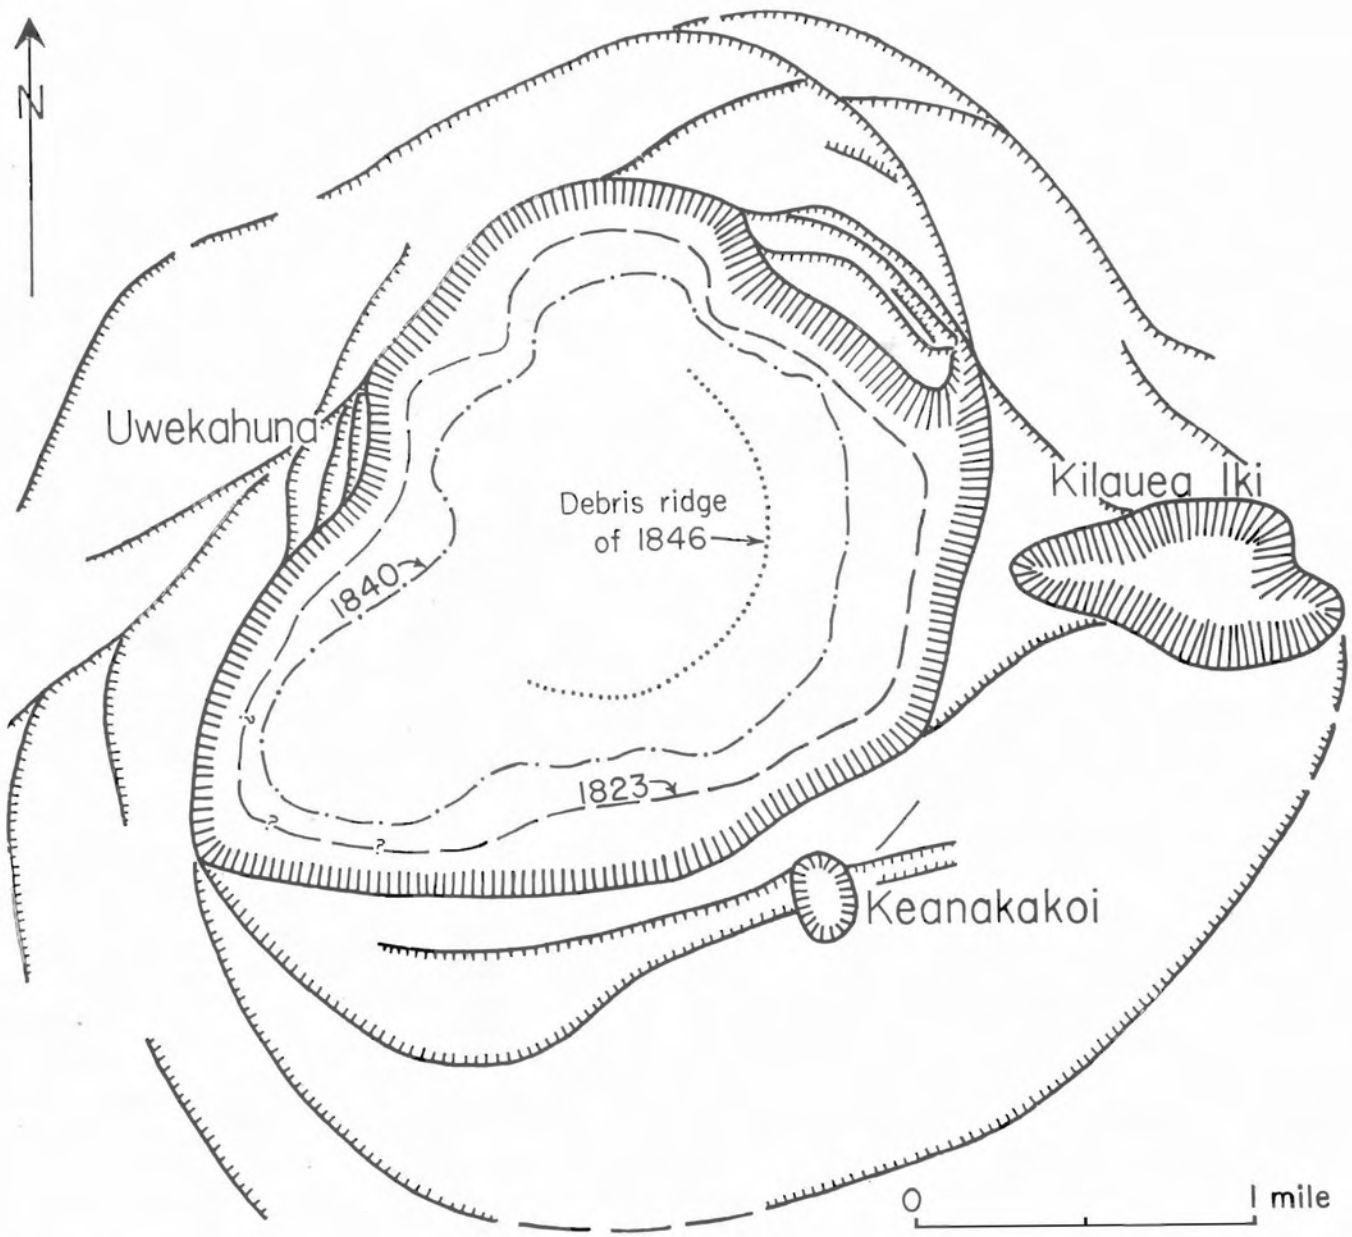

FIGURE 2. Map of Kilauea caldera showing the approximate margin of the inner depression of 1823 (adapted from the map by Malden in 1825), and 1840 (after Wilkes), and the approximate position of the ridge of elevated talus in 1846 (after C. S. Lyman).

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR APRIL–JUNE, 1955

By GORDON A. MACDONALD and JERRY P. EATON

VOLCANOLOGY

April

The volcanic activity on the east rift zone of Kilauea volcano, in eastern Puna, that had begun on February 28, continued into early April. The vents in the vicinity of the prehistoric Iilewa Crater continued fountaining, and liberating lava flows. A second flow from these vents entered the ocean on the evening of April 2. Lava extrusion stopped early on the morning of April 8. For the next two weeks the southwestern vents near Iilewa Crater continued to fume moderately to heavily, and a small pit on the northeast side of the southwesternmost vent glowed brightly, but there was no surface extrusion of lava.

On April 24 a short period of weak fountain activity occurred in the crater of the northeasternmost new cone near Iilewa Crater, and a small lava flow poured into the crater of the cone. Another small fountain and flow broke out in the same crater on the afternoon of April 26, but continued only a few hours. On the afternoon of April 27 a small lava flow broke out at a fissure in an older flow 1,000 feet southeast of the cone, and continued until the afternoon of the 28th. On April 30 activity resumed at the small pit just northeast of the southwesternmost cone of the Iilewa group, with small lava fountains, and pahoehoe flows spreading around the vent.

Volcanic tremor of the "harmonic" type was weak and irregular on the Pahoa seismograms from the beginning of the month until April 7. The resumption of weak activity at the vents near Iilewa Crater from April 24 to 30 was not accompanied by any detectable tremor.

At 4:25 A.M. on April 1 a strong earthquake occurred deep under the Kilauea caldera region. It was widely felt on the island of Hawaii, but did no damage. Very numerous earthquakes continued at Kilauea caldera throughout the month, but with gradually decreasing frequency (see table of local earthquake data). These accompanied a south-southwestward tilting of the ground at the northeast edge of the caldera totaling about 4.4 seconds of arc. At the west edge of the caldera the tilting was about 6 seconds of arc in a south-southeasterly direction. This tilting clearly indicated a sinking of the caldera floor, presumably resulting from decrease of magmatic pressure because of the release of lava in east Puna. The sinking was a continuation of the much more marked sinking of late March. (See *Volcano Letter* 527.)

The eruption in east Puna, and the accompanying effects at Kilauea caldera, will be described in detail in forthcoming issues of the *Volcano Letter*.

May

The activity that resumed at the southwestern vents of the Iilewa group on April 30 continued with gradually increasing strength into May. At first fountaining was low, and small sluggish flows were restricted to the area within about 1,000 feet of the vents. On May 16 occurred a marked recrudescence of activity. Lava fountaining became strong, and voluminous extrusion formed a broad pool of pahoehoe northeast of the vents, which drained southeastward toward the old Kalapana-Pahoa road and the coast. On May 19 a flow threatened the Iwasaki camp, and evacuation of the camp was started. (The camp had been evacuated during March, but had been partly reoccupied during the lull in activity in April.) On May 24 and 25 flows buried the upper portion of the Kamaili road and the Iwasaki camp area. All lava activity at the vent ceased suddenly at approximately 11:15 A.M. on May 26.

Harmonic tremor resumed on the Pahoa seismograph on May 4, and continued very weakly until May 9. No tremor was detected on May 10 and 11, but it resumed on May 12. It continued to be very weak until 8:30 P.M. on May 16, when it suddenly increased in strength, though it was still rather weak. It continued until May 26, when it ceased very abruptly at 11:13:47 A.M. The latter time coincided closely with the end of visible activity at the vents south of Iilewa Crater.

During the rest of May the vents near Iilewa Crater, those at and near the old Kalapana road 3.6 miles south of Pahoa, and those southwest of Puu Kii continued to fume lightly to moderately, but there was no further lava extrusion. Blue flames, possibly burning sulphur, were observed at cracks in the ground along the old Kalapana road.

Seismic activity was at a low level both in east Puna and in the Kilauea caldera area. The Pahoa seismograph recorded only 25 earthquakes during May, and only 35 were recorded by the Bosch-Omori seismograph at the northeast rim of the caldera. Westward tilting of the ground at the northeast rim of the caldera was about normal in direction and amount for that season of the year, but southward tilting continued at a moderate rate well beyond the normal time of reversal to northward tilting. This may indicate a continued sinking of the caldera floor, but may on the other hand represent merely an unusually late seasonal reversal. The Mauna Loa seismograph recorded 56 earthquakes during May.

June

The month of June was quiet both volcanically and seismically. Quiet release of volcanic fume and steam continued at the vents of the recent eruption in east Puna, and blue flames were occasionally visible at cracks along the old Kalapana road near the former Nii residence. The amount of visible steam varied greatly, probably in large part because of variations in the amount of rainfall, and temperature and humidity of the atmosphere.

The Bosch-Omori seismograph in the Whitney Laboratory of Seismology, on the northeast rim of Kilauea caldera, recorded only 18 earthquakes during June. This is the smallest number recorded since February 1953. The Pahoa seismograph recorded 28 quakes, three more than in May. The Mauna Loa seismograph recorded 52 quakes, four less than in May. Some of the quakes recorded at the Mauna Loa station originated at Kilauea, others on the Kaoiki fault zone between Kilauea and Mauna Loa, and others on Mauna Loa, probably on the east rift zone. No harmonic tremor was recorded on any of the seismographs.

A sharp earthquake felt from Naalehu to the Volcano district at 9:16 P.M. on June 12 probably originated on the Kaoiki fault. A quake of local origin rattled windows in the Waimea area at 7:11 A.M. on June 29.

During June the ground surface at the Whitney Laboratory of Seismology tilted slightly southeastward. Normally at that season of the year the direction of tilting should be northeastward. The abnormal direction of tilting may indicate a continued slight reduction of volcanic pressure beneath Kilauea caldera, but the time of the seasonal reversal from southward to northward tilting varies as much as two months and the continued southward tilting may represent merely an unusually late seasonal reversal. If so, the reversal from westward to eastward tilting in advance of the south to north reversal (it usually follows the latter by about a month) may indicate either an increase of pressure beneath Mauna Loa to the west, or a reduction of pressure beneath the Puna area to the east. The number and distribution of tilt measuring stations is inadequate to furnish the answer to this and similar problems, and the number of stations is being increased as rapidly as possible.

SEISMOLOGY

Local Earthquake Data, April–June, 1955

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Total	Local Seismicity*
Apr. 3	230	24	3	2	2	0	261	82.5
10	198	1	0	0	2	0	201	56.0
17	28	3	1	0	0	0	32	9.5
24	3	3	0	1	1	0	8	7.25
May 1	0	1	0	0	0	0	1	0.5
8	0	3	0	3	3	0	9	16.5
15	1	0	1	1	0	0	3	3.25
22	2	5	3	0	0	0	10	6.0
29	4	2	0	2	3	0	11	15.0
June 5	1	1	0	0	0	0	2	0.75
12	0	2	0	0	1	0	3	4.0
19	1	0	0	0	0	0	1	0.25
26	2	2	0	0	0	0	4	1.5

* For definition of local seismicity see *Volcano Letter* 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor ("harmonic tremor") is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

Week Beginning	Whitney Station (Northeast rim)		Uwekahuna Station (West rim)	
	Amount	Direction	Amount	Direction

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. Except for smaller earthquakes of special interest, only earthquakes classed as slight or larger were included in the list. The intensity ratings assigned are based on the Bosch-Omori seismograph at the Whitney Laboratory. This intensity scale has been extended empirically to permit its use with the Loucks-Omori and Sprengnether seismographs. The entries for a given earthquake are: date, time of arrival at the nearest station (Hawaiian standard time), intensity at the nearest station, name of the nearest station, epicenter, and general remarks.

Apr. 1, 04:24:28, Strong at Uwekahuna. Under the south rim of Kilauea caldera at a depth of about 10 km. Felt generally over the entire island of Hawaii and by a few observers on the islands of Maui and Oahu.

Apr. 2, 05:09:24, slight at Uwekahuna. Kilauea caldera.
Apr. 2, 06:37:56, Ditto
Apr. 4, 13:28:44, Ditto
Apr. 4, 13:34:14, Ditto
Apr. 6, 14:33:35, moderate at Uwekahuna. Near Kilauea caldera.
Apr. 6, 15:59:34, Ditto
Apr. 7, 01:27:22, slight at Uwekahuna. Near Hilina Pali at a depth of about 25 km.
Apr. 7, 15:48:54, slight at Uwekahuna. Near Kilauea caldera.
Apr. 9, 18:08:30, moderate at Uwekahuna. Near Kilauea caldera.
Apr. 10, 09:45:02, feeble at Uwekahuna. Southwest rift of Kilauea near the Ponohohoa Chasms at a depth of about 15 km.
Apr. 12, 08:25:44, moderate at the Whitney Laboratory. East rim of Kilauea caldera. Felt in Hawaii National Park.
Apr. 12, 12:49:56, Ditto
Apr. 22, 05:47:16, moderate at Pahoa. East rift of Kilauea near Pahoa.
Apr. 23, 07:33:51, moderate at Mauna Loa. Ten km. north of Halfway House at a depth of about 15 km. Felt at Hilo, Hawaii National Park, and Naalehu.
Apr. 24, 13:19:08, moderate at Uwekahuna. Kilauea caldera. Felt at Hawaii National Park.
Apr. 24, 09:06:19, slight at Uwekahuna. Five km. north of Halfway House at a depth of about 25 km. Felt at Hilo, Pahoa, and the Volcano area.
May 8, 16:01:57, moderate at Uwekahuna. Near Puu Kapukapu. Felt at Pahoa and Pepeekeo.
May 9, 05:44:51, slight at the Whitney Laboratory. East rim of Kilauea caldera. Felt at Hawaii National Park.
May 9, 09:35:38, Ditto
May 11, 09:06:53, moderate at Uwekahuna. Near Kilauea caldera.
May 12, 10:30:40, slight at the Whitney Laboratory. Near Kilauea caldera.
May 14, 10:34:23, slight at Uwekahuna. Near Kilauea caldera.
May 15, 02:42:23, feeble at Uwekahuna. Under Kilauea caldera at a depth of about 40 km.
May 16, 23:26:17, slight at Uwekahuna. Kilauea caldera.
May 23, 01:40:47, Ditto
May 29, 05:34:11, moderate at Uwekahuna. Near Kilauea caldera.
June 1, 01:59:50, moderate at the Whitney Laboratory. East rim of Kilauea caldera.
June 1, 03:50:50, Ditto
June 5, 17:02:11, very feeble at Naalehu. Near Pahala at a depth of about 75 km.
June 12, 21:15:56, slight at Mauna Loa. Near the Mauna Loa seismograph station at a depth of about 15 km. Felt at Pahala, Naalehu, and Hawaii National Park.
June 14, 14:29:35, slight at Mauna Loa. Near the Mauna Loa seismograph station at a depth of about 15 km.
June 27, 03:51:27, slight at Pahoa. East rift of Kilauea near Pahoa.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs at the Hawaiian Volcano Observatory (19° 25.4′ N. latitude, 155° 17.7′ W. longitude). Beginnings of phases are given in Greenwich civil time, which is 10 hours faster than Hawaiian standard time. Locations of epicenters, magnitudes, and depths of focus are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey.

Apr. 5, eI, 15:29:50, 25° N., 110° W. Gulf of California. Magnitude about 7.

Apr. 10, eP 17:50:19.8, 8° N., 125° E. Philippines aftershock. Many injured, moderate damage in Lanao province.

Apr. 19, eP 20:38:19.6, 30° S., 72° W. Near coast of Central Chile. Extensive damage from water waves at Tongoy and La Serena. Magnitude 7.

Apr. 23, iP 18:38:58.1, 24½° S., 113° W. Easter Islands region. Magnitude 6¾.

Apr. 28, eP 19:12:11.6, eT 19:50:27.1, 51° N., 178½° W. Felt: Adak. Magnitude 6½.

May 14, iP 06:13:34.1, 28° N., 139½° E. Bonin Islands region. Depth about 500 km. Magnitude 6¾.

May 30, iP 12:40:42.2, 24½° N., 142½° E. Volcano Islands. Depth about 600 km. Magnitude 7¼. Felt: Tokyo.

May 30, eP 23:39:10.8, 3° S., 137° E. Western New Guinea. Magnitude 6½.

May 31, eP 09:39:44.7, 27° S., 177½° W. Kermadec Islands region. Depth about 100 km. Magnitude 6¾.

June 2, eP 00:26:11.0, 51½° N., 180°. Andreanof Islands, Aleutian Islands. Magnitude 6¾.

June 12, eP 20:39:35.2, 49° N., 155° E. Kurile Islands.

June 14, eP 06:19:46.4, 20° N., 107° W. Off coast of Colima, Mexico. Magnitude 7.

June 20, iP 12:14:42.2, eT 12:53:15, 51½° N., 180°. Andreanof Islands, Aleutian Islands. Magnitude 6¾—7¼.

VOLCANO NOTES AND NEWS

THE LANAO EARTHQUAKE, PHILIPPINES

On April 1, at 2:15 A.M. (Philippine time), a very strong earthquake occurred in the central western part of Mindanao Island. Soon afterward the volcano Makaturing was reported in eruption.

The earthquake is briefly described by Arturo Alcaraz, in *The Philippine Geologist* (9(2):48-49). It was among the most severe experienced in the Philippines during this century. The epicenter lay between Lake Lanao and Panguil Bay. An intensity of VIII in the Rossi-Forel scale was attained in the epicentral area. The effects included fissuring and slumping in filled ground, differential settling in alluvial ground, sand boils, landslides, and a strong seiche in Lake Lanao. Many houses and public buildings were damaged. About 400 persons were killed. Of these, 174 were drowned when a large portion of Tugaya village slumped as much as 40 feet downward into the lake.

Makaturing is a dormant or extinct volcano situated south of Lake Lanao (*Volcano Letter* 523, p. 4). Mr. Alcaraz writes (personal communication) that aerial examination of the mountain in April indicates the news reports of eruption to have been incorrect. Two or three small landslides on the mountain slopes probably resulted from the earthquake of April 1.

ERUPTION OF MT. ASAMA, JAPAN

Newspapers reported a brief explosive eruption of Asama volcano at 7:46 P.M. on June 11. The eruption was stated to have lasted only about 3 minutes. It was accompanied by a loud roar, and black ash fell over neighboring areas, including the popular resort town of Karuizawa. No casualties were reported. The mountain lies in the Asama National Park, and normally during summer week ends many climbers are on its slopes. Fortunately, on June 11 visitors were discouraged by heavy rains.

The last previous activity of Asama consisted of small explosions on November 2 and 4, 1954 (*Volcano Letter* 526, p. 7).

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director

No. 529 and 530 **U. S. Geological Survey** **July–December, 1955**

PUBLISHED BY THE UNIVERSITY OF HAWAII

THE 1955 ERUPTION OF KILAUEA VOLCANO

By GORDON A. MACDONALD and JERRY P. EATON

INTRODUCTION

The 1955 eruption, on the east rift zone of Kilauea volcano in the eastern part of the Puna District, was unique in several respects and unusual in others. It was the first flank eruption of Kilauea since 1923, and the first eruption in eastern Puna since 1840. In some respects it had the aspects of three separate eruptions, each accompanied by its premonitory earthquakes. It was unusual in that the opening of the eruptive fissures in part progressed up slope, toward the central vent of the volcano, and also in the irregular manner in which activity shifted from one vent area to another. For the first time in Hawaii, and probably anywhere else, scientists were able to observe and photograph at close range the entire sequence of the development of volcanic vents, from the first opening of the fissure in the ground, through the appearance of lava, the formation of cones and flows, and the cessation of activity. Also for the first time in Hawaii, we observed the formation of a pit crater. Unusually good opportunities were presented to observe active flow fronts at close range and study the mechanics of their movement; and to obtain temperature measurements both on flow fronts and in the lava fountains.

The 1955 eruption was the first to occur in any populous area in American territory. For the first time it was necessary to evacuate fairly large numbers of people, with their movable belongings, because of volcanic danger. The staff of the Hawaiian Volcano Observatory worked in close cooperation with the Civil Defense Agency, the Police and Fire departments, the National Guard, the American Red Cross, and the Department of Public Instruction, in handling the disaster. In this connection, the responsibility of the Observatory staff was principally for prediction of the location of new points of outbreak and of the course of the flows. All orders of evacuation were issued by the Disaster Council of the County of Hawaii, with advice from the Observatory staff; and evacuation was on a purely voluntary basis. The eruption also saw the first modern attempts in Hawaii to construct barriers to deflect lava flows from certain areas. The barriers will be discussed in the detailed report on the eruption. The experience obtained with problems of human safety is of great value to all of us, particularly in view of the possibility of the development of even more serious situations in future Hawaiian eruptions.

Space here does not permit a full account of the eruption. The following pages contain only a brief summary of events. A detailed report will be published later as a bulletin of the United States Geological Survey.

ACKNOWLEDGMENTS

It is impossible to credit here all the individuals who aided us during the eruption, but to all we extend our sincere thanks. Among those who may be mentioned are: Deputy Director Peter Pakele, Edward Bento, Raymond Suefuji, Richard Chinen, Albert Kudo, Albert Wilson, and Edward Wingate, of the Civil Defense

Publication of the *Volcano Letter* will be discontinued with this issue. Beginning in January, 1956, the quarterly report of the Hawaiian Volcano Observatory will be published by the United States Geological Survey. The reports will be distributed free of charge. Persons desiring to receive the reports as they are published should request them from the Director, U. S. Geological Survey, Washington 25, D. C.

Agency; Col. Michael Roman, Captains Elroy Bohlin and Ken Cheney, and the men of the National Guard radio crews; Manager John Rolfes and Robert Spence of the American Red Cross; Principal Raymond Torii, and other teachers of Pahoa School; Deputy Chief George Martin, Captain William Kamau, and many other officers of the Hawaii Police Department; Manager C. E. S. Burns, Jr., and Myron Isherwood, of Olaa Sugar Co.; County Supervisor Richard Lyman; Chief Robert Kahakua, and other members of the Hawaii Fire Department. Special thanks are due Curtis Kamai, of the Territorial Highway Department, who worked with us constantly in the field through the first phases of the eruption, keeping flow maps up to date and aiding in many other ways; and to Arthur Lyman, of Olaa Sugar Co., whose phenomenal knowledge of the area and ever-willing counsel aided immensely in keeping track of volcanic events.

NARRATIVE OF THE ERUPTION

The events leading to the eruption may be considered to have commenced with the two strong earthquakes centered in eastern Puna on March 30, 1954. The quakes came from a focus about 12 miles deep nearly south of Pahoa, between the surface trace of the east rift zone of Kilauea volcano and the southern shore of the island. Throughout the rest of the year many earthquakes originated at centers along the east rift zone and in the caldera area. At the same time, tilting of the ground surface in the vicinity of the caldera indicated a swelling of the mountain, apparently caused by an increase of volcanic pressure beneath. The brief eruption in Kilauea caldera, from May 31 to June 3, 1954, had scarcely any effect either on the tilting of the ground surface or the sequence of earthquakes. Both continued uninterrupted through the rest of the year.

Repeatedly from November 1954 through February 1955 press releases from the Volcano Observatory called attention to the restlessness of the volcano. The possibility of eruption without appreciable further warning was pointed out, but the evidence was not sufficient to allow us to state definitely that the volcano was going to erupt, or if it did erupt, just when or where the outbreak would occur. Finally, in late February, earthquake activity increased greatly and centered in eastern Puna. Mr. and Mrs. Harold Warner reported that they were feeling large numbers of quakes, many of them accompanied by booming sounds, and that their dogs were much excited and digging persistently in the ground at their ranch, 5 miles S. 72° E. of Pahoa (Fig. 1). We spent most of February 27 at the Warner ranch, studying the phenomena. By that evening it was evident that eruption was imminent and that the outbreak would almost certainly take place in the area close to the Warner ranch. But our conservatism had caused us to wait too long. Before the prediction could be published, the eruption began.

The initial outbreak occurred within a few minutes of 8 A.M. on February 28, within a quarter of a mile of the Warner ranch house. Small lava fountains played along fissures in the ohia forest just north of the road to Pohoiki (Fig. 1-A). Two principal fissures, each about 300 feet long, trended N. 65° E., and were arranged en echelon with the more easterly fissure offset slightly to the north. A fuming fissure extended southwestward from them across the road. Farther east-northeast, two other short rows of fountains played from fissures on the south slope of the old cinder cone, Puu Honuaula (Fig. 1-B). The lava fountains were 50–150 feet high, and from them a rather sluggish lava flow spread southeastward between the base of Puu Honuaula and the road.

At approximately 2 P.M. a new group of small fountains developed farther east-northeast, in the saddle between Puu Honuaula and the next hill to the east (Fig. 1-C), and where the fissure crossed a cane-field road just west of the fountains the upper edge of a dike of incandescent lava was visible a foot or two below the ground surface. Bursts of gas from the top of the dike threw showers of glowing lapilli into the air.

The extension of the erupting fissures lay along a line trending almost directly toward the village of Kapoho, 3 miles distant, and in a hurried conference with Defense officials it was decided that Kapoho should be evacuated. By 5 P.M. the evacuation was already well under way. At 4:10 P.M. the lava flow from the vents on the south side of Puu Honuaula reached the Pohoiki road, and by 4:30 the road was completely blocked.

Activity in vent area C had essentially ceased by 4:30 P.M., but it resumed about 7:30, with the development of a chain of fountains in the area where the glowing dike had been visible earlier. A lava flow from them advanced rapidly southeastward into the cane fields.

Conditions continued essentially the same, though with fluctuations in the intensity of the lava fountaining, throughout the night and into the morning of March 1. By midmorning, activity had ceased at the vent area C, but continued at vents A and B. At 12:15 P.M. the lava fountains suddenly started to decrease rapidly in size, and by 12:20 they were completely dead. Immediately afterward, a great cloud of steam started to roll from vents B and C but not from the vents at A (Fig. 1). At most places the emission was rather gentle, and the cloud consisted entirely of white steam. Along the western portion of the row of vents at B, however, the steam roared out violently, carrying with it a cloud of black sand-sized ash. There was no trace of salt and very little trace of sulfur in the steam cloud. Apparently the rapid withdrawal of molten lava from the upper part of the eruptive conduits had allowed ground water to enter the conduits from the surrounding rocks, and contact of the water with the hot conduit walls resulted in the rapid generation of large volumes of steam. The ash was largely lithic, and apparently resulted from corrasion of the walls of the conduits by the outrushing steam.

The violent escape of steam continued until about 2:30 P.M., when it started to diminish. Gradually lessening amounts of steam poured out of the vents throughout the remainder of the afternoon and night. Lava activity at the vents was over, but lava continued to drain from tubes and open channels in the flow until about midnight.

At about 4 P.M. a small brief outbreak of lava occurred in the saddle between two unnamed hills 3,500 feet east-

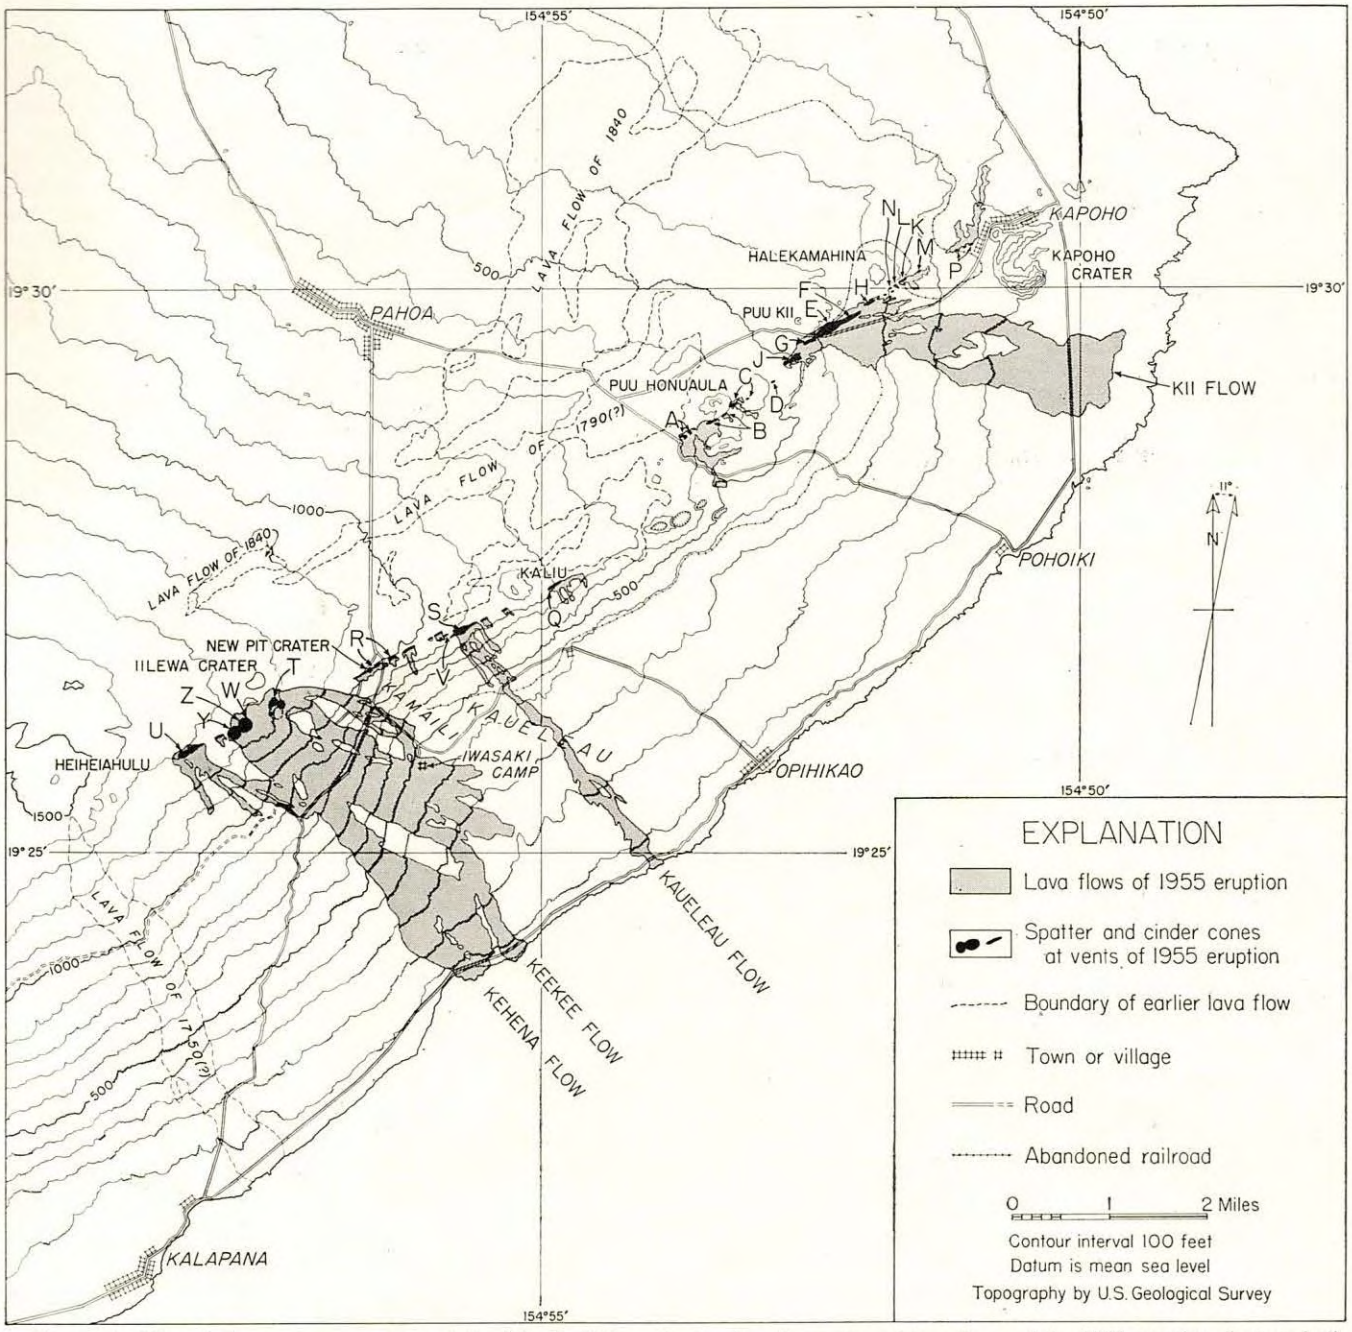

FIGURE 1. Map of the southeastern part of the island of Hawaii, showing the vents and lava flows of the 1955 eruption. Letters indicate the location of vents mentioned in the text in the order of their outbreak.

northeast of Puu Honuaula (Fig. 1-D). It lasted only a few minutes, and the flow formed in the cane field was less than 50 feet long.

The quiet condition of the vents suggested that the eruption might be over, but the continuation of large numbers of small earthquakes indicated that that was not the case. During the morning of March 2, new cracks appeared in the ground near the Pahoa-Kapoho road, 1.25 miles east-northeast of Puu Honuaula and 0.2 mile southeast of the old cinder cone, Puu Kii. The road was broken by a southeast-facing fault scarp 18 inches high, which continued east-northeastward along the bed of the old railroad with displacement as great as 3 feet. These fissures and fault scarps developed while we watched them, by a series of slow gradual movements accompanied by sharp small earthquakes of very local origin. Plantation officials were advised to move cane-field workers out of the area just southeast of the opening fissures, and the evacuation of Kapoho village (already largely accomplished) was speeded up. By 1 P.M. the fissures had spread northeastward to the vicinity of Halekamahina hill, a mile from Puu Kii, and less than a mile from the outskirts of Kapoho. The fissuring was following closely the zone of fractures formed during

the great swarm of earthquakes in the spring of 1924.

At 2:15 P.M. lava broke out in the cane field north of the Kapoho–Pahoa road (Fig. 1-E), 0.1 mile northeast of the initial fissuring across the road, and only about 250 feet from where Macdonald and B. J. Loucks were watching the development of fissures along the old railroad bed. First a cloud of dense white fume appeared, then after an interval of two or three minutes clots of incandescent lava started to shoot above the tops of the cane. Within 5 minutes of the first appearance of lava the line of fountains had increased in length to a quarter of a mile, the fountains had grown to a height of 50 feet, and very active flows of pahoehoe were spreading outward at a rate of about 40 feet a minute.

At approximately 4 P.M. the erupting portion of the fissure again lengthened downhill (Fig. 1-F). About 6:30 P.M. new vents extended the erupting fissure up slope, across the Kapoho–Pahoa road (Fig. 1-G). From 7:15 to 7:25 P.M. the eruptive fissure again lengthened 500 feet down slope east of vent F. At 8 P.M. another line of fountains broke out at H, east of vent F, and a new flow started to advance just north of the earlier flow. The fountains at vent H lasted only about 2 hours. At approximately 9 P.M. still another group of vents became active southwest of the Pahoa–Kapoho road (Fig. 1-J).

At 12:35 A.M. on March 3 a row of small lava fountains broke out on the lower southeast slope of Halekamahina hill (Fig. 1-K). At 1:30 A.M. another small outbreak occurred just to the west (Fig. 1-L), and at 2:41 still another outbreak occurred to the east (Fig. 1-M), only half a mile from the outskirts of Kapoho village. None of these groups of fountains lasted more than 2 hours. At 5:10 A.M. a small fountain broke out at N (Fig. 1), but lasted only about 45 minutes.

Vents J, G, and E were longer lived than the other vents, and became the principal vents of the eruption between March 3 and 10. They lay on fissures arranged en echelon, with each fissure offset to the left (north) in relation to the preceding one. The largest fountain was at vent E, close to the locus of the initial outbreak at 2:15 P.M. on March 2. By the early hours of daylight on March 3 this fountain averaged about 200 feet in height, and occasional bursts of cinder reached heights of 350 or 400 feet. The three groups of fountains fed a very active flow of aa. At 6:30 A.M. on March 3 the principal lobe of this flow was advancing 300 feet per hour over a front 500 feet wide, just south of the Kapoho road. Another less active lobe lay further south.

About 7 P.M. new fissures appeared in the old railroad bed at the western edge of Kapoho, and within a short time had extended through the center of the village itself. A police detail was still stationed in Kapoho, and a few people were still loading heavy appliances and the remainder of store stocks into trucks. These persons were immediately evacuated from the village, and the headquarters of the police detail was moved southward to a point on the coastal road 2.5 miles south of Kapoho.

Lava fountains broke out in the outskirts of Kapoho (Fig. 1-P) at approximately 9:30 P.M., and it seemed as though the village was doomed. By great good fortune, however, fountain activity was restricted to the westernmost part of the line of fissures, and a low ridge turned the flow of lava northward, away from the main portion of the village. Several houses in the outer part of the village were destroyed, but most of the village remained unharmed. Like that near Halekamahina, activity at the Kapoho vents was short lived. By 7:30 A.M. on March 4 lava activity at the easternmost vent had been replaced by a cloud of steam similar to those at Puu Honuaula on March 1, and by 8 A.M. activity at the Kapoho vents was over.

Still another threat to Kapoho had developed on the evening of March 3, when the big flow from the vents near Puu Kii reached the head of a shallow valley that led to the village. Although the main portion of the flow was directed down a larger valley farther south, it appeared probable that part of the flow would spill over the low divide and go down the valley toward Kapoho. However, the head of the valley was blocked by a fill on the old railroad grade, and although the lava piled up to a height of 15 to 20 feet above the level of the top of the fill, the lower mobile portion of the flow was deflected southward by the fill and none of the flow spilled into the valley toward Kapoho.

The flow crossed the coast road on the evening of March 4. On that day and the next the lava fountain at vent E reached a height of nearly 800 feet! On March 6, however, the fountains rapidly died down. By evening there was no sign of activity at the vents, and the big flow was stagnating without having reached the ocean.

Again it looked briefly as though the eruption might be over. The seismographs indicated otherwise, however. By the morning of March 7 another series of earthquakes was under way, this time originating in a zone southwest of the Puu Honuaula vents, within a mile or two on each side of the road from Pahoa to Kalapana. A new outbreak in that area appeared probable. For nearly a week we waited, while earthquakes occurred as frequently as two a minute for hour after hour. Eruption appeared more and more certain, but we could not be sure just where it would take place. The east rift zone of Kilauea lies along the top of a broad ridge, the crest of which lies about three miles south of Pahoa. If eruption occurred on the north side of the ridge, the town of Pahoa might be in immediate and drastic danger. The evacuation of Pahoa was not advised, because it appeared almost certain that the outbreak would be on the south side of the ridge; but under the direction of Richard Lyman, plans were laid for the construction by bulldozers of an earthen wall to try to divert the lava from the town if it should prove necessary. The Observatory staff took part in the planning, and the scheme had the complete approval of the citizens of Pahoa.

Finally, on the morning of March 12, cracks opened across the Pahoa–Kalapana road south of the crest of the ridge, 3.5 miles south of Pahoa. The town of Pahoa appeared to be out of danger, but the Kaueleau and Kamaili areas were in immediate jeopardy. Most persons had already left those areas, and residents of the Kalapana and Opihikao areas also had been evacuated because of the probability of isolation of those areas from food supplies and medical aid should eruption occur.

On the evening of March 12, lava broke out near Puu Kaliu (Fig. 1-Q), 2 miles east of the Kalapana road;

FIGURE 2. Fume issuing from a new fissure in vent area R, adjacent to the Kalapana road, on March 13, 1955. Lava reached the surface at this point a few minutes later. This illustrates the first phase in the formation of a new volcanic vent.

FIGURE 3. Viscous lava appearing at the surface in a new fissure across the Kalapana road, in vent area R, on the afternoon of March 13, 1955. Small explosive fountains burst through the top of the bulge of lava a minute or two later.

FIGURE 4. Spatter cone forming around a lava fountain at the new vent shown in Figure 3, about 16 hours later (morning of March 14).

and on the morning of March 13 a series of outbreaks occurred just east of the road (Fig. 1-R). Persons living in the area had already moved away, and the absence of any immediate threat to human life or movable property allowed us to spend a fascinating day watching and photographing for the first time in history the complete sequence of the development of new volcanic vents.

First, hairline cracks opened in the ground, gradually widening to 2 or 3 inches. Then from the crack there poured out a cloud of white choking sulfur dioxide fume (Fig. 2). This was followed a few minutes later by the ejection of scattered tiny fragments of red hot lava, and then the appearance at the surface of a small bulb of viscous molten lava (Fig. 3). The bulb gradually swelled to a diameter of 1 to 1.5 feet, and started to spread laterally to form a lava flow. From the top of the bulb there developed a fountain of molten lava which gradually built around itself a cone of solidified spatter (Fig. 4). The same general sequence was observed at three separate points during the day.

During the afternoon, activity spread southwestward across the Kalapana road, and by the morning of March 14 a spatter cone 30 feet high stood athwart the road.

On March 14 a lava fountain 400 feet high developed about a mile east of the Kalapana road (Fig. 1-S). Favorable conditions of wind and topography allowed us to approach within 100 feet of the base of this fountain and an unusually clear line of sight made possible excellent temperature measurements at night with an optical pyrometer. The temperature in the core of the fountain was close to 2,000° F. A lava flow from the fountain swept down through Kaueleau. On March 16 it entered the ocean, sending up great clouds of steam. Kalapana village was completely isolated.

During the afternoon of March 16 a new outbreak (Fig. 1-T) occurred south of the old Iilewa Crater, a mile southwest of the scene of the March 13 activity at the Kalapana road. Another took place two miles southwest of the road (Fig. 1-U) on March 19. Flows from the latter vents crossed the Kalapana road on the evening of March 19, but the activity of the vents lasted only about a day.

On March 20 activity increased at vent T. The lava fountain reached a height of 600 to 750 feet, and flows from it advanced into the Kamaili area. Pumice and Pele's hair fell abundantly in Pahoa, 5 miles away. A cone of pumice, cinder, and welded spatter 1,000 feet across and about 100 feet high was built around the fountain. On the morning of March 21 a tongue of one of the flows from vent T entered the head of a small valley that led directly to a small plantation camp owned by Koji Iwasaki. In an effort to keep the flow from reaching the camp, a wall about 1,000 feet long and 10 feet high was hurriedly thrown up by bulldozers working under the direction of Arthur Lyman, with Eaton's advice. During the afternoon the flow reached the barrier and was turned by it, but advanced along it only about 50 feet before the supply of lava was cut off and all movement in that tongue stopped.

The next day Robert Yamada, of Hilo, started construction of another series of short barriers to try to divert another portion of the flow from his coffee plantation. The walls were only partly successful, but did demonstrate certain valuable principles relating to the diversion of lava flows.

At 4:03 P.M. on March 20 a sharp explosion from vent area R, only about 150 feet east of the Kalapana road, threw dark ash 500 feet into the air. Several similar explosions followed within the next two hours. Air reconnaissance revealed a nearly circular pit with a mouth about 30 feet in diameter and a brightly glowing interior (Fig. 5). The walls were overhanging, the diameter of the base of the pit being at least twice that of the mouth. A tongue of pale blue and yellow flame played over the aperture at night, and the temperature of the interior was estimated on the basis of color to be at least 100° F. hotter than the cores of the lava fountains, presumably because of combustion of volcanic gas

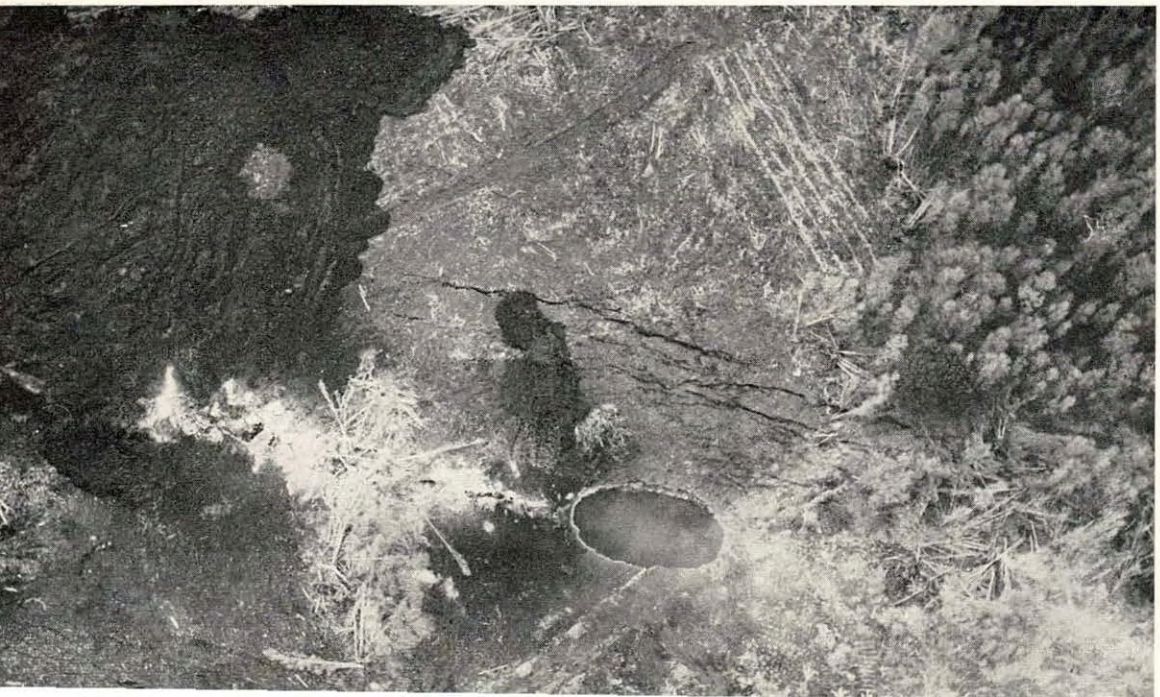

FIGURE 5. Aerial photograph showing the small pit crater formed in vent area R (Fig. 1) on the afternoon of March 20. Lava flows erupted on March 13 are visible on the left. The eruptive fissure extends across the picture from middle left to lower right.

in the pit. The edges of the pit caved back rapidly during the next few days, revealing it to be about 135 feet deep, floored with talus from the collapsing rim. The walls were covered with a tapestry of stalactites formed by melting and dripping of the old rocks under the intense heat of the burning gas. This pit is a small pit crater, similar to those along the Chain of Craters road in Hawaii National Park. The volume of ash ejected by the explosions was much less than the volume of the crater. Obviously, the crater was formed principally by collapse, probably as the result of withdrawal of molten lava beneath.

At 9 A.M. on March 25 a small outbreak occurred 0.7 mile east of the Kalapana road (Fig. 1-V). It was short-lived, however. The lava flow advanced less than 500 feet from the vent, and by early afternoon the activity was completely over.

At 8 P.M. on March 26 a new outbreak occurred 1,500 feet southwest of vent T. From this new vent (Fig. 1-W) a rapid aa flow advanced seaward along the south side of the earlier flows, and on March 28 spread across the Yamada coffee plantation and entered the sea. Small explosions caused by sea water coming in contact with the fluid hot lava threw up showers of sand of the sort that forms beaches such as the famous black sand beach of Kalapana. The fountains at cone T became inactive at 2 A.M. on March 27, though occasional roaring gas release continued at a vent on the northeast side of the cone. Early on the morning of March 27 still another vent became active at Y (Fig. 1).

On March 30 a lava fountain developed at the roaring vent on the northeast side of cone T, and a cinder and spatter cone was built around it, overlapping the adjacent older cone. On March 31 a small flow from this vent stopped only 2,000 feet from the Iwasaki camp. A flow that had started from vent Y on March 28 continued slowly down the southern edge of the previous flows and entered the ocean at Kehena on April 2. The lava fountains at vents T and Y gradually declined through April 3 to 5, and on April 6 became intermittent. Just after midnight on April 7 all lava activity ceased.

Then for more than 2 weeks things were completely quiet except for a glowing pit 10 feet across at the northeast base of cone Y and liberation of clouds of white sulphurous fume and steam from other vents. Earthquakes were very few and small. Apparently, however, molten lava continued to stand high in the conduits, for activity resumed quietly and without forewarning.

On April 24 a weak lava fountain broke out again in the crater of the first cone at vent T. It continued to play for only a few hours. Similar activity again appeared on April 26. For 3 or 4 hours scattered bursts of spatter were thrown to a height of 50 feet, and a small lava flow trickled into the bowl of the crater. The next day a flow of sluggish dense pahoehoe issued from fissures in lavas of the earlier part of the eruption about 1,000 feet southeast of the crater of cone T, and advanced 1,500 feet seaward before coming to a stop on April 28.

On April 30 weak fountaining and lava extrusion resumed at the site of the glowing pit at the base of cone Y. From then until May 16 activity at that site gradually increased. Semi-explosive ejections built a cone of loose cinder 75 feet high between cones W and Y, and close to its northeast base two small spatter cones were built. Lava spread around the vents. Then on May 16 a marked recrudescence of activity took place. The showers of discrete cinders were replaced by voluminous lava fountaining at the site of one of the two small spatter cones, and in the crater of the cinder cone. A large cone of welded spatter (Fig. 1-Z) rapidly grew around the two fountains, reaching a height of 150 feet and burying the cinder cone, the two small spatter cones, and the remnant of cone W. East of the cone was formed a broad pool of lava that spilled southeastward toward the ocean and northeastward into the crater of cone T. On May 19 the Observatory staff issued a warning of renewed danger to the Iwasaki camp; the camp, which had been reoccupied after the cessation of activity in early April, was again evacuated. At 9 P.M. lava entered the camp, destroying about half the buildings, but not until essentially all their contents had been removed.

On May 18 lava had started to spill from the pond northeast of cone Z into the valley northwest of cone T. Other small overflows into the valley occurred on subsequent days. At 11:30 P.M. on May 23 a great flood of lava broke over the divide into the head of the valley, and quickly formed another broad pond of lava north of cone T. This pond continued to grow through May 24, fed by a spectacular cascade in which the lava attained rates of flow estimated as more than 30 miles per hour. A flow worked northeastward from the pond along a line of old cracks leading toward vent area R. At 9:45 P.M. on May 24 a tongue from this flow spilled southeastward, and swept at great speed down across the intersection of the Kalapana and Kamaili roads. About 3½ hours later another similar spill-over sent lava across the Kamaili road 1,500 feet below the Kalapana road. This flow joined another slower aa flow that had spilled out of the pond near cone Z, and together they advanced on the remnant of the Iwasaki camp. One of the houses spared by the flow of May 19 had been moved away, and the metal roofing had been removed from another, but the remainder of the camp was totally destroyed in the early morning of May 25.

It almost seemed as though, with the final destruction of the camp, the volcano goddess felt her work was ended! At 11:15 A.M. on May 26, lava fountain activity ceased very abruptly, almost as though a valve had been closed in the conduit bringing the lava to the surface, and by the morning of May 27 all movement in the flows had stopped. Since then steam and sulfur gases have continued to escape from the vents, especially in vent areas J, R, and T, but there has been no other volcanic activity.

VOLUME AND COMPOSITION OF THE LAVAS

The flows and cones of the 1955 eruption cover an area of approximately 6.1 square miles, or 3,900 acres. Of this, about 1,100 acres were under cultivation. The estimated volume of the flows above sea level is approximately 111,000,000 cubic yards. The amount of lava that disappeared below sea level is unknown, but is estimated to be 5 to 10 million cubic yards. The total volume of

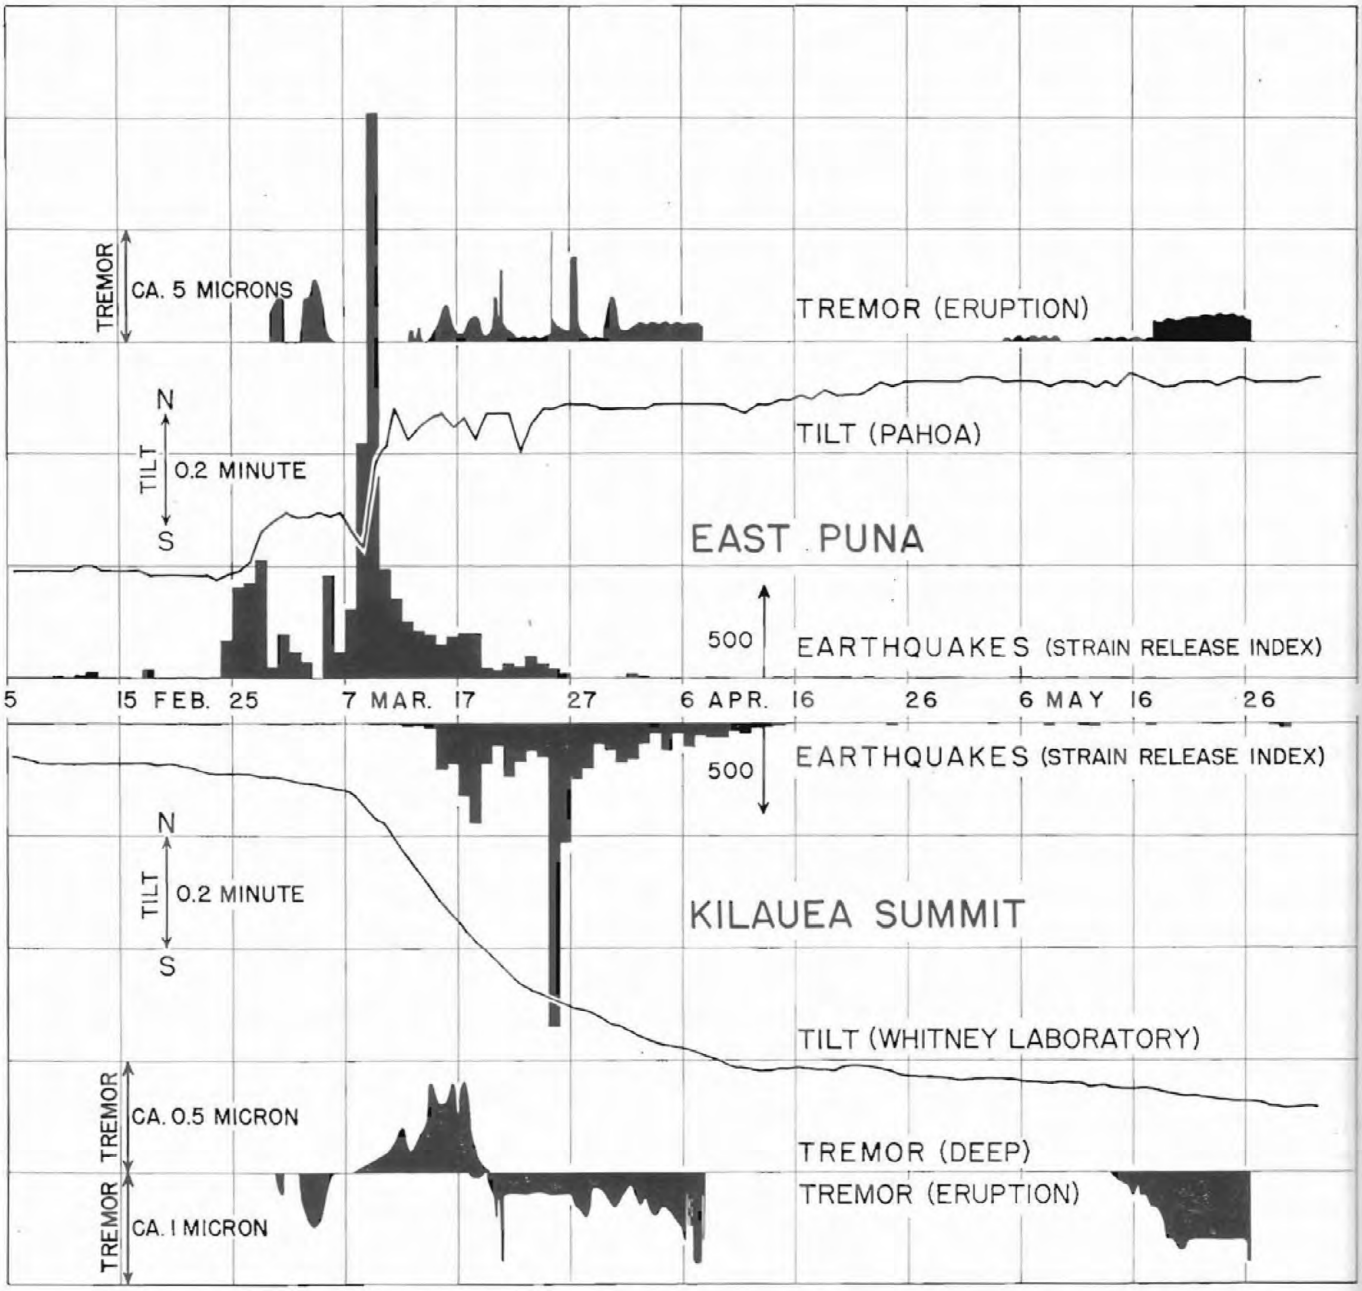

FIGURE 6. Graph showing ground tilting, strain release index, and amplitude of volcanic tremor in the eastern Puna and Kilauea summit regions during and just preceding the 1955 eruption. In the lower part of the graph tremor of deep origin is plotted above the line and tremor of shallow origin probably generated by flow of lava through the conduit near the surface is plotted below the line.

the cinder and spatter cones is approximately 2.5 million cubic yards. Thus the total volume of material extruded is approximately 120 million cubic yards. This is about twice the volume of material extruded during the 1952 eruption in Kilauea caldera, but is less than half the estimated volume of the nearby lava flow of 1840, and only about one-fifth that of the material extruded during the 1950 eruption of Mauna Loa.

The lava is basalt, containing moderately abundant phenocrysts of plagioclase. A few phenocrysts of olivine also are present in most specimens, but eight chemical analyses of the lavas made in the laboratories of the U. S. Geological Survey all show a slight excess of normative silica. The percentage of silica shows a general decrease through the course of the eruption, ranging from 51.24 in the earliest flow to 50.53 in the latest. Similarly, there was a slight decrease in the proportion of soda, and increase of magnesia and lime through the course of the eruption.

EARTHQUAKES, TILTS, AND HARMONIC TREMOR

The strain release index previously defined for the

short period, vertical Sprengnether seismograph at Uwekahuna (*Volcano Letter* 524), was extended empirically to permit its use with a Loucks-Omori seismograph. For a group of earthquakes recorded during October, 1954, on the Sprengnether and on a Loucks-Omori temporarily set up beside it, the average ratio of the maximum amplitude on the Sprengnether to that on the Loucks-Omori was 6.5. Using this ratio we can write:

S-R index $= \sqrt{(S\text{-}P)\ A} = \sqrt{(S\text{-}P)\ 6.5\ a}$, where S-P is the duration in seconds of the preliminary tremor, A is the maximum double amplitude in mm. on the Sprengnether record, and a is the maximum double amplitude in mm. on the Loucks-Omori record.

Two units into which it is convenient to divide Kilauea for a seismometric study of the eruption are east Puna (Kilauea volcano east of the bend in the east rift zone 2 miles east of Napau Crater) and Kilauea summit (Kilauea volcano minus the Puna unit defined above).

Because of the great uncertainty in reading and locating very small earthquakes, strain release indices were tabulated only for earthquakes having an index of $\sqrt{5}$ or larger. Since the significance of earthquakes occurring at abnormally large depths (greater than 25 km.) under the caldera and its environs is as yet poorly understood, and the epicenters of these earthquakes are very difficult to determine, such earthquakes were not included in the computation of strain release indices for the Kilauea summit unit.

In Figure 6 daily strain release indices from February 5 to May 31 for east Puna (based on the Loucks-Omori seismograph at Pahoa) and for Kilauea summit (based on the Sprengnether seismograph at Uwekahuna) are presented graphically. The daily strain release index for a given unit is the sum of the strain release indices of the earthquakes occurring during the day in that unit.

During the eruption sharp changes in the inclination of the earth's surface (tilt) were recorded both at Pahoa and at Kilauea caldera. At Pahoa, which lies about 5 km. northwest of the initial 1955 outbreak, the north-south component shows the clearest changes. Northward tilting at Pahoa results from a swelling of the rift zone southeast of the station. All of the tiltmeters and horizontal pendulum seismographs around Kilauea caldera recorded a large subsidence of the top of the volcano centered just east-northeast of Halemaumau. At the Whitney Laboratory, which lies about 3 km. N. 30° E. of this center of subsidence, the southward tilting recorded on the north-south component corresponds to subsidence of the caldera.

The north-south components of tilt recorded at Pahoa and at the Whitney Laboratory are plotted in Figure 6.

A gross measure of the rate of lava extrusion is provided by the amplitude of the harmonic tremor generated by the lava moving up through the feeding channels. The amplitudes of this tremor recorded on the Loucks-Omori seismograph at Pahoa and on a modified, short period, horizontal component Sprengnether seismograph operated in a basement on the east rim of Kilauea caldera also are presented in Figure 6. In addition, the amplitude of the short period tremor supposedly of deep origin recorded on the latter seismograph is given in the same figure.

This graph constitutes a summation of the most important data on earthquakes and tilt accompanying the eruption and presents this data for comparison with the time and intensity of lava extrusion (as measured by the harmonic tremor generated). The discussion of the relationship between earthquakes, tilt, and lava extrusion which follows is largely an interpretation of this graph.

Following the two big earthquakes near Kalapana on March 30, 1954, the only seismic activity which persisted in east Puna issued from the east rift zone near Pahoa. Tiny, sharp, shallow earthquakes at an average rate of about 25 per month stemmed from this region through the spring, summer, and fall of 1954. Late in the year the frequency of these earthquakes began to increase. A total of 67 occurred in November; 81, in December; 185 in January, 1955; and 350 between February 1 and February 23, 1955.

On February 23 a sharp earthquake of moderate size occurred at a depth of about 25 km. under the east rift zone of Kilauea near Makaopuhi Crater. After that date the number of earthquakes stemming from the east rift zone southeast of Pahoa rose sharply. Only 13 earthquakes from this region were recorded on February 23. This number increased rapidly to 130 on the 24th, 350 on the 25th, 600 on the 26th, and 700 on the 27th. Early on February 28 the frequency of earthquakes dropped off sharply; and at 7:45 A.M. the first harmonic tremor, heralding the beginning of a rapid flow of lava up through feeding channels, appeared on the Pahoa seismogram. The eruption had begun.

Northward tilting recorded at Pahoa between February 24 and March 1 indicates that the east rift zone was inflated during the swarm of earthquakes preceding the initial outbreak and during the brief life of the eruption on the flank of Puu Honuaula (Fig. 1, vents A-C).

While the eruption was in progress and lava was pouring out freely at the surface, very few earthquakes were recorded. Immediately after the cessation of activity at the Puu Honuaula vents (Fig. 1, A-C), earthquakes started again. The frequency of earthquakes slowly diminished after the outbreak at vent E (Fig. 1) on March 2 and as the opening of new vents came to a halt on March 3. While the most spectacular lava fountaining of the whole eruption was in progress at vent E on March 4, virtually no earthquakes were recorded.

By noon on March 5 the fountain at vent E was greatly reduced in size, and earthquakes in the eruption area had almost ceased. At about 12:30 a spectacular swarm of earthquakes began at a source near Kalalua Crater (9 miles west of the Pahoa–Kalapana road). For several hours all seismographs on Hawaii were in incessant motion. With diminishing intensity and frequency of earthquakes, this swarm lasted for about 24 hours. These earthquakes typically showed rather long period, dispersive, surface wave trains following preliminary phases which were relatively small and wholly lacking in short periods. They appear to have originated at shallow depth, perhaps about 5 kilometers.

On March 7 the Kilauea summit region began to respond to changes of the previous week in east Puna.

This response probably was made possible by splitting open of the east rift zone at depth near Kalalua Crater two days earlier. Although no increase in seismic activity at Kilauea caldera began until March 12, on March 7 the top of the volcano began to subside rapidly. At the same time a minute short period harmonic tremor closely resembling tremor from eruptions at Kilauea caldera began to record on a short period, horizontal component Sprengnether seismograph on the east rim of Kilauea caldera.

At Pahoa a brief southward tilting was under way by March 7 (Fig. 6). Several strong earthquakes originated south of the east rift zone, near Kalapana, and the number of earthquakes from the east rift itself began to increase rapidly on the same day.

On March 8 the tilting at Pahoa reversed, and a rapid inflation of the east rift zone south of Pahoa began. The dramatic swarm of earthquakes from the east rift zone intensified on March 8 and reached a maximum on March 9 when almost 1,400 earthquakes were recorded. On subsequent days the frequency of earthquakes from the east rift diminished gradually. Rapid tumescence of the east rift stopped on March 11. For the next two weeks only erratic back and forth tilting was recorded at Pahoa.

From March 7 to March 12, as the short period harmonic tremor usually associated with the outpouring of lava at Kilauea caldera steadily increased in amplitude, rapid subsidence of the caldera continued. During this interval no lava was extruded, but the east rift zone south of Pahoa was inflated to the accompaniment of an impressive swarm of earthquakes. This evidence suggests that plastic magma at depth (10 to 20 km., perhaps) oozed out from under the caldera and welled up beneath the badly fractured east rift zone.

Following the outbreak of lava on the east rift south of Pahoa on March 12, seismic activity in east Puna continued as long as new sections of the rift were being split open and new vents formed. After the last new section of the rift opened on March 26 seismic activity in Puna dropped to a very low level, where it remained for the rest of the eruption.

After a weak beginning on March 12 a swarm of earthquakes at Kilauea caldera suddenly built up to major proportions on March 15. This swarm reached a first maximum on March 18 and then declined slowly. Earthquakes of this group were mostly quite small and shallow. They appear to have originated within a few kilometers of the Uwekahuna station.

A sharp revival of earthquakes at Kilauea caldera on March 25 sent the number for the day to almost 1,100. Although the average size of the earthquakes diminished, an even greater number (almost 1,300) was recorded on March 26.

On the afternoon of March 27 a sharp shallow earthquake originating near the east rim of the caldera opened a crack across the Mamalahoa highway east of Hawaii National Park headquarters and cracked water lines in the park housing area. From March 25 to March 28 the focal zone of these earthquakes extended to depths as great as 45 km. From this same zone, about 45 km. deep under Kilauea caldera, several remarkable series of small earthquakes and spasmodic tremor were recorded prior to the 1955 eruption. The largest such series occurred from June 18 to June 21, 1954, shortly after the 1954 eruption in Kilauea caldera (see *Volcano Letter* 524).

Early on the morning of April 1, 1955, the largest earthquake that occurred during the eruption originated at a depth of about 10 km. near the south rim of Kilauea caldera.

The subsidence of the caldera which began on March 7 continued until the end of the swarm of earthquakes in the summit region in mid-April, although the rate of subsidence decreased on March 23 and again on April 10. After a very weak reversal of tilt between April 13 and April 22, slow subsidence of the caldera started once more and continued until the end of the year. Assuming the area of sinking to have been the same as that in 1924 (Wilson, R. M., 1935. *Ground surface movements at Kilauea volcano, Hawaii.* Hawaii Univ. Res. Pub. 10, pp. 54-55, fig. 8), and the amount of sinking throughout the area to have had the same proportions as in 1924, the volume of sinking in the summit region from February 20 to April 10 has been calculated to be about 216,000,000 cubic yards. This is of the same order of magnitude as the volume of lava extruded in eastern Puna during the same interval.

After the cessation of eruptive activity in Puna on April 7, the east rift zone again began to swell slowly. Only a few tiny earthquakes occurred in this region between April 7 and the revival of activity at an earlier vent on April 23. This swelling which stopped again with the revival of activity on April 23, was the only forerunner of the final phase of the eruption. The channels had remained open, and when more lava became available, perhaps oozing out from under the caldera, it simply welled up and poured out without the premonitory earthquakes resulting from further opening of the rift.

HAWAIIAN VOLCANO OBSERVATORY REPORT FOR JULY–DECEMBER, 1955

By GORDON A. MACDONALD and JERRY P. EATON

VOLCANOLOGY

July

The month of July was seismically and volcanically quiet on the island of Hawaii. The seismograph in the Whitney Laboratory of Seismology, at the northeast edge of Kilauea caldera, recorded only 21 earthquakes, most of them very small. The Mauna Loa seismograph recorded 40 quakes during the month, 12 less than during June. There also, most were very small.

The seismograph at Pahoa School recorded 29 earthquakes during July, as compared with 28 during June. Most of the quakes were small, and probably originated along the part of the east rift zone of Kilauea volcano affected by the recent eruption. At 10:23 P.M. on July 23 a quake felt strongly on the rift zone at the Pahoa–Kalapana road was felt only weakly in Pahoa and

Kaueleau. It originated at a very shallow focus near Iilewa Crater.

The ground surface at the northeast rim of Kilauea caldera tilted slightly eastward during the month. Normally during this season of the year the tilting is northeastward. The absence of northward tilting probably indicates a slight continuation of the decrease of volcanic pressure beneath the caldera that was conspicuous during the eruption in east Puna.

Volcanic activity at the surface was confined to mild steaming and fuming at the vents of the recent eruption in east Puna. On several days steam release was strong near the Nii house on the old Kalapana road, and at the vents on Namba's hill southwest of Puu Kii. However, this appeared to result from heavy rains. At one vent the sound of steam bubbling through accumulated rain water could be heard. Gas flames no longer were observed along the Kalapana road.

Except for the occasional periods of voluminous steaming resulting from heavy rains, there appears to have been a gradual, slight but definite, decrease in temperature and fume release at the east Puna vents during June and July. That, together with the low level of seismic activity, appeared to indicate that the east Puna eruption was over.

August

Volcanoes on the island of Hawaii remained fairly quiet throughout the month of August, although two deep earthquakes were felt lightly over a large part of the island group. The seismograph in the Whitney Laboratory of Seismology recorded only 23 earthquakes, two more than during the month of July. The seismograph at Pahoa School recorded 39 quakes, 10 more than during July.

Most of the seismic activity was recorded at the Mauna Loa station. Throughout most of the month activity at that station also was small, but between 11 A.M. on August 9 and midnight on August 10 more than 600 very small earthquakes were recorded. The origin of these quakes is not known with certainty, but they probably came from the nearby northeast rift of Mauna Loa.

At 7:18 A.M. on August 7 an earthquake was felt generally on the islands of Hawaii and Maui, and by many people on Oahu. It originated at a depth of about 25 miles beneath the Waimea area on the island of Hawaii. Another quake, felt to about the same degree over the same area at 2:28 A.M. on August 14, originated at a depth of about 22 miles beneath the Hilina Pali area, on the south slope of Kilauea volcano. A slight earthquake was felt at 5:27 A.M., August 19, in the volcano area. On August 29, at 2:41 and 2:44 A.M., slight quakes were felt at Nanawale Ranch, 3 miles east of Pahoa. They had their origin on the east rift zone of Kilauea.

Tilting of the ground surface at the northeast edge of Kilauea caldera was eastward, rather than north-northeastward, as is normal at that time of the year. This probably indicates a decrease of pressure beneath the volcanic structure to the south and southeast of the Whitney Laboratory.

Liberation of steam and sulfurous fume continued weak to moderate along the vent fissures of the recent eruption in east Puna. There was no sign of any resumption of volcanic activity in east Puna, or elsewhere.

September

Volcanoes on the island of Hawaii remained quiet during the month of September. The Bosch-Omori seismograph in the Whitney Laboratory of Seismology recorded only 22 earthquakes. This was one less than during August, and one more than during July. The more sensitive Sprengnether vertical seismograph at the Uwekahuna station recorded 164 quakes during the month. The Mauna Loa seismograph recorded 47, and the seismograph at Pahoa School recorded 38 quakes.

At 2:16 on the morning of September 26 an earthquake was felt strongly at the Kapapala Ranch, and weakly all over the southern part of the island, from Kalapana to south Kona. It originated on the southwest rift zone of Mauna Loa two or three miles south of Puu o Keokeo. No damage was reported.

Eastward tilting of the ground surface at the northeast rim of Kilauea caldera was approximately normal, but northward tilting was much less than usual during that season of the year. This appears to represent a small reduction in volcanic pressure beneath Kilauea and adjacent parts of the east rift zone.

October

During the month of October earthquake activity on the island of Hawaii increased somewhat over that of preceding months. The Bosch-Omori seismograph at the Whitney Laboratory of Seismology recorded 79 earthquakes, as compared with 22 during the month of September. The more sensitive Sprengnether vertical seismograph at Uwekahuna recorded 327 quakes.

Most of the earthquakes originated at or near Kilauea caldera, and probably were related to the slight sinking of the caldera region (indicated by tilting of the ground surface) that had continued ever since the end of the Puna eruption in late May. The quake felt in the Volcano district at 12:42 on the morning of October 12 came from a depth of about 15 miles beneath Kilauea caldera. Another, felt in Hilo at 10:07 P.M. on October 29, probably came from the same region. A quake felt in the Volcano district and at Pahala at 4:33 P.M. on October 24 originated near the mouth of Wood Valley, probably on the Kaoiki fault zone. Earthquakes felt at Kamuela and Umikoa at 5:17 and 11:45 P.M. on October 24 came from a depth of about 18 miles beneath the Waimea region.

The strongest earthquake of the month occurred at 4:56 P.M. on October 26, and originated near the summit of Mauna Loa. Several smaller quakes also came from Mauna Loa. Eastward tilting of the ground surface at the edge of Kilauea caldera, accompanied by less than normal northward tilting, may have indicated a small increase of volcanic pressure beneath Mauna Loa.

A series of landslides on the southwest wall of Halemaumau crater began in late September and continued into October. A large segment of the crater rim, estimated to be 100 feet long, 75 feet high, and 5 to 10 feet thick, fell into the crater during the night of October 1. The last large slide occurred on October 10, but occasional small slides continued throughout the rest of the month.

November

The Hawaiian volcanoes were very quiet through the month of November. The Bosch-Omori seismograph in the Whitney Laboratory, on the northeast rim of Kilauea caldera, recorded only 19 earthquakes during the month, the smallest number since February, 1953. The Sprengnether vertical seismograph at Uwekahuna recorded 100 quakes during November. The Loucks-Omori seismograph in the Mauna Loa station recorded 47 quakes, most of them very small.

An earthquake at 10:37 A.M. on November 2 was reported felt at Hilo, Pahoa, and in the Volcano district. It originated at a depth of about 10 miles on the east rift zone of Kilauea, near the caldera. On November 3 and 4 several tiny quakes felt in Naalehu originated very close to that town. A quake felt in central Kona at 8:16 A.M. on November 13 had its origin near Kealakekua, probably on the Kealakekua fault. At 3 P.M. on November 21 a sharp earthquake was felt only at the Volcano House and the nearby headquarters building of Hawaii National Park. Its origin was beneath the northeastern edge of Kilauea caldera.

The Pahoa seismograph recorded 17 earthquakes during November. One of these, at 8:15 P.M. on November 29, was felt at Pahoa School. It originated at a depth of about 3 miles on the east rift zone of Kilauea southeast of Pahoa. Steam and sulfur gas continued to escape from the vents of the 1955 eruption, particularly those at the old Kalapana road, those south-southeast of old Iilewa Crater, and those south of the Kapoho road. There had been essentially no change in the temperature of the escaping steam since shortly after the end of the eruption. Several places in the last flows southwest of the Kamaili–Opihikao road remained very hot. At one of them the temperature was still about 870° F. There were no signs whatever of any renewal of volcanic activity in Puna.

Tilting of the ground surface at the Whitney Laboratory was almost due eastward throughout the month. Normally at that season of the year the tilting is north-northeastward. The absence of northward tilting during November appeared still to be

the result of a slow sinking of the top of Kilauea volcano south of the Whitney Laboratory that had continued ever since the end of the Puna eruption. The sinking is believed to have been caused by a small reduction in volcanic pressure beneath the volcano. The eastward tilting, combined with an absence of northward tilting, may indicate a slight swelling of Mauna Loa volcano, but the evidence is inconclusive.

December

Except for the continued liberation of steam along the vents of the 1955 eruption, Hawaiian volcanoes remained quiet during December.

Twenty-nine earthquakes, about the average for months of volcanic quiet, were recorded during December at the Whitney Laboratory. Only 10 earthquakes from the Puna area were recorded at Pahoa during December.

On December 12 and 13 a swarm of tiny earthquakes originated about 45 km. beneath Kilauea caldera. The sensitive Sprengnether seismograph at Uwekahuna recorded about 200 earthquakes from that source on those two days. A total of 307 earthquakes, mostly very small, were registered on the Sprengnether seismograph during the month.

A small earthquake which probably originated in the Hualalai volcano was felt at Honokohau at 3:15 P.M. on December 7. The earthquake felt on the island of Oahu at 2:23 P.M. on December 26, was recorded feebly on the Uwekahuna seismograph. At 2:14 P.M. on December 28 an earthquake originating along the southwest rift of Kilauea was felt at the Kapapala ranch. Later the same day, at 6:02 P.M., an earthquake stemming from the north rim of Kilauea caldera at a very shallow depth was felt at Kilauea Military Camp.

SEISMOLOGY

Local Earthquake Data, July–December, 1955

(Based on Bosch-Omori seismograph on northeast rim of Kilauea caldera)

Week Beginning	Minutes of Tremor	Very Feeble	Feeble	Slight	Moderate	Strong	Total	Local Seismicity*

* For definition of local seismicity see *Volcano Letter* 371 or 512. Each local earthquake is assigned a seismicity value according to its strength, as follows: tremor, 0.25; very feeble, 0.5; feeble, 1.0; slight, 2.0; moderate, 3.0; strong, 4.0. These values are totaled to give the weekly local seismicity. Continuous volcanic tremor ("harmonic tremor") is ignored in the calculation. The strength assigned to the earthquake depends on the double amplitude of the maximum oscillation it causes on the Bosch-Omori seismograph, as follows: tremor, less than 0.5 mm.; very feeble, 0.5 to 4 mm.; feeble, 4 to 11 mm.; slight, 11 to 25 mm.; moderate, 25 to 60 mm.; strong, greater than 60 mm.

Table of Tilt at Seismograph Stations on Rim of Kilauea Caldera

Local Earthquakes

The data for the following local earthquakes were determined from seismographs on the islands of Hawaii and Maui operated by the Hawaiian Volcano Observatory. Except for smaller earthquakes of special interest, only earthquakes classed as slight or larger were included in the list. The intensity ratings assigned are based on the Bosch-Omori seismograph at the Whitney Laboratory. This intensity scale has been extended empirically to permit its use with the Loucks-Omori and Sprengnether seismographs. The entries for a given earthquake are: date, time of arrival at the nearest station (Hawaiian standard time), intensity at the nearest station, name of the nearest station, epicenter, and general remarks.

July 3, 10:40:18, slight at Uwekahuna. Kilauea caldera.

July 10, 14:34:49, slight at Uwekahuna. Five km. north of Apua Point.

July 23, 11:27:16, moderate at Uwekahuna. Just south of Makaopuhi Crater. Felt in Hilo.

July 23, 22:03:17, moderate at Pahoa. East rift of Kilauea near Pahoa.

July 25, 07:50:34, feeble at Naalehu. Off south shore of Hawaii at 19° N., 155° 10′ W.

July 27, 02:58, slight at Kona. Near Keahole Pt. Felt over northwest one third of the island of Hawaii.

Aug. 7, 07:17:44, strong at Kamuela. Five km. northeast of Kamuela at a depth of 40 km. Felt over the entire island of Hawaii, on Maui, and on Oahu.

Aug. 9, 21:33:25, very feeble at Uwekahuna. About 60 km. deep in the vicinity of Kilauea caldera. This earthquake is the largest of several hundred originating in the same region on Aug. 9 and Aug. 10.

Aug. 14, 02:28:05, strong at Uwekahuna. On the Hilina fault system south of the Volcano Observatory at a depth of about 25 km. Felt over the entire island of Hawaii, on Maui, on Oahu, and by a few persons on Kauai.

Sept. 19, 14:01:54, slight at Pahoa. East rift of Kilauea near Pahoa.

Sept. 26, 02:16:00, strong at Naalehu. Southwest rift of Mauna

Loa near Puu Keokeo. Felt over the southwest half of the island of Hawaii.

Oct. 12, 00 : 41 : 42, slight at Uwekahuna. Under Kilauea caldera at a depth of about 25 km. Felt at Hawaii National Park.

Oct. 24, 17 : 16 : 53, slight at Kamuela. Near Kamuela at a depth of about 25 km.

Oct. 26, 16 : 55 : 45, strong at Mauna Loa. Near the northeast end of Mokuaweoweo. Felt at Hawaii National Park.

Nov. 2, 10 : 36 : 44, slight at Uwekahuna. East rift of Kilauea near Kilauea caldera at a depth of about 15 km. Felt at Volcano, Pahoa, and Hilo.

Nov. 13, 08 : 16 : 24, (time at Uwekahuna), strong at Kona. Near Kealakekua. Felt in central Kona.

Nov. 21, 14 : 59 : 54, slight at the Whitney Laboratory. Northeast rim of Kilauea caldera. Felt at Hawaii National Park Headquarters.

Nov. 29, 20 : 15 : 20, (time at Uwekahuna), feeble at Pahoa. East rift of Kilauea southeast of Pahoa at a depth of about 5 km. Felt at Pahoa.

Dec. 12, 12 : 33 : 12, tremor at Uwekahuna (very feeble at Mauna Loa). Under Kilauea caldera at a depth of about 45 km. This earthquake is one of the largest of a swarm of about 200 earthquakes stemming from this focus on Dec. 12 and 13.

Dec. 26, 14 : 23 : 34, (time at Uwekahuna), very feeble at Haleakala. Near the north coast of Molokai. Felt on Oahu.

Dec. 28, 18 : 02 : 25, moderate at the Whitney Laboratory. Near the north rim of Kilauea caldera. Felt at Kilauea Military Camp.

Distant Earthquakes

The following earthquakes of distant origin were recorded on the seismographs at the Hawaiian Volcano Observatory (19° 25.4′ N. latitude, 155° 17.7′ W. longitude). Beginnings of phases are given in Greenwich civil time, which is 10 hours faster than Hawaiian standard time. Locations of epicenters, magnitudes, and depths of focus are from the notices of Preliminary Determinations of Epicenters published by the U. S. Coast and Geodetic Survey.

July 3, eP 14 : 33 : 56.7, 52° N., 178° E. Rat Islands, Aleutian Islands.

July 4, eP 14 : 27 : 09.8, 51½° N., 177° E. Rat Island, Aleutian Islands. Magnitude 6½—6¾.

July 6, eP 02 : 03 : 03.9, 51° N., 158° E. Kamchatka. Magnitude 6¾.

July 20, eL 00 : 11 : 15, 56½° N., 153° W. Near south coast of Kodiak Island. Magnitude 6.

July 21, eP 11 : 58 : 56.4, 25° S., 74° W. Southern Peru. Magnitude 6¾. Depth about 100 km.

July 24, iP 16 : 31 : 58.2, 24° N., 122° E. Near east coast of Formosa. Felt at Hualien and Shinko.

July 26, eL 04 : 24 : 34, 56½° N., 153° W. Kodiak Island foreshock. Magnitude 6.

July 27, eP 18 : 26 : 29.0, 56½° N., 153° W. Near south coast of Kodiak Island. Magnitude 6¼.

Aug. 6. iP 08 : 39 : 19.5, 21½° S., 177½° W. Tonga Islands region. Magnitude 6¾. Depth about 350 km.

Aug. 16, iP 11 : 56 : 17.4, 6° S., 155° E. Solomon Islands. Magnitude 7¼. Depth about 200 km.

Aug. 21, iP 17 : 45 : 14.5, 3° S., 137½° E. New Guinea. Magnitude 6¾—7.

Aug. 23, eP 15 : 39 : 21.6, 43½° N., 128° W. About 170 miles
eT 16 : 13 : 57, off coast of Oregon. Magnitude 6—6½.

Aug. 24, eL 07 : 12 : 26, 44½° N., 129½° W. Off coast of Oregon.
eT 07 : 36 : 47,

Aug. 28, eP 20 : 23 : 48.9, 14° N., 91° W. Near coast of Guatemala. Magnitude 6¾. Depth about 60 km.

Sept. 3, eP 12 : 46 : 34.8, 14° N., 91° W. Guatemala. Felt. Magnitude 6½. Depth about 100 km.

Sept. 3, iP 16 : 35 : 21.7, 1° N., 123° E. Celebes.

Sept. 8, eP 03 : 36 : 56.3, 7° S., 155½° E. Solomon Islands.

Sept. 13, eP 02 : 07 : 44.8, 52° N., 176° W. Andreanof Islands,
eT ?02 : 45 : 48, Aleutian Islands. Magnitude 5¾—6. Depth about 60 km.

Sept. 15, eP 12 : 42 : 06.1, 5° S., 134½° E. Off coast of western New Guinea. Magnitude 6¾.

Sept. 20, eP 13 : 30 : 00.2, 32° S., 178° W. Kermadec Islands. Magnitude 6½.

Sept. 22, eP 03 : 36 : 55.0, 24° N., 123° E. Off east coast of Formosa. Felt: Taipeh.

Sept. 25, eP 19 : 11 : 13.9, 6° N., 127½° E. Off east coast of Mindanao, Philippine Islands. Felt: Mindanao. Magnitude 6½. Depth about 100 km.

Sept. 26, iP 08 : 38 : 17.7, 15½° N., 92½° W. Chiapas, Mexico. Magnitude 6¾. Depth about 200 km.

Oct. 5, eP 09 : 06 : 47.9, 53½° N., 161° E. Near east coast of Kamchatka.

Oct. 10, eP 09 : 07 : 33.1, 5° S., 153° E. New Britain. Magnitude
eL 09 : 25 : 45, 7¼.

Oct. 13, iP 09 : 35 : 58.6, 9½° S., 161° E. Solomon Islands. Magnitude 7.

Oct. 14, eL 09 : 09 : 44. 3° S., 103½° W. Pacific Ocean, west of Galapagos Islands. Magnitude 6—6¼.

Oct. 21, iP 19 : 10 : 14.4, 21° S., 179° W. Fiji Islands. Depth about 650 km. Magnitude 6¼.

Oct. 21, eP 23 : 22 : 08.6, ½° S., 123½° E. Northern Celebes.

Nov. 10, iP 01 : 51 : 32.3, 15° S., 174° W. Samoa Islands. Depth about 100 km. Magnitude 7¼—7½.

Nov. 14, eP 13 : 32 : 36.1, 17½° N., 145½° E. Marianas Islands. Depth about 150 km.

Nov. 15, eP 10 : 13 : 49.2, 55½° N., 155° W. Off south coast of
eT 10 : 51 : 03, Alaska Peninsula. Magnitude 6—6¼.

Nov. 22, eP 03 : 33 : 37.1, 24½° S., 123° W. Eastern Tuamotu
eS 03 : 41 : 14.1, Archipelago. Magnitude 6¾—7.
eL 03 : 52 : 16.1,
eT 04 : 30 : 51,

Nov. 23, eP 06 : 38 : 32.2, 50½° N., 157° E. Near south coast of
eL 06 : 52 : 33, Kamchatka. Depth about 60 km. Magnitude 7—7¼.

Dec. 19, eP 03 : 25 : 42.1, 8½° N., 127° E. Near east coast of Mindanao Island, Philippine Islands.

Dec. 27. iP 17 : 29 : 48.4, 32° S., 180°. Kermadec Islands. Depth about 400 km.

VOLCANO NOTES AND NEWS

CHANGE IN VOLCANO OBSERVATORY STAFF

On December 12, Dr. Jerry P. Eaton replaced Gordon A. Macdonald as Director of the Hawaiian Volcano Observatory. The rest of the staff remains unchanged. Dr. Macdonald will be transferred to the United States mainland in the summer of 1956, and will be attached to the Denver office of the General Geology Branch of the Geological Survey. No replacement for him has yet been named.

ERROR IN Volcano Letter 526, "KAUAI, AN ANCIENT HAWAIIAN VOLCANO"

A phrase was omitted in the first sentence on page 2 of *Volcano Letter* 526. The sentence should read: "The rocks that accumulated in the big summit caldera are named the Olokele formation, and those that filled the small caldera on the southeastern slope of the shield are named the Haupu formation."

POSSIBLE ERUPTIONS NEAR NECKER ISLAND AND WEST OF THE HAWAIIAN CHAIN

On August 20 the crew and passengers of a M.A.T.S. plane sighted an oval area of steaming turbulent water, about a mile across, between Necker and Nihoa Islands in the northern part of the Hawaiian chain. The patch was surrounded by a thin line of yellowish surf, and near one end of the oval was what appeared to be an acre or two of dry land. Yellowish water drifted off down current. The next day all this had disappeared, and there was left only a slick appearance of the water surface where the turbulence had been, and a series of large waves sweeping outward away from the area.

The description is typical of submarine eruptions, and it appears probable that a brief submarine eruption did occur. The supposed dry land that disappeared so quickly probably was a raft of floating pumice. Hawaiian pumice is so permeable that it floats only a very short time.

The eruption occurred in a part of the Hawaiian Islands in which there has been no known previous volcanic activity during historic times. It is quite possible, however, that such activity may have occurred. The nearby islands are uninhabited. The area lies away from the regular shipping lanes, and although it is visited nowadays by many fishing boats, this is a rather recent development. Eruptions could easily have occurred in that area during the 19th century without being observed by anyone. Even today, with frequent air travel over the area, only one plane chanced to see it.

Although it was not specifically foreseen, the eruption is not surprising. The entire Hawaiian ridge, from Kure and Midway Islands on the northwest to Hawaii on the southeast, is volcanic. The northwestern islands are mostly old and deeply eroded, but geologically young lava flows are found on both Oahu and Kauai. Geologists working in the islands have long recognized the possibility that volcanic activity might occur again on those islands. The probability is small. It has not occurred during all the time the Hawaiian people have lived in the islands, and it is not likely to occur in the lifetime of any living person. But it is nevertheless a distinct possibility.

On September 22 planes reported brown and yellow streaks in the ocean and smoke rising from the water about 385 miles due west of Honolulu (205 miles south of Necker Island). The reports made a much less definite picture than those of August 20, and it is not at all certain that the disturbance was of volcanic origin.

VOLCANIC ACTIVITY IN OTHER PARTS OF THE WORLD

Volcanoes in many parts of the world have been active in recent months. Mount Etna, in Sicily, was active in late June and July, and lava flows threatened several villages. On September 3 an outbreak 14 miles south of Mexicali, in northern Lower California, Mexico, appears to have been a low temperature eruption related to mud volcanoes and geysers rather than to ordinary volcanic eruptions. A similar eruption appears to have occurred in the same region in 1877. In October a ship passing through the Philippine Sea reported boiling water about 600 miles east of the Didicas Rocks, where volcanic activity built a dome in 1952 and 1953. This position is at approximately 19° 10′ N., and 132° 15′ E., nearly due south of the Daito Islands, and a little south and west of a point where a submarine eruption was reported in 1854 (Sapper, K., Vulkankunde, p. 320). On October 22 long-dormant Bezymyanny volcano in Kamchatka erupted, and continued active into late November.

Particularly abundant activity occurred in Japan. The following information was supplied by Mr. Akira Suwa, Chief of the Volcanological Subsection of the Central Meteorological Observatory. On July 24 Naka-dake, one of the vents of Aso volcano in central Kyushu, broke into strombolian eruption, throwing incandescent bombs to a height of 200 to 300 meters above the crater rim. On October 13 eruption commenced at the South Peak of Sakurajima, near the southern end of Kyushu. Activity continued until the end of the month. On November 19 a minor explosion occurred at Me-akan-dake, near the Akan caldera in eastern Hokkaido.

Stromboli, off the western coast of Italy, was reported in eruption on January 3, 1956. On January 4 Merapi volcano, in central Java, erupted, sending glowing clouds down the mountainside toward populous districts at the base of the volcano.

STAFF OF HAWAIIAN VOLCANO OBSERVATORY

U. S. Geological Survey:

Gordon A. Macdonald, Volcanologist, Director
Jerry P. Eaton, Seismologist
Chester K. Wentworth, Geologist, part-time
Burton J. Loucks, Instrument Maker
John C. Forbes, Assistant Instrument Maker
Akira Yamamoto, Secretary

Seismograph Station Operators:

Hilo Station:
Sister M. Thecla, St. Joseph's School
