ABSTRACT

Statewide regression equations are defined for estimating peak discharges of floods having recurrence intervals ranging from 2 to 500 years. Contributing drainage area, main-channel slope and mean annual precipitation are the independent variables required for estimating flood discharges for rural streams. For urban streams the percentage of the basin that is impervious and served by storm sewers also is required. The regression equations are applicable for watersheds draining less than 2,500 mi^2 (6,500 km^2) that are not significantly affected by regulation. For the rural streams, the regression equations are presented in graphical form for easy application.

Calibration of a U.S. Geological Survey rainfall-runoff model and synthesis of long-term annual peak data for 60 small watersheds is discussed. Synthetic frequency curves, generated using six long-term rainfall stations, are combined into one frequency curve and weighted with the observed frequency curve at each site. Use of the rainfall-runoff model parameters to estimate flood discharges reduces the standard error for selected frequencies by 9-12 percent. However, collection of the necessary rainfall-runoff data to determine the model parameters is time consuming and expensive.

Annual peak data, basin and climatic characteristics, log-Pearson Type III statistics, and the flood-frequency relations are presented for 188 gaging stations.

INTRODUCTION

The design of highway bridges, culverts, embankments, dams, levees, and other structures near streams, requires a knowledge of the magnitude and frequency of floods. Flood-plain management programs and flood-insurance rates also are based on information on flood magnitude and frequency.

The purpose of this report is to provide methods for estimating the magnitude and frequency of floods for Oklahoma streams draining less than 2,500 mi^2 (6,500 km^2). Flood discharge records at 165 gaging stations throughout the State were used to define the flood-frequency curve for each site. Estimates of selected frequency floods were related to basin, climatic, and channel-geometry characteristics by multiple regression techniques. These analyses indicated that contributing drainage area, main-channel slope and mean annual precipitation were the most significant variables for estimating flood discharges for rural streams in Oklahoma. The regression equations derived in these analyses are presented in graphical form and provide a simple and reliable technique for estimating flood frequency for rural streams. The methods developed for calculating the magnitude and frequency of floods do not apply to streams significantly affected by regulation. Procedures given by Sauer (1974b) for adjusting flood discharges for the effect of urbanization were compared with the results of modeling three urban watersheds in Oklahoma City using a U.S. Geological Survey rainfall-runoff model. This comparison indicated there was not sufficient justification for revising Sauer's earlier report (1974b). For completeness the equations from Sauer's report (1974b) are given in this report so that flood discharges may be adjusted for urbanization.

The calibration of the rainfall-runoff model and generation of long-term synthetic data for these 3 urban watersheds and 57 rural watersheds are discussed in this report. Procedures are given for combining synthetically derived flood-frequency curves with flood-frequency curves based on observed data. Possible applications of the model parameters in estimating flood magnitude and frequency are illustrated. Flood data for 188 stations (including 23 stations not used in the analysis) are given in appendices A, B, and C. The majority of the 23 stations not used in the analysis were watersheds draining

less than 100 mi^2 (260 km^2) with less than 8 years of annual peak data or obvious time-sampling bias.

This report should be used in preference to an earlier report by Sauer (1974a) for estimating flood discharges for rural streams draining less than 2,500 mi^2 (6,500 km^2) because (1) it is based on 4 years of additional data and many additional gaging station records, (2) it utilizes long-term synthetic data generated at 57 small-stream sites (excluding 3 urban sites) by rainfall-runoff modeling procedures, and (3) it uses methods outlined in U.S. Water Resources Council Bulletin 17 (1976) for computing station flood-frequency curves. This report does not provide techniques for estimating flood discharges for streams draining more than 2,500 mi^2 (6,500 km^2) and, therefore, Sauer's report (1974a) should be used for estimating flood frequency for the large streams.

The contents of this report do not necessarily reflect the official views or policies of the Federal Highway Administration. The report is the result of a cooperative agreement among the Oklahoma Department of Transportation, the Federal Highway Administration, and the U.S. Geological Survey. Most of the small-stream data used in this report were collected under this cooperative agreement. The large watershed data were collected for many years (beginning about 1930) as part of cooperative programs with various State and Federal agencies. Data on the main-channel width and depth, on basin slope for the large watersheds, and on annual flood peaks for several small watersheds were obtained from the Agricultural Research Service, U.S. Department of Agriculture, Chickasha, Okla. Long-term daily precipitation records and storm precipitation reductions to 5-minute increments were obtained from the National Oceanic and Atmospheric Administration.

ESTIMATING TECHNIQUES

This section briefly outlines the procedures to use when estimating flood magnitude and frequency for an unregulated site draining less than 2,500 mi^2 (6,500 km^2) in Oklahoma. A detailed discussion of the data base, the computation of the station flood-frequency curves, and the multiple regression

analysis are discussed in subsequent sections of this report. The reader interested in the justification of the relations or the analytical techniques should consult these sections.

RURAL GAGED SITES

When estimating flood magnitude and frequency for rural gaged sites, first check figure 1 for gage location and station number. Using this station number determine the appropriate flood discharge value from appendix A. This is a weighted estimate, $Q_{x(w)}$, for recurrence interval x based on the station data (app. B) and the regression estimate, $Q_{x(r)}$. This weighting procedure is explained later in the report and illustrated in the section on "Application of Techniques." This section is entitled "Rural Gaged Sites" because at the present time (1977), there are no urban gaged sites in Oklahoma with sufficient record to define a flood-frequency curve. Appendix A does contain flood-frequency curves for three urban sites (07159450, 07242200, 07242220) but these frequency curves were estimated using a rainfall-runoff model.

UNGAGED RURAL SITES

Multiple regression techniques were used to relate estimates of the 2-, 5-, 10-, 25-, 50-, 100-, and 500-year floods (app. B) to basin, climatic and channel-geometry parameters. Of all the parameters investigated, drainage area, main-channel slope, and mean annual precipitation were the most significant for estimating flood peaks for ungaged rural sites. The three parameters used in the regression equations are listed in appendix A for each station and defined as follows:

(1) Drainage area, (A) - The contributing draining area of the basin, in square miles (mi^2).

(2) Main-channel slope, (S) - The slope, in feet per mile (ft/mi), determined from elevations at points 10 and 85 percent of the distance along the channel from the gaging station to drainage basin divide.

(3) Mean annual precipitation, (P) - The mean annual precipitation for the basin, in inches (in), during the period 1931-60. See figure 2.

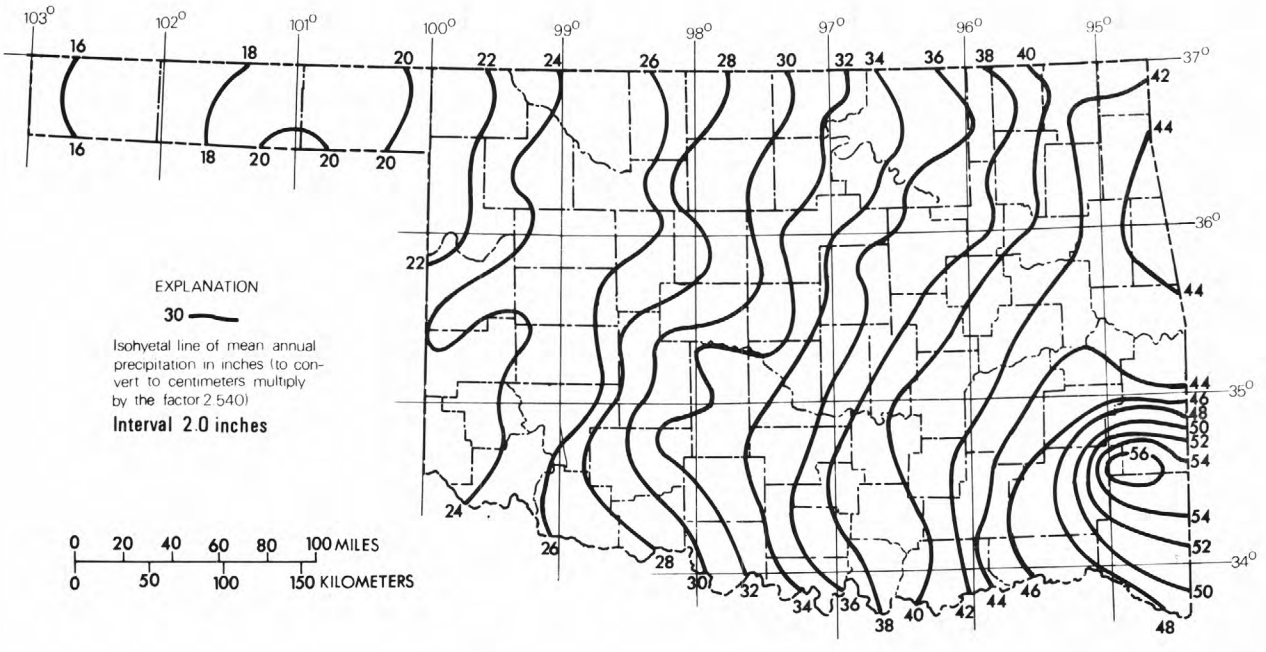

Figure 2.--Mean annual precipitation for the period 1931-60.

The model used in the regression analysis has the following form:

$$Q_x = a\ A^b\ S^c\ P^d \quad (1)$$

where Q_x = peak discharge, in cubic feet per second (ft^3/s) for recurrence interval x,

a = regression constant

b, c, and d = regression coefficients, and

A, S, and P = basin and climatic parameters as defined above.

The following equations were computed by regression analyses.

$$Q_2 = 0.111\ A^{0.66}\ S^{0.23}\ P^{1.92} \quad (2)$$

$$Q_5 = 1.00\ A^{0.67}\ S^{0.26}\ P^{1.45} \quad (3)$$

$$Q_{10} = 2.99\ A^{0.68}\ S^{0.28}\ P^{1.22} \quad (4)$$

$$Q_{25} = 9.49\ A^{0.69}\ S^{0.30}\ P^{0.97} \quad (5)$$

$$Q_{50} = 20.0\ A^{0.69}\ S^{0.31}\ P^{0.81} \quad (6)$$

$$Q_{100} = 38.6\ A^{0.70}\ S^{0.32}\ P^{0.67} \quad (7)$$

$$Q_{500} = 140\ A^{0.71}\ S^{0.33}\ P^{0.40} \quad (8)$$

The above equations are based on English units of measurements. They are not applicable for use with metric units. To convert the final answers of discharge from cubic feet per second to the metric equivalent of cubic meters per second, multiply by the factor, 0.0283. Equations 2-8 are shown graphically in figures 3, 4, 5, 6, 7, 8, and 9 respectively.

To estimate flood magnitude and frequency for ungaged rural sites, first determine the drainage area and main-channel slope (as defined above) from the best available map or field survey. The mean annual precipitation can be determined from figure 2. Enter figures 3-9 with drainage area along the top scale and move downward vertically to the appropriate main-channel slope curve. Move horizontally across to the appropriate mean annual precipitation curve and downward vertically to the discharge scale to obtain $Q_{x(r)}$, the regression estimate. Use of figures 3-9 is illustrated in the section on "Application of Techniques."

UNGAGED SITES NEAR GAGING STATIONS

The combined use of the regression equations or graphs (figs. 3-9) and the station data can be used for estimating the magnitude and frequency of floods for ungaged sites near gaging stations and on the same stream. The following procedure is suggested for use if the site has a drainage area within 50 percent of the drainage area of the gaging station. Define the ratio $R = \frac{Q_{x(w)}}{Q_{x(r)}}$, where $Q_{x(w)}$ is the weighted estimate (app. A) and $Q_{x(r)}$ is the regression estimate (figs. 3-9). This ratio represents the correction needed to adjust the regression estimate, $Q_{x(r)}$, to the weighted estimate, $Q_{x(w)}$, at the gaged site. The following equation derived by Sauer (1974a) gives the correction factor R', for an ungaged site that is near a gaged site on the same stream,

$$R' = R - \frac{\Delta A}{0.5A_g}(R - 1.00) \qquad (9)$$

where ΔA is the difference between the drainage areas of the gaged and ungaged sites, and A_g is the drainage area of the gaged site. The correction factor R' is multiplied times the regression estimate, $Q_{x(r)}$, for the ungaged site to make adjustment for the nearby station data. If the drainage area of the ungaged site is 50 percent more than or less than the gaged site, that is, $\Delta A/A_g$ is greater than 0.5, equation 9 should not be used and the regression equations 2-8 should be used without adjustment. If the drainage area of the ungaged site is within 50 percent of two gaged sites, the frequency calculations for the ungaged site can be made by interpolation of the weighted station values ($Q_{x(w)}$) for each gaged site. Interpolation should be on the basis of drainage area. If the flood discharges for the ungaged site are affected by urbanization, they should be modified by techniques given in the following section.

UNGAGED URBAN SITES

For estimating flood magnitude and frequency for ungaged urban sites, the percentage of the basin impervious and served by storm sewers is required in addition to the variables needed for rural sites. The percentage of the basin impervious can be determined from aerial photographs, recent U.S. Geological Survey topographic maps or field surveys. The percentage of the basin served by storm sewers should be determined from the best available storm sewer and

drainage map. After determining the percentage of the basin impervious and served by storm sewers, obtain R_L, the urban adjustment factor, from figure 10 (Leopold, 1968). The urban adjustment factor R_L, is the ratio of the mean annual flood under urban conditions to rural conditions. The following equations computed by Sauer (1974b) can be used to adjust estimates from equations 2-8 to urban conditions:

$$Q_{2(u)} = R_L\, Q_2 \tag{10}$$

$$Q_{5(u)} = 1.60\ (R_L-1)\ Q_2 + 0.167\ (7-R_L)\ Q_5 \tag{11}$$

$$Q_{10(u)} = 1.87\ (R_L-1)\ Q_2 + 0.167\ (7-R_L)\ Q_{10} \tag{12}$$

$$Q_{25(u)} = 2.21\ (R_L-1)\ Q_2 + 0.167\ (7-R_L)\ Q_{25} \tag{13}$$

$$Q_{50(u)} = 2.46\ (R_L-1)\ Q_2 + 0.167\ (7-R_L)\ Q_{50} \tag{14}$$

$$Q_{100(u)} = 2.72\ (R_L-1)\ Q_2 + 0.167\ (7-R_L)\ Q_{100} \tag{15}$$

$$Q_{500(u)} = 3.30\ (R_L-1)\ Q_2 + 0.167\ (7-R_L)\ Q_{500} \tag{16}$$

To apply the above equations, use the R_L value determined from figure 10, determine Q_2 from figure 3, and the appropriate value of Q_x from figures 4-9. Sauer (1974b) provides more information on the assumptions made in computing equations 10-16.

ACCURACY AND LIMITATIONS

The accuracy of the regression equations 2-8 can be expressed in two ways, percent or equivalent years of record. The accuracy in percent referred to as the standard error of estimate, is the accuracy to be expected, on the average, two-thirds of the time. Hardison (1969) related the standard error of estimate and streamflow variability to equivalent years of record. When converted to equivalent years of record, the standard error of estimate is expressed as the number of actual years of streamflow records needed at the ungaged site to provide an estimate equal in accuracy to the standard error of estimate. The accuracy of the regression equations 2-8 is summarized in table 1. The accuracy of the urban equations 10-16 could not be determined because of the paucity of actual urban runoff data to compare with the computed values.

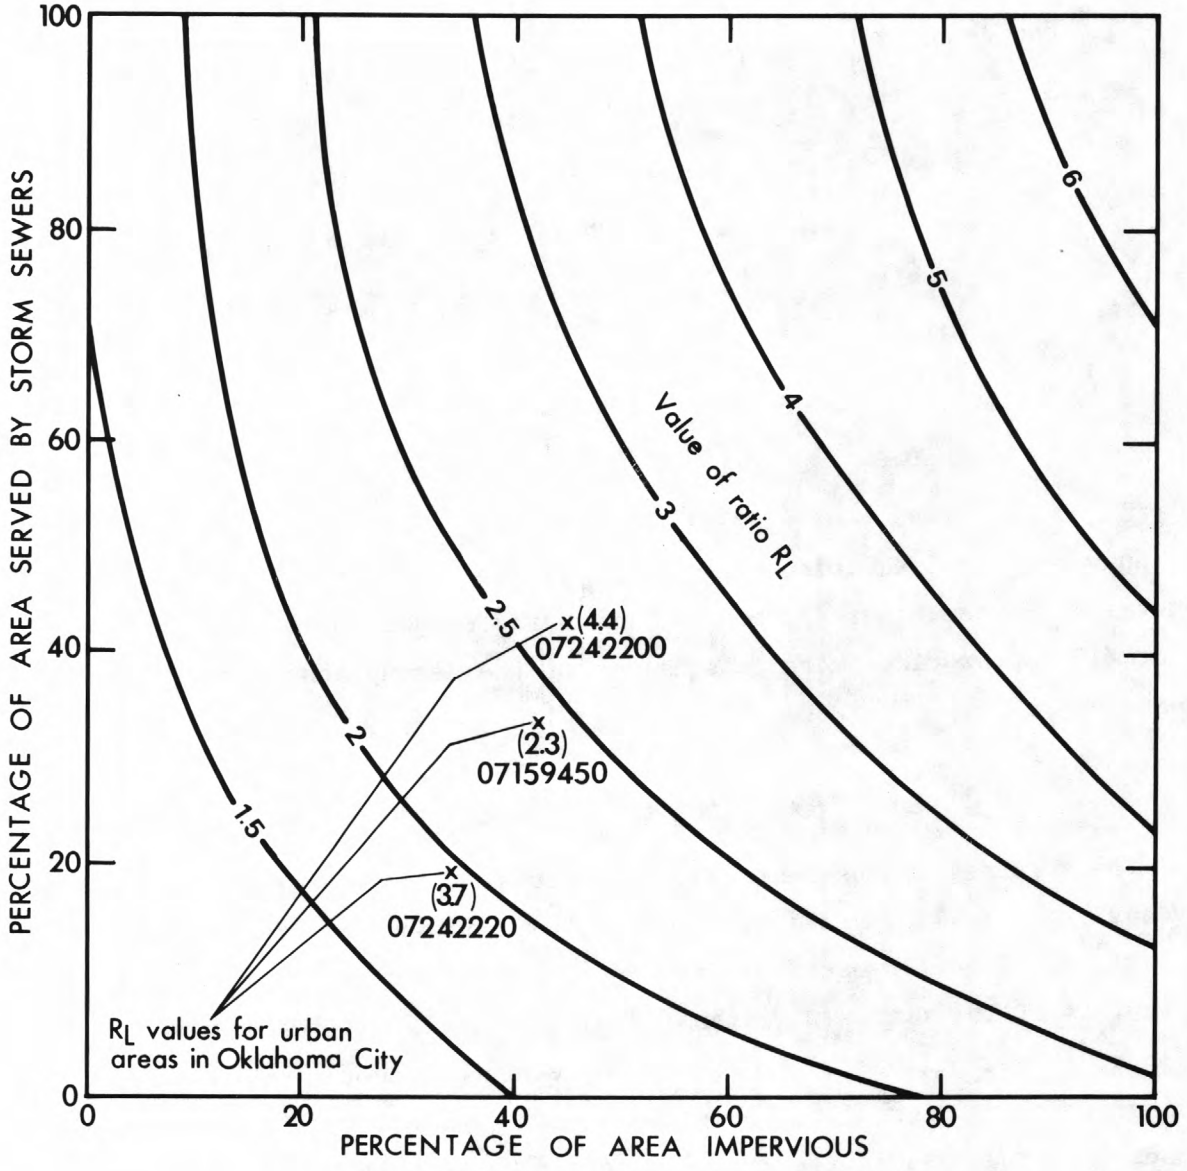

Figure 10.--Relationship of the urban adjustment factor, R_L, to the percentage of the area impervious and served by storm sewer (Adapted from Leopold, 1968).

Table 1.--Accuracy of regression equations

Recurrence interval in years	Standard error of estimate, in percent	Equivalent years of record
2	48*	3
5	40	6
10	39	8
25	40	10
50	42	11
100	45	12
500	53	12

*Variables other than A, S, and P are significant for estimating Q_2. Inclusion of these variables in the regression equation reduces the standard error of Q_2.

The increase in the standard error of estimate as the recurrence interval increases is indicative of the larger time-sampling error for the higher recurrence interval floods. This increase in time-sampling error simply means that it is more difficult to predict the larger floods with the same years of actual record. Because the time-sampling error increases more than the standard error of estimate, the equivalent years of record increases with recurrence interval. The 12 years equivalent record for Q_{100} means that the regression estimate is as accurate as an estimate of Q_{100} based on 12 years of actual record.

Split-sampling techniques were used to verify that the standard errors of estimate given in table 1 were indicative of the true predictive accuracy of the regression equations. Regression equations were computed using 83 gaging stations randomly distributed about the State. Estimates of Q_{10}, Q_{50}, Q_{100}, and Q_{500} from these equations were compared to station estimates from the remaining 82 stations not used to compute the equations. The resultant standard errors agreed closely with those in table 1.

The regression equations should not be used to predict flood discharges on drainage basins in excess of 2,500 mi^2 (6,500 km^2) or those basins having values of S and P outside the range of values used to define the equations. In defining equations 2-8 values of S ranged from 2.6 - 246 ft/mi (0.49 - 4.65 m/km) and P ranged from 15.4 - 54.0 in (391.2 - 1,371.6 mm). Equations 2-8 should not be used for those basins significantly affected by regulation. Estimates from equations 2-8 can be adjusted by equations 10-16 to account for urbanization effect.

Extreme local conditions such as deep sandy soils, shallow clay soils or variations in vegetative cover may cause discharge estimates to vary from regionalized values. Engineering judgment should be used when applying equations 2-8.

APPLICATION OF TECHNIQUES

Estimates of flood magnitude and frequency for rural gaged sites are combinations of station data and regression estimates. The equivalent years of record concept is used to combine station estimates with regression estimates of peak flow to obtain a weighted estimate at the gaged site. This procedure was described by Sauer (1974a) and is expressed in the following equation:

$$Q_{x(w)} = \frac{Q_{x(s)}\ (N) + Q_{x(r)}\ (E)}{N + E} \qquad (17)$$

where $Q_{x(w)}$ is the weighted estimate for recurrence interval x (app. A), $Q_{x(s)}$ and $Q_{x(r)}$ are the station (app. B), and regression estimate (figs. 3-9) for recurrence interval x, N is the number of actual years of record at the gaged site and E is the equivalent years of record for recurrence interval x (table 1). The weighted estimate is considered more reliable than either the regression or station data when making an estimate of flood frequency at gaged sites. The following example illustrates how a weighted estimate is calculated and how to use figures 3-9. The example computation is for the station 07159000 Turkey Creek near Drummond.

Table 2.--Computation of a weighted flood-frequency curve for Turkey Creek near Drummond (07159000)

Recurrence interval, x (years)	$Q_{x(s)}$ (ft^3/s)	N years	$Q_{x(r)}$ (ft^3/s)	E years	$Q_{x(w)}$ (ft^3/s)
2	2730	28	3580	3	2810
5	7260	28	7600	6	7320
10	11900	28	11600	8	11800
25	20000	28	17700	10	19400
50	27800	28	22200	11	26300
100	37200	28	29200	12	34800
500	66200	28	46700	12	60400

The columns $Q_{x(s)}$ and N reflect the computed frequency curved defined from the 28-year record at station 07159000. The column labeled $Q_{x(r)}$ was computed by using figures 3-9 and the following basin and climatic characteristics for station 07159000:

$A = 248\ mi^2\ (642\ km^2)$

$S = 5.70\ ft/mi\ (1.08\ m/km)$

$P = 27.2\ in\ (690.9\ mm)$

Enter the figures with drainage area ($248\ mi^2$) along the top scale. Move downward (following the dotted lines) to the main-channel slope curves to 5.70 ft/mi. Move horizontally across to the mean annual precipitation curves to 27.2 in. Move downward to the discharge scale to obtain $Q_{x(r)}$ given above in table 2. The weighted estimates, $Q_{x(w)}$, were computed from equation 17 using values of E from table 1.

To utilize some of the information in table 2, assume an estimate of the 100-year flood is needed upstream from station 07159000 on Turkey Creek. Assume the following hypothetical basin and climatic characteristics:

$A = 150\ mi^2\ (388\ km^2)$

$S = 10.00\ ft/mi\ (1.89\ m/km)$

$P = 27.0\ in\ (685.8\ mm)$

The following data and calculations are needed to estimate Q_{100} at the ungaged site.

(1) Gaged site, 07159000 Turkey Creek near Drummond

$A_g = 248\ mi^2\ (642\ km^2)$

$Q_{100(r)} = 29{,}200\ ft^3/s\ (826\ m^3/s)$, from figure 8 or equation 7

$Q_{100(w)} = 34{,}800\ ft^3/s\ (985\ m^3/s)$, from appendix A or the previous example

$R = Q_{100(w)}/Q_{100(r)} = 1.19$

(2) Ungaged site on Turkey Creek

$A = 150\ mi^2\ (388\ km^2)$

$Q_{100(r)} = 24{,}500\ ft^3/s\ (693\ m^3/s)$, from figure 8 or equation 7

$\Delta A = 98\ mi^2\ (254\ km^2)$

$\frac{\Delta A}{A_g}$ = 0.40 (This is less than 0.5, therefore, R' should be computed from equation 9 and used to adjust $Q_{100(r)}$)

$R' = 1.19 - \frac{98}{0.5(248)} (1.19 - 1.00) = 1.04$

$Q_{100} = Q_{100(r)} (R') = 24{,}500 (1.04) = 25{,}500 \text{ ft}^3/\text{s} (722 \text{ m}^3/\text{s})$

Therefore, the estimate of the 100-year flood at the ungaged site on Turkey Creek is 25,500 ft^3/s (722 m^3/s) after the regression estimate is adjusted for the station data at station 07159000.

For the sake of illustration, assume the ungaged site on Turkey Creek is an urban site and an estimate of Q_{100} is needed under urban conditions. Assume the basin is 40 percent impervious and that 20 percent of the basin is served by storm sewers. The following data and calculations are needed to estimate Q_{100} for this urban site:

Q_{100} (rural conditions) = 25,500 ft^3/s (722 m^3/s), from previous example

Q_2 (rural conditions) = 2,880 ft^3/s (81.5 m^3/s), from figure 3 or equation 2

R_L = 2.1, from figure 10

$Q_{100(u)}$ = 29,500 ft^3/s (835 m^3/s), from equation 15

Therefore, the estimate of the 100-year flood under urban conditions for this ungaged watershed is 29,500 ft^3/s (835 m^3/s). This is an increase of 16 percent over the 100-year flood for rural conditions.

ANNUAL PEAK DATA

The first step in a flood-frequency analysis is to assemble and review all the pertinent annual peak discharge data. The flood-frequency analysis for streams of less than 2,500 mi^2 (6,500 km^2) presented in this report is based on annual peak data collected through September 30, 1975, at 165 gaging stations. These gaging stations plus all stations less than 100 mi^2 (260 km^2) and all stations less than 2,500 mi^2 (6,500 km^2) with 8 or more years of unregulated record are shown in figure 1. For this analysis, only those stations with at

least 8 years of flood peak data free of significant regulation and man-made effects were used. Annual peak stages and discharges are given in appendix C for those gaging stations shown in figure 1. A summary of the distribution of drainage areas, average observed length of record per station and effective record length for those stations used in the regression analysis is given in table 3. Effective record length is the resultant record length after combining the observed and synthetic data. Computation of effective record length is discussed in a later section of this report.

Table 3.--Summary of drainage area distribution, average observed length of record and effective length of record

Drainage area (square miles)	Number of stations	Average observed length of record (years)	Effective length of record (years)
Less than 1	17	15	17
1 to 5	29	12	15
5 to 10	21	12	17
10 to 50	33	13	17
50 to 100	6	18	18
100 to 500	27	22	22
500 to 1000	20	29	29
1000 to 2510	12	34	34
	165	19	21

A comparison of the above summary with a summary given in Sauer (1974a) shows that the number of stations less than 100 mi^2 (260 km^2) has been increased by 45 stations. The increase is due partly to obtaining annual peak data from the Agricultural Research Service. The number of stations greater than 100 mi^2 (260 km^2) is essentially the same as given by Sauer (1974a). The average observed length of record is closely related to the size of the basin corresponding to the early history of establishing streamflow stations on large streams. The longer record for the stations less than 1 mi^2 (2.6 km^2) is due to the inclusion of five long-term Agricultural Research Service stations. The Geological Survey small-stream data-collection program did not begin, on a large scale, until 1964 under a special project with the Federal Highway Administration and Oklahoma State Department of Transportation. The effective length of record for the small-streams stations indicates the increase in

record length due to the rainfall-runoff modeling results. Records ranging from 49 to 69 years in length were generated using long-term precipitation data at 6 National Weather Service stations in and around Oklahoma. The incorporation of these synthetic data with the observed flood records is discussed later in this report.

This report completes the data analysis of a small-streams project with the Federal Highway Administration and Oklahoma State Department of Transportation. The project originally had 99 gaging stations in the data collection network. Starting in 1972, the data-collection network was reduced annually to provide funds for data analysis. By September 1975 the network had been reduced to 36 gages which included 8 flood-hydrograph gages and 28 crest-stage gages. The last reduction in the data-collection network (September 1975) was based on a computer analysis (Carrigan and Golden, 1975) from which was determined the optimum subset of gages to be retained for a given level of annual operating costs with the information content of the reduced network being the factor optimized. The computer program determined which pairs of gages were highly correlated and identified those gages which contributed the least amount of information to the network. Operation of the optimum subset of gages for an additional 5-8 years should provide sufficient data to verify the rainfall-runoff modeling results and to provide long-term annual peak data to verify or to update equations given in this report.

ANALYTICAL TECHNIQUES

The earlier section on "Estimating Techniques" describes how to estimate flood discharges for Oklahoma streams without providing any documentation for the analysis. This section discusses the technical details of the analysis, namely the computation of the station flood-frequency relations, the regression analysis and the rainfall-runoff modeling results. Several by-products of the rainfall-runoff modeling are also discussed including the application of the model parameters to estimating flood discharges.

STATION FLOOD-FREQUENCY RELATIONS

The relation of flood-peak magnitude to probability of occurrence, or recurrence interval, is referred to as a flood-frequency relation or curve. Probability of occurrence is the percent chance of a given flood magnitude being exceeded in any one year. Recurrence interval is the reciprocal of probability of occurrence times 100, and is the average number of years between exceedances. For instance, a flood having a probability of occurrence of 2 percent has a recurrence interval of 50 years. This does not imply cyclic flood conditions, but only that a 50-year flood will be exceeded, about once in 50 years, on the average, over a very long time period. In fact, it may be exceeded in successive years.

Flood-frequency relations were defined for those gaging stations with 8 or more years of record, following guidelines in U.S. Water Resources Council Bulletin No. 17 (1976). Logarithms of annual peak discharges were fitted to the Pearson Type III distribution giving weight to historical peaks and high outliers, omitting low outliers and using the generalized skew map in Water Resources Council Bulletin No. 17 (1976). For those stations having less than 25 years of record, the value from the generalized skew map was used directly in computing the flood-frequency relation. For those stations having more than 25 years of record, the station skew was weighted with the generalized skew map to give a weighted skew as recommended in Water Resources Council Bulletin No. 17 (1976). Estimates of the 2-, 5-, 10-, 25-, 50-, 100-, and 500-year floods and the log-Pearson Type III statistics for these estimates are given for each station in appendix B. The small watersheds for which synthetic annual peak data were generated are indicated in appendix B with an asterisk. For these stations the station frequency curve is a weighted average of the observed and synthetic frequency curves. The generation of synthetic annual peak data and the weighting of synthetic and observed frequency curves are discussed in subsequent sections of this report.

REGRESSION ANALYSIS

Estimates of the magnitude and frequency of flooding commonly are needed at ungaged sites. Therefore, it is necessary to transfer flood frequency data

from gaged sites to ungaged sites. This can be accomplished by defining the relations between peak discharges of selected frequencies and basin or climatic characteristics measured from maps or taken from readily available reports. Multiple regression techniques were used to relate estimates of the 2-, 5-, 10-, 25-, 50-, 100-, and 500-year floods (given in app. B) to basin, climatic, and channel-geometry parameters.

Many parameters were investigated in the multiple regression analysis in an attempt to find the best relations for estimating flood discharges. The following parameters were investigated as possible predictors of flood discharge: contributing drainage area, main-channel slope, main-channel length, main-channel elevation (average of elevations at 10 and 85 percent of channel length), a soils index, mean annual precipitation, the 2-year, 24-hour rainfall, gage slope (slope of streambed in immediate vicinity of gage), basin shape factor (length divided by the square root of drainage area), basin slope (computed perpendicular to main channel from drainage area divide), main-channel depth, main-channel width, and main-channel cross-sectional area. Of all the parameters investigated, the three found statistically significant were contributing drainage area, main-channel slope, and mean annual precipitation. The equations using the 2-year, 24-hour rainfall in place of the mean annual precipitation could be used with little loss in accuracy because the two climatic variables are so highly correlated. Mean annual precipitation was selected as the predictor parameter because it is based on a denser raingage network with a longer period of record. The channel-geometry characteristics were investigated because of the applicability of main-channel width for estimating flood discharges in Kansas (Hedman, Kastner, and Hejl, 1974). For Oklahoma, however, channel-geometry characteristics presently available are no better predictors of flood discharges than basin and climatic characteristics that are more readily determined. Channel-geometry characteristics for the small watersheds less than 100 mi^2 (260 km^2) were determined from cross sections run for contracted-opening measurements, slope-area measurements, culvert measurements, and step-backwater surveys. If the small watershed channel-geometry characteristics had been determined in the field, then main-channel width might have been more useful in estimating flood discharges. The

use of channel-geometry characteristics, determined from field measurements, should be considered in future analyses.

TESTING OF ASSUMPTIONS AND APPLICABILITY OF REGRESSION EQUATIONS

A nonlinear regression equation of the form $Q_x = a\ A^{bA^c}\ S^d\ P^e$ was also investigated. For a value of c=0, the nonlinear equation reduces to the same form as equation 1. Several trials were made using the above equation, each time changing the value of c. The minimum value of the standard error of estimates occurred at c=-0.01, but this standard error was not significantly lower than the linear equation (1) of the form $Q_x = a\ A^b\ S^c\ P^d$. As a further check on linearity of the regression relations the residuals (deviations of observed data from regression relation) for Q_{10} and Q_{100} were plotted against drainage area and main-channel slope. The drainage area-residual plot and the main-channel slope-residual plot indicated a linear trend throughout the range of variables used in the analysis. The hypothesis of linearity of the regression relation was accepted.

The residuals from equations 4 and 7 were plotted on maps to check for regional bias. These plots did not indicate any significant regional trends. As a further check for regional trends, the State was divided into three regions and regression equations were computed for each region. The approximate boundaries were those stations west of latitude 98° 30' (Region 1), those stations east of latitude 96° 00' (Region 3), and the remaining stations in the central part of the State (Region 2). The significant parameters in these regional equations were either drainage area and main-channel slope or drainage area alone. The standard errors of the regional equations were within five percent of the statewide equations. The following table indicates the average percent difference between estimates from the statewide equations and the regional equations for the 10- and 100-year floods. The percent difference is the statewide equation estimate minus the regional equation estimate.

	Region 1	Region 2	Region 3
10-year flood	+5	-3	+4
100-year flood	+9	-3	+5

There is essentially little difference in the flood frequency estimates or the standard errors between the statewide equations and the regional equations. The above tests and comparisons indicate that there are no significant advantages in using regional equations. Therefore, equations 2-8 are considered applicable statewide within the limitations given in an earlier section of this report.

Comparisons of estimates from equations 2-7 with estimates from equations 3-8 in Sauer's report (1974a), indicate a considerable difference for small watersheds. For watersheds less than 100 mi^2 (260 km^2) the difference is generally 20-30 percent less than Sauer's equations. For watersheds over 100 mi^2 (260 km^2) the estimates from equations 2-8 average within $\pm$ 11 percent of Sauer's equations for all recurrence intervals.

The primary reason for this difference for the small watersheds is Sauer's adjustment of the short-term frequency curves (figs. 2 and 3 in Sauer's report (1974a)). Sauer assumed (correctly) that the small watershed flood frequency data were not representative of long-term flood records because of below normal rainfall for the period 1962-71 (the period of record for most small watersheds). The adjustment increased the small watershed flood frequency data to remove the bias of the time-sampling error. The rainfall-runoff modeling, described in the next section of this report, indicated that this adjustment was too large for the small watersheds.

RAINFALL-RUNOFF MODEL CALIBRATION AND SYNTHESIS

A long-term record of synthetic flood peaks was generated to provide "independent" estimates of selected frequency floods by using a rainfall-runoff model developed by the Geological Survey (Dawdy, Lichty, and Bergmann, 1972). These synthetic estimates of selected frequency floods were combined with similar estimates from actual data at each site to increase the effective length of record for the small watersheds.

The rainfall-runoff model was calibrated and synthetic flood peaks were generated for 60 small watersheds (including three urban sites in Oklahoma City) in Oklahoma (fig. 11). Data for five small watersheds were obtained from the annual reports of the Agricultural Research Service (Hydrologic Data for Experimental Agricultural Watersheds in the United States 1956-67) or directly from Agricultural Research Service, Chickasha, Okla. All concurrent rainfall and runoff data required to calibrate the model are stored in the data files of the Geological Survey. In the calibration phase optimal values for the model parameters were determined by minimizing the sum of the squared differences between the computed and actual runoff utilizing concurrent rainfall and runoff at the gaging station. The optimal values of the model parammeters gave the best fit of hydrograph shape and volume between actual and computed hydrographs. During the synthesis phase the optimal values of the model parameters were used in conjunction with long-term rainfall and daily evaporation data to synthesize a long record of flood peaks. The logarithms of the annual peak series were fit to a Pearson Type III distribution to provide a synthetic flood-frequency curve for each long-term rainfall station. The 10 model parameters and their application in the modeling process are given in table 4 and the values of the parameters derived for the 60 small watersheds are given in table 5. The parameters DRN and TP (equal to 0.5 TC) were held constant during the calibration and synthesis phase. All other parameters were constrained within the range of reasonable occurrence in the field or within values computed from observed hydrographs. The rainfall-runoff model is described in greater detail by Thomas and Corley (1974) and Dawdy, Lichty, and Bergmann (1972).

The evaporation data at Canton Dam were used for all sites west of Oklahoma City and evaporation data at Fort Gibson Dam were used for all sites east of Oklahoma City in both the calibration and synthesis phase (see fig. 11). The sensitivity of the model to daily evaporation inputs did not justify transposing the evaporation data at Canton or Fort Gibson Dams to the small watershed being modeled. Long-term rainfall data at six National Weather Service sites were used - Oklahoma City, Dallas, Tex., Amarillo, Tex., Springfield, Mo., Wichita, Kans., and Shreveport, La. (fig. 11). Based on

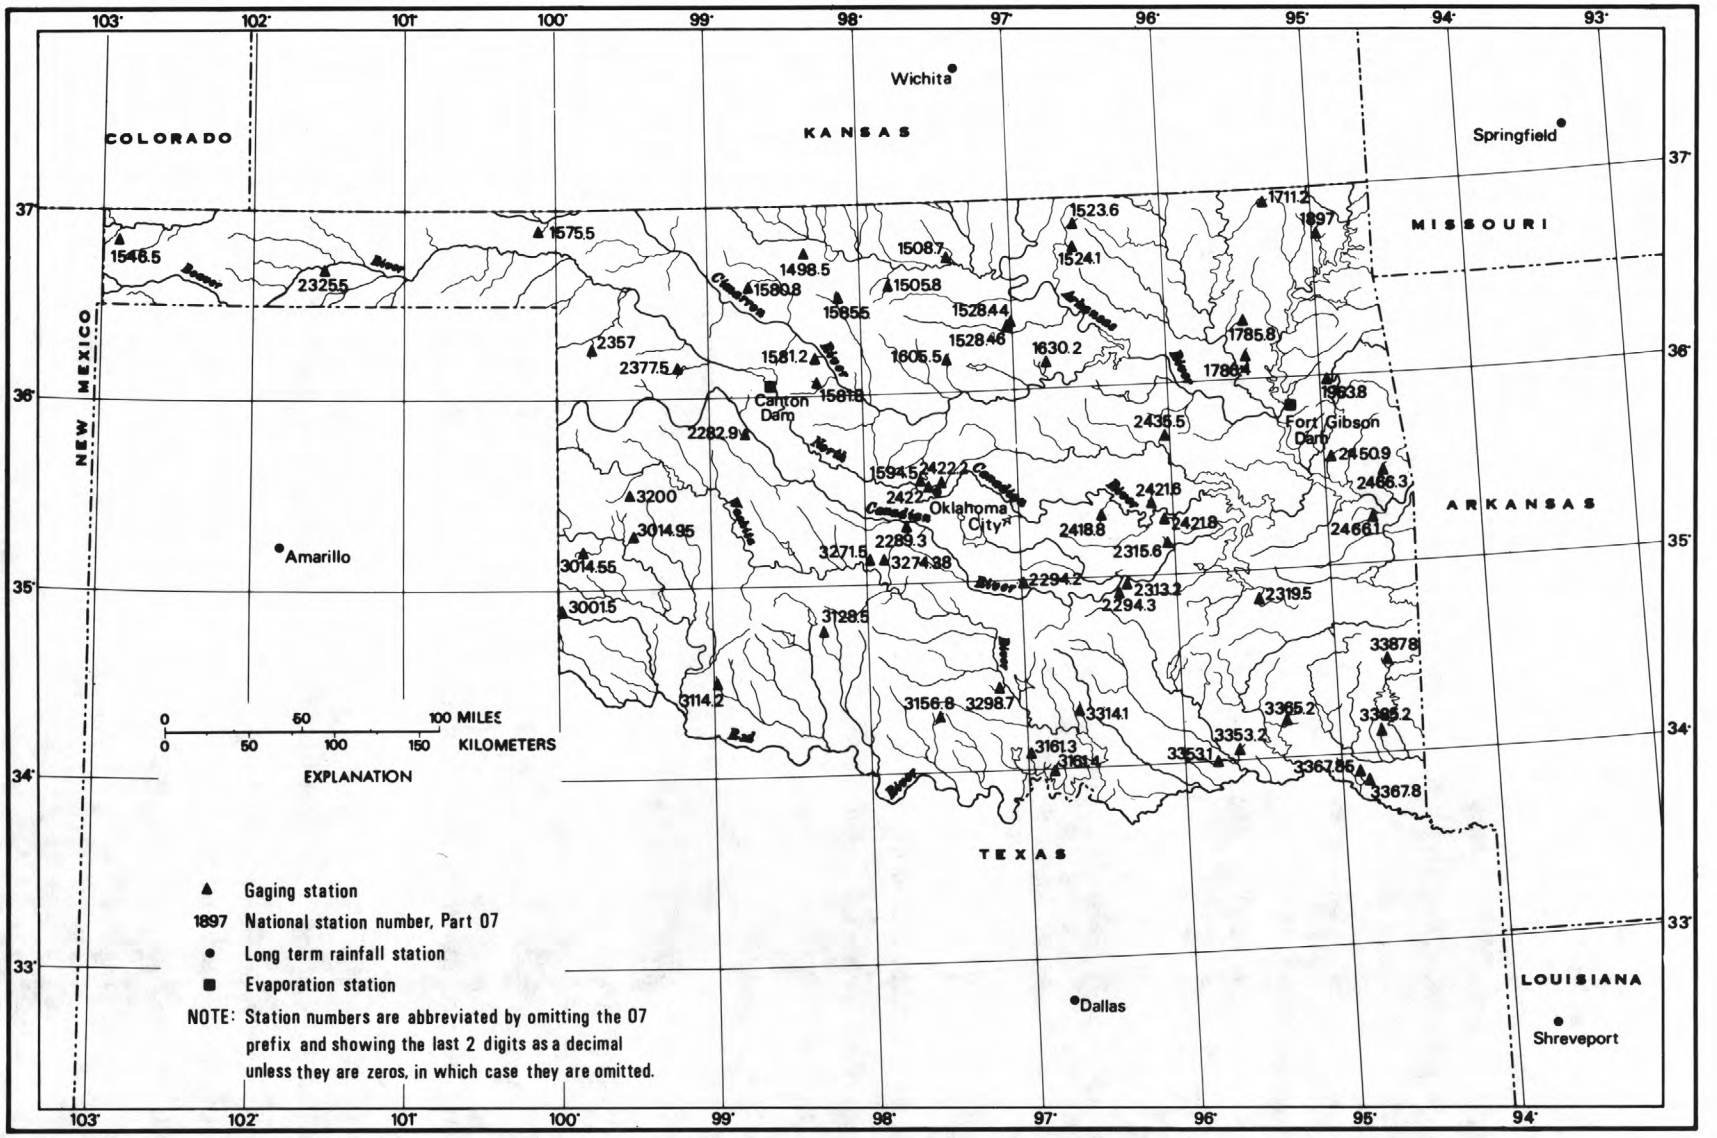

Figure 11.--Location of small-stream sites, evaporation stations and long-term rainfall stations used in the rainfall-runoff model.

Table 4.--The 10 model parameters and their application in the modeling process

Parameter identifier	Units	Application
PSP	inches	The combined effect of initial moisture content and soil suction at the wetted front at field capacity - functions of soil type
RFG	-	Ratio of the suction at the wetted front for soil moisture at wilting point to that at field capacity - function of hydrologic conditions in basin
KSAT	inches per hour	The minimum (saturated) value of hydraulic conductivity used to determine infiltration soil rates - function of soil type
BMSM	inches	Soil moisture storage volume at field capacity - function of average depth of soil zone
EVC	-	Coefficient to convert pan evaporation to potential evapotranspiration values
DRN	inches per hour	A constant drainage rate for redistribution of soil moisture - function of soil type
RR	-	Proportion of daily rainfall that infiltrates the soil - function of hydrologic conditions in basin
KSW	hours	Time storage coefficient for linear reservoir routing - function of basin characteristics
TC	minutes	Base time of unit translation hydrograph which is the time of concentration - function of basin characteristics
TP	minutes	Location of the unit translation hydrograph peak - function of basin characteristics

* Urban site - each basin calibrated using 20 percent impervious cover

rainfall input at each long-term rainfall station, six synthetic flood frequency curves were computed for each small watershed. A weighted average of the six synthetic frequency curves was obtained for each small watershed by procedures discussed in the next section of this report.

WEIGHTING OF FLOOD-FREQUENCY CURVES FOR THE MODELED WATERSHEDS

Two separate weightings of data from frequency curves were necessary to incorporate the synthetic flood-frequency data from the rainfall-runoff model with the actual flood-frequency data. First, the six synthetic frequency curves were combined into one. Then the weighted synthetic curve was combined with the frequency curve derived from observed data at each of the 57 rural small-stream sites.

In the first weighting process two methods of combining the six synthetic curves were investigated. In the first method the synthetic estimate of Q_x using rainfall at each long-term rainfall station was related to a combination of model parameters given in table 5 (R. W. Lichty, oral commun., 1976). The second method involved weighting the synthetic estimate of Q_x for each long-term rainfall station inversely proportional to the distance from the small watershed site to the long-term raingage. To illustrate the first process, the equations derived for the 100-year flood are given below for each long-term rainfall station:

Oklahoma City — Standard error

$$\frac{Q_{100}}{A} = 1433\ LAG^{-.736}\ FR^{-.106} \qquad 8\% \qquad (18)$$

Dallas — Standard error

$$\frac{Q_{100}}{A} = 1703\ LAG^{-.711}\ FR^{-.078} \qquad 9\% \qquad (19)$$

Amarillo — Standard error

$$\frac{Q_{100}}{A} = 1207\ LAG^{-.803}\ FR^{-.139} \qquad 10\% \qquad (20)$$

Springfield — Standard error

$$\frac{Q_{100}}{A} = 1083\ LAG^{-.726}\ FR^{-.134} \qquad 11\% \qquad (21)$$

Shreveport — Standard error

$$\frac{Q_{100}}{A} = 1232\ LAG^{-.641}\ FR^{-.093} \qquad 8\% \qquad (22)$$

Wichita — Standard error

$$\frac{Q_{100}}{A} = 1450\ LAG^{-.762}\ FR^{-.102} \qquad 9\% \qquad (23)$$

where Q_{100} = the synthetic 100-year flood estimated based on rainfall data at the respective rainfall station

A = contributing drainage area, in square miles

LAG = basin lag, in hours, defined as time from centroid of rainfall excess to centroid of runoff

LAG = KSW + TC/2 for a triangular-shaped translation hydrograph as used in the model (see table 4 for definitions of TC and KSW)

FR = infiltration rate, in inches per hour

FR = KSAT [1 + PSP/3 (0.8 RGF + 0.2)] (Simplification of equations 5 and 6 in Dawdy, Lichty, and Bergmann (1972) - see table 4 for definitions of KSAT, PSP, and RGF)

The form of FR was determined by changing the constants and coefficients in the FR expression until the minimum standard error was obtained for equations 18-23. The constant and coefficients in equations 18-23 were then plotted on maps and lines of equal values were drawn as illustrated in figures 12-14. The determination of the weighted estimate of Q_{100} (synthetic) is illustrated as follows using station 07242160: (1) determine the regression constant (a_{100}) from figure 12 (1350), (2) determine the coefficient of LAG (b_{100}) from figure 13 (-0.723), (3) determine the coefficient of FR from figure 14 (-0.108), (4) compute $\frac{Q_{100}}{A} = a_{100}\ LAG^{b100}\ FR^{c100} = \frac{Q_{100}}{A} = 1350\ LAG^{-0.723}\ FR^{-0.108} = 572.258$, (5) multiply $\frac{Q_{100}}{A}$ by A to get the weighted estimate of 9440 ft^3/s.

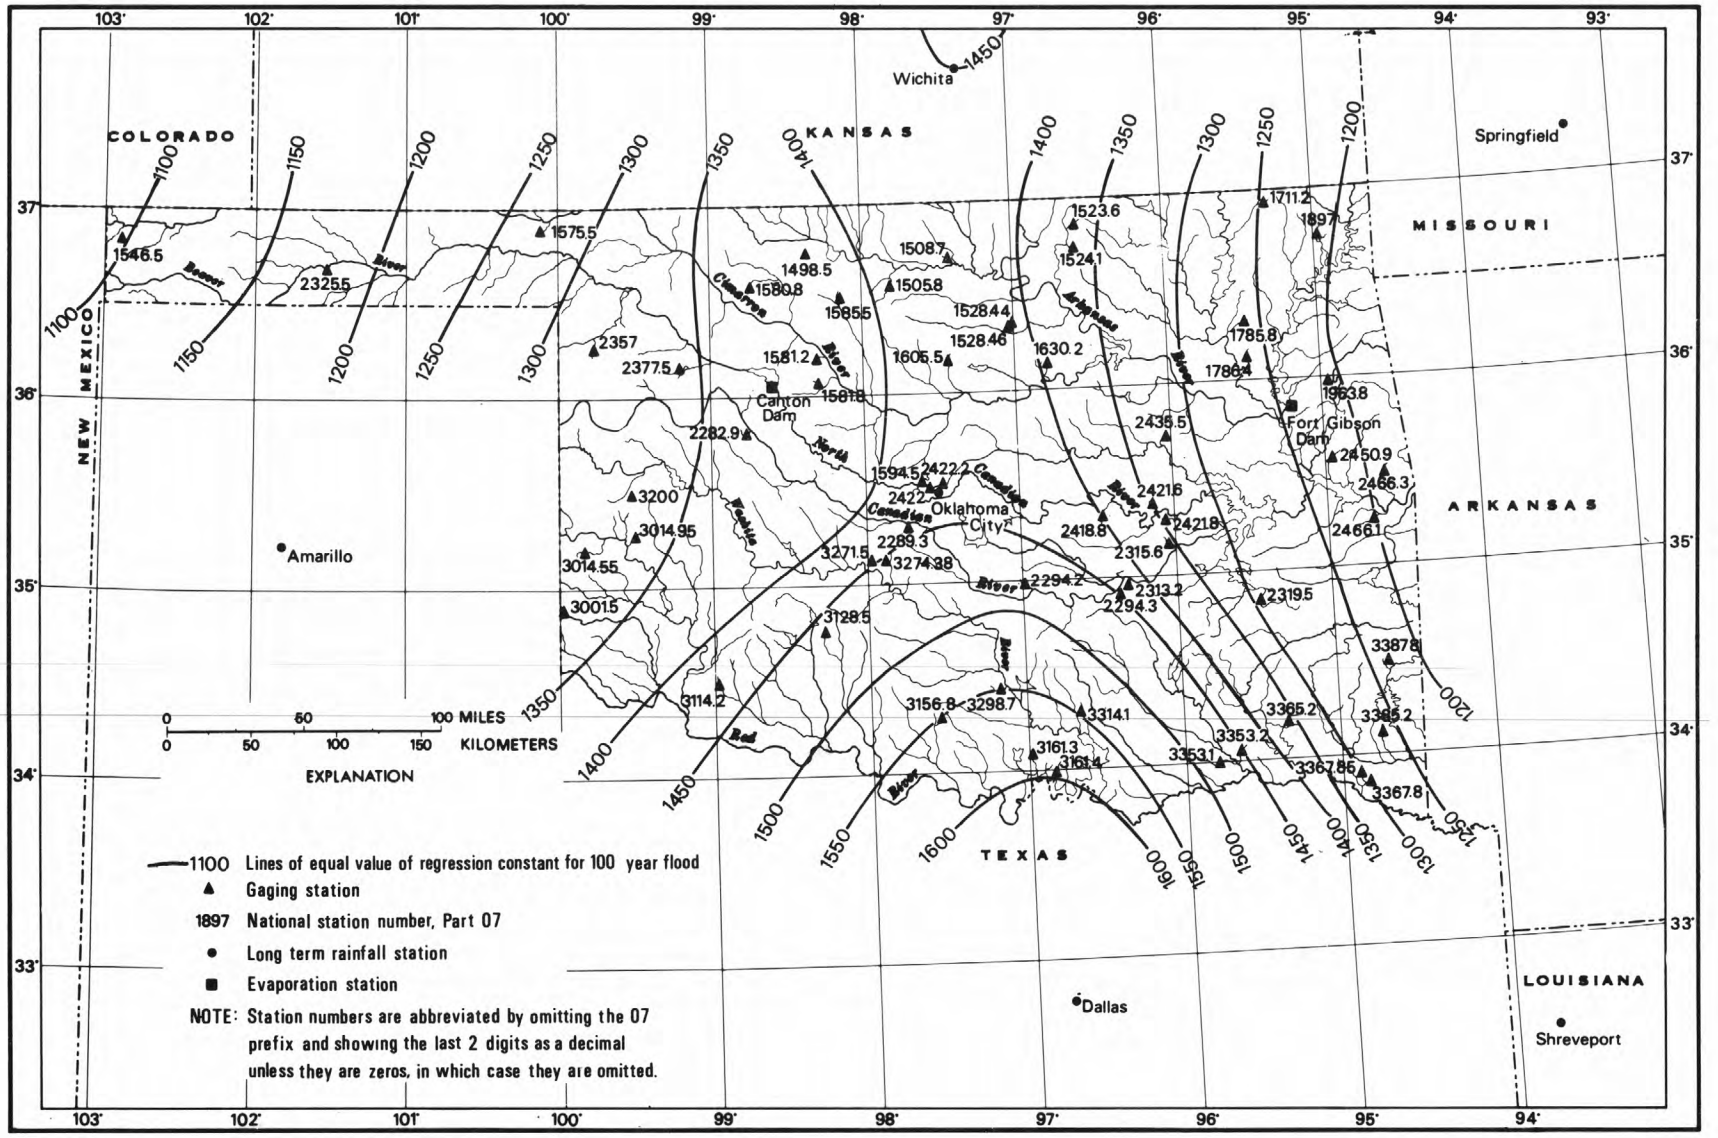

Figure 12.--Regression constant for computing the weighted synthetic 100-year flood.

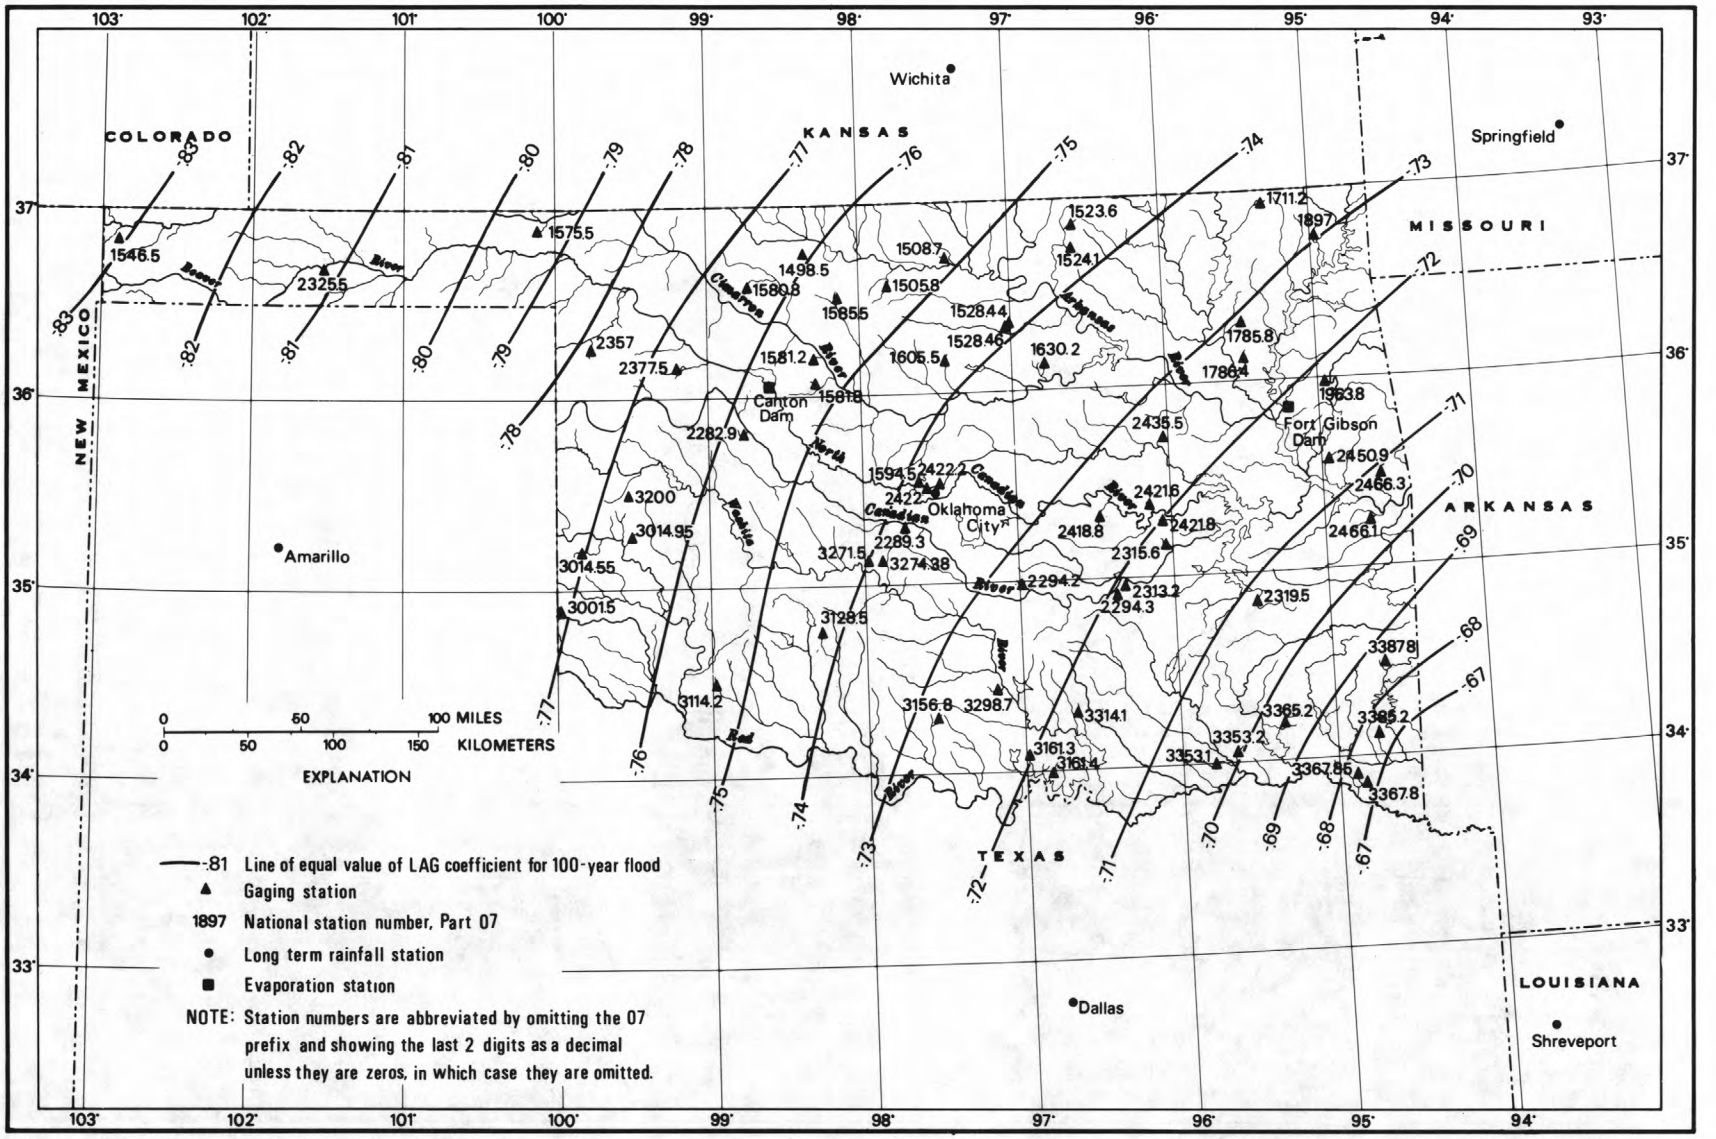

Figure 13.--Coefficient of LAG for computing the weighted synthetic 100-year flood.

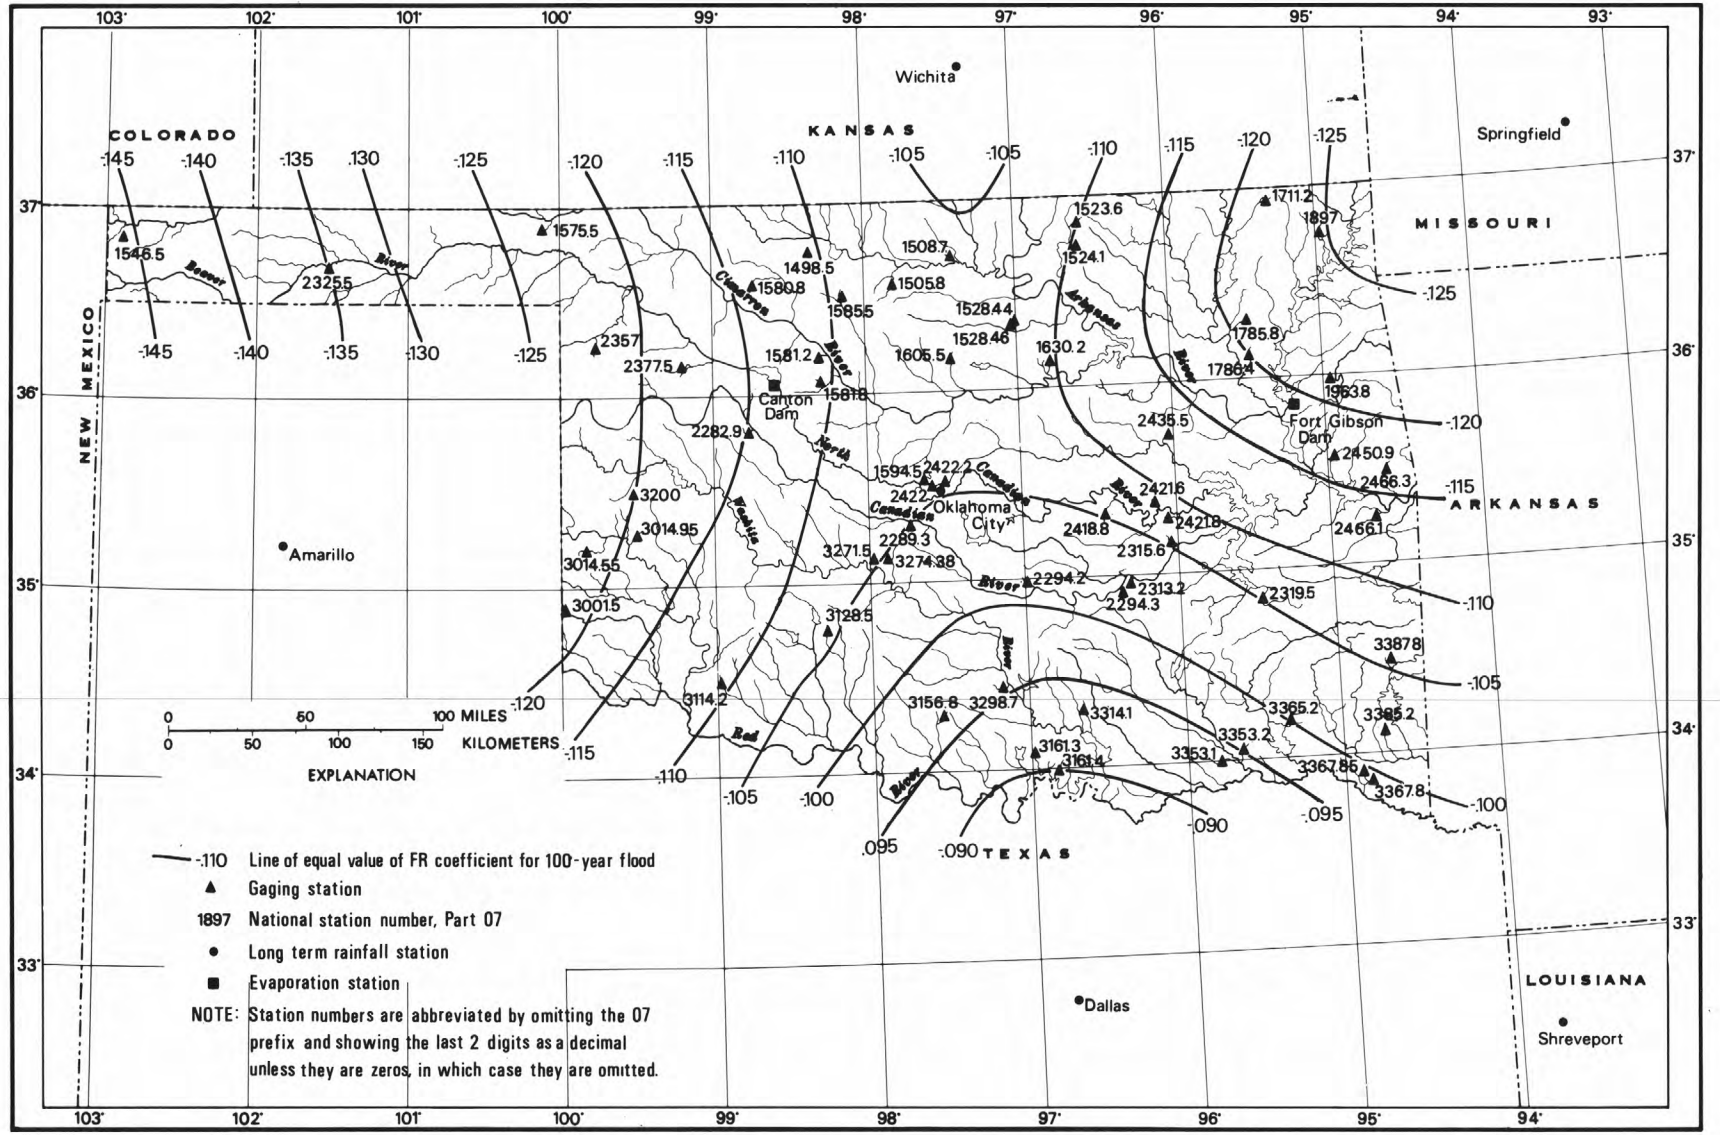

Figure 14.--Coefficient of FR for computing the weighted synthetic 100-year flood.

In the second method of combining the six synthetic curves a weighted estimate was calculated by weighting the estimate of Q_x from each long-term rainfall station with the reciprocal of the distance from the small watershed site to the rainfall station. Oklahoma City, Dallas, Springfield, and Shreveport were used to determine the weighted estimate in the southeast quarter of the State; Oklahoma City, Springfield, and Wichita were used in the northeast quarter; Oklahoma City, Wichita, and Amarillo were used in the northwest quarter; and Oklahoma City, Dallas, and Amarillo were used in the southwest quarter. The distance weighting method proved to give virtually the same estimates of flood discharges as the earlier method of relating Q_x to LAG and FR. Since the distance weighting procedure was simpler and easier to apply, it was used for all recurrence intervals. However, one advantage of the "LAG-FR Method" is that once equations like 18-23 are computed for a given State or region, estimates of Q_x can be made for a new site after the model parameters have been determined in the calibration phase. It would not be necessary then to generate synthetic flood peaks from each of the long-term rainfall stations.

After the weighted synthetic Q_x was estimated for each small watershed, this estimate was weighted with Q_x from the flood-frequency curve based on recorded data. The final weighting factors were determined by evaluating the following equation (R. W. Lichty, oral commun., 1976)

$$V_{tot} = \overline{V}_{model} + \overline{V}_T (1 - r), \qquad (24)$$

where V_{tot} = total variance between observed and synthetic estimates of Q_x

$\overline{V}_{model}$ = average variance of synthetic estimate of Q_x

$\overline{V}_T$ = average time-sampling variance of the observed estimate of Q_x

r = the average interstation correlation coefficient for annual peaks.

The average time-sampling variance and average interstation correlation coefficient are described by Hardison (1971). If r = 0 then the total variance is simply the sum of the modeling variance and the time-sampling variance. An r value of 0.25 was computed for the Oklahoma stations. Equation 24 is based on the assumptions that (1) the observed and synthetic estimates of flood discharge are independent and (2) the observed values of Q_x and $\overline{V}_T$ are unbiased. Because basin and climatic characteristics of a given watershed undoubtedly

influence the computation of both estimates of flood discharge, the two estimates are truly not independent. However, since the correlation of the two estimates cannot be computed, they are assumed to be independent. The second assumption is more defensible. The average standard deviation of the logarithms of annual peaks for the small watersheds modeled was 0.34 log units compared to 0.37 log units for the 165 stations used in the regression analysis. The mean of the annual peaks for the small watersheds modeled was 2.8749 log units. This compares favorably to a mean annual flood of 2.8572 log units computed by substituting the average basin and climatic characteristics of the model watersheds in equation 2. Although equation 24 cannot be rigorously defended, it does provide an objective procedure for combining the observed and synthetic estimates. Equation 24 was evaluated for recurrence intervals of 2, 10, and 100. The total variance, V_{tot}, was computed as

$$\sum_{i=1}^{N} \frac{(Q_x \text{ (observed)} - Q_x \text{ (synthetic)})^2}{N}$$

where N is the number of stations modeled (57). The weighting factors for the observed and synthetic estimates are given below.

Recurrence Interval, in years	Weighting Factors	
	Observed	Synthetic
2	0.8	0.2
10	0.6	0.4
100	0.5	0.5

The final weighted estimate of Q_x for each station was determined by the sum of the observed and synthetic estimates multiplied by the appropriate weighting factors in the table above. The weighting factors give more weight to the observed results at the 2-year recurrence interval and equal weight to the two estimates at the 100-year recurrence interval. The values of Q_2, Q_{10}, and Q_{100} were plotted on log-probability paper and a curve drawn through them to determine Q_5, Q_{25}, Q_{50}, and Q_{500}. The final weighted flood-frequency relations are shown in appendix B as the station flood-frequency relations.

The average length of record for those stations modeled was 11 years. At the 100-year recurrence interval equal weight was given to the synthetic and observed estimates. This indicates that the rainfall-runoff modeling doubled the record length by adding the equivalence of 11 years of information for

estimating the 100-year flood. The effective length of record given in table 3 was computed using the weighting factors above for the 10-year recurrence interval and procedures described by Hardison (1976). The observed and synthetic estimates of flood discharges were assumed to be independent in computing the effective length of record.

APPLICATION OF MODEL PARAMETERS IN ESTIMATING FLOOD FREQUENCY

Equations 18-23 were based on estimates of Q_x based on synthetic data from each long-term rainfall station. The standard errors of these equations are low because the most important model parameters used to generate $Q_{\frac{100}{A}}$ were represented in LAG and FR. A step-backward regression of the final weighted discharges (computed in the previous section) versus the model parameters was made to determine the applicability of the model parameters in estimating flood frequency. This analysis indicated that in addition to drainage area, KSW and FR were the most significant model parameters. Hydrologically LAG should be a better estimator than KSW because LAG involves the time of concentration of the basin. A regression analysis of final weighted discharge versus A, LAG, and FR (same form as defined earlier) for 57 stations yielded the following equations:

	Standard error	
$Q_{10} = 575\ A^{0.91}\ LAG^{-0.59}\ FR^{-0.32}$	31%	(25)
$Q_{50} = 1060\ A^{0.92}\ LAG^{-0.64}\ FR^{-0.28}$	33%	(26)
$Q_{100} = 1293\ A^{0.92}\ LAG^{-0.65}\ FR^{-0.27}$	35%	(27)
$Q_{500} = 1905\ A^{0.92}\ LAG^{-0.68}\ FR^{-0.24}$	40%	(28)

A similar regression analysis for the same 57 stations was made using basin and climatic characteristics as independent variables. This analysis yielded the following equations:

		Standard error	
Q_{10}	$44.8\ A^{0.74}\ S^{0.22}\ P^{0.51}$	42%	(29)
Q_{50}	$= 404\ A^{0.76}\ S^{0.24}$	44%	(30)
Q_{100}	$= 457\ A^{0.76}\ S^{0.25}$	47%	(31)
Q_{500}	$= 585\ A^{0.75}\ S^{0.27}$	49%	(32)

In this analysis P was not a significant variable for Q_{50}, Q_{100}, and Q_{500}. A comparison of equations 25-28 with equations 29-32 indicates that the standard error can be reduced by 9-12 percent by using model parameters in place of customary basin and climatic characteristics. However, to determine LAG and FR a concurrent record of rainfall and runoff must be collected. Equations 25-28 can only be used to estimate flood discharges for those basins which have been calibrated with the Geological Survey Rainfall-Runoff Model. Equations 29-32 give essentially the same answers as equations 4, 6-8.

Because of the importance of the hydrograph shape parameters in hydrology, a regression analysis was also made relating TC, KSW, and LAG (in hours) to basin and climatic characteristics. The following equations were computed in this analysis:

		Standard error	
KSW	$= 0.093\ A^{0.229}\ S^{-0.345}\ I^{2.92}$	38%	(33)
TC	$= 0.388\ L^{0.440}\ S^{-0.452}\ I^{2.20}$	40%	(34)
LAG	$= 0.206\ A^{0.239}\ S^{-0.280}\ I^{2.54}$	40%	(35)

where A is drainage area and S is main-channel slope as defined earlier, L is the main-channel length and I is the 2-year, 24-hour rainfall (fig. 15). The computed values of KSW and TC from equations 33 and 34 are compared to the observed values in figures 16 and 17. Equations 33-35 can be used to estimate the hydrograph shape parameters required in certain rainfall-runoff procedures for computing design hydrographs. Equations 33-35 are applicable for A ranging from 0.003 - 25.4 mi^2 (0.008 - 65.8 km^2), S ranging from 9.2 - 154 ft/mi (1.74 - 29.1 m/km), L ranging from 0.072 - 11.5 mi (0.116 - 18.5 km), and I ranging from 2.40 - 4.25 in (61.0 - 108.0 mm).

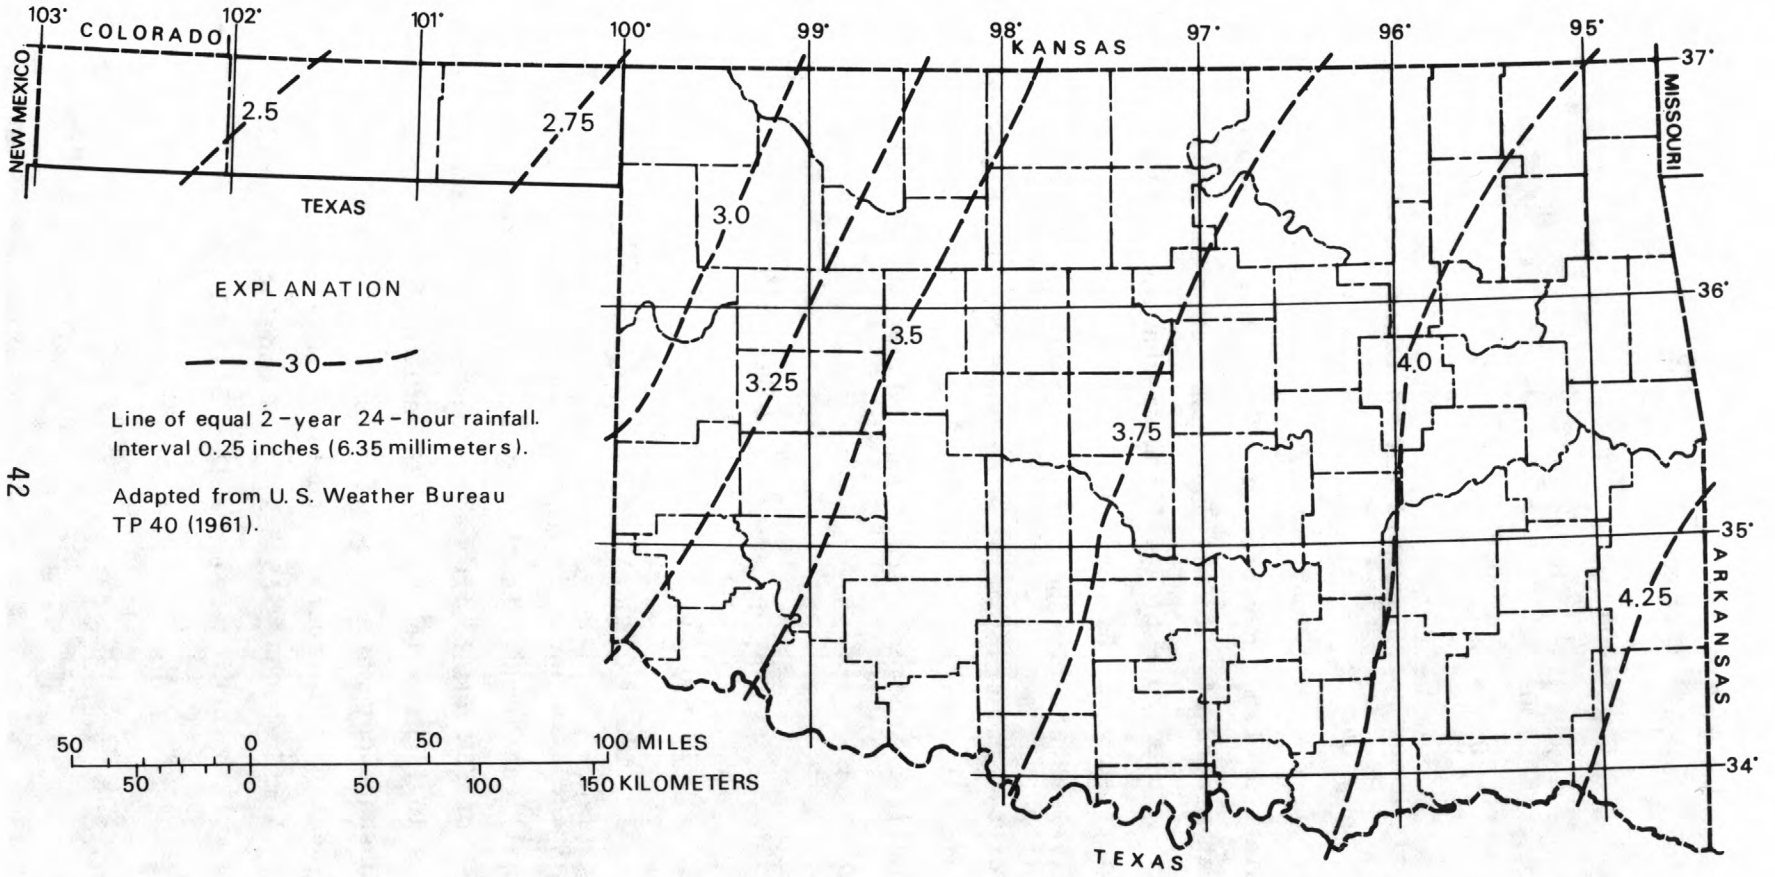

Figure 15.--The 2-year 24-hour rainfall for the period 1940-58.

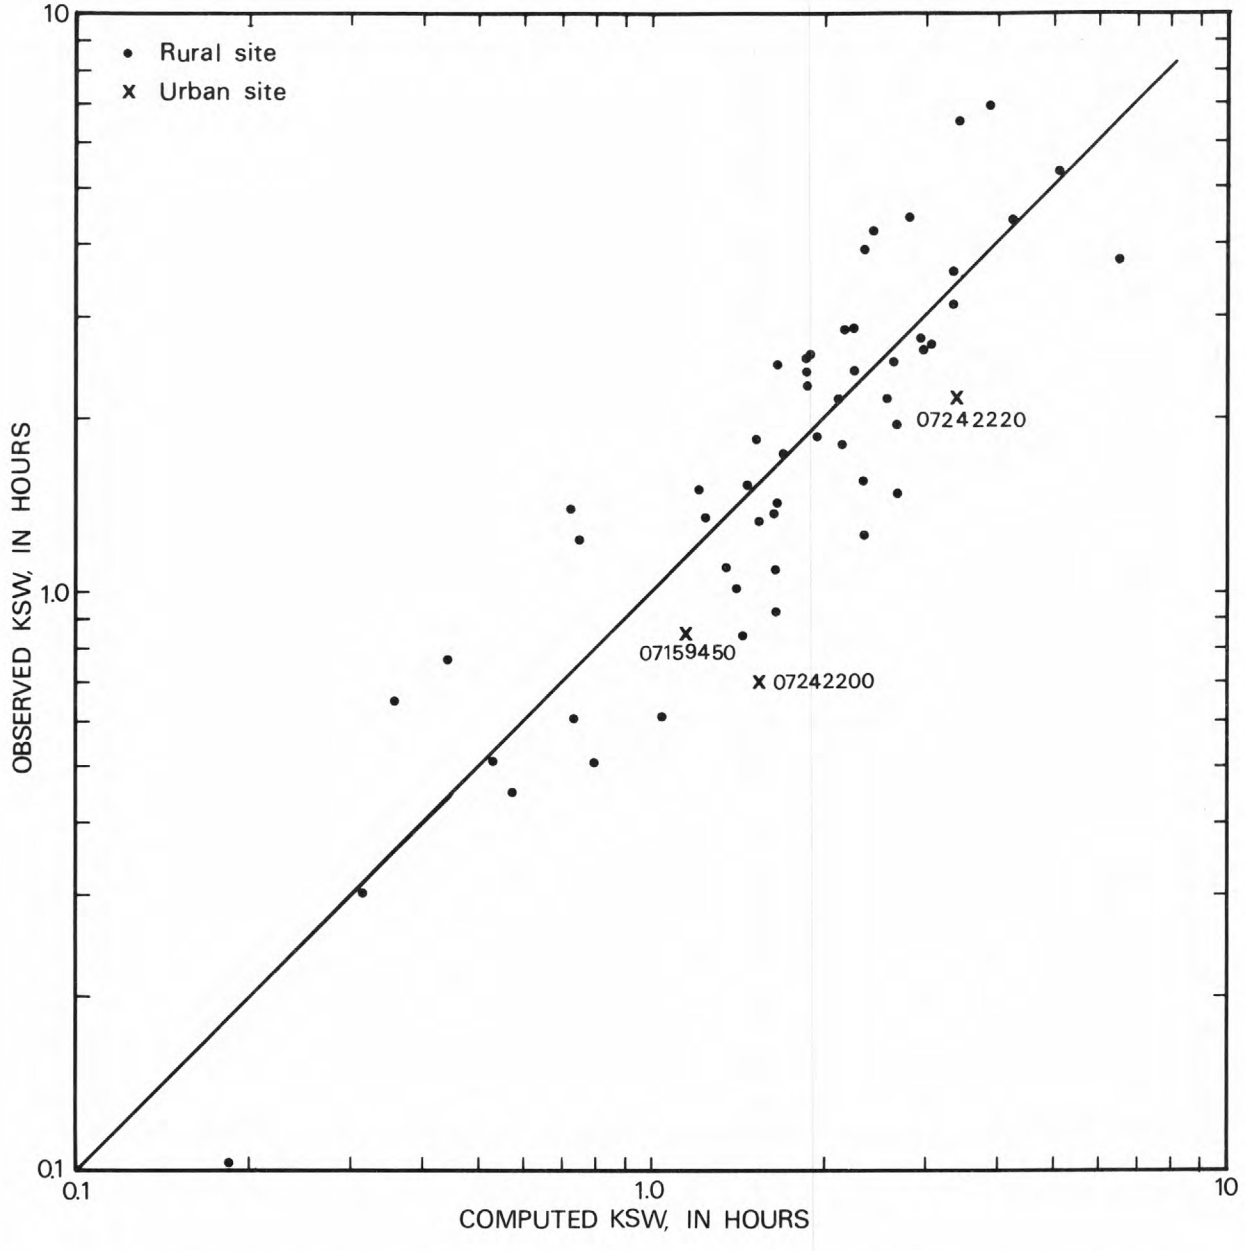

Figure 16.--Comparison of observed and computed values of the linear storage routing coefficient.

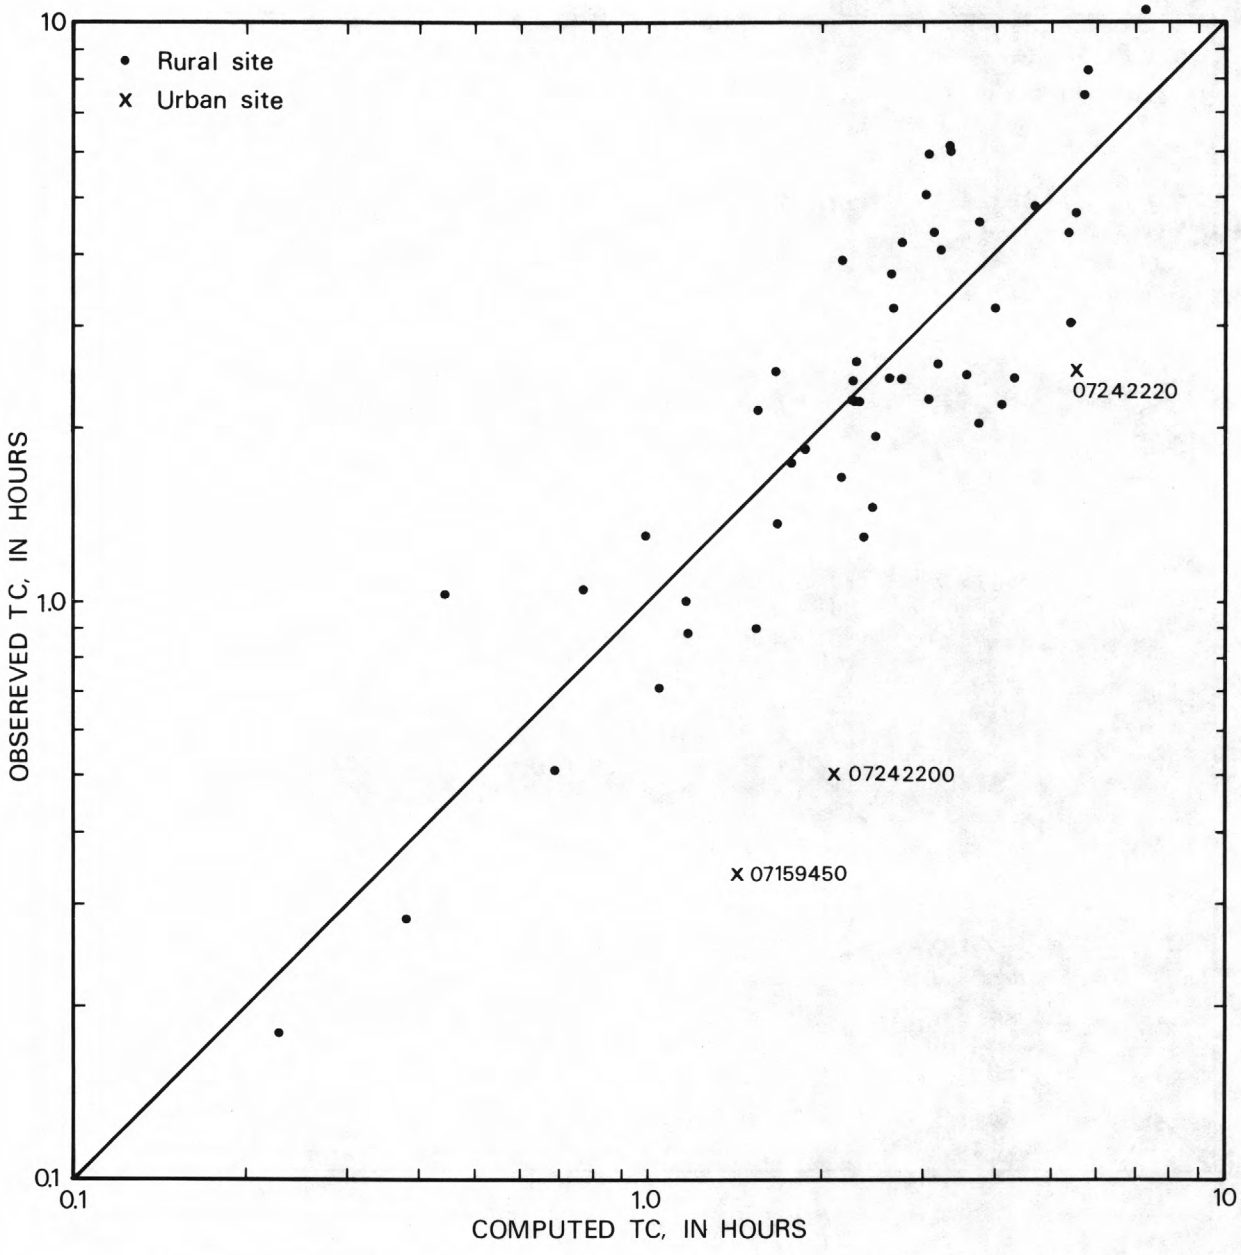

Figure 17.--Comparison of observed and computed values of the time of concentration.

The runoff volume parameters in the model are not used in any other rainfall-runoff estimating procedure. Furthermore, the interaction of the runoff volume parameters during calibration tends to obscure their true values. Therefore, no attempt was made to regionalize or relate the runoff volume parameters to basin and climatic characteristics.

EFFECT OF URBANIZATION ON FLOOD DISCHARGES

Equations 10-16 given earlier in this report are applicable for estimating flood frequency for basins affected by urbanization. These equations were partly based on figure 10 which was derived by Leopold (1968) from urban studies throughout the country. Rainfall-runoff modeling results for three urban watersheds in Oklahoma City were compared to results derived by Leopold (1968) in figure 10. The rainfall-runoff model was calibrated for the three urban basins and flood-frequency curves were synthesized using 61 years of rainfall data in Oklahoma City. These urban flood-frequency curves are plotted in figures 18-20 along with the flood-frequency curves representing conditions before urbanization. For stations 07242200 and 07242220 the "before urbanization" flood-frequency curves were computed using equations 2-8 presented earlier in this report. For station 07159450 the "before urbanization" flood-frequency curve is a weighted average of the frequency curve of equations 2-8 and the station frequency curve for station 07159500. Station 07159500 was operated just a few hundred feet downstream from station 07159450 from 1950-58 which was before the basin became urbanized. The ratios of the mean annual flood after urbanization to before urbanization are plotted in figure 10 for the three urban basins. As observed in figure 10, the rainfall-runoff modeling results indicate a greater increase in the mean annual flood than Leopold's results in two out of three cases. Station 07159450 agrees with Leopold's results but stations 07242200 and 07242220 indicate a somewhat greater effect for urbanization. One possible reason that station 07159450 shows less effect for urbanization is the storage effect of a large pond and several undersized culverts in the basins. However, there is not sufficient evidence from the rainfall-runoff modeling to warrant changing figure 10 for urban basins in Oklahoma and the urban equations computed by Sauer (1974b) and presented

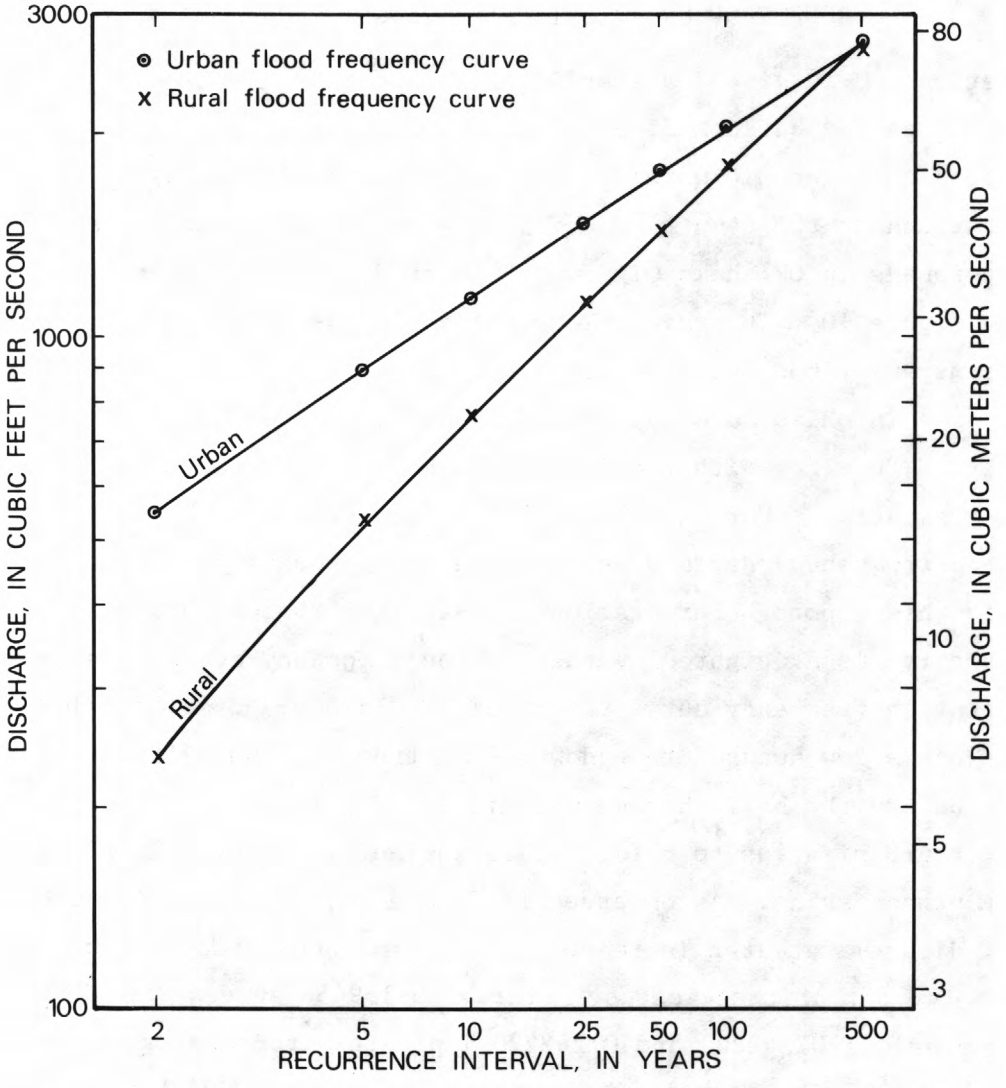

Figure 18.--Comparison of flood-frequency curves for Bluff Creek at Oklahoma City (07159450).

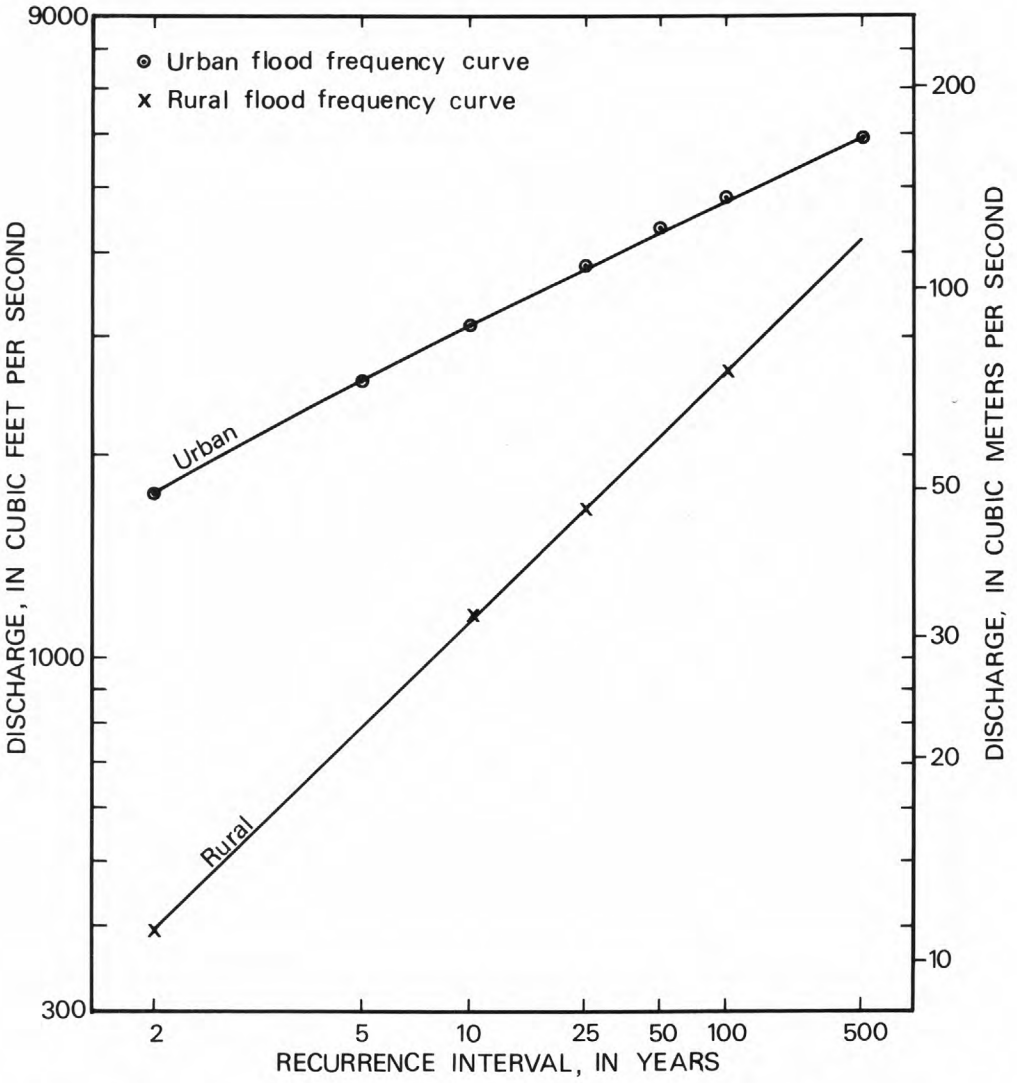

Figure 19.--Comparison of flood-frequency curves for Deep Fork at Portland Ave.,Oklahoma City (07242200).

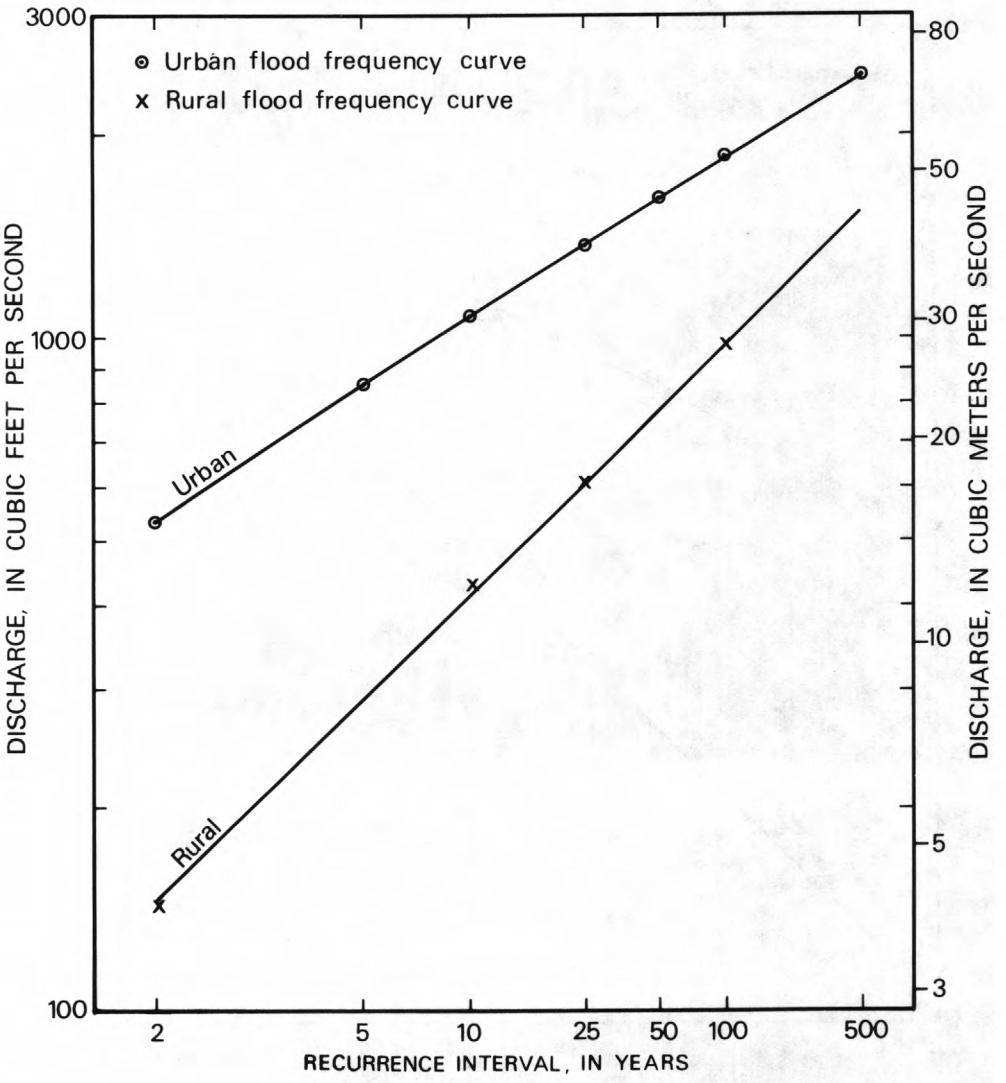

Figure 20.--Comparison of flood-frequency curves for Deep Fork at Eastern Ave., Oklahoma City (07242220).

earlier in this report (equations 10-16) are still considered the best estimates of urban flood frequency for Oklahoma.

The hydrograph parameters, TC and KSW, are also affected by urbanization. This effect may sometimes be obscured by the surcharging effect of the storm sewers and ponding effect of undersized culverts that usually exists in an urban watershed. The observed (modeling results) and computed values (from equations 33 and 34) of KSW and TC for three urban watersheds (07159450, 07242200, 07242220) in Oklahoma City are plotted in figures 16 and 17 respectively. As noted in these figures, the values of KSW and TC are reduced by urbanization, particularly the values of TC. Values of KSW are reduced less than TC probably because of the surcharging and ponding effect mentioned earlier.

Obviously, there is insufficient urban runoff data in Oklahoma upon which to base more rigorous estimating relations. At present (1977) urban data collection is underway at 15 sites in Oklahoma City. Urban data collection to date indicates that earlier results derived by Leopold (1968) might be underestimating the effects of urbanization in Oklahoma. However, in the absence of sufficient data indicating otherwise, the results of Leopold (1968) are assumed to be applicable for estimating urban flood-frequency curves in Oklahoma.

SUMMARY

The results of rainfall-runoff modeling for 57 small watersheds were combined with observed data at 165 sites to compute regression equations for estimating flood discharges at sites draining less than 2,500 mi^2 (6,500 km^2). These equations are not applicable to basins significantly affected by regulation. Methods are given for estimating flood discharges for urban areas in Oklahoma.

The results of rainfall-runoff modeling for 57 rural watersheds and 3 urban watersheds are summarized. The model parameters are shown to have applicability in estimating flood discharges, but considerable data-collection effort is required.

Data collection should continue for both rural and urban small watersheds. A rural data-collection program for an additional 5- to 8-year period would provide sufficient long-term data to verify or to update the equations given in this report. Urban data collection is needed to improve present methods of estimating flood discharges. Until sufficient data are available indicating otherwise, equations given in this report and Sauer's (1974b) should be used for estimating flood-frequency curves for urban areas in Oklahoma.
