CONVERSION FACTORS AND VERTICAL DATUM

<u>Multiply</u>	<u>By</u>	<u>To obtain</u>
cubic foot per second (ft ³ /s)	0.02832	cubic meter per second
foot (ft)	0.3048	meter
foot per day (ft/day)	0.3048	meter per day
foot squared per day (ft ² /d)	0.09290	meter squared per day
gallon per minute (gal/min)	0.00006309	cubic meter per second
gallon per minute per foot (gal/min)/ft	0.2070	liter per second per meter
inch (in.)	0.0254	meter
mile (mi)	1.609	kilometer
square mile (mi ²)	2.590	square kilometer

Specific conductance is expressed in microsiemens per centimeter at 25 degrees Celsius.

Temperature in degrees Fahrenheit (°F) or degrees Celsius (°C) may be converted as follows:

$$^{\circ}\text{C} = 5/9 (^{\circ}\text{F} - 32)$$

$$^{\circ}\text{F} = 9/5 (^{\circ}\text{C}) + 32$$

Sea level: In this report, sea level refers to the National Geodetic Vertical Datum of 1929--a geodetic datum derived from a general adjustment of the first-order level nets of the United States and Canada, formerly called Sea Level Datum of 1929.

SUMMARY OF THE SAN JUAN STRUCTURAL BASIN REGIONAL AQUIFER-SYSTEM ANALYSIS, NEW MEXICO, COLORADO, ARIZONA, AND UTAH

**By Gary W. Levings, John Michael Kernodle,
and Condé R. Thorn**

ABSTRACT

Ground-water resources are the only source of water in most of the San Juan structural basin and are mainly used for municipal, industrial, domestic, and stock purposes. Industrial use increased dramatically during the late 1970's and early 1980's because of increased exploration and development of uranium and coal resources.

The San Juan structural basin is a northwest-trending, asymmetric structural depression at the eastern edge of the Colorado Plateau. The basin contains as much as 14,000 feet of sedimentary rocks overlying a Precambrian basement complex. The sedimentary rocks dip basinward from the basin margins toward the troughlike structural center, or deepest part of the basin. Rocks of Triassic age were selected as the lower boundary for the study. The basin is well defined by structural boundaries in many places with structural relief of as much as 20,000 feet reported. Faulting is prevalent in parts of the basin with displacement of several thousand feet along major faults.

The regional aquifers in the basin generally are coincident with the geologic units that have been mapped. Data on the hydrologic properties of the regional aquifers are minimal. Most data were collected on those aquifers associated with uranium and coal resource production. These data are summarized in table format in the report. The regional flow system throughout most of the basin has been affected by the production of oil or gas and subsequent disposal of produced brine. To date more than 26,000 oil- or gas-test holes have been drilled in the basin, the majority penetrating no deeper than the bottom of the Cretaceous rocks.

The general water chemistry of the regional aquifers is based on available data. The depositional environments are the major factor controlling the quality of water in the units. The dominant ions are generally sodium, bicarbonate, and sulfate. A detailed geochemical study of three sandstone aquifers--Morrison, Dakota, and Gallup--was undertaken in the northwestern part of the study area. Results of this study indicate that water chemistry changed in individual wells over short periods of time, not expected in a regional flow system. The chemistry of the water is affected by mixing of recharge, ion filtrate, or very dilute ancient water, and by leakage of saline water.

The entire system of ground-water flow and its controlling factors has been defined as the conceptual model. A steady-state, three-dimensional ground-water flow model was constructed to simulate modern predevelopment flow in the post-Jurassic rocks of the regional flow system. In the ground-water flow model, 14 geologic units or combinations of geologic units were considered to be regional aquifers, and 5 geologic units or combinations of geologic units were considered to be regional confining units. The model simulated flow in 12 layers (hydrostratigraphic units) and used harmonic-mean vertical leakance to indirectly simulate aquifer connection across 3 other hydrostratigraphic confining units in addition to coupling the 12 units.

INTRODUCTION

The San Juan structural basin in New Mexico, Colorado, Arizona, and Utah has an area of about 21,600 mi² (fig. 1). The study area is that part of the structural basin that contains rocks of Triassic or younger age and, therefore, is less areally extensive than the structural basin, about 19,400 mi². Triassic through Tertiary sedimentary rocks are emphasized in this study because the major aquifers in the basin are in these rocks.

Ground-water resources are the only source of water in most of the basin and are used mainly for municipal, industrial, domestic, and stock purposes. Industrial use increased dramatically during the late 1970's and early 1980's because of increased exploration and development of uranium and coal resources. By the end of 1991, all major uranium mines had ceased production. The limited surface water of the basin has been fully appropriated.

During 1984-90, the U.S. Geological Survey conducted a regional assessment of the San Juan structural basin that involved review and analysis of previous studies, acquisition of new data in selected areas, geochemical analysis of three sandstone aquifers in the northwestern part of the basin, and development of a computer model to simulate ground-water flow. This investigation, which is summarized in this report, is one of several studies of the U.S. Geological Survey Regional Aquifer-System Analysis (RASA) program.

The general purpose of the RASA program is to better understand the Nation's ground-water resources. Previous studies of ground-water resources have been on a local scale, responsive to local, immediate needs. These studies usually have been restricted within political boundaries. However, hydrologic studies are needed on a regional scale for defining total ground-water resources and for planning the most effective development and use of these resources. Thus, the concept of regional aquifer-system analyses was developed.

Purpose and Scope

The purpose of this report is to summarize the important aspects of the geology, hydrology, and geochemistry of the San Juan structural basin aquifer system. These descriptions are derived from the results and published reports of the study. In addition, previously published reports on the hydrology and geology of the basin provided an extensive source of data to supplement the work done on this project. These previously published reports are cited in the references section of the following reports:

Craig (in press) described the geologic framework of the San Juan structural basin and presents numerous maps showing the depth to top and thickness of the aquifers;

Kernodle (in press) described the hydrology and simulation of the ground-water flow system by use of a 12-layer digital model; and

Dam (1995) described the geochemistry of the Morrison, Dakota, and Gallup aquifers in the northwestern part of the basin.

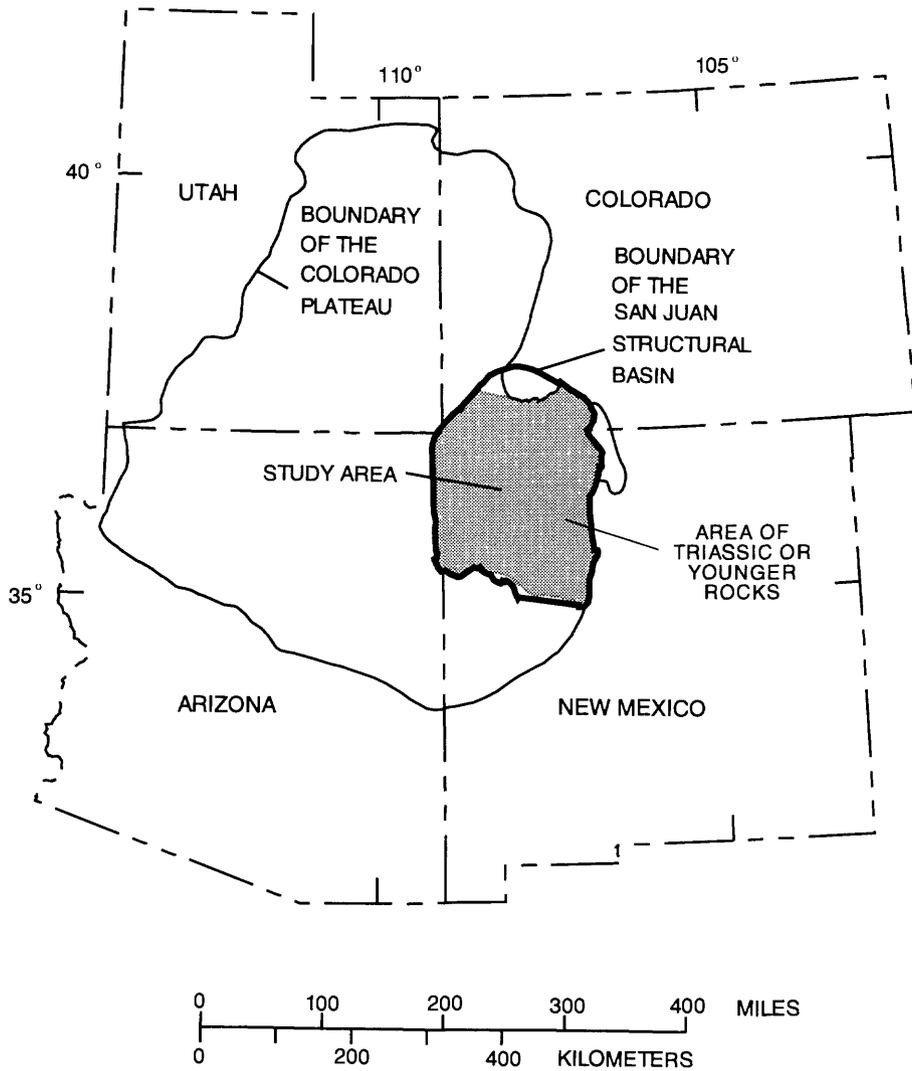

Figure 1.--Location of the San Juan structural basin, Colorado Plateau, and study area.

Early in the project, the decision was made to use Geographic Information Systems (GIS) technology to develop the general automated data compilation, data analysis, and map-production capabilities needed for regional geologic and hydrologic resource studies. The development of new GIS program interfaces to high-accuracy automated cartographic drafting systems allowed for direct generation of publication-quality cartographic products. Hydrologic Investigations Atlases (HA's) were prepared for 10 aquifers using GIS technology. The aquifers generally are coincident with the geologic units. In descending stratigraphic order the geologic units (and HA references) are the: (1) San Jose, Nacimiento, and Animas Formations (Levings and others, 1990b); (2) Ojo Alamo Sandstone (Thorn and others, 1990b); (3) Kirtland Shale and Fruitland Formation (Kernodle and others, 1990); (4) Pictured Cliffs Sandstone (Dam and others, 1990b); (5) Cliff House Sandstone (Thorn and others, 1990a); (6) Menefee Formation (Levings and others, 1990a); (7) Point Lookout Sandstone, including the Hosta Tongue (Craig and others, 1990); (8) Gallup Sandstone (Kernodle and others, 1989); (9) Dakota Sandstone (Craig and others, 1989); and (10) Morrison Formation (Dam and others, 1990a). When data were sufficient for analysis, these HA's include such information as depth to the top, approximate altitude and configuration of the top, and thickness of the geologic unit; potentiometric surface of water in each geologic unit; hydrologic characteristics such as transmissivity, hydraulic conductivity, and storage coefficient; well characteristics such as discharge and specific capacity; hydrographs of selected wells; and water-quality data such as temperature, pH, dissolved solids, specific conductance, and major constituent concentrations.

Summary of Previous Work

Thousands of reports describing the hydrology, geology, or water chemistry of the San Juan structural basin have been published beginning with the first reports on its geology in the late 1800's. A bibliographic reference for reports on the geology and hydrology of the San Juan Basin was published in 1979 and includes more than 2,500 entries (Wright, 1979). These reports served as a source of supplemental data for the interpretations described in this report and the HA's prepared for this study. Although many of these reports provided a wealth of information, the investigations often terminated at political boundaries. The RASA investigation assembled, organized, and assimilated this geohydrologic information on a regional basis.

Regional Analysis of the San Juan Structural Basin

Physical Setting

The San Juan structural basin occupies the eastern third of the Navajo Section of the Colorado Plateau physiographic province (Fenneman, 1931). Distinctive landscape features are mesas, rock terraces, retreating escarpments, canyons, dry washes, and mountains. In some parts volcanic necks and buttes are abundant. Altitudes in the study area range from 4,500 ft in San Juan County, Utah, to about 11,000 ft in Cibola County, New Mexico.

The San Juan structural basin is located in the arid Southwestern United States and therefore typically has mild winters with periodic cold-front storms; hot, dry, and windy springs and early summers; warm and monsoonal late summers; and cool, clear autumns. However, within the San Juan structural basin, a wide range of climatic conditions primarily are determined by topographic altitude and, to a lesser extent, by slope aspect. The low-altitude central and northwestern parts of the basin have an upper Sonoran climate, the warmest temperatures, and the least amount of precipitation. The mountainous regions around most of the northern and eastern perimeter of the basin are in the Canadian climate zone and have the coolest temperatures and the most precipitation.

Annual precipitation in the high mountainous areas along the northern and eastern margins of the basin is as much as 40 in., whereas annual precipitation in the lower altitude, central basin is generally less than 8 in. Mean annual precipitation in the study area is about 12 in. Most winter precipitation is snowfall, especially in the higher mountain areas where snowpack typically exceeds 100 in. Spring runoff from melting snowpack in the mountains accounts for the majority of surface water in the basin. Summer convective thunderstorms locally may drop considerable amounts of water in a very brief period of time, often causing severe and dangerous flash floods.

Potential mean annual evaporation ranges from a low of less than 40 in. in the northeastern part to more than 60 in. in the northwestern part of the study area. Throughout most of the area potential evaporation greatly exceeds precipitation. With additional losses to transpiration, the potential annual water deficit is large throughout most of the area. Because of the timing of rain and snowfall, however, water periodically is available for runoff and ground-water recharge regardless of the annual potential deficit.

Population and Economy

Data obtained from documents published by the U.S. Bureau of the Census (1980 and 1985) were used to calculate the population of the study area. The population in 1970 was calculated to be about 134,000. The population increased to about 194,000 in 1980, 212,000 in 1982, 221,000 in 1984, and then decreased to about 210,000 in 1985. The economy of the basin is supported by exploration for and development of natural gas, petroleum, coal, and uranium resources; urban enterprise; farming and ranching; tourism; and recreation. The rise and fall in population were related to changes in the economic strength of the minerals, oil, and gas industries, and support services. Uranium-mining and -milling activities underwent rapid growth from the 1950's until the late 1970's and early 1980's when most uranium-mining activity came to an abrupt end. Likewise, the oil and gas industry prospered until about 1983 and then declined rapidly.

The population in the basin has since risen to 225,000 in 1990 (U.S. Bureau of the Census, 1990). The increase may, in part, be due to a surge in the development of coal-bed methane from the Fruitland Formation and may also be due to the rapid growth of tourism in the Four Corners area. Both of these areas of development promote growth in service-oriented commerce and industry.

Resource Development

The San Juan structural basin contains a number of geologic units that are different with respect to water-yielding properties, water chemistry, and flow. Ground-water development in the basin has not been uniformly distributed either areally within individual geologic units or from unit to unit. Along the southern part of the basin, ground-water levels have declined significantly in response to pumping to dewater the Morrison Formation for underground uranium mining. In other areas, strip mining of shallow coal beds has led to the dewatering of the Fruitland Formation. The San Juan structural basin is a major gas and oil producing area, and as a result, ground water has been produced as a by-product. Disposal of ground water has been by injection into selected subsurface units. The exploration and development of these activities peaked in the early 1980's. At that time, water pumpage was projected to triple from 1980 to 2005 (Frenzel, 1983, p. 53 and 63). At the present time (1992) development of these resources has decreased significantly. All major uranium mines have ceased production of uranium ore; strip mining of coal continues but no new mines have been opened since the early 1980's; and oil and gas exploration has been declining since the mid- to late 1980's. The renewed interest in the production of coal-bed methane, from the Fruitland Formation, has resulted in a flurry of drilling activity, which began in the late 1980's and is expected to continue into the early 1990's.

GEOLOGIC SETTING

The San Juan structural basin is a northwest-trending, asymmetric structural depression at the eastern edge of the Colorado Plateau (fig. 1). The basin is primarily in northwestern New Mexico but includes areas in southwestern Colorado, northeastern Arizona, and extreme southeastern Utah. It is one of several large basins interspersed or embayed into the ranges and chains of the Rocky Mountain area and is, in a sense, a structural embayment of the Colorado Plateau into the southwestern edge of the Rocky Mountains. The northern and eastern rims are structurally complex; however, the southern part of the basin merges with a volcanic plateau and on the west the margin is locally complex. Several subbasins, reentrants, or embayments extend from the basin proper into the adjoining uplifts and plateaus.

Underlying the San Juan structural basin are (1) a Precambrian basement complex composed of igneous and metamorphic rocks; (2) gently dipping and flat-lying Paleozoic, Mesozoic, and Cenozoic sedimentary rocks as thick as 14,000 ft (Fassett and Hinds, 1971, p. 4); (3) a variety of Upper Cretaceous and Cenozoic igneous rocks; and (4) various unconsolidated deposits of Quaternary age. For the most part, these sedimentary rocks dip from the basin margins toward the troughlike structural center, the deepest part of the structural basin. Older sedimentary rocks, which crop out around the basin margins, are overlain by younger rocks toward the center of the structural basin. Volcanic rocks of Tertiary age and various deposits of Quaternary age also are present in the basin.

The present San Juan structural basin has been the site of marine and continental deposition, and its present configuration is largely a result of early to mid-Tertiary Laramide tectonic events. Although rocks of Cambrian, Devonian, Mississippian, Pennsylvanian, and Permian age are present in the basin (see fig. 2), they were not included as part of this study. The rocks of Triassic age (primarily the Chinle Formation) were selected as the lower boundary for the study. The Chinle Formation and its lateral equivalent, the Dolores Formation, were deposited in various continental and fluvial environments and consist of variegated claystone and shale, siltstone, sandstone, conglomerate, and limestone. After deposition of Triassic rocks, erosion over most of the basin resulted in a widespread unconformity between Triassic and Jurassic rocks.

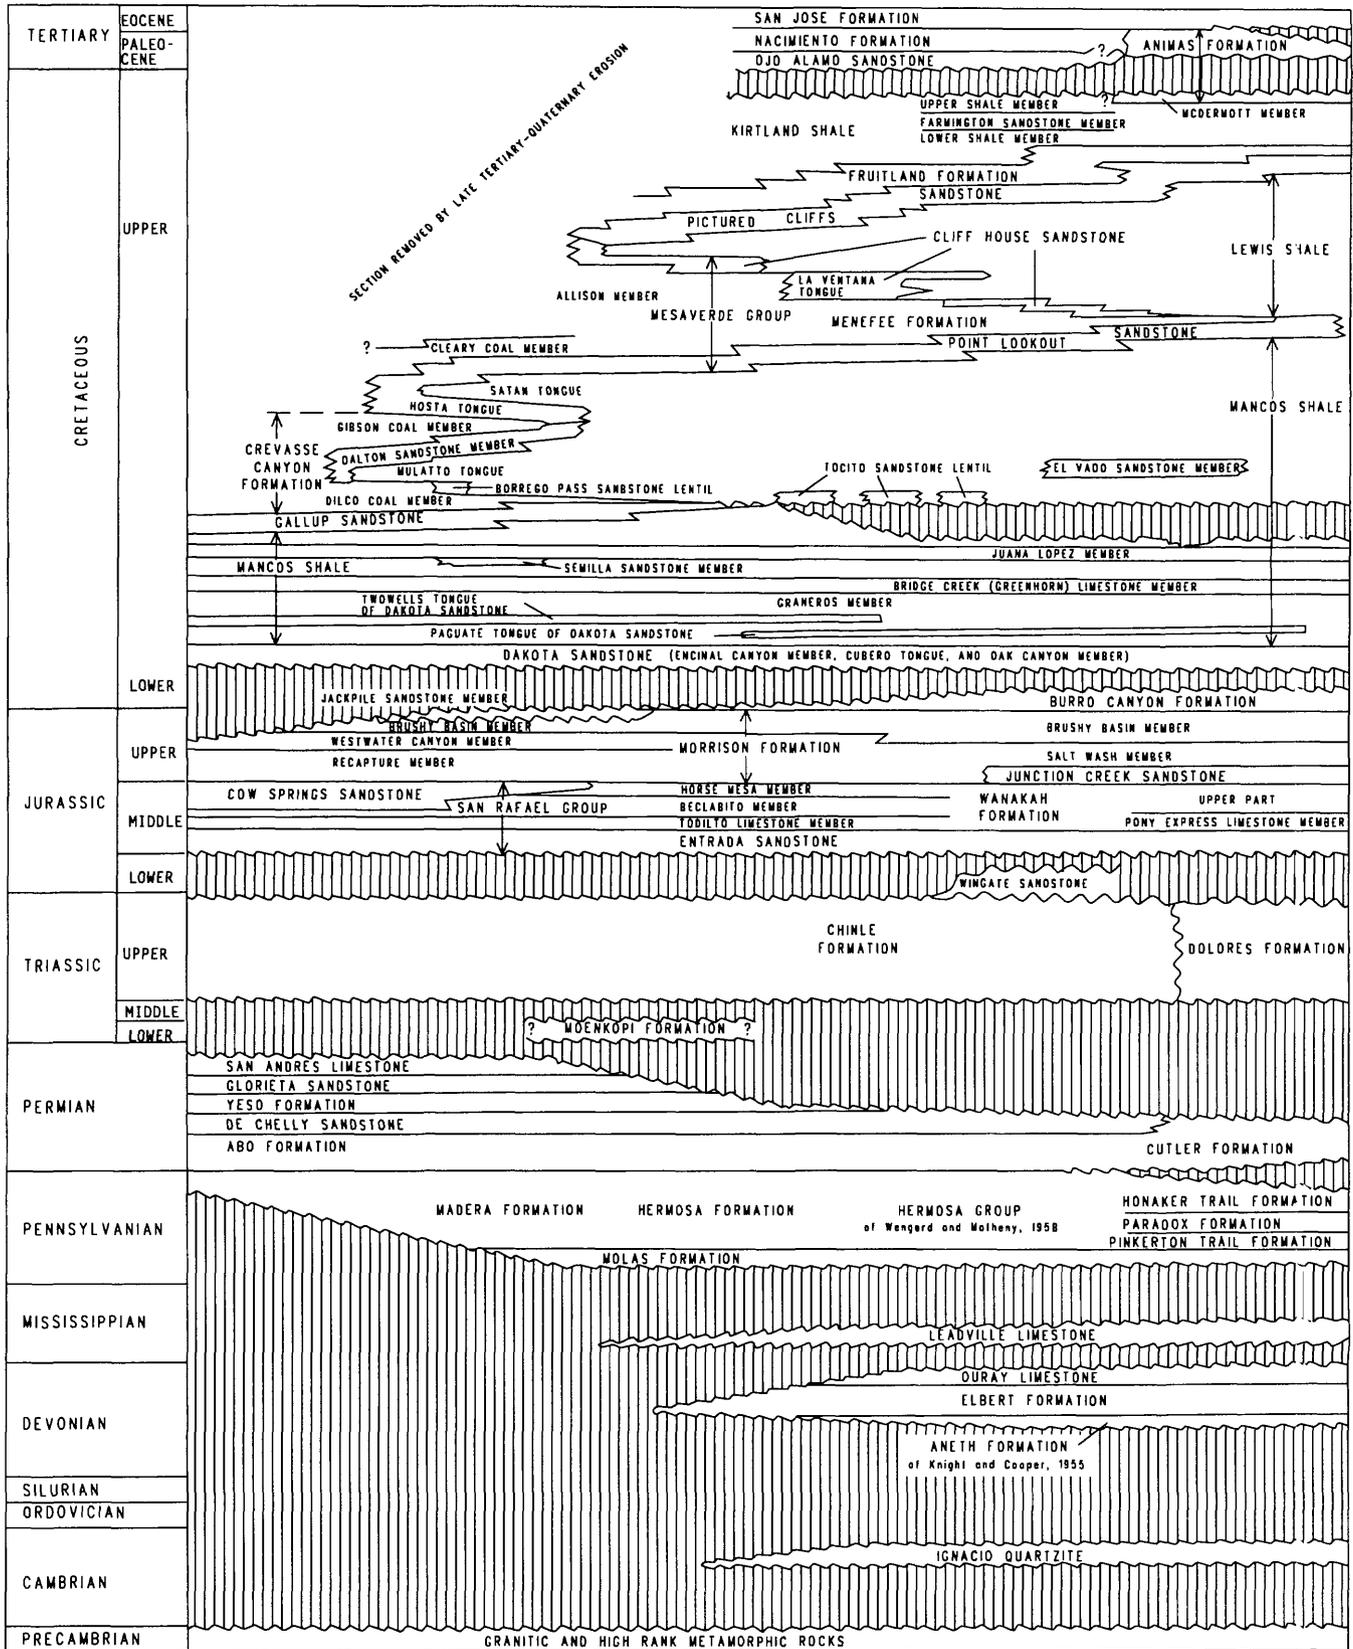

The lowermost Jurassic rocks, the San Rafael Group (fig. 2), are sandstones from dune fields and limestones from marine waters. Uplift and volcanic activity to the southwest preceded deposition of the overlying Middle to Upper Jurassic Morrison Formation. The Morrison Formation was deposited on a vast plain in a variety of fluvial and lacustrine environments. Much of the Morrison contains volcanic debris.

Again, erosion before deposition of the Cretaceous rocks resulted in an unconformity between the Dakota Sandstone and the Morrison Formation. The Cretaceous is characterized by numerous transgressions and regressions of the Late Cretaceous epicontinental sea, which deposited intertonguing sequences of shale and sandstone and lesser amounts of limestone and coal in marine, nearshore marine, beach, paludal, and fluvial environments. As the sea withdrew, the area was once again dominated by terrestrial sedimentation over a vast alluvial plain traversed by streams and dotted with swamps in which coal deposits subsequently formed.

During early Tertiary time, renewed tectonic activity accompanied by volcanism, referred to as the Laramide Orogeny, shaped the structural basin. Deposition continued into late Miocene or early Pliocene time when broad, regional uplifting occurred and erosion removed large amounts of Tertiary and pre-Tertiary rocks. Erosion has continued, resulting in Quaternary deposits of unconsolidated alluvium, local eolian dunes, talus, and colluvium. A summary of geologic nomenclature and lithologic characteristics of regional units of this study is presented in table 1 (all tables are in the back of the report).

Figure 2.--Time- and rock-stratigraphic framework and nomenclature. Ruled lines indicate a hiatus in the sequence of beds.

STRUCTURAL FEATURES AND FAULTING

The structural evolution of the San Juan structural basin is complex. Tectonism began as early as late Paleozoic time. The present basin formed mainly during the Laramide Orogeny (Late Cretaceous-early Tertiary time), although some downwarping and local uplifting along basin margins probably recurred during middle Tertiary and possibly late Tertiary time (Kelley, 1951, p. 130).

Structural boundaries of the basin generally are well defined, but in some areas, the basin merges gradually into adjacent depressions or uplifts (Kelley, 1951, p. 124). Four major structural elements may be delineated in the structural basin: large, elongate, domal uplifts; low, marginal structural platforms; abrupt monoclines; and the central basin (fig. 3) as defined by Kelley (1951, p. 126). Subsurface structural relief within the basin varies: about 2,500 ft along the Chaco Slope; 3,000 ft in the central basin; and 4,000 ft along the Hogback Monocline at the Four Corners Platform. With respect to the Nacimiento Uplift and San Juan Uplift, the structural relief within the basin is 14,000 ft and 20,000 ft, respectively (Kelley, 1957).

Faulting, as mapped on the 1:500,000-scale State geologic map, is shown in figure 3. The faulting is associated with some of the areas of major uplift—San Juan Uplift, Nacimiento Uplift, and Zuni Uplift—and the Puerco Fault Zone at the western edge of the Rio Grande Rift.

In general, the faults are high-angle, northeast-trending faults of small displacement. An exception is the area of the Nacimiento Uplift, an area of complex faulting, resulting in thrust-faulted areas, tilted fault blocks, grabens, and high-angle faults trending west, northwest, and northeast (Woodward and others, 1972). In the Puerco Fault Zone displacement along individual faults is in the range of several tens to a few hundred feet; Cenozoic activity resulting in the Rio Grande Rift, however, has also resulted in northeast-trending normal faults having structural relief of as much as 3,000 ft, downdropped to the east. Faulting in the Chaco Slope seems to be associated with several small, plunging anticlines and elliptical domes that have created high-angle faults ranging in strike from north to east. Fault orientation and displacement in the Crownpoint-Grants, New Mexico, area (also known as the Grants Uranium Belt) are more disheveled than elsewhere, often leading to some localized structure as in the area just south of Crownpoint. Faulting in the Zuni Uplift is generally high angle with displacement from a few feet to as much as 1,000 ft.

HYDROLOGIC SETTING AND PROPERTIES OF THE REGIONAL AQUIFERS

In the San Juan structural basin, the terms "aquifer" and "confining bed" have been associated, for the most part, with the formal name of a geologic unit (formation, member, or tongue) that forms a significant part of the aquifer or confining bed. It is recognized that the aquifers and confining beds are not necessarily restricted to one geologic unit but may include all or parts of several geologic units; however, data on relative permeabilities were inadequate for more precise delineation of aquifers and confining units. Figure 4 shows the relation of geologic units to regional hydrogeologic units and model layers.

The distinction between aquifer and confining bed can also be one of perspective. In many cases, units that are considered confining beds on a regional scale can, and do, yield small quantities of water to wells from localized lenticular sandstones. These wells often supply water for stock use and represent a significant percentage of the total number of water wells in the basin. From a regional perspective, however, these units are considered to be confining beds in the evaluation of ground-water resources and the development of a three-dimensional, steady-state ground-water flow model. For example, the Menefee aquifer is considered to be an aquifer on a local scale and a confining bed on a regional scale because water is found in localized, discontinuous lenticular sandstones.

Figure 4.--Relation of geologic units to regional hydrogeologic units and model layers.

In a simplified conceptual model of the ground-water flow system in the San Juan structural basin, water enters the ground-water flow system from precipitation on outcrops and from stream-channel loss as streams cross the outcrop. Recharge from direct precipitation occurs only after near-surface demands for moisture are met by the water that does not run off and a residual amount of water reaches the zone of saturation. These near-surface demands include evaporation, sublimation, and transpiration.

Once water is in the ground-water flow system it moves downgradient to areas of natural or human-induced discharge in accordance with Darcy's law (Darcy, 1856). Areas of natural discharge include springs and seeps in topographically low parts of the outcrop, discharge from the outcrop to stream channels, and upward movement across less permeable beds to the surface along fault planes, fractures, and, less commonly, along dikes. Examples of spring discharge along fault planes and fractures are at the southern end of the Nacimiento Uplift in the southeastern part of the study area (fig. 3).

Another important method of natural discharge is water moving from one aquifer, across a less permeable unit, to another aquifer that has lower hydraulic head. Water also might move across a less permeable unit directly to land surface where it would contribute to soil moisture and hence to evaporation or transpiration.

Human-induced discharge occurs at flowing or pumped wells or in conjunction with open-pit or subsurface mining operations. Free-flowing wells are commonplace in the basin and most of them are completed in multiple aquifers; the percentage of water contributed by each aquifer is unknown. Pumped wells or controlled flowing wells also are common and supply water for municipal, small-community, private-domestic, and livestock needs. The majority of these wells are windmill powered and result in small yields, but some are capable of yielding large quantities of water. Mine-dewatering operations have been a major source of ground-water discharge in the south-central part of the basin. Some mines required the removal of as much as 3 ft³/s of ground water to keep the mine from flooding. All of the mines presently are closed, dewatering has ceased, and ground-water levels are now recovering from reductions in head that commonly exceeded 1,000 ft.

Complexities in the flow system arise because of nonuniformity in the aquifers. The aquifers may thin or pinch out, or the composition and hydraulic properties may vary in space. Aquifers also may have preferred directions of ground-water flow that are controlled by the orientation of fracture systems or by a persistent orientation of the aquifer's matrix of sedimentary materials. Other pore-filling liquids or gasses may be present, creating barriers to the movement of water, or water in parts of an aquifer may be saline enough to create a density barrier to movement of freshwater. All of these conditions are present to some degree in the San Juan structural basin.

Evaluation of the ground-water flow system in the basin is hampered by the inadequate areal distribution of water wells across the basin. In most of the aquifers, the wells are concentrated on or near the outcrop because sufficient water for most uses is obtained from the shallowest source available. Thus hydrologic data available for the aquifers in the interior of the basin are restricted to data for oil- or gas-test holes. Another problem in evaluating hydrologic data is that many wells are completed in more than one aquifer. Wells are drilled to a depth sufficient to provide the required amount of water with perforations in any interval that will produce water. Thus, a measured water level or specific capacity and water-quality sample represent a composite from multiple aquifers and cannot be used in the analysis of flow systems in the basin. In analyzing data it was necessary to examine the well records to select only those wells that represented single-aquifer completions.

The ground-water flow system has been altered in parts of the basin because it has been a major source for energy fuels--oil, gas, uranium, and coal. The exploration and production of these resources have had a significant effect on ground-water development since the 1950's. To date, more than 26,000 oil- or gas-test holes have been drilled in the basin, the majority penetrating no deeper than the bottom of Cretaceous rocks. This activity has resulted in production of significant amounts of water as a by-product. The water produced is disposed of in one of several ways: (1) reinjection into producing zones to repressure the zone; (2) reinjection into zones for disposal; and (3) evaporation in surface pits. In the late 1980's and early 1990's, the production of coal-bed methane from the Fruitland aquifer in the central basin was the major energy-related activity. Considerable volumes of ground water were produced in conjunction with natural gas, which has resulted in the need for additional disposal wells in the area.

Although the uranium era in the basin began in the late 1940's, its effect on ground-water resources peaked in the late 1970's when most production was from underground mines in the Grants Uranium Belt. Production in the area was primarily from the Morrison aquifer and secondary production was from a localized aquifer within the Wanakah confining unit (the permeable Todilto Limestone Member of the Wanakah Formation), and from the Dakota aquifer. With ore being mined from depths as much as 3,000 to 4,000 ft below land surface, large quantities of ground water were pumped to dewater the producing units. Most of the water was from the Morrison aquifer and overlying Dakota aquifer. By 1992 all active underground mines had ceased operation. Dewatering was not the only activity to affect ground-water resources. Exploratory drilling for uranium-resources evaluation in the northwestern part of the study area resulted in many of the test holes being completed as water wells. These wells tap the Morrison aquifer and in some instances underlying units. Most of these wells have sufficient head to flow at land surface. Many of these wells are allowed to flow constantly, resulting in a lowering of the pressure head in the Morrison aquifer in this area.

The mining of commercial coal resources in Upper Cretaceous rocks in the San Juan structural basin has had a localized effect on ground-water resources. In the immediate area of the strip mines, ground-water flow in the host rocks has been interrupted where strip mines have intercepted the water table, causing ground water to enter the pits.

Data on hydrologic properties of the regional aquifers are minimal. Because most water for the majority of the aquifers is used for stock or domestic purposes, very little data have been collected to determine transmissivity, storage coefficient, or hydraulic conductivity of the aquifers. The distribution of transmissivity, storage-coefficient, and hydraulic-conductivity data is localized throughout the basin. Most of these data were collected to analyze the effects of uranium production on the Morrison, Dakota, and Gallup aquifers. As a result, data are concentrated in areas where mines in these aquifers were proposed. Transmissivity and storage-coefficient data are shown on maps for the Morrison aquifer (Dam and others, 1990a), Gallup aquifer (Kernodle and others, 1989), and Ojo Alamo aquifer (Thorn and others, 1990b). The extent to which transmissivity or storage-coefficient data can be transferred to other parts of the basin is unknown, but the range in values indicates a lack of uniformity throughout the basin.

Transmissivity values for aquifers in the San Juan structural basin vary by several orders of magnitude as a result of the wide variation in hydrogeologic conditions. Conditions that most affect transmissivity are the percentage of sand and its degree of sorting within each aquifer and the aquifer thickness. The areal distribution of measured or reported transmissivity values in each aquifer is generally restricted to the shallow areas of the aquifers near the outcrop where wells are located. Exceptions are wells in the Morrison, Dakota, and Gallup aquifers used for mine dewatering.

Transmissivity values for 108 drawdown and recovery tests (62 for the Morrison, Dakota, and Gallup aquifers) are presented in table 2. The range in transmissivity for all aquifers is 0.001 to 2,000 ft²/d, and median values for all aquifers range from 0.01 to 140 ft²/d. An example of how transmissivity can change with depth is shown by data for the Ojo Alamo aquifer. Three tests were conducted on two wells more than 4,000 ft deep near the center of the basin, resulting in calculated transmissivity values ranging from 0.05 to 0.39 ft²/d. In contrast, transmissivities for nine tests conducted on water wells near the outcrop of the Ojo Alamo ranged from 57 to 245 ft²/d. The range in transmissivity is probably representative of the changes that can be expected with depth in the individual aquifers in the basin.

Minimal data for storage coefficients in the study area are primarily for wells in the Morrison, Dakota, and Gallup aquifers. Values of storage coefficient for 15 tests range from 0.00001 to 0.0002. Most of these values are at the low end of the range for confined aquifers (0.00001 to 0.001) given by Lohman (1972, p. 8).

The values of hydraulic conductivity shown in table 2 (except for the Morrison aquifer) represent average values calculated for an unknown number of oil and gas wells in the deeper parts of the basin (Reneau and Harris, 1957, p. 43). Data for the Morrison aquifer were obtained from tests on three wells. The values of hydraulic conductivity are near the lower end of the range for sandstone (0.000134 to 1.34 ft/day) given by Freeze and Cherry (1979, p. 29).

Table 2 also contains discharge data for 504 wells and specific-capacity data for 162 wells. Most of these values are reported and represent discharges measured by bailing or pumping for short periods of time. For discharge data obtained for windmill-powered wells, the discharge value may be limited by the capacity of the piston pump and may not reflect a discharge that the aquifer is capable of yielding. The specific capacity of the well is probably a better indicator of the potential aquifer yield because drawdown is used in the calculation. Thus the specific capacity determined for two windmill-powered wells that have approximately the same discharge will be different because of the difference in drawdown. Maps showing well locations and discharge and specific-capacity data for selected aquifers are presented in the HA-720 series reports.

The San Juan structural basin, as defined for this investigation, is a virtually self-contained ground-water flow system whose boundaries generally are clearly defined. A ground-water flow boundary is any physical feature or mechanism that alters the movement of water in the ground-water flow system or is a sink or source of water to the system. These boundaries may be internal or limiting geologic features, surface sources or sinks, or contrasts in the properties of the pore-filling liquids.

Examples of geologic boundaries are faults, dikes, changes in hydraulic properties, and geometry of the hydrostratigraphic units. The boundaries may define the limits of the flow system but, more generally, are internal to the system and redirect ground-water movement. Faults (fig. 3) may act as a flow barrier by partly or completely offsetting aquifers and confining units. Faulting also can cause fractures in nearby friable rocks, which, in turn, usually lead to a local increase in permeability and porosity. At depth, these faults may be a barrier to horizontal ground-water flow but, because of their limited extent, probably are not significant on a regional scale. Hydraulic contrasts between aquifers and confining units and an aquifer system's internal geometry also influence ground-water flow.

Outcrop area boundaries include aquifer interaction with surface-water bodies or associated alluvial deposits, recharge infiltrating from precipitation, and evapotranspiration. Surface-water interaction at the outcrop may be either a source of water to the aquifer or a discharge from it, depending on the relative hydraulic-head difference. Streams, lakes, and reservoirs are surface-water bodies that directly influence an aquifer in its outcrop area. Surface-water bodies may either gain water from or lose water to the aquifer. Generally, in the higher altitude parts of the basin (more than 7,500 feet above sea level) streams lose water to aquifers and in the lower altitude parts streams gain water. In either losing or gaining situations, the quantities of water relative to surface flow usually are too small to detect locally.

Recharge from precipitation is a boundary type that contributes water to the aquifer system. This distributed recharge on the area of aquifer outcrop is the residual from total precipitation after losses to evapotranspiration and surface runoff. Evapotranspiration is a boundary in the ground-water system where water in the zone of saturation is affected by surface processes. Evapotranspiration generally occurs in areas of ground-water discharge, primarily in the valleys of the gaining streams described previously. Evapotranspiration of ground water is assumed to be zero in areas where depth to water is more than several tens of feet.

The presence of oil or gas in a part of the ground-water flow system indicates a stagnant area of ground water. There are two mechanisms of oil and gas entrapment and one additional mechanism of gas entrapment. Oil and gas may be concentrated by structural or stratigraphic traps. In both of these types of traps, the presence of oil precludes the flow of freshwater. However, structural traps usually are small in area and stratigraphic traps usually are in low-permeability units that are very resistant to any form of fluid flow. A structural trap may affect several aquifers in the stratigraphic section, whereas a stratigraphic trap is areally restricted to one unit or horizon.

Gas may be dissolved in water (the third mechanism). In addition, gas will adsorb and absorb on coal, particularly along cleats and microfractures (Fassett, 1989). The presence of gas of this nature is characteristic of coal beds in the Fruitland aquifer. In this instance, the presence of gas does not necessarily preclude the movement of water, but other evidence, primarily water-quality data (Dam and others, 1990b; Kernodle and others, 1990), suggests that water in the Fruitland aquifer and underlying Pictured Cliffs aquifer is dissimilar to water in overlying and underlying units (Thorn and others, 1990a,b) and may at least be partially hydraulically isolated from them.

Fluid density contrasts, if great enough, can be a barrier to ground-water flow. Density is a function of the quantity of dissolved chemicals in the water and, to a much lesser degree, of the temperature of the water. The highest reported density of water from a post-Triassic aquifer in the basin is 1.20 grams per cubic centimeter at 20 °C (Dwight's ENERGYDATA, Inc.¹ BRIN data base, Oklahoma City, Oklahoma). This water is from a well completed in the Morrison aquifer near the confluence of the La Plata River with the San Juan River, northwest of Farmington, New Mexico. The reported dissolved-solids concentration of the water was 286,900 milligrams per liter (mg/L), or more than eight times that of sea water (Chow, 1964). All other nearby wells completed in the Morrison aquifer, the nearest of which is about 3 mi away, have a reported density of 1.06 grams per cubic centimeter or less, indicating that the anomaly is very localized within the Morrison aquifer.

If the local density gradient is high enough, water of this density will affect the movement of water within the ground-water flow system (Davies, 1989). It is doubtful that geochemical differences in host rock/water interactions over so short a distance as observed here created the sharp density gradients that exist today in the same general area for several different aquifers. Therefore, it is reasonable to assume that conditions of long-term flow stagnation led to the observed density anomalies.

In the simplest conceptual model based on the previously discussed boundaries, movement of water is from areas of recharge (outcrops) down dip to areas of discharge in response to differences in the altitude of the potentiometric surface. Recharge to the aquifers is from infiltration of precipitation and streamflow on outcrops. In the San Juan structural basin three discharge areas to stream or river reaches generally are recognized: (1) the lower reach of the San Juan River, (2) the Puerco River drainage in the southwestern part of the study area, and (3) parts of the Rio Puerco and Rio San Jose in the southeastern part of the study area. Subsurface discharge from the basin probably occurs in two areas; however, the magnitude is small. One area of discharge is the Four Corners area across the Four Corners Platform, and the other is along the southeastern part of the study area into the Rio Grande Rift. In addition to the horizontal component of flow there is a vertical component between some aquifers. The magnitude of this vertical component is discussed in much greater detail by Kernodle (in press).

¹Use of trade names in this report is for identification purposes only and does not constitute endorsement by the U.S. Geological Survey.

As previously discussed, the regional ground-water flow system includes many aquifers that can be, in most cases, equated to the geologic units that have been mapped in the basin. These geologic units were previously discussed in the text and are listed in table 1.

The regional flow system for each aquifer has certain unique characteristics, but also follows a pattern similar for all aquifers throughout the basin. Ground water occurs under both water-table and artesian conditions: in most cases under water-table conditions in the outcrop areas and under confined conditions as the unit dips toward the center of the basin and is overlain by younger rocks. Data are not sufficient to determine the transition zone from water-table to confined conditions for each of these aquifers; in fact, this zone is not distinct in some of the units. For example, the Menefee aquifer is, for the most part, composed of the Menefee Formation, a silty shale as much as 2,000 ft thick. Locally, it contains significant water-yielding sandstone lenses throughout its thickness. These sandstone lenses are not hydraulically interconnected and, because they are encased in silty shale having a much lower hydraulic conductivity, are often confined. Pumping for extended periods of time, however, will dewater the sandstone lenses, converting them to unconfined aquifers. Although the Menefee aquifer has been extensively developed as a source of stock wells, it is considered both an aquifer and a confining layer in the model simulation (Kernodle, in press).

A potentiometric-surface map was prepared for each of the aquifers presented in the HA-720 series reports. The paucity and limited areal distribution of data placed severe constraints on the analysis of flow systems in the aquifers. The areal distribution of data for each aquifer is around the periphery of the basin near the outcrop area and is inadequate for construction of potentiometric surface maps. As the depth to each aquifer increased toward the center of the basin, wells were completed in the next shallower aquifer that provided sufficient water. Therefore, data often were not available for the deeper parts of the basin. To try to supplement water-well data for these areas, drill-stem test data for oil- or gas-test holes were used where available. However, the purpose of a drill-stem test is to determine the potential for oil or gas production, not to determine the potentiometric surface of water; therefore, the best water-producing zones commonly are bypassed and hydrologic data are for less permeable zones. These data generally are all that are available for aquifers in the deeper parts of the basin.

Another constraint is that data have been collected over a period of many years and do not represent any one time period. For several of the aquifers, water use has been minimal (stock and domestic use) and no declines have been detected. For the Morrison, Dakota, and Gallup aquifers, however, significant quantities of ground water have been withdrawn for uranium exploration and development. Some parts of the basin, particularly the south-central area, had declines of several hundred feet during the early to mid-1980's. Hydrographs for several wells in these units and the general trend in ground-water levels are shown in figure 5. As withdrawals decreased in the late 1980's because of mine closures, water levels in some wells began to recover.

During this RASA study, more than 600 wells were field inventoried and water levels measured when possible. These data were used to supplement existing data in the compilation of the potentiometric-surface maps for the HA-720 series reports.

GROUND-WATER CHEMISTRY

The descriptions of water-quality data for water wells and springs are based on 1,135 analyses from the U.S. Geological Survey's computerized National Water Information System (NWIS) data base. Data for 128 oil- and gas-test holes, from Dwight's ENERGYDATA, Inc. BRIN data base, are also presented. Well records were checked to assure, to the extent possible, that a particular sample represents water from only one hydrogeologic unit and not a mixture of water from more than one hydrogeologic unit. Analyses that did not balance electrochemically within 5 percent were deleted from the data base. For wells that had multiple analyses, the most recent analysis was selected.

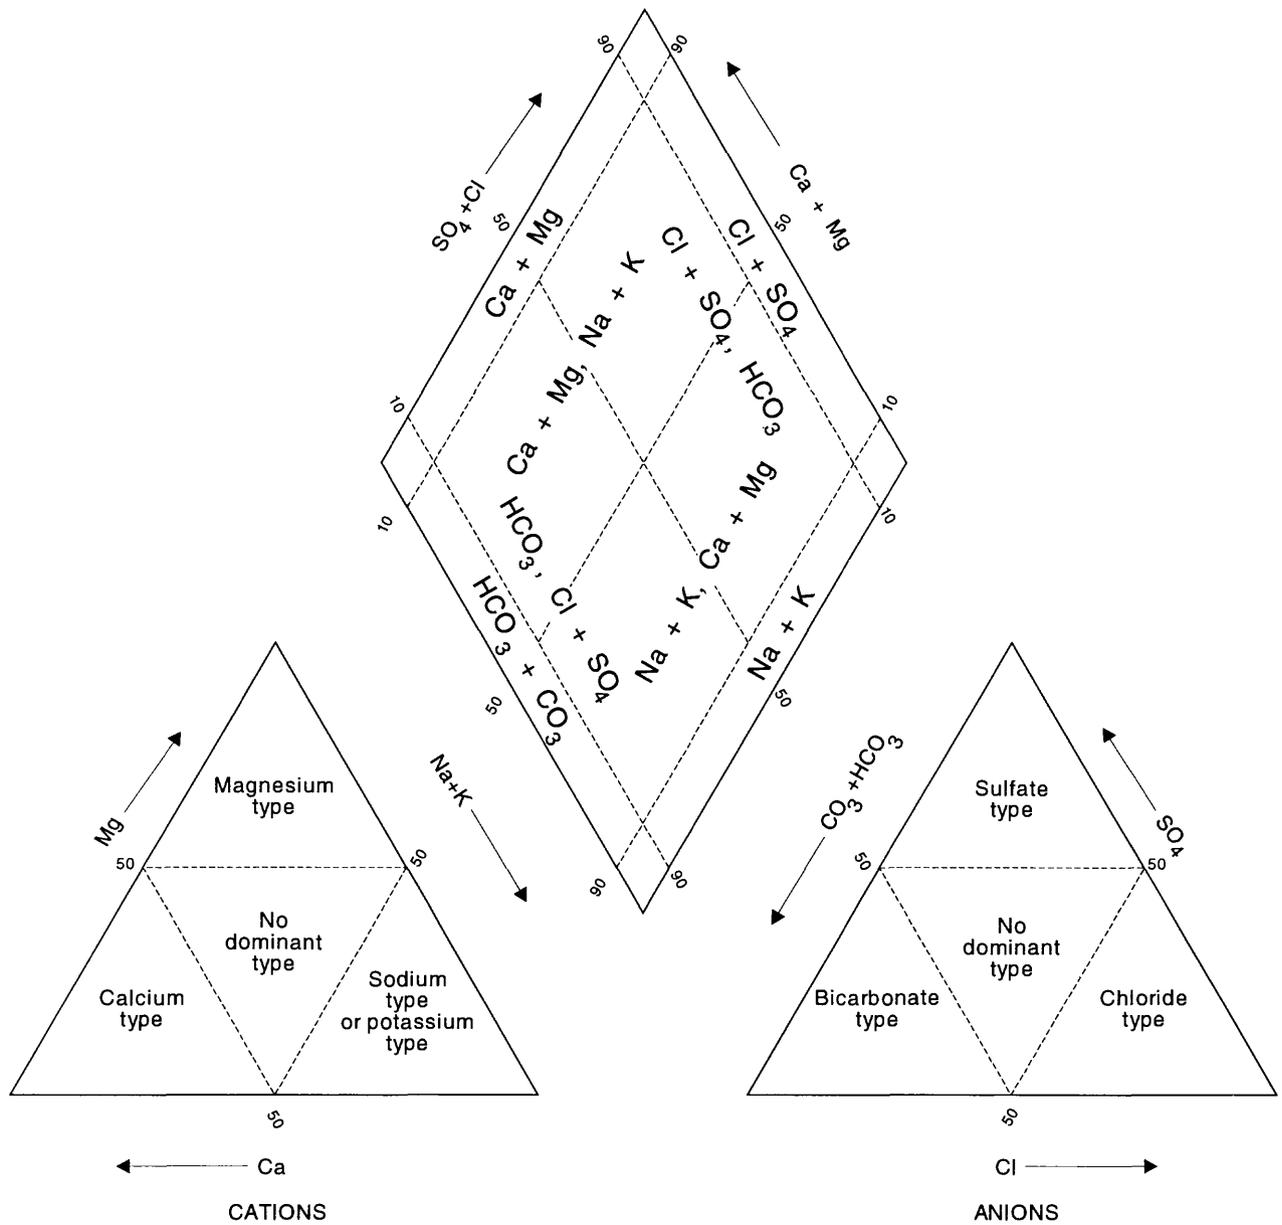

Most water-quality data were collected in the areas of outcrop. Few data are available for the deeper, more central parts of the basin. Data plotted on the water-analysis diagrams represent chemical signatures of water in the vicinity of outcrops, near areas of recharge. Data for oil- and gas-test holes represent the water chemistry of hydrogeologic units in the deeper parts of the basin. Oil and gas companies used different analytical procedures than those used by the U.S. Geological Survey to obtain concentrations of the various constituents. Therefore, data for the test holes are not plotted on the water-analysis diagrams but are presented in a table to illustrate water chemistry in the deeper parts of the basin. The oil- and gas-test hole data are not referenced to any drinking-water standards as are the data from the U.S. Geological Survey's NWIS data base.

Maximum contaminant levels (MCL's) and secondary maximum contaminant levels (SMCL's) are listed in table 3. Maximum contaminant level is the federally enforceable maximum level of a contaminant in public drinking water at which there are no known, anticipated, or adverse effects on the health of persons and that allows an adequate margin of safety (U.S. Environmental Protection Agency, 1986a, p. 528). Secondary maximum contaminant level is the maximum permissible level of a contaminant in water intended for public water-supply systems; the SMCL's are not federally enforceable but are intended as guidelines for the States (U.S. Environmental Protection Agency, 1986b, p. 590). The percentages of samples above the MCL's and SMCL's for pertinent constituents are shown in tables 4-8.

The chemistry of water in water wells and springs from selected hydrogeologic units is displayed on water-analysis diagrams. In the following sections reference is made to naming a water type characteristic of a particular geologic unit. This was achieved by seeing how many analyses plot into a particular field shown in the two larger triangles in figure 6. For example, if most of the analyses plot in the calcium portion of the cation triangle and the bicarbonate portion of the anion triangle then the water would be a calcium, bicarbonate type.

Quality of Water from Hydrogeologic Units in Rocks of Tertiary Age

Tertiary geologic units in the San Juan structural basin represent a sequence of sedimentary rocks of nonmarine origin including fluvial, eolian, and lacustrine deposits. Lithology of the Tertiary geologic units and associated aquifers predominantly consists of sandstones, siltstones, shale, tuffaceous sandstones, and volcaniclastic deposits of varying proportions. On a regional scale the San Jose, Nacimiento, and Animas aquifers are hydraulically connected and serve as one of the primary water-yielding units of the San Juan structural basin (Levings and others, 1990b). Another important water-yielding unit of Tertiary age is the Ojo Alamo aquifer. The HA of Levings and others (1990b) contains maps displaying the distribution of temperature, sulfate, fluoride, dissolved solids, and chemical constituent diagrams of water from the combined San Jose, Nacimiento, and Animas aquifers. A discussion of temperature, dissolved solids, and chemical constituent diagrams of water from the Ojo Alamo aquifer can be found in Thorn and others (1990b).

CHEMICAL CONSTITUENTS

- SO₄ - Sulfate
- CO₃+HCO₃ - Carbonate + bicarbonate
- Cl - Chloride
- Ca - Calcium
- Mg - Magnesium
- Na+K - Sodium + potassium

Figure 6.--Water-analysis diagram showing fields of dominant water types, in percent of total equivalents per million (from Back, 1966).

The primary water type of hydrogeologic units in rocks of Tertiary age is a sodium, bicarbonate, sulfate type (fig. 7; table 4). Some differences are evident among some of the individual units. The dominant anions for all units are sulfate and bicarbonate of almost equal proportions. Only one sample from the Nacimiento aquifer (fig. 7B) indicates chloride as the dominant anion. Sodium is the dominant cation. The sodium, chloride type water might represent leakage of oil-field brine water from deeper geologic units that have oil and gas accumulations. Dissolution and solution of the more soluble mineral phases contained within the aquifer matrix could account for the resultant water chemistry. Uranium mineralization is present in the Ojo Alamo aquifer (Finch and McLemore, 1989) and could influence the water chemistry associated with some hydrogeologic units in rocks of Tertiary age.

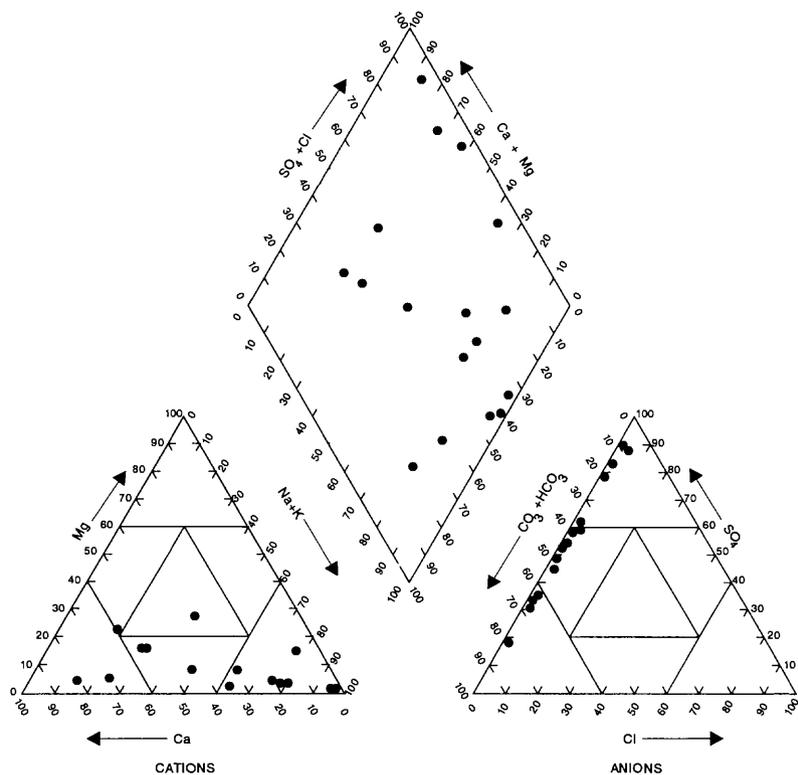

Quality of Water from Hydrogeologic Units in Rocks of Cretaceous Age

Cretaceous geologic units in the San Juan structural basin represent repeated transgressive and regressive marine shore-zone environments and, to a smaller extent, nonmarine environments. The dominant lithology consists of sandstones, siltstones, shales, and conglomerates. Many Cretaceous units are important producers of natural resources. For example, commercial coal deposits are concentrated in the lower part of the Fruitland and Menefee Formations and sections of the Crevasse Canyon Formation (Fassett, 1989). Large accumulations of coal-bed methane are concentrated in the Fruitland Formation. Oil and gas are concentrated in the Pictured Cliffs Sandstone, Menefee Formation, Point Lookout and Gallup Sandstones, Mancos Shale, and Dakota Sandstone (Matheny and Ulrich, 1983, p. 820-825). Uranium is concentrated in the Fruitland and Menefee Formations and the Dakota Sandstone (Finch and McLemore, 1989, p. 29). For further discussion and maps displaying the distribution of selected water-quality constituents in water from aquifers in rocks of Cretaceous age the reader is referred to Kernodle and others (1990) for the Kirtland Shale and Fruitland Formation, Dam and others (1990b) for the Pictured Cliffs Sandstone, Thorn and others (1990a) for the Cliff House Sandstone, Levings and others (1990a) for the Menefee Formation, Craig and others (1990) for the Point Lookout Sandstone, Kernodle and others (1989) for the Gallup Sandstone, and Craig and others (1989) for the Dakota Sandstone.

Water-quality constituents in water from hydrogeologic units in rocks of Cretaceous age are listed in tables 5 and 6, and water-analysis diagrams are displayed in figure 8. Changes in water type are evident from the uppermost to the lowermost unit. Sodium is the dominant cation in water from all aquifers in rocks of Cretaceous age displayed in figure 8. Calcium is present in water from the Pictured Cliffs and Cliff House aquifers, Menefee confining unit, and Gallup aquifer. Chloride is the dominant anion in water from the Kirtland aquifer; chloride and bicarbonate are the dominant anions in water from the Fruitland and Pictured Cliffs aquifers. Anions of bicarbonate and sulfate are dominant in water from the Cliff House aquifer, Menefee confining unit, and the Point Lookout, Gallup, and Dakota aquifers. The water types displayed in figure 8 are sodium, chloride type (Kirtland aquifer); sodium, chloride, bicarbonate type (Fruitland and Pictured Cliffs aquifers); sodium, sulfate, bicarbonate type (Cliff House aquifer, Menefee confining unit, and the Point Lookout and Gallup aquifers); and sodium, sulfate type (Dakota aquifer).

The largest contributor to the water chemistry of hydrogeologic units in rocks of Cretaceous age within the San Juan structural basin is brine waters associated with oil and gas accumulations. The high concentrations of sodium and chloride shown in table 6 for some of the units are characteristic of brine waters associated with oil and gas production. Vertical leakage between units would allow these brine waters to be introduced into units that have no significant oil and gas accumulation. Some high chloride concentrations in ground water could also result from dissolution of chloride minerals associated with marine deposits. Waters that indicate the presence of calcium, for example the Pictured Cliffs aquifer (fig. 8C), could be explained by exchange of calcium ions in shale units for sodium ions in ground water.

Quality of Water from Hydrogeologic Units in Rocks of Jurassic Age

Jurassic geologic units in the San Juan structural basin are of nonmarine origin and represent stream channels, flood plains, lakes, and eolian and sabkha environments. Dominant lithology is quartzose and arkosic sandstones, siltstones, claystones, limestones, and evaporites. Uranium mineralization is found in the Morrison Formation; Brushy Basin, Westwater Canyon, Recapture, and Salt Wash Members of the Morrison Formation; and the Todilto Limestone Member of the Wanakah Formation; the greatest production comes from the Westwater Canyon Member (Finch and McLemore, 1989, p. 29). The Entrada Sandstone is a host rock for small amounts of oil accumulation (Matheny and Ulrich, 1983, p. 820-825).

The chemistry of water from hydrogeologic units of the Jurassic geologic units is shown in tables 6 and 7, and selected units are displayed in figure 9. The dominant cation for all units shown in figure 9 is sodium and the dominant anions are bicarbonate and sulfate; the water type can be described as a sodium, bicarbonate, sulfate type. The presence of chloride in some Jurassic units may be due to dissolution of evaporite minerals common to some of the units. Uranium mineralization found in many of the units could also be a major contributor to the concentrations of trace elements.

Quality of Water from Hydrogeologic Units in Rocks of Triassic Age

Triassic geologic units of the San Juan structural basin were deposited in nonmarine environments such as stream channels, flood plains, and eolian and lacustrine settings. Dominant lithology consists of siltstones, shales, sandstones, and limestones. Small amounts of uranium mineralization are present in the Chinle Formation (Finch and McLemore, 1989).

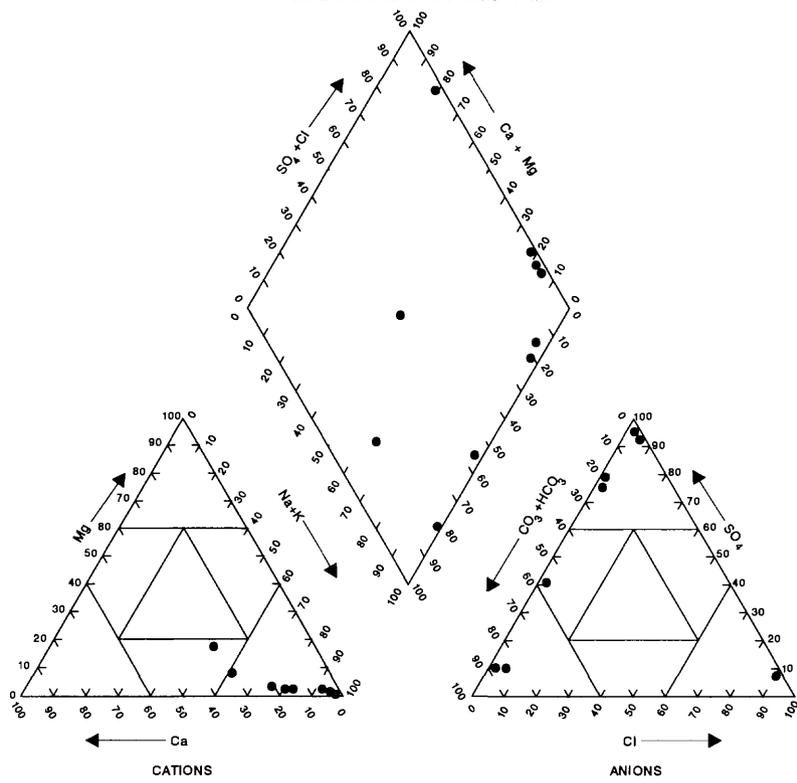

The chemistry of water from the Chinle confining unit is displayed in table 8 and figure 10. Sodium is the dominant cation; some analyses indicate that calcium is also present (fig. 10). No anions are dominant in water from the Triassic units. The dissolution and solution of soluble minerals coupled with the effects of uranium mineralization are likely the leading contributors to the water chemistry within the Triassic units.

GEOCHEMISTRY OF THREE SANDSTONE AQUIFERS

During the project, detailed geochemical analysis was undertaken to examine the source of solutes and hydrologic controls that affect the concentration and distribution of solutes in three sandstone aquifers in the northwestern part of the basin (Dam, 1995). The Gallup, Dakota, and Morrison aquifers, which are stratigraphically equivalent to the Gallup Sandstone, Dakota Sandstone, and Morrison Formations, were chosen for detailed geochemical analysis. The focus of Dam's report is on the Morrison aquifer; data for the Gallup and Dakota aquifers are provided for comparison and examination of vertical changes in flow and quality. Hydrologic and water-quality data for the underlying Entrada aquifer also are evaluated for the effects that water from this unit may have had on the Morrison aquifer. These aquifers were selected because of available single-completion water wells with known completion data, ground-water modeling results, mineralogical analyses, and minimal disturbances to the natural ground-water system as experienced in other parts of the basin. These aquifers are used extensively as a water supply for industry, communities, and livestock in this part of the basin.

Samples were obtained from 38 wells in the area and analyzed for major ions, trace elements, oxygen and deuterium isotopic ratios, and radioisotopes of ^3H , ^{14}C , and ^{36}Cl . Conclusions based on the geochemical results are (1) the flow system in the Morrison aquifer involves several members, not just the Westwater Canyon Member of the Morrison Formation, (2) temporal changes in water-chemistry concentrations are a result of changes in hydraulic head in individual sandstone layers that contribute water to the well, (3) water chemistry changes over short periods of time in regional aquifers, and (4) the chemistry of the water is affected by mixing of recharge, ion filtrate, or very dilute ancient water and by leakage of saline water.

SIMULATION ANALYSIS OF THE GROUND-WATER FLOW SYSTEM

A steady-state, three-dimensional ground-water flow model was constructed to simulate modern predevelopment flow in the post-Jurassic part of the aquifer system in the San Juan structural basin (Kernodle, in press). The model used the McDonald and Harbaugh (1988) modular finite-difference code to represent the aquifer system using 38,264 active cells located within a block of 100 rows, 100 columns, and 12 layers. The model explicitly simulated flow in 12 layers (derived from the 14 regional hydrogeologic units) and used vertical harmonic leakance to indirectly simulate aquifer connection across 3 other hydrogeologic units (derived from the 5 confining units) in addition to coupling the 12 layers.

The entire hydrologic system of the basin was simulated. All boundaries to the natural system were given analogous numerical equivalents, and no arbitrary boundaries, such as planes of symmetry within the flow system or expedient constant-head sinks or sources, were imposed on the numerical representation of the system. Streams were simulated as general-head boundaries, and direct recharge from precipitation was simulated as a recharge velocity applied directly to the outcrop areas of the hydrogeologic units. With one exception, no other boundary types or conditions were simulated other than those imposed by the internal irregularities of the aquifer system. The one exception was a general-head boundary that was used to simulate recharge flow through the Chuska Sandstone, a massive eolian dune deposit, and into upturned components of the Cretaceous aquifer system.

The ground-water system was defined, described, and quantified in the HA-720 series of map atlases. The maps and illustrations printed in the series showing aquifer tops, bottoms, thicknesses, and other hydrogeologic properties were constructed directly from GIS data bases that later were used to construct the ground-water flow model.

Stream/aquifer interaction, direct recharge from precipitation, and downward leakage from the Chuska Sandstone were the external boundary conditions that were simulated. Streambed leakage contributed 135 ft³/s to the aquifer system, direct recharge contributed 56 ft³/s, and downward leakage from the Chuska Sandstone contributed 4 ft³/s. A computed discharge of 195 ft³/s to the lower reaches of the major streams and rivers in the basin balanced the steady-state water budget of the ground-water flow system.

Outcrop boundary conditions were found to most strongly control hydraulic heads and head distributions in the San Juan Basin. Less significant in the simulations were the simulated horizontal hydraulic-conductivity values, and least significant were the simulated horizontal anisotropy and vertical hydraulic-conductivity values.

Table 1.—Summary of geologic nomenclature and lithologic characteristics of regional units in the San Juan structural basin

System	Formation	Approximate maximum thickness (feet)	General lithologic description
Tertiary	San Jose Formation	2,700	Interbedded, very fine to coarse-grained, locally conglomeratic, arkosic sandstone and variegated siltstone and shale.
	Nacimiento Formation	1,300	Interbedded gray shale and discontinuous lenses of arkosic sandstone; locally constant carbonaceous lenses.
	Animas Formation	2,700	Interbedded, tuffaceous sandstone, conglomerate, and shale; McDermott Member distinctly purple in color.
	Ojo Alamo Sandstone	400	Overlapping, sheetlike sequences of arkosic sandstone and conglomerate; locally contains interbedded lenses of shale.
Cretaceous	Kirtland Shale		Interbedded, repetitive sequences of lenticular sandstone, siltstone, and shale and claystone.
	Fruitland Formation		Interbedded, repetitive sequence of lenticular sandstone, siltstone, and shale with coal common.
	Pictured Cliffs Sandstone	400	Upward-coarsening, very fine to medium-grained sandstone, with thin interbeds of dark shale in lower part.
	Lewis Shale	2,400	Dark shale and silty shale with thin interbeds of silty limestone, siltstone, and fine-grained sandstone in lower part.
	Cliff House Sandstone	Depends on location and tongues present; maximum 1,000	Consists of several very fine to fine-grained sandstone tongues. Interbeds of dark shale are common.
	Menefee Formation	2,000	Interbedded sequences of lenticular sandstone, siltstone, and dark shale and claystone. Carbonaceous shale and coal common in lower and upper parts.
	Point Lookout Sandstone	350	Very fine to medium-grained sandstone with thin interbeds of dark shale in lower part.
	Mancos Shale	2,300	Dark shale and silty shale with thin interbeds of silty limestone, siltstone, and fine-grained sandstone.
	Crevasse Canyon Formation	700	Interbedded sequence of lenticular sandstone, siltstone, and shale and claystone with carbonaceous shale and claystone with carbonaceous shale and coal common in lower and upper parts where deposited in fluvial environments and coal swamps.
	Gallup Sandstone	600	Sandstone with some conglomerate, shale, carbonaceous shale, and coal.
	Dakota Sandstone	500	Consists of several members and tongues of sandstone. Fine- to coarse-grained sandstone, with dark shale, siltstone, and minor carbonaceous shale.
Jurassic	Morrison Formation	1,100	Fine- to coarse-grained locally conglomeratic sandstone, sandy siltstone, and shale and claystone; also contains thin limestone beds.
	Entrada Sandstone	330	Crossbedded silty sandstone and very fine to medium-grained quartzose sandstone.
Triassic	Chinle Formation	1,600	Consists of nonmarine deposits of claystone and shale, siltstone, and sandstone from various depositional (stream-channel, flood-plain, eolian, and lacustrine) environments.

Table 2.--Summary of hydrologic characteristics of hydrogeologic units in the San Juan structural basin

[--, no data]

Hydrogeologic unit	Transmissivity (feet squared per day)			Storage coefficient		Hydraulic conductivity (feet per day)	Discharge (gallons per minute)			Specific capacity (gallons per minute per foot of drawdown)		
	Range or value	Median	Number of tests	Range or value	Number of tests		Range or value	Median	Number of wells	Range or value	Median	Number of wells

¹Value from deep test hole near the center of the basin.

²Value is an average determined from oil- and gas-test holes.

³Not a regional hydrogeologic aquifer.

⁴Values from Stone and others (1983, p. 41).

Table 3.—Selected maximum contaminant levels and secondary maximum contaminant levels from the U.S. Environmental Protection Agency (1986a, b)

[mg/L, milligrams per liter; µg/L, micrograms per liter]

Property or constituent	Maximum contaminant level	Secondary maximum contaminant level
pH		6.5-8.5
Sulfate		250 mg/L
Chloride		250 mg/L
Fluoride	4 mg/L	2 mg/L
Dissolved solids		500 mg/L
Nitrate (as nitrogen)	10 mg/L	
Arsenic	50 µg/L	
Barium	1,000 µg/L	
Cadmium	10 µg/L	
Chromium	50 µg/L	
Lead	50 µg/L	
Mercury	2 µg/L	
Selenium	10 µg/L	

Table 4.--Selected properties of and constituents in water from hydrogeologic units in rocks of Tertiary age

[Upper number is number of samples; middle numbers are sample value or range of sample values; lower number is median value; --, no data or not applicable; number in () is percentage of samples that exceed the maximum contaminant level for primary drinking-water regulations (U.S. Environmental Protection Agency, 1986a); number in [] is percentage of samples that exceed the maximum contaminant level for secondary drinking-water regulations (U.S. Environmental Protection Agency, 1986b); <, less than; >, greater than]

Hydrogeologic unit	Dissolved constituents, in milligrams per liter							
	Specific conductance (microsiemens per centimeter at 25 degrees Celsius)	pH (standard units)	Temperature (degrees Celsius)	Calcium (Ca)	Magnesium (Mg)	Sodium (Na)	Potassium (K)	Alkalinity, total as calcium carbonate

¹Not a regional hydrogeologic aquifer.

Table 8.--Selected properties of and constituents in water from hydrogeologic units in rocks of Triassic age

[Upper number is number of samples; middle numbers are sample value or range of sample values; lower number is median value; --, no data or not applicable; number in () is percentage of samples that exceed the maximum contaminant level for primary drinking-water regulations (U.S. Environmental Protection Agency, 1986a); number in [] is percentage of samples that exceed the maximum contaminant level for secondary drinking-water regulations (U.S. Environmental Protection Agency, 1986b); <, less than; >, greater than]

Hydrogeologic unit	Specific conductance (microsiemens per centimeter at 25 degrees Celsius)	pH (standard units)	Temperature (degrees Celsius)	Dissolved constituents, in milligrams per liter				Alkalinity, total as calcium carbonate
