CONVERSION FACTORS

For readers who may prefer to use SI units rather than inch-pound units, the conversion factors for the terms used in this report are listed below:

Inch-pound	Multiply by	Metric (SI)
acre	4,047	square meter
ft (foot)	0.3048	meter
ft^3/s (cubic foot per second)	0.0283	cubic meter per second
in (inch)	25.4	millimeter
mi (mile)	1.609	kilometer

Temperature in degrees Fahrenheit (°F) can be converted to degrees Celsius (°C) as follows:

$$\text{Temp °C} = (\text{temp °F} - 32)/1.8$$

WATER-RESOURCES MONITORING IN THE COTTONWOOD CREEK AREA,

SHASTA AND TEHAMA COUNTIES, CALIFORNIA, 1982-83

By Ronald P. Fogelman and Kristin D. Evenson

ABSTRACT

The Cottonwood Creek study area, located in the Redding basin in northern California between Redding and Red Bluff, contains a network of surface-water sites and wells for monitoring surface-water quality and ground-water levels and quality. This network was established to provide baseline information on the ground-water conditions prior to the completion of two proposed dams, one to be located on Cottonwood Creek and one to be located on South Fork Cottonwood Creek.

Analysis of monthly ground-water levels from September 1982 through October 1983 shows that water levels are lowest in the autumn and highest in the spring. The ground-water surface slopes to the east and has a mound near the town of Cottonwood at the Anderson-Cottonwood Irrigation District Canal. Further studies in this area would provide information needed for any subsequent modeling studies. Data are also insufficient in the area upstream from the damsites, specifically in the areas of future impoundment, so the monitoring network could be expanded to include wells in these areas.

Comparison of ground-water quality samples from the period of lowest water levels to those collected during the period of highest water levels showed little chemical variation. Ground water is good to excellent with respect to recommended drinking-water standards. Chemical water types varied little throughout the area; ground water north of Cottonwood Creek is either sodium magnesium or magnesium sodium bicarbonate; south of Cottonwood Creek the predominant water type is calcium magnesium or magnesium calcium bicarbonate. Surface-water samples from Cottonwood Creek and South Fork Cottonwood Creek have water which is chemically similar to ground water from south of Cottonwood Creek.

INTRODUCTION

The U.S. Army Corps of Engineers is planning to construct dams on Cottonwood Creek and South Fork Cottonwood Creek in Shasta and Tehama Counties in northern California. As part of the planning phases of this project, the Corps of Engineers asked the U.S. Geological Survey to monitor ground-water levels and water quality in the lower Cottonwood Creek basin in order to define baseline, preconstruction conditions. In the autumn of 1982, the Survey established a network of observation wells to monitor both water levels and water quality. A network of surface-water sites also was established to monitor water quality in the main streams and their tributaries. This report documents the data collected during 1982-83.

Location and General Features

The Cottonwood Creek basin is located in the Redding basin west of the Sacramento River between Redding and Red Bluff (fig. 1). Cottonwood Creek is currently an unregulated stream that drains the eastern slopes of the Coast Ranges and flows eastward to its confluence with the Sacramento River. Two damsites, Dutch Gulch on Cottonwood Creek and Tehama on South Fork Cottonwood Creek, are located about 15 miles upstream from the Sacramento River. The area monitored for water levels and water quality is generally downstream from the damsites and upstream from the Sacramento River. There are few wells located on the borders of the area, especially in the areas adjacent to and within the areas of future impoundment.

Most of the ground-water development in the area has been for domestic purposes. The Anderson-Cottonwood Irrigation District Canal and Cottonwood Creek supply most of the water for agricultural needs.

The geology of the area has been described by many authors. The Corps of Engineers has performed detailed geologic investigations as part of their damsite evaluations, so a detailed discussion of the geology will not be included in this report. Briefly, the area is underlain by the Pliocene Tehama Formation which is characterized by fluviatile sediments of clay, silt, sand, and gravel derived from the Coast Ranges and has variable permeability (Olmsted and Davis, 1961, p. 36). The Pleistocene Red Bluff Formation unconformably overlies the Tehama Formation and is generally less than 50 ft thick. It is characterized by poorly sorted gravels having a reddish silty or sandy matrix (Olmsted and Davis, 1961, p. 35). The Red Bluff Formation is largely above the zone of saturation but may contain small bodies of perched water caused by intermittent layers of hardpan (Olmsted and Davis, 1961, p. 92-93).

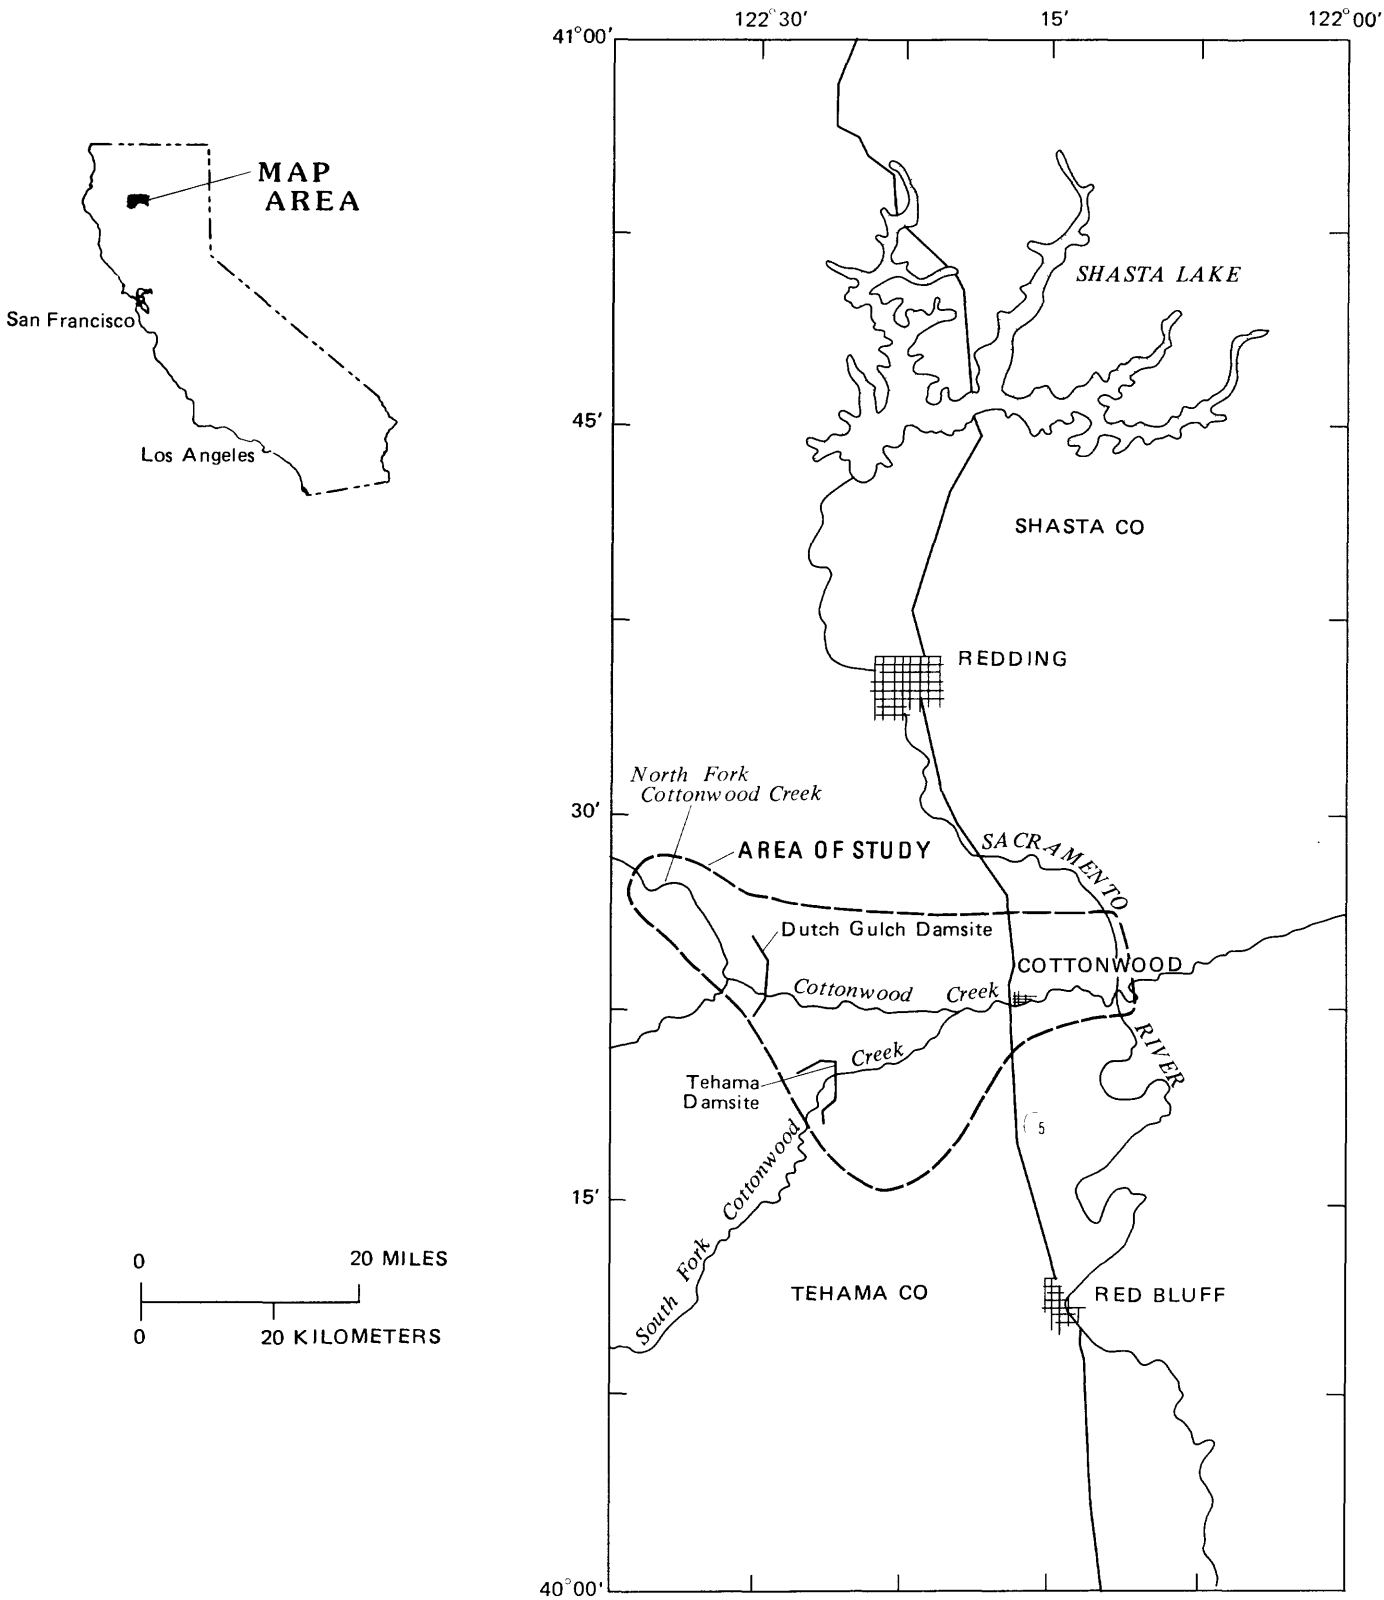

FIGURE 1.-Index map.

Purpose and Scope

The purpose of this report is to document ground-water and surface-water conditions, both water levels and water quality, from data collected in 1982-83. The scope of the work included:

1. Collection of well data (construction and lithologic information), from drillers' reports, for water wells in the area.

2. A selective field inventory of wells chosen from the evaluation of data collected for item 1.

3. Development of a network of wells to monitor ground-water levels and water quality that would be representative of the ground water in the area.

4. Development of a network of stream sites to monitor surface-water quality in the area.

5. Surveying water-level measuring points for monitoring wells in order to have ground-water levels and stream-flow stations at common datum.

6. Collection of monthly ground-water levels and semiannual water-quality samples from networks established for items 3 and 4.

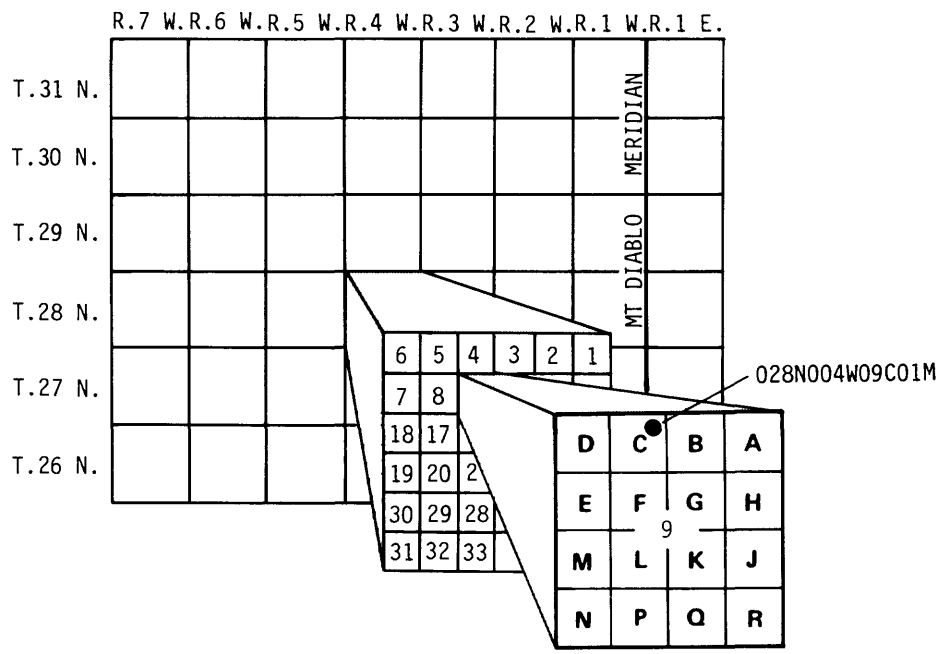
7. Analysis of water-level data by constructing water-level contour maps and hydrographs and by describing trends.

8. Analysis of water-quality data by classifying water into chemical types, by classifying water for agricultural and domestic uses, and by detecting areas or well sites where specific chemical constituents either exceed recommended limits or vary from the average concentrations in the area.

Well-Numbering System

Wells are identified according to their location in the rectangular system for the subdivision of public lands. The identification consists of the township number, north or south; the range number, east or west; and the section number. Each section is further divided into sixteen 40-acre tracts lettered consecutively (except I and O), beginning with A in the northeast corner of the section and progressing in a sinusoidal manner to R in the southeast corner. Within the 40-acre tract, wells are sequentially numbered in the order they are inventoried. The final letter refers to the base line and meridian. All wells in the study area are referenced to the Mount Diablo base line and meridian (M). The diagram below shows how the well number 028N004W09C01M is derived.

Well numbers shown in figures in this report are tract sequence numbers. Township, range, and section numbers have been omitted for simplicity.



ESTABLISHMENT OF MONITORING NETWORKS

During June and July 1982 about 200 wells were selectively inventoried. These wells were located from drillers' reports which contained thorough well-location and well-construction information. Only wells with complete well-construction information were included in either the water-level or water-quality network, as it was necessary to know what aquifer the measured or sampled water came from. Once a well was located, the fieldperson determined whether the well could be measured or sampled, updated construction data, obtained the owner's permission to measure or sample, and noted the exact measuring or sampling point.

From the 200 wells inventoried, about 100 wells were selected for the ground-water level monitoring network, and about 50 wells were selected for the ground-water quality monitoring network (pl. 1). These wells were considered adequate to represent the ground-water conditions in the area. Because of the development of ground water, most of the wells are located in the area downstream from the proposed damsites and generally near the two forks of Cottonwood Creek. The majority of these wells are domestic wells between 100 and 200 ft deep that penetrate layers of clays and gravels. Wells monitored near the borders of the area were also domestic wells penetrating clays and gravels; however, the depths varied in these wells. The shallowest and deepest wells in the monitoring network are located in the hills bordering the area.

Currently there are 97 wells in the water-level network; 94 are measured monthly, and 3 are equipped with continuous recorders. Currently there are 47 wells in the water-quality network. Several miscellaneous samples were taken from newly drilled Corps of Engineers' test wells. A summary of the data collected is given in tables 3, 4, and 5 at the end of this report.

About 25 surface-water sites selected for water-quality monitoring correspond with the current network of streamflow-measurement sites used for related studies. These sites are located at existing gaging stations and at miscellanous sites on the two forks of Cottonwood Creek and their tributaries (pl. 1). Water samples are collected semiannually from all sites that are flowing at the time of sampling. A summary of the data collected is given in table 6 at the end of the report.

CHEMICAL QUALITY OF WATER

Methods

Samples of ground water were taken from 47 wells during October 1982, May 1983, and October 1983. Samples from domestic wells or other wells having pressure systems were collected only after sufficient water had been pumped to assure obtaining a sample representative of water from the aquifer.

Surface-water quality samples were collected during May 1982, October 1982, and April 1983 at all sites where there was flow. Several sites were dry in the autumn and were sampled only in the spring.

Water temperature, specific conductance, pH, and alkalinity were measured at each sampling site. Temperature of the sample was simultaneously taken with a handheld thermometer and a direct-reading conductivity-temperature meter. A portable pH meter was used to determine pH, and the alkalinity was determined by the electrometric-titration process described by Brown and others (1970, p. 42). In an attempt to reduce human and instrument error, all determinations at the well site were made at least twice. When field determinations were completed, the remaining sample was field treated and refrigerated until being shipped to the U.S. Geological Survey Denver Central Laboratory in Arvada, Colo., for laboratory analysis. Samples that required it were filtered with a 0.45-micrometer membrane filter. Samples to be analyzed for nutrients were chilled by packing in ice immediately after filtering.

At the Denver Central Laboratory, all samples were analyzed for concentrations of calcium, magnesium, sodium, potassium, alkalinity, chloride, sulfate, nitrate plus nitrite as nitrogen, fluoride, silica, dissolved solids (residue on evaporation at 180°C method), aluminum, arsenic, iron, manganese, and orthophosphate using methods described by Brown and others (1970). The October 1982 samples also were analyzed for boron. Samples from three depth intervals from well 029N006W02P01M also were analyzed for trace metals (table 5). Physical well data are on file in the Survey computer and office files. The results of field and laboratory analyses are shown in table 4.

Water-Quality Standards

In this report the chemical constituents and properties are discussed in terms of their importance from the standpoint of toxicity or annoyance to humans and from the standpoint of toxicity to agricultural crops (phytotoxicity). Concentrations are compared with Federal standards. As a result of the Safe Drinking Water Act (Public Law 93-523), the U.S. Environmental Protection Agency (EPA) issued the National Interim Primary Drinking Water Regulations (1977) and the National Secondary Drinking Water Regulations (1979) (table 1). The term "Primary" in the title refers to mandatory limits as they pertain to public health. The term "Secondary" refers to recommended limits as they pertain to aspects of public water supplies that affect the public welfare in ways not related to health, such as an aesthetic characteristic of the water. These limits are used in this report for comparison and represent statutory limitations on public drinking-water supplies and not on private residential water sources. The local authority is the State of California, which adopted and described the Federal standards in the California Domestic Water Quality and Monitoring Regulations (California Department of Health, Sanitary Engineering Section, 1977).

Recommended limits for constituents in water used for agriculture (table 1) are given in National Academy of Sciences and National Academy of Engineering (1973).

Table 1.-- Drinking and agricultural water standards

Constituent	U.S. Environmental Protection Agency drinking-water standards		Recommended maximum concentrations in irrigation water[3]
	Primary[1]	Secondary[2]	
	Maximum concentration, in milligrams per liter		
Aluminum	--	--	5.0-20.0
Arsenic	0.05	--	0.1-2.0
Boron	--	--	[4]0.75-1.0-2.0
Chloride	--	250	--
Dissolved solids	--	500	--
Fluoride	[5]1.6	--	1.0-15.0
Iron	--	0.3	5.0-20.0
Manganese	--	0.05	0.2-10.0
Nitrate (as nitrogen)	10	--	--
Sulfate	--	250	--

[1]U.S. Environmental Protection Agency, 1977.

[2]U.S. Environmental Protection Agency, 1979.

[3]National Academy of Sciences and National Academy of Engineering, 1973. If two values are given, the lower value is the maximum recommended for use continuously on all soils. The upper value is the maximum recommended for use up to 20 years on fine-textured, neutral to alkaline soils.

[4]The three values shown denote the maximum concentration recommended for continuous use on all soils for boron sensitive crops, semitolerant crops, and tolerant crops, respectively.

[5]Based on mean annual maximum daily air temperature between 22 and 26°C.

Water Types

Water can be classified into general chemical types by use of a system based on the relative concentration of major cations and anions, as in the following examples: A "calcium bicarbonate" type water designates water in which calcium amounts to 50 percent or more of the cations and bicarbonate to 50 percent or more of the anions, in chemical equivalents; "sodium calcium bicarbonate" designates water in which the sodium and calcium are first and second, respectively, in order of abundance among the cations but neither amounts to 50 percent of all the cations; "sodium sulfate bicarbonate" designates water in which the sulfate and bicarbonate are first and second in order of abundance among the anions, as above (Piper, Garrett, and others, 1953).

The distribution of water types in ground water throughout the Cottonwood Creek area, based on the samples collected during October 1982, is shown on plate 2. South of Cottonwood Creek (generally south of Gas Point Road), ground water is a calcium magnesium or magnesium calcium bicarbonate type. Within this general water-type combination, the area along the South Fork of Cottonwood Creek and along Pine Creek shows water of a more calcium-rich nature. North of Cottonwood Creek the ground-water type is a sodium magnesium or magnesium sodium bicarbonate. The trilinear diagram (fig. 2) shows this variation in water types.

Samples collected during May 1983 display similar water-type patterns. However, water from 13 wells differed in water type from October 1982 samples due to small changes in ionic concentrations.

Water samples also were collected from the main streams and tributaries in the same months as the ground-water samples. The water type determined for the surface water was a calcium magnesium or magnesium calcium bicarbonate, which is similar to the chemical character of ground water sampled in the area. The calcium-rich waters in the South Fork Cottonwood Creek-Pine Creek areas indicated for ground water also were observed in the surface water (fig. 2).

Strand (1962) showed the area south of Cottonwood Creek to be underlain by the continental Tehama Formation which may explain the calcium-rich nature of the ground water. The area north of Cottonwood Creek is underlain by the Red Bluff Formation. The thin (usually less than 50 ft thick) Red Bluff Formation overlies the interbedded Tehama and Tuscan Formations (Olmsted and Davis, 1961, p. 90); however, the sodium-rich water type may suggest that the source area of the ground water may be in the older marine Cretaceous sedimentary rocks of the Coast Ranges, possibly the Chico Formation or lower Cretaceous rocks (formerly called Shasta Series, now obsolete).

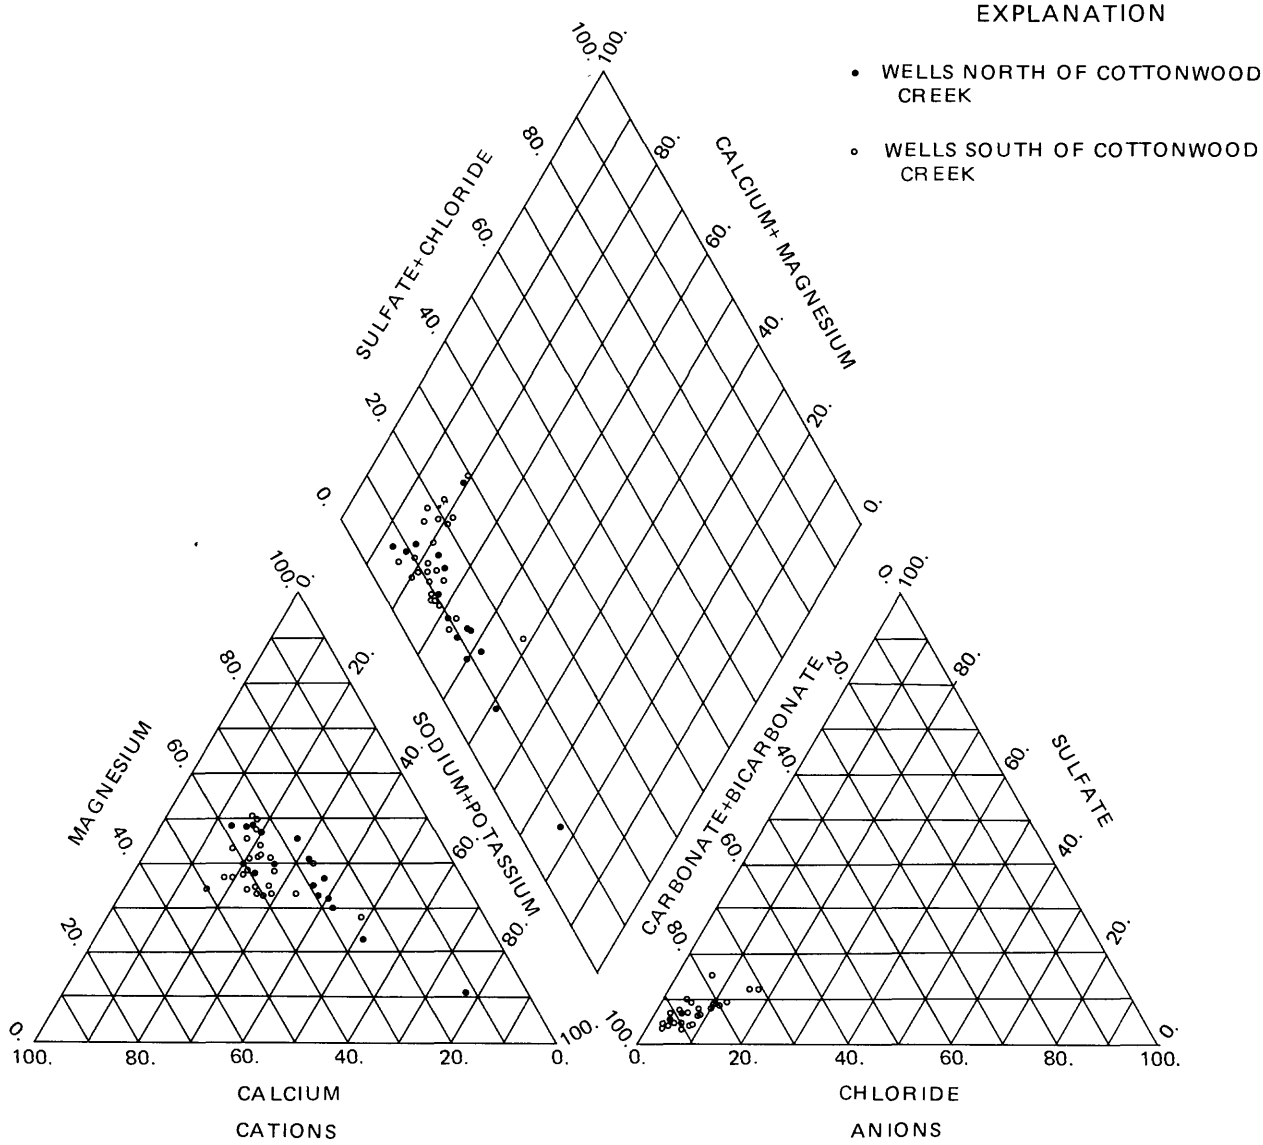


FIGURE 2.-Trilinear diagram showing water quality in the Cottonwood Creek area, October 1982.

Summary of Chemical Analyses

Ground Water

Ground-water quality in the Cottonwood Creek area is considered good to excellent with respect to recommended drinking-water standards. The ranges of concentrations and the mean and median concentrations found in the Cottonwood Creek area for samples collected during October 1982 and May 1983 are shown in table 2. The results of the individual field and lab analyses are shown in tables 4 and 5 at the end of this report.

Water from well 029N006W02K01M (actually located in 029N005W06P) had high nitrate (as nitrogen) concentrations (12 mg/L during October 1982 and 9.2 mg/L during May 1983). The EPA primary drinking-water limit for nitrate (as nitrogen) is 10 mg/L. Generally the most abundant form of nitrogen in ground water is nitrate (Hem, 1970); therefore, total nitrogen values were assumed to be roughly equivalent to nitrate concentrations. In this study all water samples were analyzed for dissolved nitrite plus nitrate as nitrogen.

Nitrate toxicity does not usually affect adults and older children, but it may cause a temporary blood disorder known as methemoglobinemia in children less than 4 months old; it occasionally is fatal. The incidence of fatality is very low in the United States where public water supplies are used. Most cases of nitrate toxicity are associated with high nitrate concentrations in domestic wells caused by inadequate sealing of supplying aquifers from surface contaminations.

For most agricultural purposes, nitrate in irrigation water is considered an asset because of its nutrient value; therefore, no limits have been established for nitrate-nitrogen in irrigation water.

Well 029N006W02K01M is a shallow domestic well located at a farmhouse surrounded by pasture. The depth of the well is 100 ft, the first perforation open to the formation is at 60 ft, and water levels have fluctuated from about 30 to 50 ft below land surface. The shallow well depth, shallow water level, and locale of this well lead to the conclusion that the nitrate problem is probably a result of surface contamination. It is only a local point-source problem and is not indicative of nitrate concentrations in the ground water of the area.

Water from test well 029N006W06P01M drilled by the Corps of Engineers exceeded the EPA primary drinking-water limit for arsenic at two of the three depth intervals sampled. Water samples from 246 ft had an arsenic concentration of 0.066 mg/L, and samples from 176 ft had an arsenic concentration of 0.06 mg/L.

Arsenic can be acutely or chronically toxic to humans and plants. The EPA has established 0.05 mg/L as the primary drinking-water standard. The National Academy of Sciences and National Academy of Engineering (1973) recommended maximum concentrations of 0.1 mg/L for irrigation water and 0.2 mg/L for livestock watering.

Water from wells 030N006W10K02M and 029N006W12B01M exceeded the 0.05-mg/L secondary standard for manganese, with concentrations of 0.066 and 0.13 mg/L, respectively. Manganese is objectionable in public water supplies because it affects taste, stains plumbing fixtures, spots laundered clothes, and causes accumulation of oxide deposits in distribution systems.

Manganese concentrations of a few tenths to a few milligrams per liter in solution are toxic to some plants. For this reason, a limit of 0.2 mg/L has been recommended for manganese in irrigation water used continuously on all soils. It should be noted that higher concentrations of manganese in irrigation water can be tolerated, depending on individual plant sensitivity and soil texture, drainage, pH, and alkalinity and in duration or continuity of application (National Academy of Sciences and National Academy of Engineering, 1973).

Well 029N006W02P01M was sampled at three intervals during October 25-26, 1982, for trace metals as well as the standard chemical analyses used in the semiannual ground-water samples. The sample depths were 246 ft, 176 ft, and 104 ft.

These samples show that concentrations of calcium, magnesium, sulfate, manganese, cadmium, molybdenum, strontium, and vanadium decrease with increasing depth, and dissolved solids, sodium, alkalinity, chloride, arsenic, boron, lead, lithium, and zinc concentrations increase with increasing depth.

Surface Water

Surface-water quality samples from Cottonwood Creek, South Fork Cottonwood Creek, and their tributaries were collected during the spring and autumn to reflect the high- and low-flow periods. Water-quality analyses from the samples of May and October 1982 and April 1983 are listed in table 6 at the end of the report.

Comparison of the spring and autumn analyses shows that there was generally an increase in concentrations of major ions during the low-flow periods. Dissolved-solids concentrations ranged from 48 to 163 mg/L and from 43 to 248 mg/L and had mean concentrations of 121 and 102 mg/L in the spring analyses of 1982 and 1983, respectively, whereas dissolved-solids concentrations ranged from 63 to 214 mg/L and had a mean concentration of 139 mg/L in the autumn.

GROUND-WATER LEVELS

Description of Ground-Water Levels

Water-level maps of September 1982 (pl. 3) and March 1983 (pl. 4) show altitudes of the ground-water surface based on water-level measurements. These maps show the low and the high ground-water conditions in the study area. The maps for both September and March show the same eastward, downstream slope of the ground-water surface from the damsites. Also apparent in both maps is a ground-water mound located between the confluence of the South Fork of Cottonwood Creek and the town of Cottonwood; in both months this mound was approximately the same size and shape. Water levels from wells in this area changed less throughout the year as compared with wells in the rest of the study area. The Anderson-Cottonwood Irrigation District Canal runs through the center of this area; because it is not lined it is probably the cause of the higher ground-water levels and suppressed water-level fluctuations. Water levels downstream from the town of Cottonwood also slope generally eastward toward the Sacramento River.

After an analysis was made of the relation of water levels to well depth (or depth to the first perforation), it was determined that generally the deeper the well the deeper the water level. The basin area near the creeks, where well depths showed little variation, indicates that water-table conditions exist, as shown by the rapid response to precipitation shown in figures 3-5 and the contour maps (pls. 3 and 4). The water levels in many of the wells in the bordering areas varied with respect to the contours drawn between the wells in the basin area, indicating that local conditions such as local confinement or perched water may exist. Contours were not extended to these bordering wells.

Results of pumping tests with multilevel piezometers performed by the Corps of Engineers at the proposed Tehama and Dutch Gulch damsites indicate that confined flow conditions exist at those sites (Carl Cole, U.S. Army Corps of Engineers, oral commun., 1983).

Hydrographs

Water-level fluctuations in the Cottonwood Creek area are representative of the basin part of the study area as can be seen by the location of each of the groups of wells. Wells located close to the proposed Dutch Gulch damsite are shown in figure 3, and wells located along South Fork Cottonwood Creek near the proposed Tehama damsite are shown in figure 4.

The changes in water levels shown in the hydrographs for wells in the ground-water mound area (fig. 5) are different from those of the rest of the study area. Although water levels in these wells fluctuate throughout the year, the range of fluctuation is much less than the range of fluctuations found over the rest of the area. Leakage from the Anderson-Cottonwood Irrigation District Canal may cause this mound and could explain the suppressed fluctuations of water levels in these wells.

The three hydrographs show virtually the same seasonal patterns. The lowest water levels occurred from September to November and then rose through March; from April through July water levels declined. Precipitation records from the station located at the Coleman Fish Hatchery show the same pattern as the water levels, indicating that water levels respond quickly to precipitation.

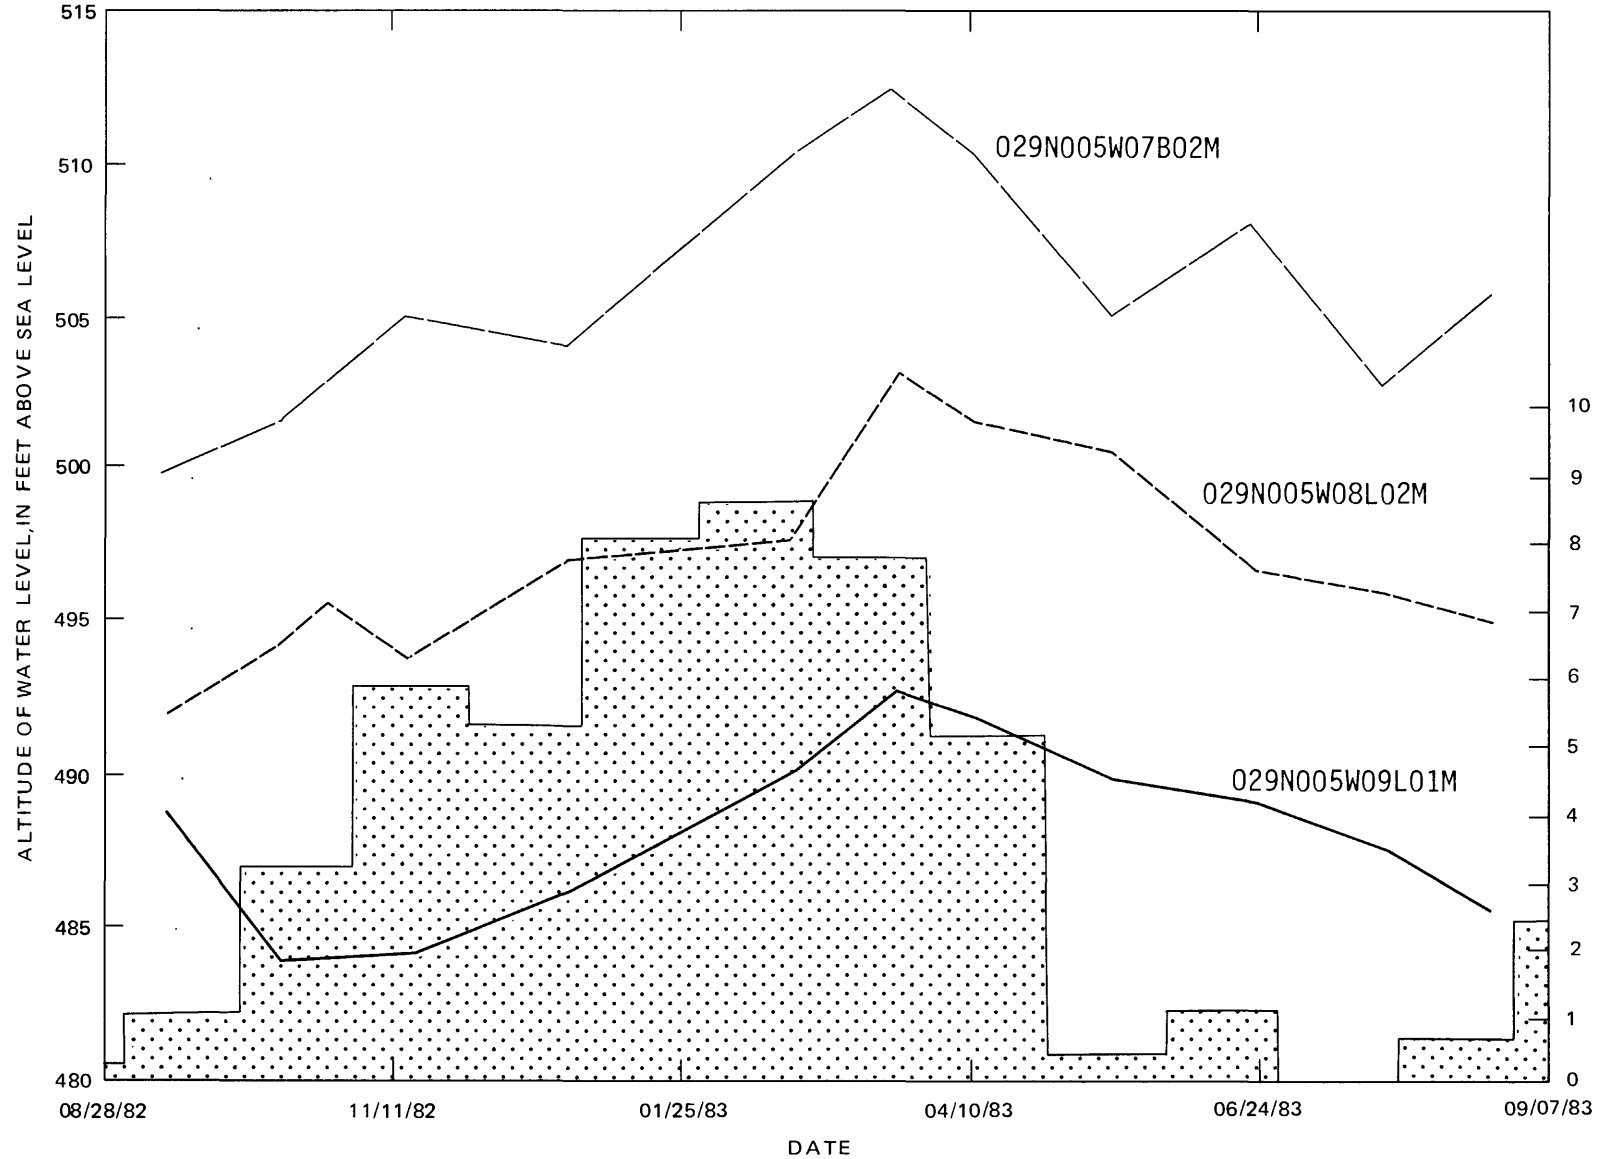

FIGURE 3.-Hydrographs of wells near Dutch Gulch damsite and precipitation at Coleman Fish Hatchery.

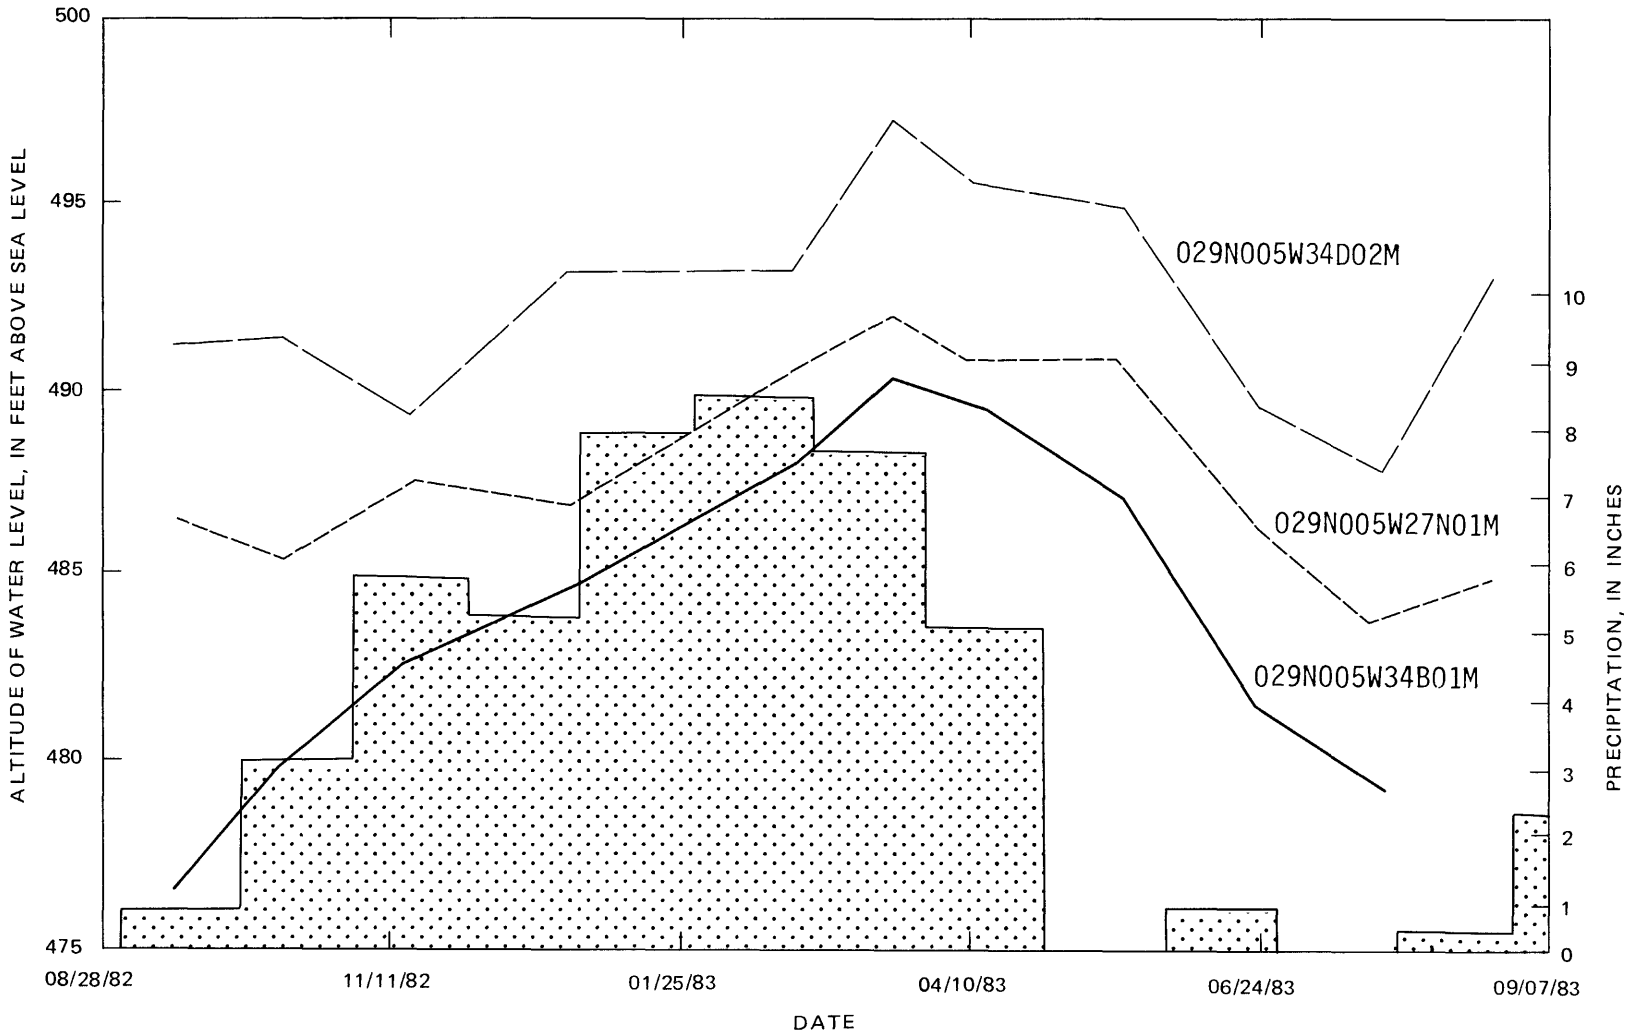

FIGURE 4.-Hydrographs of wells near Tehama damsite and precipitation at Coleman Fish Hatchery.

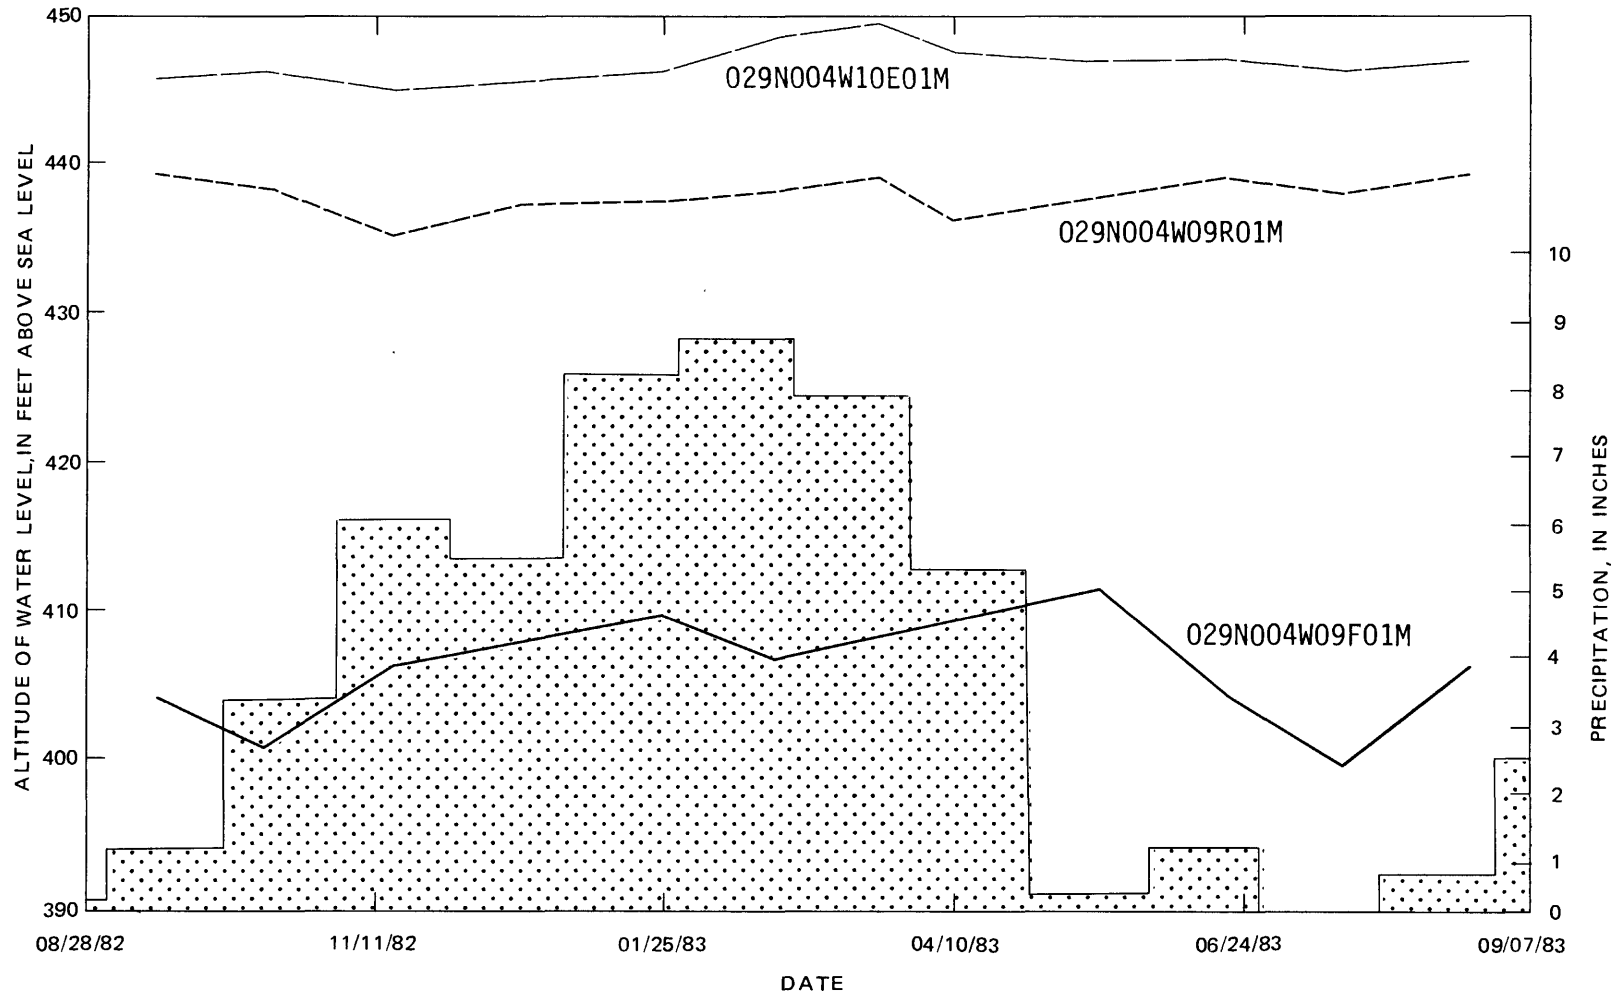

FIGURE 5.-Hydrographs of wells near Cottonwood and precipitation at Coleman Fish Hatchery.

SUMMARY AND CONCLUSIONS

Ground-water quality in the Cottonwood Creek area is considered good to excellent with respect to recommended standards. Chemical quality varied little both spatially and seasonally.

Ground-water levels were higher in the spring and lower in the autumn, coinciding with precipitation patterns. The ground-water surface slopes downstream from the damsites toward the Sacramento River, but two areas are anomalous to this trend. One area is a ground-water mound near the town of Cottonwood where the probable cause is leakage from the Anderson-Cottonwood Irrigation District Canal. The other area is in the hills that border the basin on the north and south. Inspection of drillers' logs from wells in this area indicates that clay layers are present and could cause local confinement or perched water in some wells.

Data are insufficient in the area upstream from the damsites, specifically in the areas of future impoundment. These areas are likely to experience the greatest impacts from the dams, so the monitoring network could be expanded to include wells in these areas. At this time (1984), information has not been located for wells in this area. A detailed well inventory and local research may successfully locate suitable monitoring wells. It may be necessary to drill new wells in areas where no wells exist.

Further studies in the area of the ground-water mound near the town of Cottonwood might provide the reasons for the existence of the mound. The data included in this report indicate that water levels do not fluctuate in the mound area as they do in the rest of the study area. Detailed information of the hydrology in this area would be needed for any subsequent modeling studies.
