## AVAILABILITY OF BOOKS AND MAPS OF THE U.S. GEOLOGICAL SURVEY

---

Instructions on ordering publications of the U.S. Geological Survey, along with prices of the last offerings, are given in the current-year issues of the monthly catalog "New Publications of the U.S. Geological Survey." Prices of available U.S. Geological Survey publications released prior to the current year are listed in the most recent annual "Price and Availability List." Publications that are listed in various U.S. Geological Survey catalogs (see back inside cover) but not listed in the most recent annual "Price and Availability List" are no longer available.

Prices of reports released to the open files are given in the listing "U.S. Geological Survey Open-File Reports," updated monthly, which is for sale in microfiche from the U.S. Geological Survey, Books and Open-File Reports Section, Federal Center, Box 25425, Denver, CO 80225. Reports released through the NTIS may be obtained by writing to the National Technical Information Service, U.S. Department of Commerce, Springfield, VA 22161; please include NTIS report number with inquiry.

Order U.S. Geological Survey publications by mail or over the counter from the offices given below.

### BY MAIL

#### Books

Professional Papers, Bulletins, Water-Supply Papers, Techniques of Water-Resources Investigations, Circulars, publications of general interest (such as leaflets, pamphlets, booklets), single copies of Earthquakes & Volcanoes, Preliminary Determination of Epicenters, and some miscellaneous reports, including some of the foregoing series that have gone out of print at the Superintendent of Documents, are obtainable by mail from

U.S. Geological Survey, Books and Open-File Reports  
Federal Center, Box 25425  
Denver, CO 80225

Subscriptions to periodicals (Earthquakes & Volcanoes and Preliminary Determination of Epicenters) can be obtained ONLY from the

Superintendent of Documents  
Government Printing Office  
Washington, D.C. 20402

(Check or money order must be payable to Superintendent of Documents.)

#### Maps

For maps, address mail orders to

U.S. Geological Survey, Map Distribution  
Federal Center, Box 25286  
Denver, CO 80225

Residents of Alaska may order maps from

Alaska Distribution Section, U.S. Geological Survey,  
New Federal Building - Box 12  
101 Twelfth Ave., Fairbanks, AK 99701

### OVER THE COUNTER

#### Books

Books of the U.S. Geological Survey are available over the counter at the following Geological Survey Public Inquiries Offices, all of which are authorized agents of the Superintendent of Documents:

- WASHINGTON, D.C.--Main Interior Bldg., 2600 corridor, 18th and C Sts., NW.
- DENVER, Colorado--Federal Bldg., Rm. 169, 1961 Stout St.
- LOS ANGELES, California--Federal Bldg., Rm. 7638, 300 N. Los Angeles St.
- MENLO PARK, California--Bldg. 3 (Stop 533), Rm. 3128, 345 Middlefield Rd.
- RESTON, Virginia--503 National Center, Rm. 1C402, 12201 Sunrise Valley Dr.
- SALT LAKE CITY, Utah--Federal Bldg., Rm. 8105, 125 South State St.
- SAN FRANCISCO, California--Customhouse, Rm. 504, 555 Battery St.
- SPOKANE, Washington--U.S. Courthouse, Rm. 678, West 920 Riverside Ave..
- ANCHORAGE, Alaska--Rm. 101, 4230 University Dr.
- ANCHORAGE, Alaska--Federal Bldg, Rm. E-146, 701 C St.

#### Maps

Maps may be purchased over the counter at the U.S. Geological Survey offices where books are sold (all addresses in above list) and at the following Geological Survey offices:

- ROLLA, Missouri--1400 Independence Rd.
- DENVER, Colorado--Map Distribution, Bldg. 810, Federal Center
- FAIRBANKS, Alaska--New Federal Bldg., 101 Twelfth Ave.

Effects of Highway Runoff on  
Streamflow and Water Quality

## METRIC CONVERSION FACTORS

For readers who wish to convert measurements from the inch-pound system of units to the metric system of units, the conversion factors are listed below:

| Multiply inch-pound unit  | By          | To obtain metric unit  |
|---|-------------|--|
| <i>Length</i>   |             |  |
| inch (in)   | 25.4        | millimeter (mm)  |
| foot (ft)   | .3048       | meter (m)  |
| mile (mi)   | 1.609       | kilometer (km)   |
| <i>Area</i>   |             |  |
| acre  | 4,047       | square meter (m <sup>2</sup> )   |
| acre  | .4047       | hectare (ha)   |
| square mile (mi <sup>2</sup> )  | 259.0       | hectare (ha)   |
| square mile (mi <sup>2</sup> )  | 2.590       | square kilometer (km <sup>2</sup> )  |
| <i>Volume</i>   |             |  |
| gallon (gal)  | 3.785       | liter (L)  |
| gallon (gal)  | .003785     | cubic meter (m <sup>3</sup> )  |
| million gallons (Mgal)  | 3,785       | cubic meter (m <sup>3</sup> )  |
| cubic foot (ft <sup>3</sup> )   | .02832      | cubic meter (m <sup>3</sup> )  |
| acre foot (acre-ft)   | 1,233.5     | cubic meter (m <sup>3</sup> )  |
| <i>Flow</i>   |             |  |
| cubic foot per second (ft <sup>3</sup> /s)                                    | .02832      | cubic meter per second (m <sup>3</sup> /s)   |
| cubic foot per second per square mile [(ft <sup>3</sup> /s)/mi <sup>2</sup> ] | .01093      | cubic meter per second per square kilometer [(m <sup>3</sup> /s)/km <sup>2</sup> ] |
| <i>Mass</i>   |             |  |
| ton (short, 2,000 lb)   | .9072       | megagram (Mg) or metric ton (t)  |
| pound avoirdupois (lb avdp)   | .4536       | kilogram (kg)  |
| pound (lb)  | 453.59      | gram (g)   |
| <i>Temperature</i>  |             |  |
| degree Fahrenheit (°F)  | 5/9 (°F–32) | degree Celsius (°C)  |
| <i>Specific conductance</i>   |             |  |
| micromho (μmho) per centimeter at 25 °C                                       | 1.000       | microsiemens (μS) per centimeter at 25 °C  |

# Effects of Highway Runoff on Streamflow and Water Quality in the Sevenmile Creek Basin, a Rural Area in the Piedmont Province of North Carolina, July 1981 to July 1982

By Douglas A. Harned

## Abstract

An evaluation of water-quality data from streams that receive stormwater runoff from a segment of Interstate Highway 85 in North Carolina indicated increased levels of many constituents compared to levels in nearby undeveloped basins. Additional data collected from a network of dry and wet atmospheric deposition collectors, lysimeter samples, soil surveys, wind measurements, and road sweepings helped define the general sources and migration of chemical substances near the highway. The eight study basins, located in a rural area in the Piedmont of North Carolina, had a combined area of 17.5 square miles and drained a 4.8-mile-long segment of the interstate. The average traffic flow along this section was 25,000 vehicles per day.

During storm runoff, streamflow in basins traversed by the highway rose and fell more rapidly than that in the undeveloped basins. This more rapid response is due to the impervious, paved area of the basins and the man-made drainage systems designed to rapidly move water off the highway.

Alkalinity, specific conductance, and concentrations of calcium, sodium, and chloride were greater at the highway stations than in the undeveloped basins as a result of highway salting for control of ice. Specific conductance and concentrations of dissolved and total nitrogen peaked at the beginning of each storm event. The data indicated that, for the study basins, highway runoff had little or no effect on suspended sediment, water temperature, dissolved oxygen, and pH. However, the pH at all stations decreased during stormflow because the rainfall drained off by the streams had pH values less than 5.7.

High metals concentrations were found in the soils within 100 feet of the highway and in the soil water infiltrating the soil zone. Chromium, copper, nickel, and zinc concentrations in the streams near the highway generally were above the maximum levels recommended by the U.S. Environmental Protection Agency (EPA) for the protection of aquatic life. Lead and cadmium concentra-

tions frequently exceeded the maximum levels recommended by the EPA for drinking water.

The highway is a source of contaminants to surrounding areas. Particulate and metal loads in dustfall and chemical-constituent concentrations in soils decrease exponentially with distance from the highway. The highest concentrations of contaminants were found on the downwind side. Increased concentrations of metals (cadmium, chromium, iron, lead, nickel, and zinc) in rainfall were observed in samples collected near the highway and in samples collected approximately one-half mile away. Material loading due to dustfall was greater than loading due to rainfall. Loading due to saltated particles, those heavier particles bounced along the highway surface, was higher than loading due to dustfall. Saltation loads were greatest during the winter months because of highway deicing and sanding, which supplied an estimated two-thirds of the saltated materials. The remaining one-third of the saltated load came primarily from the deposition of particles from vehicles. Some of the greatest constituent concentrations were measured in the soil water sampled from the lysimeters located adjacent to the highway.

## INTRODUCTION

Multiple-lane, controlled-access superhighways are an integral part of modern society. Highway systems move large volumes of traffic rapidly, safely, and effectively. However, once these roads are in place, their use and maintenance continually affect the surrounding environment. Traffic on the highways is a source of chemical substances to areas near the roads and to remote areas via transport by air and by streams that drain the highways.

Any complete assessment of the effects of development on water quality should include the effects of highways. Although the magnitude of these effects varies, different stretches of highway that have similar climate, topography, and traffic density should have similar kinds of

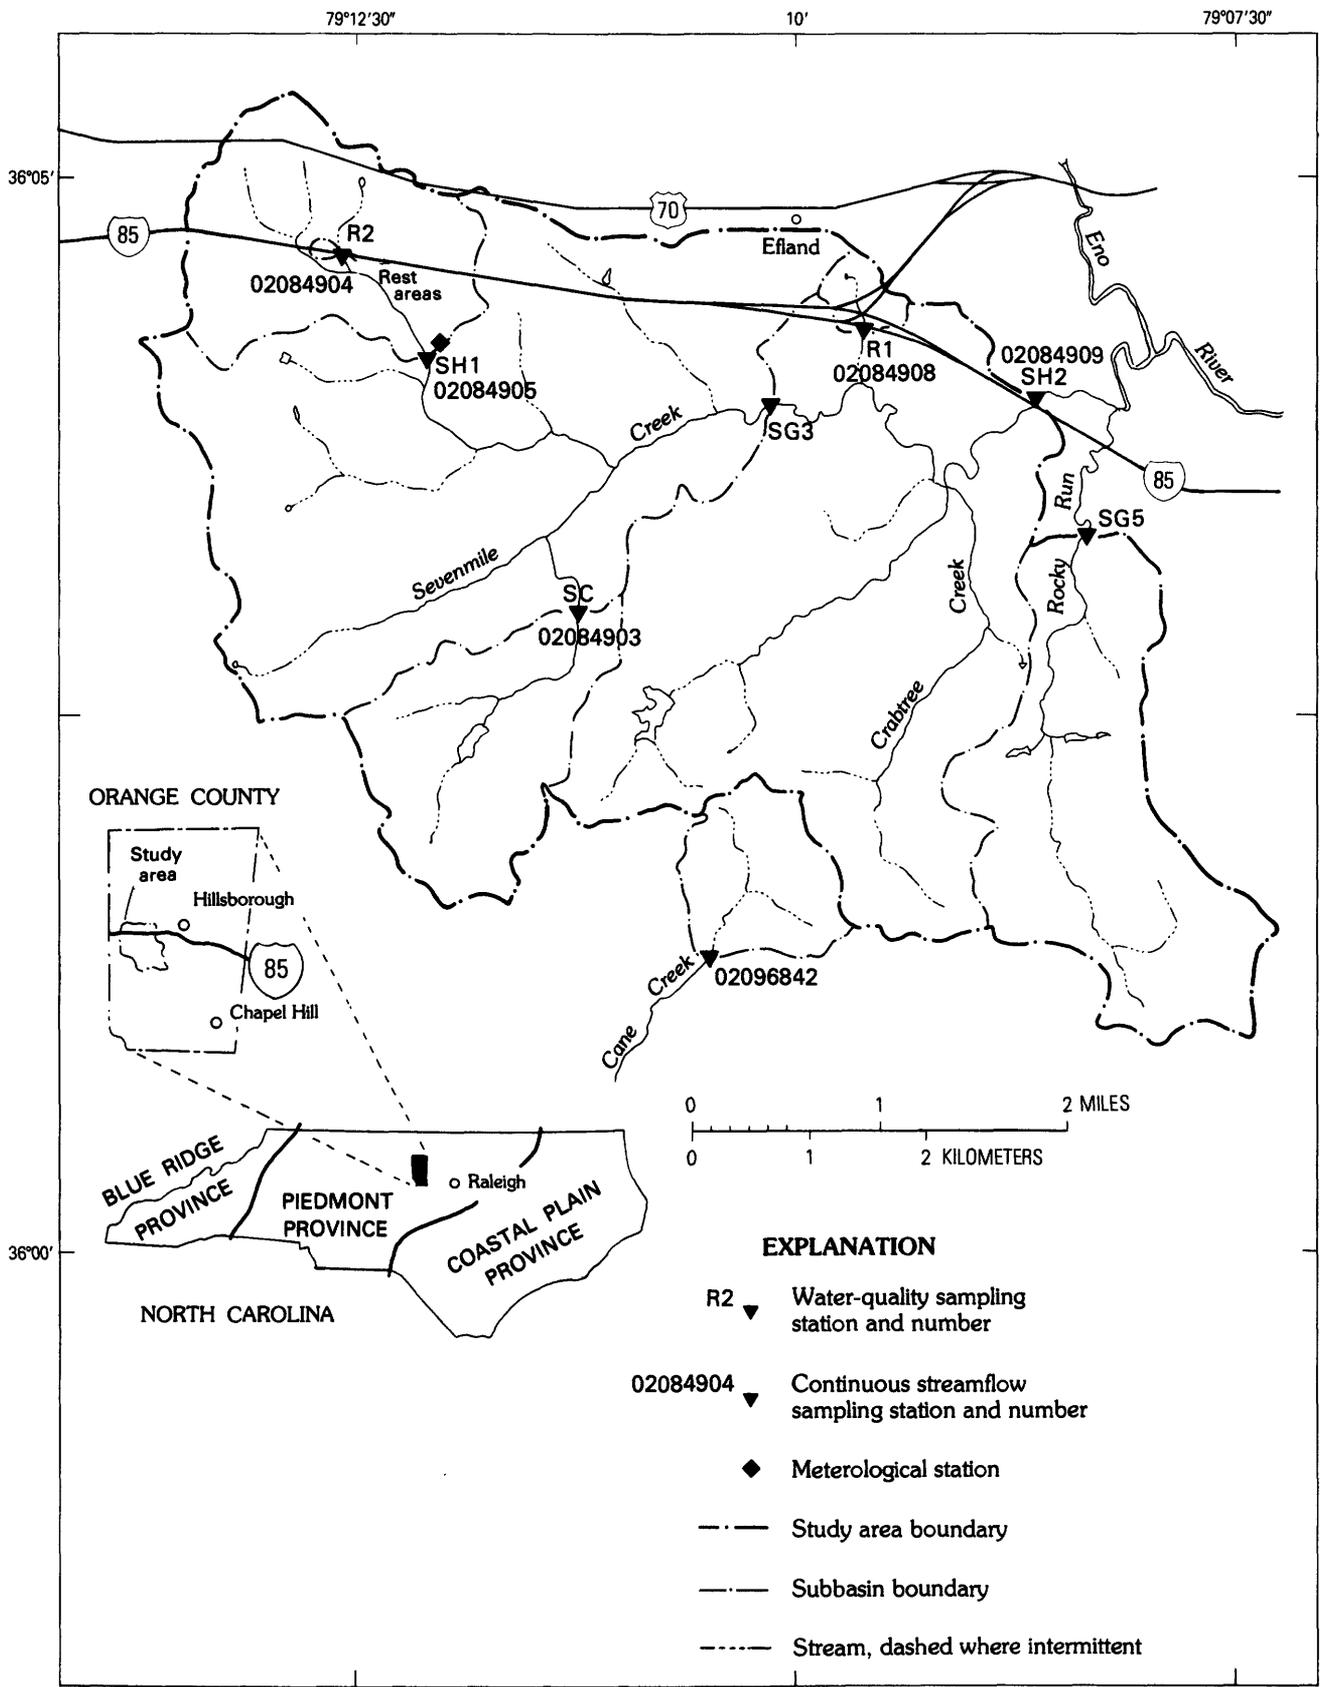

Figure 1. Study area, sampling points, and subbasins, Sevenmile Creek basin, North Carolina.

environmental effects. The superhighway is an easily identifiable type of land use that may show a range of effects that can be related to measurable independent variables.

Sevenmile Creek, which drains Interstate Highway 85 (I-85) near Efland, N.C., was one of the basins chosen in a national research study by the Federal Highway Administration (FHA) to identify the sources of pollutants in runoff from major highways and to assess the migration of particulate and chemical substances into the surrounding environment. Four sites were studied: a basin draining a section of I-94 in Milwaukee, Wis.; a basin draining a section of Highway 50 in Sacramento, Calif.; a basin draining a section of I-81 in Harrisburg, Pa.; and the Efland, N.C., I-85 site. The Milwaukee and Sacramento sites are urban, and the Harrisburg and Efland sites are rural. Traffic flow along I-85 near Efland was the lowest of all four sites. A qualitative and quantitative comparison of results determined at the four sites by Kobriger and others (1982) allows general conclusions to be made about pollutant sources and migration. Dupuis and others (1984) presented the results obtained from field-monitoring programs at the Wisconsin I-94 site, the Efland I-85 site, and an additional site in Wisconsin along State Highway 15. The Dupuis and others (1984) study included the results of biological monitoring that were not available at the time this report was written.

An FHA report series (Gupta and others, 1981) that preceded and precipitated the Kobriger study is another valuable and current source of data and information about the water quality of highway runoff. The Gupta reports examine the body of literature related to highway runoff, describe highway-runoff water-quality characteristics, and outline procedures for monitoring and evaluating these characteristics.

## Purpose and Scope

This report describes the effects of storm runoff from a segment of a major highway system, I-85, on the water quality and flow characteristics of Sevenmile Creek, a small rural stream. By defining, in a general manner, the sources and migration of chemical constituents near the highway, comparisons can be made to areas unaffected by highway contaminants.

The study area, in Orange County, N.C., includes the drainage basin of Sevenmile Creek, which drains a 4.8-mi-long segment of I-85 (fig. 1). Two small stream basins, Rocky Run and Cane Creek, are adjacent to the Sevenmile basin and were used as control areas because their flows are unaffected by highway runoff. The combined drainage area of the basins is 17.5 mi<sup>2</sup>.

Hydrologic data used in this investigation were collected in the Sevenmile Creek and Rocky Run basins from July 1981 to June 1982 and in the upper Cane Creek basin

from October 1973 to September 1981. Data were obtained from measurements of rainfall, streamflow, water temperature, specific conductance, pH, dissolved-oxygen concentration, suspended-sediment concentration, and concentrations of major constituents, metals, and nutrients. Measurements were made of atmospheric deposition quality, chemical quality of the water infiltrating the unsaturated zone, metals in the soils near the highway, wind speed and direction, and the physical and chemical nature of material collected from the road surface.

Biological data were collected but not evaluated in this report because the results were not available at the time this report was written. No evaluation was made of water quality of the ground water in the saturated zone in the study basins because no data were available for the saturated zone.

## Acknowledgments

The data for this study were collected primarily by U.S. Geological Survey (USGS) personnel in coordination with REXNORD, Inc., a Milwaukee, Wis., based engineering firm under contract with the Federal Highway Administration (FHA). REXNORD personnel included Thomas Dupuis, N.K. Kobriger, Joseph Kuderski, and William Kreutzberger. The FHA reports for the national study (Kobriger and others, 1982; Dupuis and others, 1984) contain much of the data discussed in this USGS report and were a source for some of the illustrations and tables.

The USGS personnel who were substantially involved in planning the method of study and collecting data for Sevenmile Creek and adjacent basins are R.G. Garrett, J.M. West, C.E. Simmons, S.S. Howe, and N.M. Jackson, Jr.

Helpful technical reviews of this report were received from R.W. Coble, W.C. Meeks, N.M. Jackson, Jr., C.E. Simmons, and S.R. Ellis.

## BASIN DESCRIPTION

The study area is located near Efland, Orange County, in the northern Piedmont province of North Carolina (fig. 1) along a 4.8-mi-long segment of I-85. The drainage basin of Sevenmile Creek, which has several small tributaries that drain the highway, is included in the area. Several other tributaries, including Crabtree Creek and Rocky Run, drain rural areas south of the highway. Sevenmile Creek joins the Eno River in the northeastern corner of the study area. Another small basin, the headwater reach of Cane Creek, is in an almost entirely forested area south of the Sevenmile Creek basin. Cane Creek flows south to the Haw River. The combined drainage areas of Sevenmile Creek, tributaries to Sevenmile Creek, and the Cane Creek study area encompass 17.5 mi<sup>2</sup>.

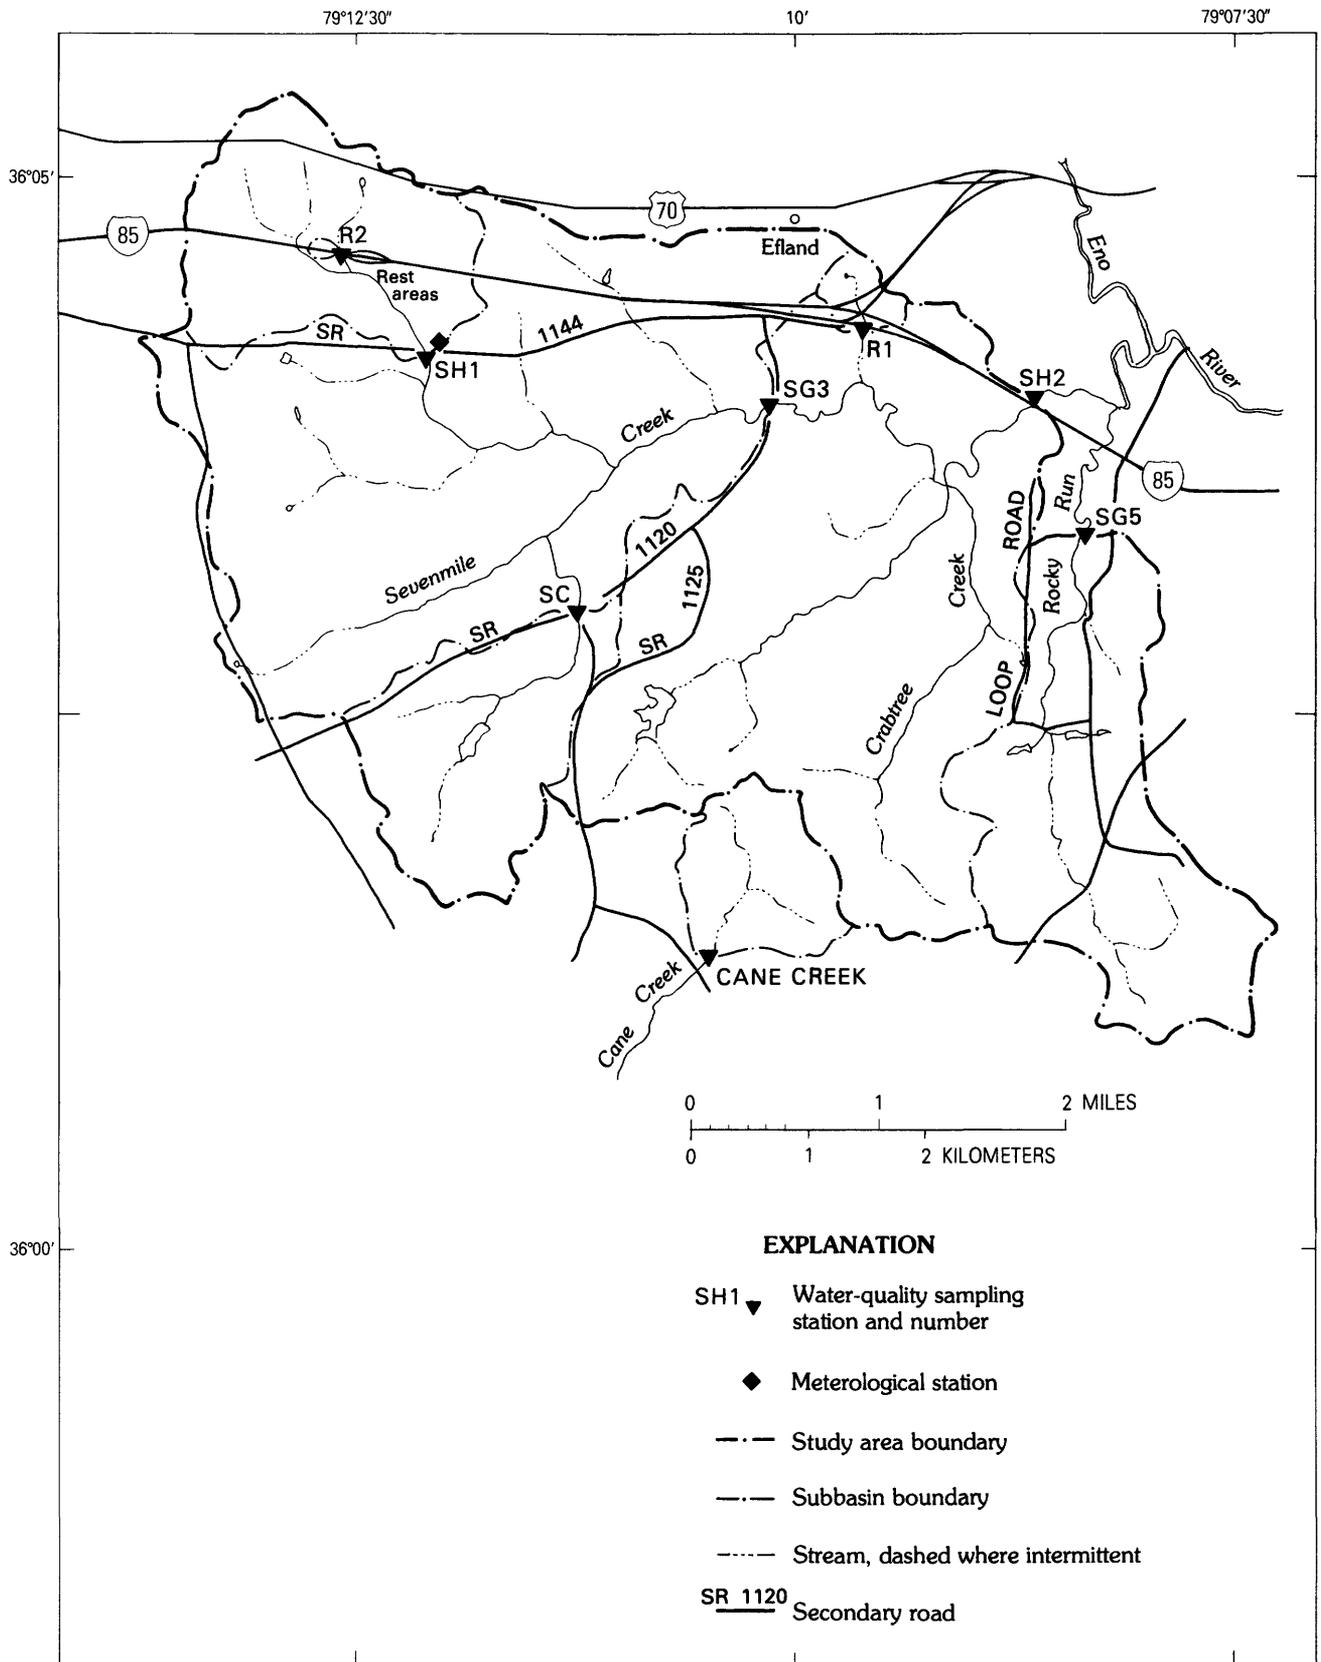

Figure 2. Principal roads in the study area, Sevenmile Creek basin, North Carolina.

The study area was divided into eight subbasins, each represented by a sampling station, to provide data from both developed and undeveloped sections (fig. 1). Two stations, R1 (Road-1; 02084908) and R2 (Road-2; 02084904), were established to record water-quality data from stormwater runoff from the highway. Stations SC (Stream control; 02084903) and Cane Creek (02096842) provided background data to compare with data from the runoff stations R1 and R2. Two other stations, SH1 (Stream hydrology-1; 02084905) and SH2 (Stream hydrology-2; 02084909), were located to gather data from larger areas. SH1 was placed downstream from R2, where the drainage from a large section of I-85 could be measured. SH2 was placed on the furthest downstream point on Sevenmile Creek. Water-quality samples were collected periodically at stations SG3 (Stream grab-3), to provide data for Sevenmile Creek at its approximate midpoint in the study area, and SG5 (Stream grab-5), to provide data from the Rocky Run basin. Station SH2 was located 0.5 mi upstream from the point at which Rocky Run flows into Sevenmile Creek. SH2 (drainage area 14.5 mi<sup>2</sup>), SG5 (2.4 mi<sup>2</sup>), and Cane Creek (0.64 mi<sup>2</sup>) mark the downstream end points of the entire study area (17.5 mi<sup>2</sup>).

The Sevenmile Creek basin is a potential source for the regional water-supply system of Orange County and the city of Chapel Hill, N.C. (Orange County Planning Department, 1981).

## Basin Characteristics

### Topography

Rolling hills characterize the landscape of the study area. Land-surface altitudes range from approximately 770 to 550 ft above the National Geodetic Vertical Datum of 1929 (NGVD of 1929). Traveling from west to east, I-85 loses approximately 110 ft of altitude and, therefore, has an overall slope within the basin of about 23 ft/mi.

The average stream gradient is approximately 48 ft/mi and ranges from about 100 ft/mi in the headwater reaches (Cane Creek and near station R1) to 15 ft/mi along the downstream segment of Sevenmile Creek.

### Geology

Geology affects natural water quality. To better define the significance of geology relative to man-related basin characteristics such as land use, rock type was used as an independent variable in correlation analysis of water-quality data. In addition to ground-water quality, rock type influences the yield of wells and the base flow of streams (Simmons and Heath, 1979; Daniel and Sharpless, 1983).

The predominant bedrock in the study area is folded and fractured metavolcanic rock and igneous rock intruded into the metavolcanic rock (Allen and Wilson, 1968).

Generally, the bedrock is overlain by unconsolidated residual material, termed regolith, that results from weathering of the bedrock. Regolith has a great effect on the natural quality of ground water.

### Climate

Weather in the northern Piedmont is relatively mild year round (National Oceanic and Atmospheric Administration, 1982). The Appalachian Mountains in western North Carolina serve as a partial barrier to cold-air masses moving across the Plains States, tempering the severity of winter storms in the Piedmont. The coldest temperatures usually occur when cold northeastern air masses move southward. Overall, more than half of the winter days have subfreezing temperatures. An average winter has two snowfalls of more than an inch in depth and an average of 4 days per year of freezing rain. Maximum temperatures in the summer are between 90 and 100 °F.

Rainfall, generally, is evenly distributed throughout the year; the greatest average rainfall is in July, and the least is in November. Most summer rainfall occurs during convective storms, which can be quite severe. Normal precipitation, as measured at the National Oceanic and Atmospheric Administration station at the Greensboro-High Point-Winston-Salem Regional Airport, is 42.33 in/yr (period of record 1929–81). The precipitation measured at the study site rain gages during the study period of July 1981 to June 1982 was 53.91 in; therefore, the study period represented a relatively wet year.

### Land Use

Land use is a basin characteristic that can be used to quantify the effect of man on the landscape and was used as an independent variable in correlation analysis of the water-quality data. Most of the study area is rural except for development in the town of Efland and along certain roads in the Sevenmile Creek basin. The principal roads in the basin are shown in figure 2. Road length, a measure of development, is one independent variable used in correlation analysis of water-quality data.

The land-use categories shown in figure 3 were obtained by overlaying a USGS Land-Use Data Analysis (LUDA) map published in 1977, a USGS topographic map published in 1968, and an unpublished USGS orthophotoquad made from an aerial photograph taken in 1973. Spot field checks were made to verify certain features of the final map. Although the data sources used to compile the map are somewhat outdated, the field checks indicate that, within the range of accuracy possible in this kind of reconnaissance mapping, the resulting land-use breakdown represented in figure 3 is suitable for the purpose of this analysis. The numbers used in figure 3 correspond to the system of land-use categorization used on the USGS LUDA maps (Anderson and others, 1976).

**Table 1.** Percentage of land-use types in the eight subbasins of the study area  
 [Drainage area in square miles for each site is shown in parentheses]

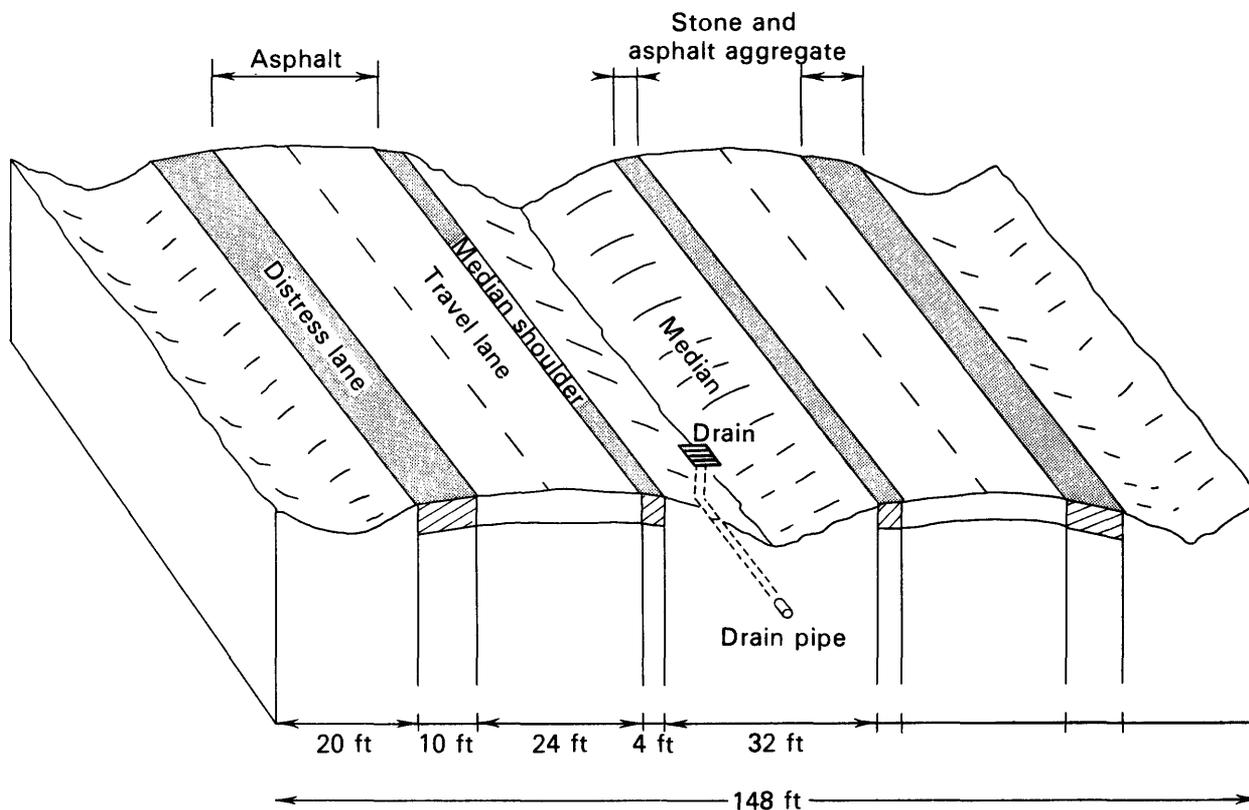

| Number used in figure 3 | Land-use type<br>Description            | Subbasin     |                |              |               |              |              |             |                      | Study area <sup>1</sup><br>(17.5) |

<sup>1</sup>Study area percentages do not sum to the study area total because of an overlap of drainage areas.

The percent of land-use type within each subbasin is shown in table 1. Forest, cropland, and residential areas are the predominant land uses in all the subbasins except R1 and R2. The predominant land-use types within the subbasin for R1 are pasture and transportation; the subbasin for R2 is completely covered by road area. The most highly developed basins are SH1 (which includes R2) and R1. The Cane Creek subbasin, which is 97 percent forest, is the least developed area.

### Highway Characteristics

The 4.8-mi-long section of I-85 that passes through the study area is a four-lane divided highway that has a grass median strip. The pavement is asphalt in the travel lanes and stone and asphalt aggregate in the distress lane and median shoulders. A typical cross section of the highway, showing the road design, is given in figure 4.

**Figure 4.** Typical cross section of Interstate 85 near Efland, N.C., showing road design and drainage (Kobriger and others, 1982).

There are two rest areas, one for each side of the highway. Each rest area contains a small, self-contained sewage-treatment facility that processes wastewater from the restrooms. The effluent from these facilities enters the tributary to Sevenmile Creek that is just downstream from the R2 station.

An average of 25,000 vehicles per day traveled through the basin during the study period. Monthly averages ranged from a low of 22,000 vehicles per day in January 1982, to a high of 28,000 vehicles per day in August 1981, November 1981, and June 1982. Traffic flow along I-85 usually was lowest during the winter months.

Highway maintenance activities included repairing the roadway; sanding, salting and snowplowing for the removal of ice and snow; applying herbicide and fertilizer; and roadside mowing. Of these practices, only data from road sanding and salting and herbicide application could be obtained for this analysis.

## DATA COLLECTION

Data-collection efforts were coordinated between the USGS and REXNORD, Inc. Day-to-day operation and maintenance of the equipment, periodic water-quality and meteorological sampling, stream gaging, and storm-event sampling were conducted by the USGS staff. The USGS staff also performed field analyses, when appropriate, for pH, water temperature, conductivity, and dissolved oxygen. Samples collected by the USGS were mailed to REXNORD's laboratory in Milwaukee, Wis., for analysis. The REXNORD staff made several sampling trips to collect biological specimens and to vacuum segments of I-85 to obtain samples of the material on the road surface. This report was based on the data available at the time the report was written and, in particular, the data that the USGS staff collected.

A summary of the equipment, equipment location, and sampling frequency for each site is presented in table 2. The instrumentation included analog-to-digital recorders (ADR's) for gage height; automatic water samplers, which activated with each rise in stream stage; temperature and specific conductance monitors; recording rain gages; a recording anemometer; and atmospheric deposition samplers, which collected dustfall during dry periods in one container and precipitation during wet periods in another. Other collectors were used to gather dustfall from specific sources. Water-quality samples were also collected manually. Lysimeters were used to collect samples of water infiltrating the soil zone.

All of the stations, except SG3 and SG5, were equipped with ADR's, which are used to record the stream stage data. The stages measured at each station were related to discharge by use of weirs and flowmeters. Stage-discharge relations defined in this process were then applied to the stage data to determine discharge.

Water-quality sampling was conducted at SH1, SH2, SC, R1, and R2 by using automated stage-activated samplers. Samples from the automatic samplers were supplemented with periodic, manually collected samples and field water-quality analyses. Samples were collected manually at sites SG3 and SG5. Specific conductance and water temperature were continuously monitored at SH1, SH2, and SC. Analyses of fecal coliform bacteria, fecal streptococcus bacteria, specific conductance, pH, water temperature, suspended-sediment concentration, and dissolved oxygen concentration were determined by the USGS. All other analyses, including analyses of major ionic constituents, metals, nutrients, and organics, were conducted by REXNORD, Inc.

The variety of devices used to collect atmospheric deposition included recording rain gages, plastic buckets on mounts used to collect dustfall (dust buckets), wet-dry collectors, and a saltation catcher—a bucket capped by a section of slotted pipe set at road-surface level. The locations of these devices at station R2 are shown in figure 5. Wet-dry collectors were also located at the SC and SH1 sites.

Lysimeters designed to collect samples of soil water were installed at the R2 site. The locations of these four lysimeters are shown in figure 5.

Analysis of the effects of the highway on water quality is complicated by background levels of constituents and highway maintenance operations. Truly natural pollution effects are difficult to separate from ambient background water and air-quality data, making pollution-source identification more difficult. The Cane Creek station was used in an earlier study of the natural or background water quality of North Carolina streams (Simmons and Heath, 1979). Because no station in the Sevenmile Creek basin provides data representative of an undeveloped area, Cane Creek data were used. The samples collected at Cane Creek were analyzed at the USGS laboratory in Doraville, Ga.

## SOURCES AND TRANSPORT MECHANISMS OF CONSTITUENTS

The principal sources of materials commonly found in highway-runoff water are vehicles, atmospheric fallout, highway maintenance, and road structure degradation. Vehicles contribute materials from fluid leaks and spills; automobile body rust; and the wear of brake linings, tires, bearings, and moving engine parts. Atmospheric sources are fallout from vehicle exhaust and other air pollution. Highway maintenance, such as road deicing, spraying of roadsides with pesticides, and using fertilizers, also affects runoff water quality. Finally, degeneration of the road itself, including pavement wear, the rusting of steel highway structures, and the leaching of petroleum from asphalt, contributes to the material deposited in nearby streams. A

<sup>1</sup>Includes wet-dry collector.

<sup>2</sup>Includes 5-6 manual samples for oil, bacteria, pesticides, and wet-sieve separations.

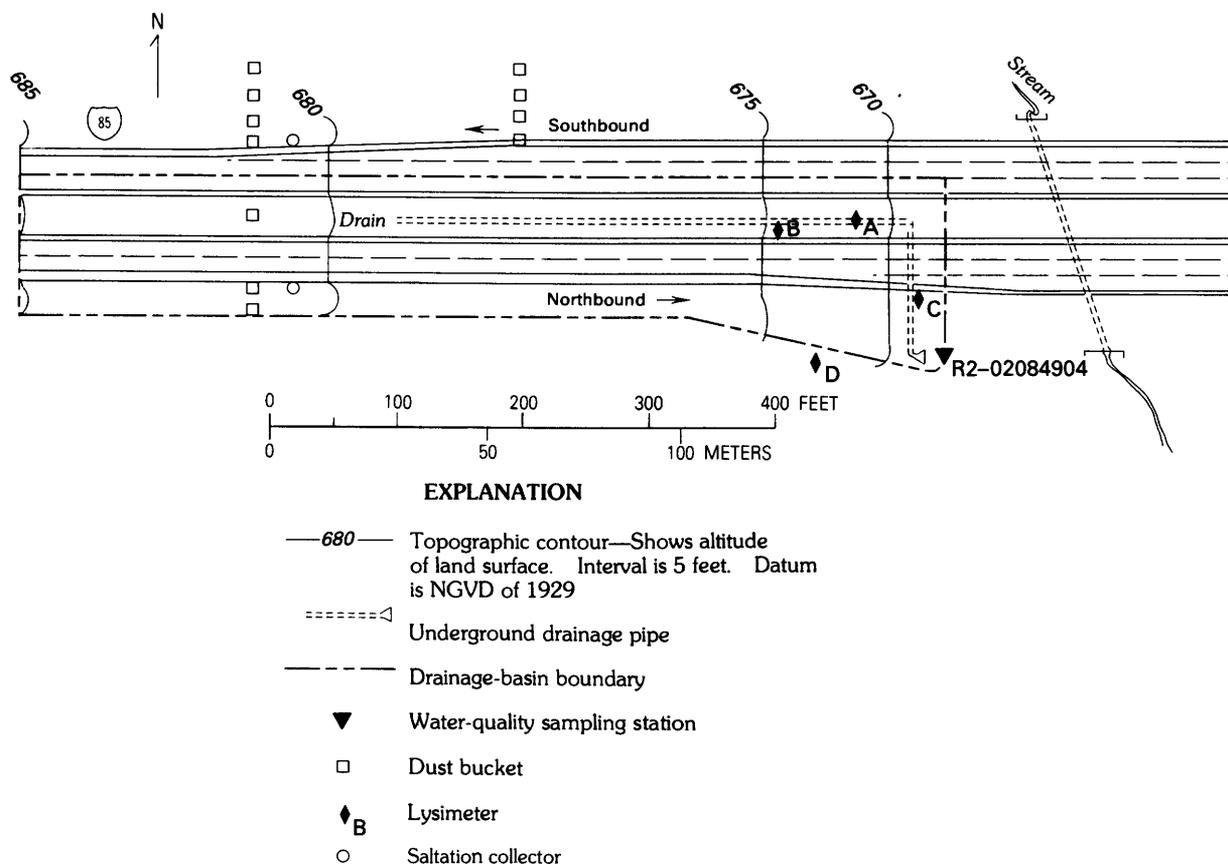

<sup>3</sup>Includes automated and manual multiple-sample collection during storms.

list of constituents commonly found in highway runoff and associated sources of the substances is shown in table 3.

Another source of chemical constituents in runoff in the Sevenmile Creek basin is development unrelated to the highway system, such as minor industrial and residential development in Efland (see Land Use), the two small wastewater treatment plants serving the highway rest areas, and two intensive feed-lot operations located in the western

section of the SG3 subbasin and the northern section of the SC subbasin. Geological influences also contribute to constituent loads in streams, as discussed in Basin Characteristics.

The principal transport mechanisms include stormwater washoff and solution, entrainment in the air, and saltation along the ground. Stormwater washes and dissolves the material accumulated from the road and median

**Figure 5.** Locations of dust buckets, saltation collectors, and lysimeters at site R2.

**Table 3.** Sources of common highway-runoff chemical constituents

[Modified from Kobriger and others, 1982, v. I, p. IV-1-2]

| Constituent                      | Source  |
|----------------------------------|---|
| Asbestos                         | Clutch and brake-lining wear.   |
| Bromide                          | Exhaust.  |
| Cadmium                          | Tire wear (filler material), insecticide application.   |
| Chloride                         | Deicing salts (NaCl, CaCl <sub>2</sub> ).   |
| Chromium                         | Metal plating, moving engine parts, brake-lining wear.  |
| Copper                           | Metal plating, bearing and bushing wear, moving engine parts, brake-lining wear, fungicides and insecticides applied by maintenance operations. |
| Cyanide                          | Anticake compound (ferric ferrocyanide, Prussian Blue or sodium ferrocyanide, Yellow Prussiate of Soda) used to keep deicing salt granular.     |
| Iron                             | Autobody rust, steel highway structures (guard rails, and so on), moving engine parts.  |
| Lead                             | Leaded gasoline (exhaust), tire wear (lead oxide filler material), lubricating oil and grease, bearing wear.                                    |
| Nutrients                        | Atmosphere, roadside fertilizer application, bird droppings, trucks hauling livestock and stockyard waste.                                      |
| Pathogenic bacteria (indicators) | Soil, litter, bird droppings, trucks hauling livestock and stockyard waste.   |
| Particulates                     | Pavement wear, vehicles, atmosphere, road maintenance.  |
| Petroleum                        | Spills, leaks, and blow-by of motor lubricants, antifreeze and hydraulic fluids, asphalt surface leachate.                                      |
| Pesticides                       | Spraying of highway rights-of-way, atmosphere.  |
| Manganese                        | Moving engine parts.  |
| Nickel                           | Diesel fuel and gasoline (exhaust), lubricating oil, metal plating, bushing wear, brake-lining wear, asphalt pavement.                          |
| Rubber                           | Tire wear.  |
| Sulfate                          | Roadway beds, fuel.   |
| Zinc                             | Tire wear (filler material), motor oil (stabilizing additive), grease.  |

surfaces, carries particles and dissolved constituents in surface runoff, or transports dissolved material through the soils by infiltration. The array of devices designed to sample surface water, such as stage-activated automatic samplers, combined with manual-sampling schemes, gives a measure of the role of stormwater transport. Lysimeters give an estimate of the quality of water that moves through the soil zone.

Air currents caused by moving vehicles may either briefly blow materials short distances or entrain them for longer periods in the atmosphere. Dry atmospheric deposition collectors, including dust buckets and wet-dry collectors, measure the effect that air movement has on material transport. Measurements of rainwater quality are particularly important because of the air-cleansing effect rain has on entrained dust particles and gases. Saltation collectors measure the fraction of larger sized particles that bounce off the road surface.

### Atmospheric Sources

Dust particles carried by air currents and atmospheric gases combine and react with precipitation and affect rainwater quality. The sources of these materials in the air are difficult to determine because some materials may have been transported long distances. Statistical analysis of the chemical characteristics of precipitation collected at the

SH1 station from 14 storms indicates that the atmosphere is a major source of metals and nitrogen and that the rainwater is acidic (table 4). All pH values were below 5.7, which is the theoretical pH of pure water in equilibrium with atmospheric carbon dioxide concentrations (Interagency Task Force on Acid Precipitation, 1981).

### Highway Sources

Materials derived from highway activities were collected at the R2 site by using dust buckets and saltation collectors (see location map, fig. 5) and from road-sweep material and soil samples.

A comparison of highway dustfall conditions to background conditions is shown by the summary of loading rates of particulates and metals measured near the R2 station at the highway and the wet-dry collector located near the SH1 station, about one-half mile from the highway (table 5). Background dustfall conditions, represented by data from the wet-dry collector, can be compared to the highway conditions measured by data from the R2 dust buckets. Adding the wet and dry fractions together shows that (table 5, column 10) the proportion of the total loading rate attributable to background conditions is unexpectedly high, ranging from a low of 42 percent of the total zinc loading rate to a high of 93 percent of the total particulate loading

**Table 4.** Statistical summary of chemical concentrations in rainfall samples from the SH1 station, July 1981 to July 1982 [mg/m<sup>2</sup>, milligrams per square meter; mg/L, milligrams per liter; µg/L, micrograms per liter; —, no data]

| Characteristic                          | Mean | Standard deviation | Range    | Statistical median load (mg/m <sup>2</sup> ) | Number of samples |

<sup>1</sup>Calculated by using means of samples from both collectors. Because each of the two saltation collectors was located on the outside median strip, saltation material in the central median strip was not collected.

<sup>2</sup>Calculated as (column 6) - (column 1) × 100.

rate at the highway station. The high percentage of background dustfall may indicate high ambient dust levels from widespread sources or, more likely, load contribution to the SH1 wet-dry collector from the highway system.

A distinct relation exists between the constituent levels measured in the dust buckets and the distance of the bucket from the highway. This relation, when plotted, takes the form of an exponential die-off curve (fig. 6). In this diagram, both total particulate material and total lead content of the samples are high next to the road, and just 30 ft away, the totals are much lower. The metals concentration of the uppermost centimeter of soil (fig. 7), as with the levels measured in the dust buckets, is highest in samples taken nearest to the highway. Also, the highest concentrations of iron, lead, and zinc are found on the north side of the freeway, probably because the predominant wind direction is to the north.

The results of a comparison of wet deposition to dry deposition reveal that material loading is greater during dry periods than during wet periods, particularly for metals deposition (see table 5, columns 4 and 5).

The summary of saltation-collector data shown in table 5 allows a comparison of highly localized material loading near the highway system to the diffused dustfall loadings near and one-half mile away from the highway. The loads caught by the saltation collectors are higher than

those measured from dustfall and wet atmospheric deposition.

There is a seasonal pattern in the loading rate of total particulates collected by the saltation collectors (fig. 8). The highest total particulate loads, observed during the winter months, correspond to a general decrease in traffic flow and rainfall and a slight increase in average wind speed. The seasonality probably is a result of road deicing operations, including road sanding that occurred during the winter months.

## EFFECTS OF THE HIGHWAY ON STREAM DISCHARGE

Discharge measured during sampling usually was greater than the daily mean discharge because most samples were collected during high rates of runoff during storm events. Both measures of discharge indicate that station SH2 had the greatest streamflow followed by SH1, SC, Cane Creek, R1, and R2. Logically, the greater the size of the drainage area, the greater the discharge, as shown in table 6. However, the catchment area of site R2 was the smallest of all the stations. The high discharge per square mile at site R2 resulted because approximately one-half of this area is paved.

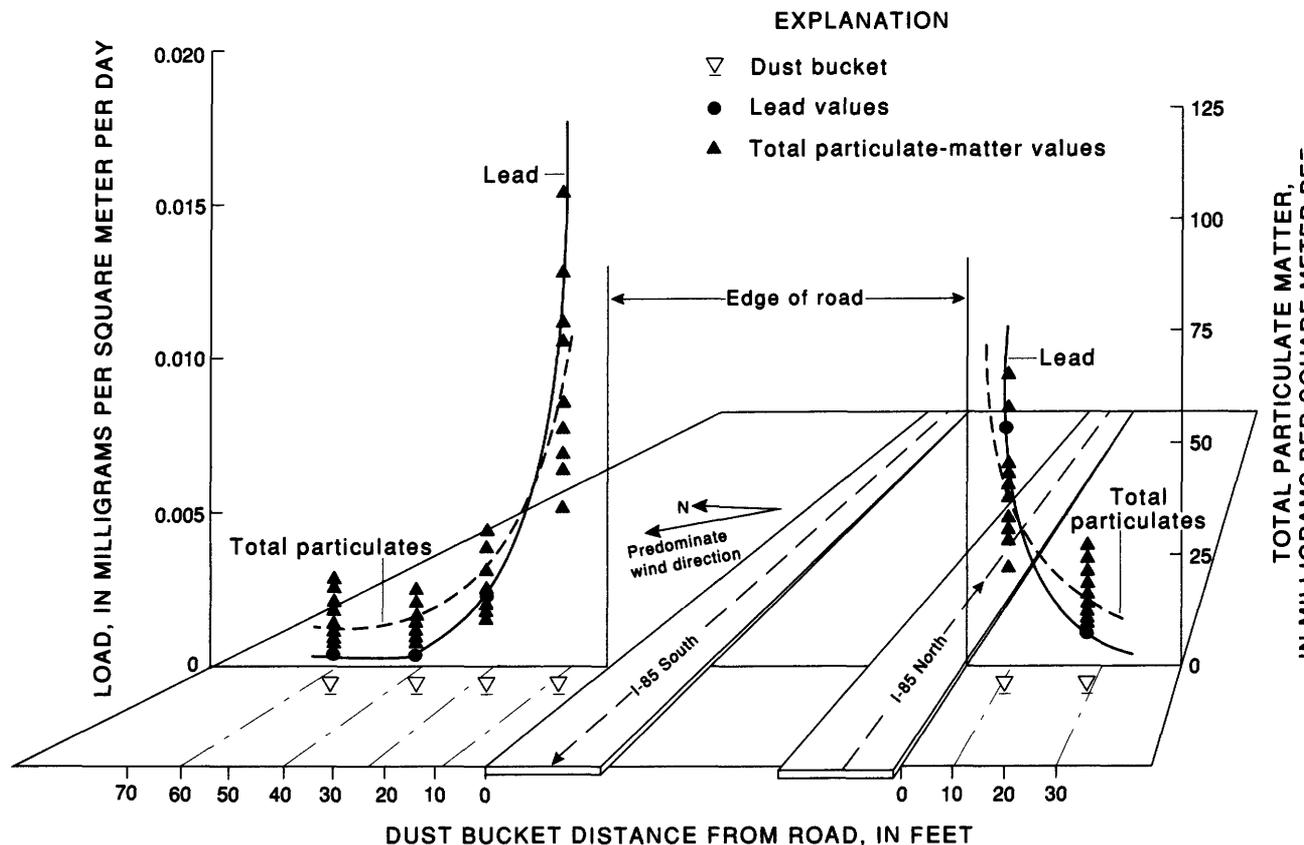

Figure 6. Lead and particulate fallout near highway station R2 (Kobriger and others, 1982).

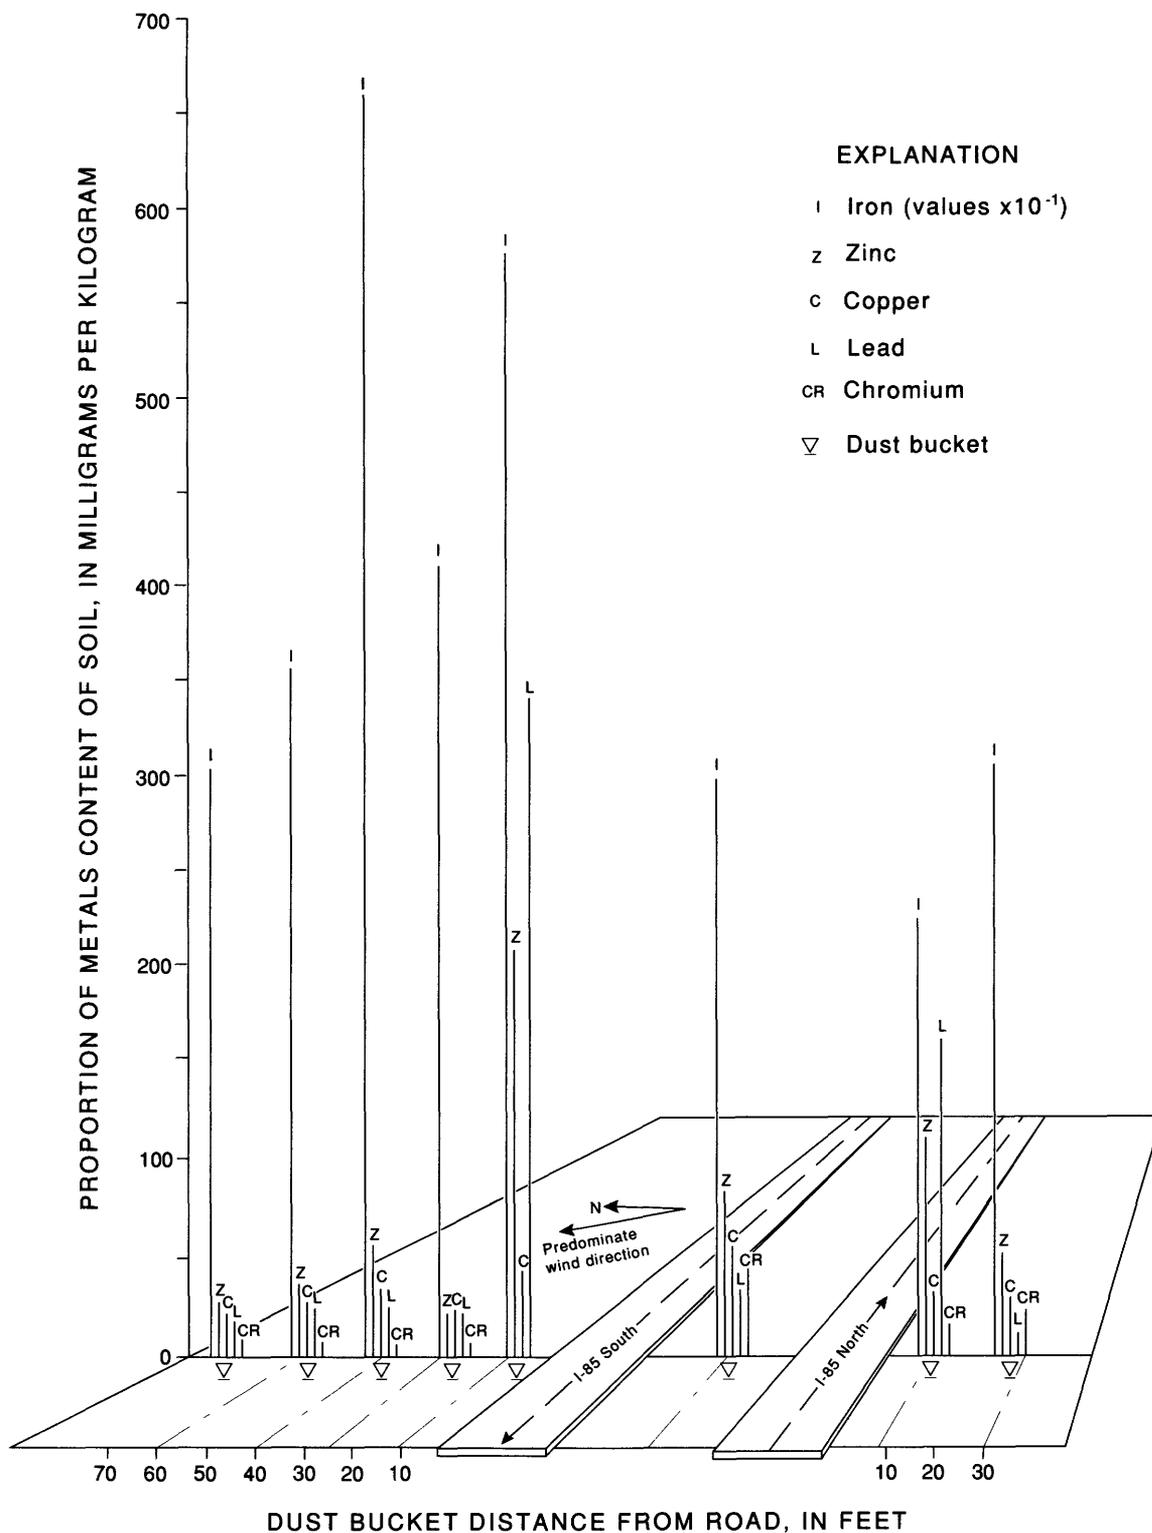

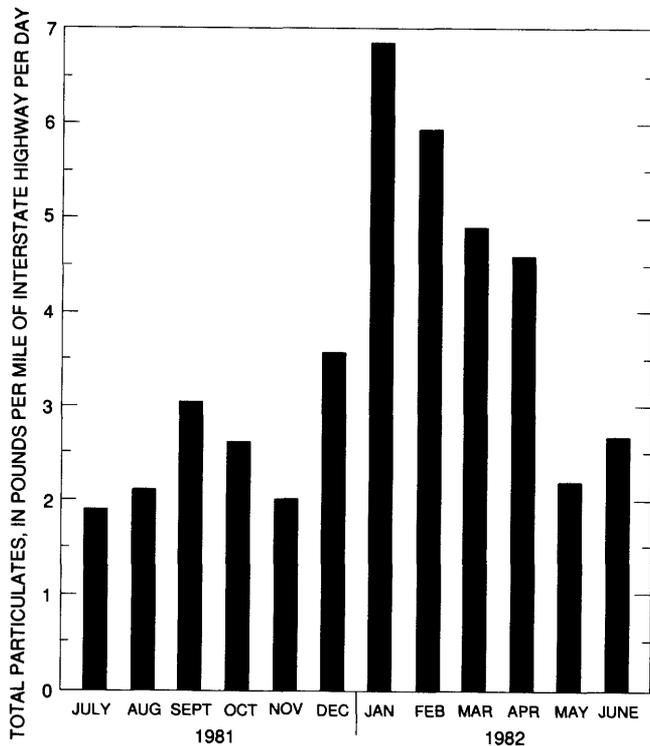

Figure 7. Proportion of metals content in soil near highway station R2 (Kobriger and others, 1982).

Comparisons among stations for a single storm event show the relative hydrologic responses of the streams and demonstrate a common effect of development on those responses. The storm of September 5, 1981, was monitored

for discharge at all of the stations, except SC, and for water quality at all of the stations, except SC and Cane Creek. About 1.5 in of rainfall were measured during a 5-h period. Graphical representations of hourly rainfall (hyetographs)

**Figure 8.** Seasonal loading rate of total particulates near highway station R2.

and continuous streamflow (hydrographs) for this storm are shown in figures 9 and 10. The runoff response observed for this storm was typical of storm events observed during the entire study period.

The hyetographs for stations SC (P3) and SH1 (P1) on figure 9 and SH2 (P2) on figure 10 generally are similar in overall form; the only difference is the distribution of rainfall at the beginning of the storm. In particular, the intensity of rainfall observed at station SH2 was greater than at the other two rainfall stations. The stream responses to the rainfall, shown in figures 9 and 10, are dramatically different from each other. Runoff in the smallest basin, R2, nearly half of which is covered by impervious highway pavement, responded within minutes to the rainfall, and the maximum discharge coincided with periods of most inten-

sive rain. The stormflow recession was brief after the rain stopped (fig. 9). This response is expected because most of the precipitation runs off quickly in a small basin that has a large proportion of impervious cover and has a manmade drainage system. Relatively little water is stored in surface pools or in soil that would later drain out of the basin and create a prolonged recession.

The runoff response at station R1 was similar to that at R2, as evidenced by the runoff peaks in the hydrograph that nearly match the spikes in the hyetograph. The response at R1 was delayed somewhat in comparison to R2 because R1 is a larger basin having less basin area that is impervious. The streamflow recession at R1 also was longer in duration than that observed at R2 because of the greater surface and ground-water storage area in the R1 basin.

The relative effect of impervious area on the floodflow of a stream can be seen by comparing the Cane Creek hydrograph to those of R1 and R2. The Cane Creek basin, which has a much greater drainage area than either R1 or R2, showed a much more subdued initial response to the storm. Streamflow in Cane Creek only began to increase 2 h after rainfall began, peaking slowly and having a long recession period. The total volume of runoff for the period shown was greatest at R1 even though the drainage area of the Cane Creek basin is more than four times that of R1. The slow rise and long recession observed at Cane Creek are characteristic of an undeveloped forested basin having no impervious area. The rapid rises and recessions observed at R1 and R2 and the high peak flows observed at R1 are characteristic of small, developed or urban basins containing substantial impervious areas.

A comparison between the hydrographs for stations SH1 and SH2 (fig. 10) demonstrates an attenuated response for SH2, which is typical of the larger drainage areas that have greater streamflow travel times. The imprint of the storm hyetograph, as well as effects of impervious area, shows in the SH1 hydrograph but does not show in the hydrograph of the downstream SH2 station. The SH2 hydrograph is the cumulative response of flows from numerous smaller tributaries. These tributaries flow through basins that have different basin characteristics but which are predominantly cropland and forest. The resultant

<sup>1</sup>Period of record, October 1973 to October 1981. The period of record for the Sevenmile Creek stations was July 1981 to July 1982.

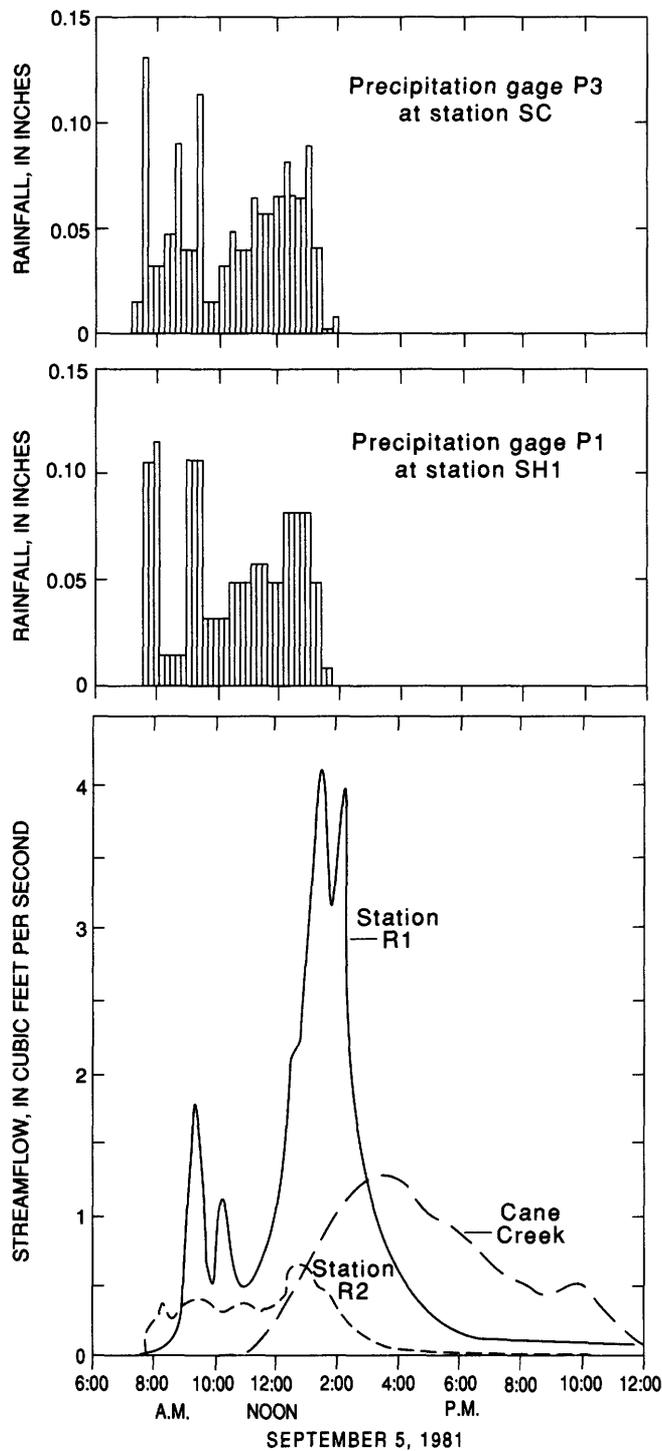

Figure 9. Rainfall hyetographs for stations SC and SH1 and streamflow hydrographs for stations R1, R2, and Cane Creek for the storm of September 5, 1981.

hydrograph for SH2 represents an average flow response from the tributaries and has a general shape that is between those of the Cane Creek and R2 stations.

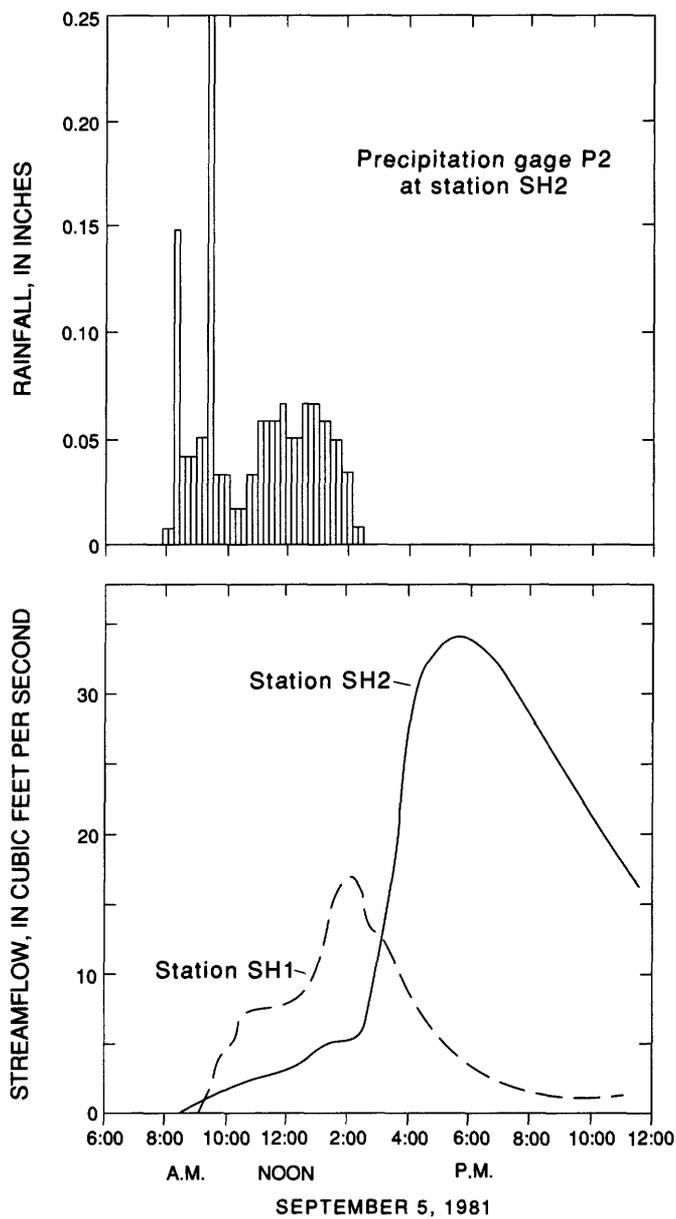

Figure 10. Rainfall hyetograph for station SH2 and streamflow hydrographs for stations SH1 and SH2 for the storm of September 5, 1981.

A correlation analysis was used to test for relations among streamflow, land use, and geology. No statistically significant relations were found.

## EFFECTS OF HIGHWAY RUNOFF ON WATER QUALITY

### Physical Characteristics

A statistical summary of water-quality characteristics of water discharge, water temperature, dissolved oxygen,

pH, and suspended sediment for the Sevenmile Creek stations and the Cane Creek station is shown in tables 7–10. Specific conductance, which is included in these tables, is discussed later in the section on major dissolved constituents. In all tables of water-quality characteristics, the chemical and physical characteristics for the Sevenmile Creek stations are primarily representative of higher flow conditions than conditions for Cane Creek. The physical and chemical characteristics for Cane Creek represent a full range of flow conditions.

### Suspended Sediment

The statistical summaries for suspended sediment presented in tables 7–10 do not conclusively show any effects from the highway system. In fact, other variables probably are more important in controlling sediment concentrations and loads in the stream than the highway system. Stations SH1 and R1 had the highest mean suspended-sediment concentrations, yet R2, the station that should show the greatest highway effect, had quite low concentrations. Stations SC and SH2 had suspended-sediment concentrations greater than the background levels observed at Cane Creek and station SG5. In all subbasins, the elevated concentrations of suspended sediment can be accounted for by an examination of land use near the sampling station. For example, the R1 station is located just downstream from a dirt and gravel access road that is a sediment source for the stream. Stations SH1 and SC are near farm fields that may provide considerable sediment in overland runoff. However, these observations are not supported by statistical correlations. No statistically significant relation between suspended-sediment concentrations and basin land use was found. Apparently, land-use effects on sediment concentrations in the stream are either so localized or so variable that the general analysis used did not reveal any correlations.

A comparison of the data derived from the stations during storm events indicates that land use has an effect on sediment discharge response. The suspended-sediment concentrations at stations R1, SH1, and SH2 during the rainstorm of September 5, 1981, are shown in figures 11–13. The sediment concentration responses at both R1 and SH1 show rapid peaks at the beginning of the event and just before the first peak in streamflow. At both sites, the first early peak was followed by another sediment concentration rise associated with a second peak in streamflow. The first rapid sediment peak observed at both R1 and SH1 probably represents the flushing of readily available sediment from local land uses. On the other hand, the sediment response observed at station SH2 showed one peak in sediment concentration that nearly coincided with the peak in streamflow. This response could be expected for basins that have no extensive development (Overton and Meadows, 1976) and is similar to the response observed at Cane

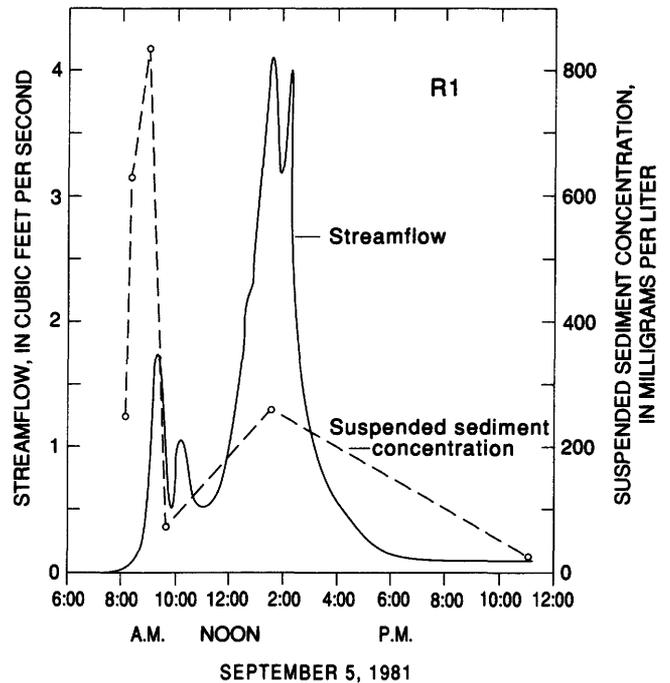

Figure 11. Suspended-sediment concentration at station R1 during the rainstorm of September 5, 1981.

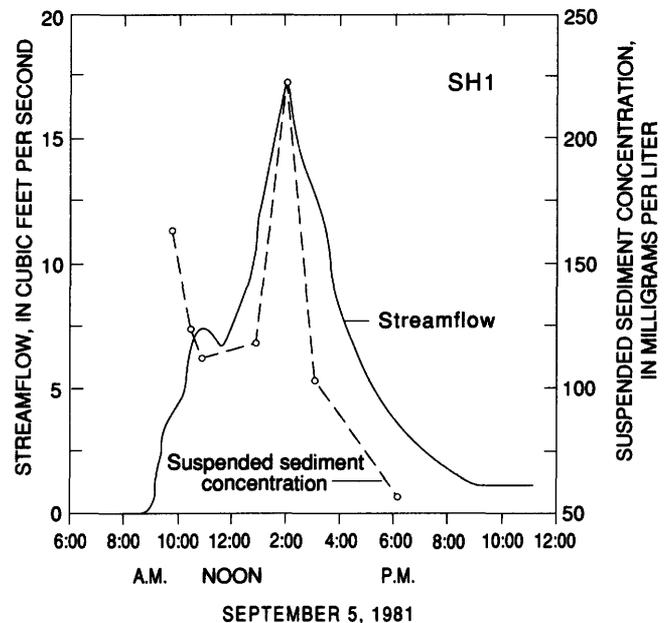

Figure 12. Suspended-sediment concentration at station SH1 during the rainstorm of September 5, 1981.

Creek for other storms. There were not enough data for SH2 to demonstrate whether the peak sediment concentration occurred before the streamflow peak, which is what would be expected for a basin that contains some development.

**Table 7.** Statistical summary of physical characteristics of water at the highway-runoff stations R1 and R2, July 1981 to July 1982

[ft<sup>3</sup>/s, cubic feet per second; °C, degrees Celsius; mg/L, milligrams per liter; JTU, Jackson turbidity units; μS/cm, microsiemens per centimeter at 25 °C; —, no data]

<sup>1</sup>pH mean calculated by using hydrogen-ion concentrations.

## Water Temperature and Dissolved Oxygen

No difference among stations that could be related to highway runoff effects was observed for dissolved-oxygen concentrations and water temperatures. Water temperatures were measured and used to determine the percent saturation of dissolved oxygen. A comparison of dissolved-oxygen water-temperature relations among stations indicates that the sample values generally are near or just below dissolved-oxygen saturation values (tables 7–10). Station SC had consistently lower dissolved-oxygen levels than the other stations but was still approximately 76 percent saturated. These lower values can be explained by the relatively stagnant and, therefore, poorly aerated segment of the stream at the SC station. Runoff from the highway probably did not introduce enough oxygen-demanding material into the surrounding streams to make a noticeable difference in dissolved-oxygen concentrations.

## pH

A comparison of pH values (tables 7–10) of the streams yields no significant differences among the highway, rural, and background stations. In addition, no seasonal patterns were evident. However, during storms, a substantial decrease in pH was evident at the R1, R2, and SH1 stations because low pH rainfall collected in the streams. A slight peak in pH occurred at R1 and R2 at the beginning of a storm, possibly representing the effect of material washed off the road. No significant statistical correlations were found between pH and basin geology, land use, or stream discharge.

## Chemical Characteristics

Material derived from the highway causes detectable differences in levels of dissolved constituents, nutrients, and minor elements and materials in the streams near the road system compared to the streams in the rural and forested basins.

### Major Dissolved Constituents

A summary of water-quality statistics of major dissolved constituents for the Sevenmile Creek stations and the Cane Creek station is shown in table 11. Analyses for the Sevenmile Creek stations (sites R1, R2, SH1, SH2, SG3, SG5, and SC) were made for calcium, sodium, sulfate, chloride, and alkalinity. In addition to these constituents, analyses for the Cane Creek station were made for silica, magnesium, potassium, bicarbonate, sulfate, fluoride, dissolved solids, and hardness.

The highest mean values for all the constituents measured (except sulfate) were at station R2. The statistics shown in table 11 include samples taken during a winter snowstorm when the highway was salted for ice control.

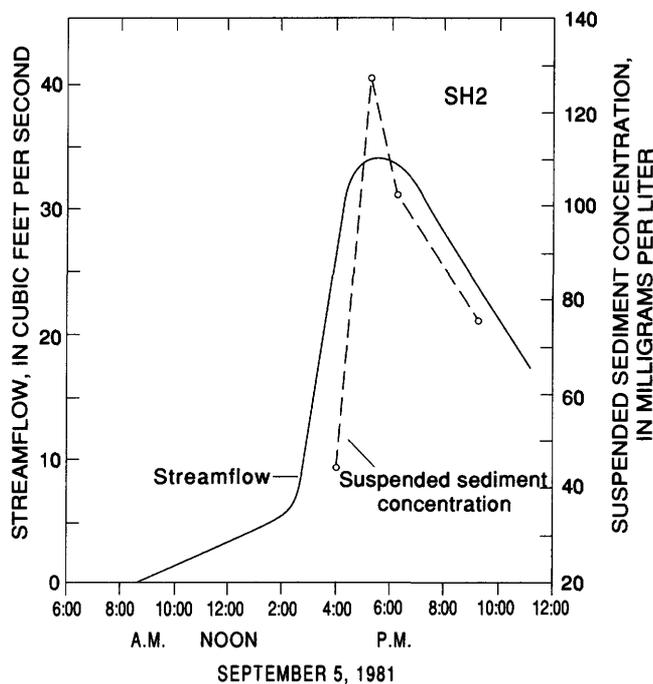

Figure 13. Suspended-sediment concentration at station SH2 during the rainstorm of September 5, 1981.

The runoff from melting snow and ice carried much of this salt to surrounding streams, resulting in large concentrations of dissolved calcium, sodium, and chloride as measured at R2. The effect of road salting is reflected in the specific conductance results as well (tables 7–10). The highest mean-sample specific conductance was 3,530  $\mu\text{S}/\text{cm}$  at R2, and the lowest was 44  $\mu\text{S}/\text{cm}$  at the Cane Creek station. Clearly, the practice of road salting has a dramatic effect on the water quality of streams that receive drainage from the road. In addition to the major components of the salt, the deicing agents used on the stretch of highway near R2 included detectable amounts of copper, cyanide, iron, lead, and zinc (table 12).

Station R1 had the second highest concentrations (table 11) of dissolved calcium, sodium, and chloride. High concentrations also were measured downstream at SH1 and even at SH2. The other stations had concentrations approximately equal to or slightly higher than the background levels detected at the Cane Creek station.

Not surprisingly, dissolved calcium, sodium, and chloride correlate (regression coefficient ( $r^2$ )  $\geq 0.72$ , at a probability ( $pr$ ) = 0.05) with the transportation and utilities category of land use (table 1, transportation and utilities) and with discharge per unit of drainage area ( $r^2 \geq 0.90$ ). All stations were used in the correlation analysis.

Specific conductance, a measure of the ability of water to conduct an electric current, is an approximation of the amount of ionic material dissolved in water. The mean specific-conductance values at each station (tables 7–10)

**Table 11.** Statistical summary of major dissolved constituents, hardness, and alkalinity at stations R1, R2, SH1, SH2, SG3, SG5, and SC, July 1981 to July 1982, and at Cane Creek, October 1973 to October 1981

had the same pattern as the dissolved sodium, calcium, and chloride concentrations (table 11); station R2 had the highest specific-conductance levels, followed by R1, SH1, and SH2. Stations SH1, SG3, SG5, and SC had specific-conductance levels near the background levels at the Cane Creek station.

Concentrations of dissolved materials in streams generally are diluted by floodflows, and, therefore, specific-conductance values usually vary inversely with discharge. However, peaks in specific-conductance values were

observed at R1 and R2 during the earliest flush of runoff from storm events, well before the peaks in discharge occurred.

#### Nutrients

Summaries of nutrient statistics for the Sevenmile Creek stations and the Cane Creek station are shown in table 13. The few analyses of nitrogen and phosphorous concentrations do not show any clear effects of highway runoff on

Ammonia is a reduced form of nitrogen that, in streams, is readily oxidized to nitrite and then to nitrate by aerobic aquatic bacteria. Algae use ammonia first in preference to other forms of nitrogen. Because of the transiency of ammonia nitrogen, the presence of concentrations greater than 0.5 mg/L as nitrogen is considered indicative of contamination by human or animal wastes or by fertilizers (Weiss and others, 1973). The only station that periodically had total ammonia nitrogen concentrations above 0.5 mg/L was SH1. The average dissolved ammonia concentration for SH1 was 15 times greater than that of Cane Creek. The reason for the high concentration of ammonia at SH1 is the upstream rest-area sewage-treatment plants. By the time water flows from SH1 downstream to station SG3, and later to SH2, most of the ammonia has been removed or converted to other forms of nitrogen and has been diluted by

increased flows. This pattern is seen in the decrease of mean nitrite-plus-nitrate concentrations as well. The highest basinwide levels of nitrite-plus-nitrate occurred at SH1, and a considerable reduction was recorded downstream at SG3 and even more at SH2.

Although R1 and R2 are upstream and SH1 is downstream from the wastewater-treatment plants, R1 and R2 had mean concentrations of all nitrogen species, except nitrite-plus-nitrate, equal to or greater than the nitrogen levels observed at SH1. These increased nitrogen levels were probably caused by deposition from vehicles and deposition of sewage mist entrained in the air by the treatment-plant aerators. The only statistically significant correlation ( $r^2=0.88$ ) found between nitrogen and basin characteristics was between mean total ammonia concentration and road length, supporting the observation that the

<sup>3</sup>Calculated value: Ammonia nitrogen plus organic nitrogen.

road does indeed have an impact on nitrogen concentrations.

Some nutrient data were collected for stations SH1 and SH2 during the September 5, 1981, rainstorm. As observed earlier in suspended-sediment concentrations (figs. 12 and 13), the data from these stations indicate that total nutrient concentrations (table 13) show a pattern of rapid increase in concentration with the initial runoff flush of rainfall. The nutrient concentrations peak just before the maximum stream discharge and decline in concentration during the recession. Because nutrients can attach to sediment, total nutrient concentrations may vary similarly to the sediment concentrations in response to changing streamflow, and dissolved nutrient concentrations may be diluted by floodflows. However, a rainstorm that occurred February 11, 1981, clearly showed a peak and recession for concentrations of virtually all the nitrogen species examined. The response of total and dissolved nitrogen concentrations to changing streamflow at Cane Creek is shown in figure 14. The peak in total nitrogen concentrations probably was caused by the flushing of nutrient-rich material, which builds up during low flow, from the streambed. The source of this nutrient-rich material probably was the rest-stop wastewater-treatment plants. The peak in dissolved nitrogen concentrations may be related to the atmospheric contribution of nitrogen during rainfall (table 4).

The nitrogen concentrations present at all stations are high enough to allow abundant algal growth. A total nitrogen concentration of 0.5 mg/L, or greater, is thought to be sufficient for high algal productivity (Crawford, 1983).

#### Phosphorus

A comparison of mean total phosphate (as  $\text{PO}_4$ ), dissolved orthophosphate, and total phosphorus among stations shows a concentration pattern similar to that found for nitrogen. Stations R1 and R2, which are close to the highway, and station SH1, which is located just downstream from the rest-stop sewage-treatment plants, had relatively high concentrations of phosphorus compared to stations SH2, SG3, SG5, SC, and Cane Creek. Even so, the phosphorus concentrations measured at the highway stations are low compared to levels commonly found in North Carolina Piedmont rivers (Harned, 1980; Harned and Meyer, 1981; Crawford, 1983). Phosphorus concentrations at station SH1 were the greatest, having means almost twice as great as at stations R1 and R2, and at least six times as great as at stations SH2, SG3, SG5, SC, and Cane Creek. These comparisons indicate that the effect of the sewage-treatment plants is more important than the role the roadway may play as a source of phosphorus.

The phosphorus concentrations observed at stations R1, R2, and SH1 are sufficient to support a high algal-productivity level. Total phosphorus concentrations of 0.1 mg/L, or greater, are considered to be great enough to allow

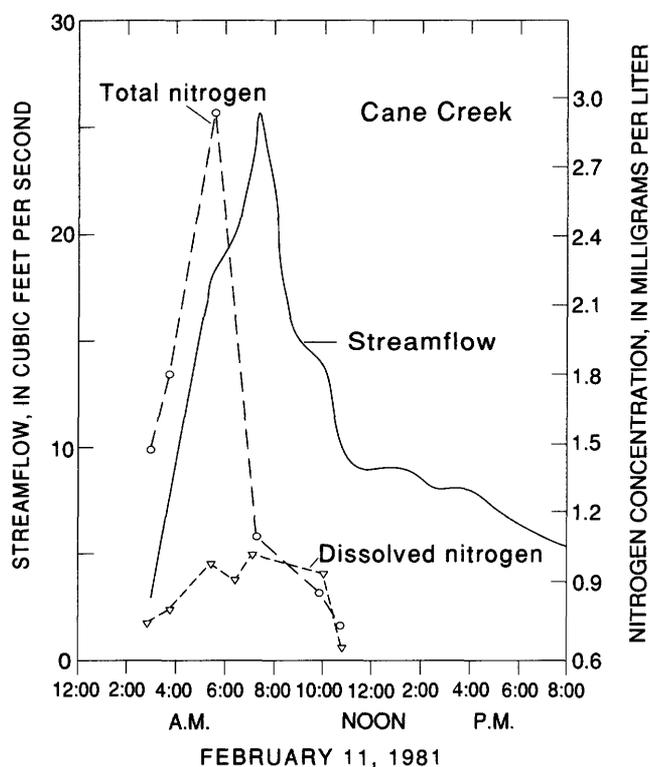

Figure 14. Hydrograph and dissolved- and total-nitrogen concentrations for the storm of February 11, 1981, at Cane Creek.

abundant algal growth (Crawford, 1983). The phosphorus concentrations observed at the other stations are sufficient for moderate to low algal productivity. No significant statistical correlations were found between basin characteristics and total phosphate, dissolved orthophosphate, and total phosphorus.

#### Minor Constituents

Statistical summaries for trace elements and oil and grease concentrations in highway runoff at the study stations are given in table 14. Trace-element analysis for the Sevenmile Creek stations included total cadmium, chromium, copper, iron, lead, nickel, and zinc. Cane Creek samples were analyzed for these elements and for arsenic, cobalt, manganese, mercury, and selenium. Oil and grease concentrations were not determined for station R2 or Cane Creek. Samples taken at R1, SC, and SH2 during one storm event were analyzed for a suite of synthetic organic substances.

#### Trace Elements

As discussed in the Highway Sources section, data indicate that the highway system is a source of metals contamination to the surrounding air and soil. Measurable concentrations of cadmium, chromium, iron, lead, nickel,

and zinc were found in the dust buckets and wet-dry collectors (table 5). The fallout of these metals on the land surface near the road shows a strong relation of concentration levels to distance from the road. This relation can readily be observed in both the fallout data (fig. 6) and in the proportion of metal content in the surface soil near the highway (fig. 7). However, we have yet to address the question, do the data show substantial metals contamination of the streams that drain the highway?

The answer to this question is a qualified yes. In a comparison of the mean values shown in table 14, chromium, copper, and zinc showed patterns of greater concentrations in stations R1, R2, and SH1, which were affected by the highway, than in the rural and background stations SG5, SC, and Cane Creek. Surprisingly, no patterns were apparent in the cadmium and lead concentrations. Although highway runoff commonly affects lead concentrations (Kobriger and others, 1982), only a slight increase above background concentration was noted at the stations affected by the highway. In addition, although stations R2, SH1, and SH2 showed higher concentrations of nickel than stations SG5 and SC, station R1 showed a seemingly anomalously low nickel concentration. The concentration of chromium at Cane Creek also seems anomalously high compared to the other station data. The relatively high concentration of chromium may be attributed to the difference in laboratory procedures used by the USGS, which analyzed the Cane Creek data, and REXNORD, which analyzed the Sevenmile Creek data.

Water-quality criteria established by the U.S. Environmental Protection Agency (1980) can be used to compare the observed concentrations of metals to levels recommended for water supply and protection of aquatic life. Two sets of maximum contaminant levels generally are given; the first establishes levels suitable for the protection of freshwater aquatic life, and the second establishes levels recommended for domestic water supply to protect human health. Many of the aquatic-life criteria are set to vary depending on the water hardness. A sliding scale of criteria values is used because toxicity to aquatic life of metals and other constituents is greater if water hardness is lower. Unfortunately, hardness was not measured at any of the Sevenmile Creek stations. The hardness measured at Cane Creek (table 11) averaged 15 mg/L (as  $\text{CaCO}_3$ ) and had a standard deviation of 5.1 and a range of 9 to 30 mg/L (31 samples). These are relatively low hardness values even for streams in the North Carolina Piedmont, which have mean concentrations of about 23 mg/L ( $\text{CaCO}_3$ ) (Harned, 1980; Harned and Meyer, 1981; and Crawford, 1983).

A hardness value of 23 mg/L for Piedmont streams was used to devise water-quality criteria according to U.S. Environmental Protection Agency guidelines (1980). The percentages of samples that had cadmium, chromium, copper, lead, nickel, and zinc concentrations greater than criteria levels for protection of aquatic life are given in table

15. The percentages of samples containing metals concentrations that exceeded the recommended criteria levels for drinking water are given in table 16. Many of the metals concentrations at all the stations exceeded criteria levels for protection of aquatic life; only nickel did not exceed the criteria levels at any station. Few metals concentrations exceeded levels set for drinking water; lead and cadmium concentrations were higher than the drinking-water criteria for several stations. Even metals concentrations for cadmium, chromium, copper, and zinc found in rainwater sampled at SH1 were higher than the criteria recommended for the protection of aquatic life. Although the percentages of sample concentrations that exceed criteria levels tended to be high in several samples from stations R1, R2, and SH1, the stations affected by the highway, distinguishing these percentages from the percentages that exceeded criteria at the other stations is difficult. Not surprisingly, no statistically significant correlations were found between mean metals concentration and basin characteristics. Finally, the use of the Piedmont streams hardness values in this analysis yields more moderate criteria than those that would be calculated by using the Cane Creek hardness value.

#### Oil and Grease

Mean-total oil and grease concentrations for the Sevenmile Creek stations are listed in table 14. Although no data were collected for the R2 and Cane Creek stations, the effect of highway runoff on water quality is quite apparent. Station R1 had much higher concentrations than the rural stations. Station SH1 also had somewhat increased concentrations in comparison to those at the rural stations.

#### Synthetic Organics

During the rainstorm of April 8–10, 1982, samples were collected at stations R1, SC, and SH2 and later analyzed for a variety of synthetic organic substances (table 17). Two discrete samples from station R1 were examined: one sample was collected 3 h before the peak in streamflow, and one was collected 4 h after the peak. A sample was composited from several stream samples collected during the storm at stations SC and SH2. The only organic substance detected was the herbicide 2,4-D. An herbicide-2,4-D concentration of 19  $\mu\text{g/L}$  was measured in the postpeak sample at station R1; the composited sample had a concentration of 3.8  $\mu\text{g/L}$ . Herbicide 2,4-D had been applied along the road 2 weeks prior to the rainstorm of April 8–10, 1982. The measured concentrations of herbicide 2,4-D are well below the 100 mg/L interim standard established by the State of North Carolina for raw water supply (North Carolina Environmental Management Commission, 1986).

## Soil-Water Quality

Samples from the four lysimeters (A, B, C, and D) shown in figure 5 were collected after about 25 storm events monitored at station R2. Lysimeters provide a gross estimate of the quality of the water as it drains through the first 6 in of topsoil. A summary of the results of chemical analyses of the water that had moved through the soil zone is given in table 18.

Only lysimeter C, on the northbound right-of-way 6 ft from the edge of the pavement, and lysimeter D, at the edge of the woods on the northbound right-of-way, operated satisfactorily during the study. The sample collection bottles for lysimeters A and B in the median area were inundated during storms because of runoff in the median and splashing from passing vehicles. Although splashing

was also a minor problem at lysimeter C, the lysimeter was inundated only a few times.

Virtually all of the chemical-constituent concentrations were greater than concentrations observed in the water of the nearby streams. Furthermore, no relation between distance from the road and soil-water quality was found; in fact, some of the highest concentrations in nitrogen, copper, and iron were observed at lysimeter D, the furthest away from the pavement. The high concentrations of constituents in the soil water, and those in the soil (fig. 7), indicate that the soil system surrounding the highway accumulated and retained many of the pollutants derived from the use and maintenance of the highway. However, because the lysimeters malfunctioned, these results do not show whether the water sampled was a representation of soil-water quality or a worst-case representation of surface runoff.

**Table 14.** Statistical summary of trace elements and oil and grease concentrations at stations R1, R2, SH1, SH2, SG3, SG5, and SC, July 1981 to July 1982, and at Cane Creek, October 1973 to October 1981

## CONSTITUENT LOADS

### Mass Balance for Constituent Sources

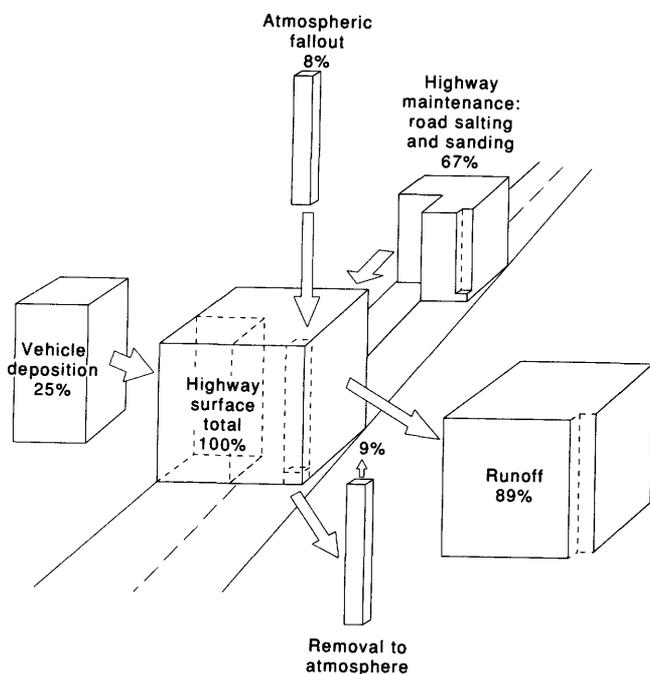

A mass balance, including the major sources of material accumulated on the highway surface and the principal means of removal of the material from the highway, was calculated by Kobriger and others (1982). The mass balance for total dissolved solids for station R2 is illustrated in figure 15.

The mass balance was derived by using a series of approximations in a modeling process (Kobriger and others, 1982) that did not take full consideration of the possible errors and uncertainty involved. Three components were examined: material deposition, highway-surface load, and material removal. Mean daily rates of deposition were determined from loads calculated from surface-water runoff data and atmospheric deposition data. The deposition rate was the mean daily rate of deposition for the time period from the end of a major storm to the beginning of the next major storm. It was assumed that each storm washed the highway surface clean. The deposition rate was calculated as the load washed out during the second storm divided by the number of days between the first and second storms. Atmospheric fallout was estimated from dust-bucket and wet-dry collector data. The highway-surface load was determined by considering measurements of the amount of

**Table 17.** List of trace synthetic organic substances tested and their detection limits

[All values are reported in micrograms per liter]

| Constituent         | Detection limit |
|---------------------|-----------------|

| 2,4-D               | 2.0             |
| 2,4,5-T             | .5              |
| Silvex              | .5              |

**Figure 15.** Mass balance of total dissolved-solids load at station R2 for the period of June 30, 1981, through April 2, 1982 (Kobriger and others, 1982). (Load unaccounted for is model error.)

material found on the road surface and data from road salting and sanding. Vehicular deposition was calculated as the difference between the highway surface load and the salting-sanding and atmospheric load.

As in the analysis of lysimeter results, some of the material load probably moved into the ground-water system. However, no accounting for removal through the ground-water system was made in this analysis.

The resultant mass balance, as shown in figure 15, emphasizes the relative impact of road salting and sanding and vehicle deposition as sources of material available on the highway surface for washoff into streams. Road maintenance accounted for 67 percent of the material that was washed into nearby streams during the period studied (Kobriger and others, 1982). The remaining material came mainly from deposition of particles from vehicles.

### Constituent Loads in Streams

Daily loads of dissolved solids and a suite of metals were computed by first defining linear relations (regression equations) between instantaneous discharge and constituent load and then by using the known daily discharges. Regression equations having slopes statistically different from zero ( $p=0.05$ ) were used to estimate the loads. The estimated annual loads are listed in table 19, and the annual loads per

square mile are shown in table 20. The dissolved-solids loads for stations R1, R2, SH1, and SH2, listed in table 20, are shown in figure 16, which shows the percentage of basin area in the transportation and utilities land-use category. The bar plots shown in figure 16 suggest that there may be a relation between the transportation and utilities land use and dissolved-solids load; however, available data were insufficient to test this relation statistically. The total-metals loads listed in table 20 are shown in figure 17.

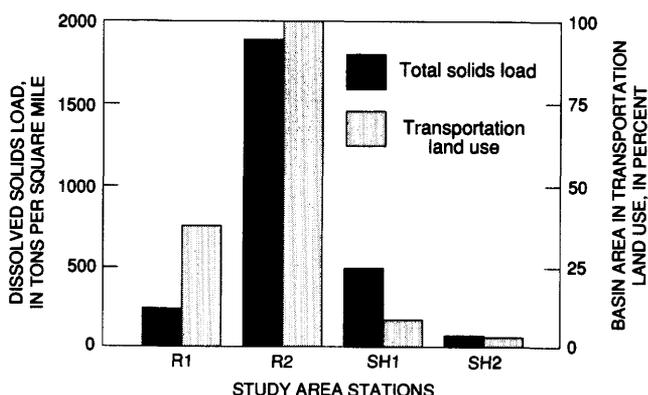

An examination of loads verifies the results of the constituent-concentration comparisons among stations. As noted in the earlier comparison of constituent concentrations, the stations affected by highway runoff (R1, R2, and SH1) show high total metals and total dissolved solid loads relative to those at station SH2, which are indicative of water quality of most of the Sevenmile Creek basin, and to those of station SC, which are from a basin that is predominately rural (table 19). In particular, station R1 had relatively high total lead, iron, and zinc loads, and station R2 had high dissolved-solids, copper, iron, and zinc loads.

### SUMMARY

An evaluation of the water quality of streams that receive stormwater runoff from a segment of Interstate Highway 85 indicated increased levels of many constituents when compared to nearby undeveloped basins. The study area included eight sampling stations: R1 and R2 were near the highway; SC and SG5 received no runoff from the highway but represented rural land uses; Cane Creek drained an undeveloped, almost completely forested basin; SH1 was located downstream from R2 and included a highway rest-stop area and minor residential and urban land uses; SG3 was located downstream from R2, SH1, and SC; and SH2 was located downstream from SG3 and R1. The basins had a combined drainage area of 17.5 mi<sup>2</sup> and drained a 4.8-mi-long segment of I-85. The asphalt highway consisted of two northbound and two southbound lanes and, on each side of the road, entry and exit lanes for highway rest-stop areas. The daily mean traffic flow along the highway was greatest during August 1981, at 28,000 vehicles per day, and least during January 1982, at 22,000 vehicles per day. The yearly mean traffic flow was 25,000 vehicles per day.

In addition to the stream sampling stations, rain gages were located at sites SH1, SH2, and SC, wet-dry atmospheric-deposition collectors were located near sites R2 and SC, and a weather station having a recording anemometer and thermometer was located at site SH1. The particulate samplers near R2 included devices designed specifically to measure saltation particle loads bounced along the highway surface. Four lysimeters were located near the road at station R2 to sample the quality of water in the soil. Road surface material, obtained from soil samples and highway sweepings, also was part of the study. Areal data on geology and land use for each basin were compiled to allow testing for correlation of basin characteristics with water quality.

During storm runoff, streamflow affected by the highway (stations R1, R2, and SH1) rose and fell more rapidly than in the streams in the undeveloped basins (SC

**Figure 16.** Annual dissolved-solids loads for the study stations and the percentage of basin area in the transportation land-use category.

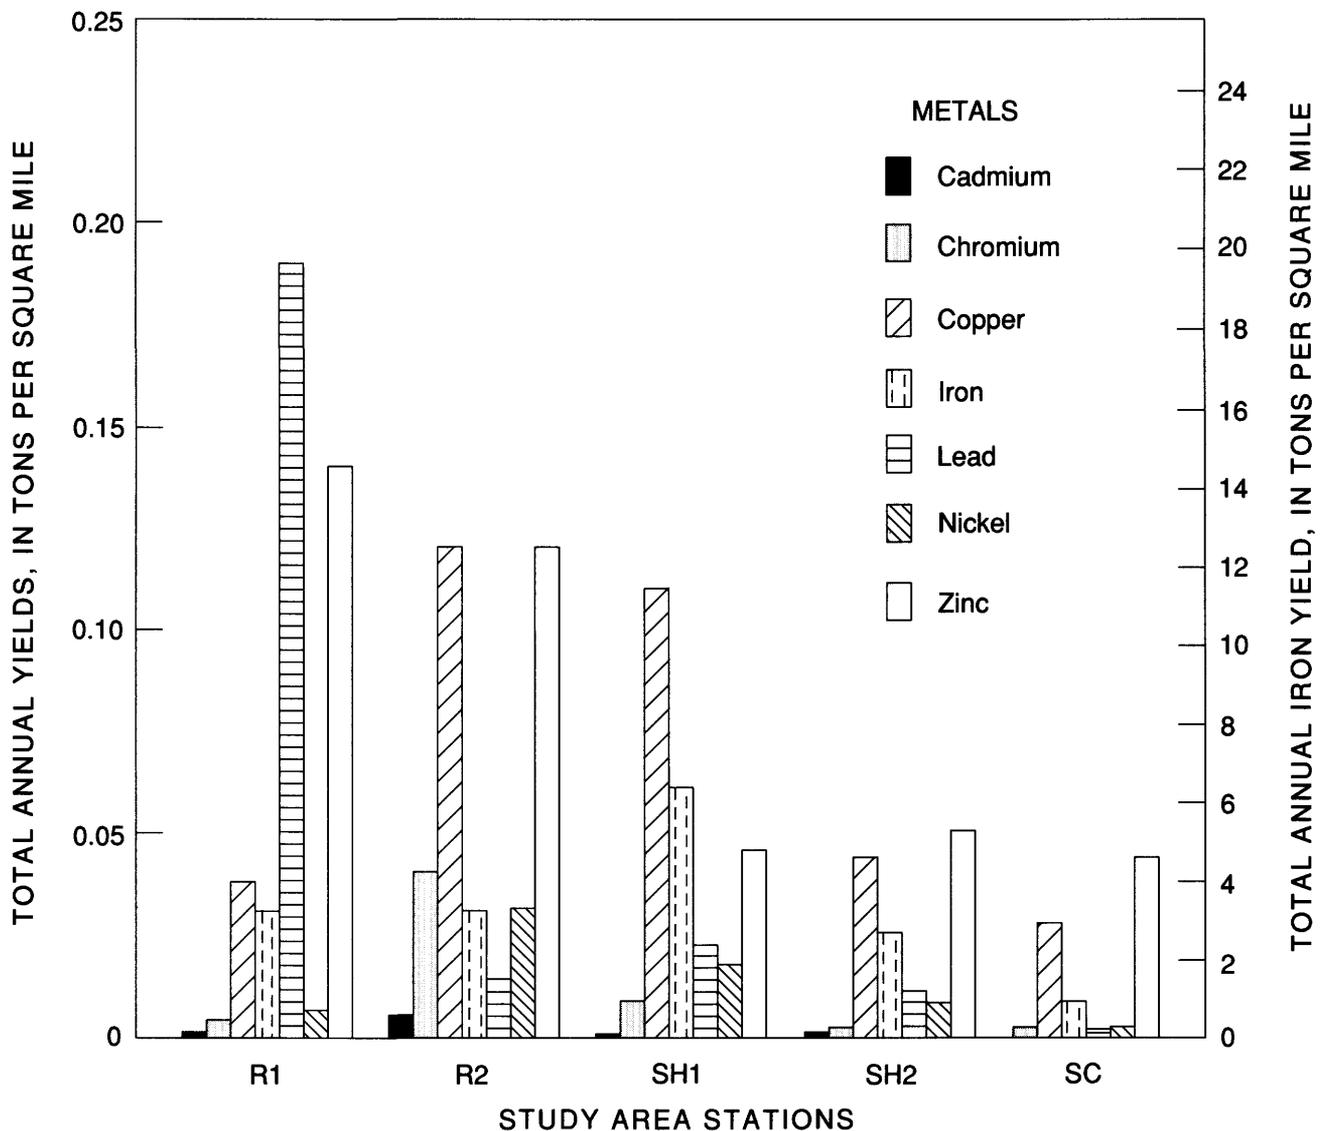

Figure 17. Total annual metals loads for the study stations.

Table 20. Annual subbasin loads, in tons per square mile

[—, no data]

| Constituent           | Highway stations |       |       | Sevenmile Creek | Rural station |
|-----------------------|------------------|-------|-------|-----------------|---------------|
|                       | R1               | R2    | SH1   | SH2             | SC            |
| Dissolved solids----- | 240              | 1,800 | 460   | 61              | —             |
| Cadmium-----          | .0014            | .0056 | .0014 | .0017           | —             |
| Chromium-----         | .0054            | .041  | .010  | .0033           | 0.0035        |
| Copper-----           | .038             | .12   | .11   | .043            | .028          |
| Iron-----             | 3.1              | 3.1   | 6.2   | 2.6             | .93           |
| Lead-----             | .19              | .015  | .023  | .012            | .0027         |
| Nickel-----           | .0071            | .031  | .018  | .0090           | .0034         |
| Zinc-----             | .14              | .12   | .046  | .051            | .044          |

and Cane Creek). This rapid runoff response results from the impervious nature of the highway and the manmade drainage system that was designed to move water quickly off the highway. Station R2, which gaged the discharge from an area that is approximately one-half paved, had the highest discharge per square mile (2.78 (ft<sup>3</sup>/s)/mi<sup>2</sup>), and Cane Creek, a forested basin, showed the lowest discharge per square mile (0.45 (ft<sup>3</sup>/s)/mi<sup>2</sup>).

The highway stations (R1 and R2) had the greatest concentrations of calcium, sodium, and chloride and the highest values of specific conductance and alkalinity primarily from road salting. The highest mean sample specific conductance was 3,530  $\mu$ S/cm measured at R2, and the lowest was 44  $\mu$ S/cm measured at the background station at Cane Creek. In general, highway station R2 had the highest constituent-concentration levels followed by highway station R1, midbasin station SH1, the station furthest downstream SH2, and the other stations. This pattern reflects the effect of the road—the further downstream the station was from the highway, the less the effects in water quality downstream.

No conclusive effects from highway runoff were observed for nutrients. However, mean nitrite-plus-nitrate, phosphorus, total organic carbon, and ammonia concentrations were high at stations SH1 and SH2, probably because the rest-area wastewater-treatment-plant effluent was upstream from station SH1, which was in turn upstream from SH2. Nitrogen and phosphorus concentration levels were sufficient to allow abundant algae growth, although phosphorus concentrations were low compared to those of larger Piedmont rivers. During storms, stations SH1 and SH2 had dissolved- and total-nitrogen concentrations that peaked rapidly during stormflow. The peaks probably were caused by the flushing from the streambed of the nutrient-rich material that accumulated during low flow. The source of this nutrient-rich material probably was the rest-stop wastewater-treatment plants.

Increased metals concentrations, as much as 10 times greater than background levels, were found in the soils near the highway at station R2 and in the water that infiltrates the soil zone. Chromium, copper, nickel, and zinc concentrations observed at the stations that were affected by the highway (R1, R2, and SH1) generally were higher than concentrations observed at the background stations SG5, SC, and Cane Creek. Many of the concentrations of cadmium, chromium, copper, lead, nickel, and zinc exceeded the maximum recommended levels for the protection of aquatic life, and lead and cadmium concentrations frequently exceeded the maximum levels recommended for drinking water. Concentrations of cadmium, chromium, copper, and zinc in rainwater, collected at SH1, exceeded the criteria recommended for the protection of aquatic life.

Stations R1 and SH1 showed high concentrations of oil and grease compared to those of stations SH2, SG3, SG5, and SC. The effects of highway runoff on suspended

sediment, water temperature, dissolved oxygen, and pH could not be determined. However, pH declined during stormflow at all stations because rainfall having pH values less than 5.7 entered the streams.

Some of the highest constituent concentrations were measured in the soil water sampled from the lysimeters located near the highway. The highest concentrations of iron, chromium, zinc, total nitrite-plus-nitrate, total Kjeldahl nitrogen, and total phosphorus in water were found in the soil-water samples. The source of these constituents is the use and maintenance of the highway.

The highway is a source of chemical constituents to surrounding areas. The high proportion of the total dustfall loading rate at SH1, located approximately one-half mile from the highway, suggests that dust from the highway can be carried considerable distances. However, the constituent levels observed in dustfall and in soil samples generally decreased exponentially with increased distance from the highway. Dust constituent loads and constituent concentrations in the soil were greater on the downwind side of the highway. Material loading from dustfall was greater than loading from wet precipitation. Saltated particle loads were higher than loads from other particle deposition probably because of the greater size of saltated particles. Saltation loads were highest during the winter months because of highway salting and sanding. About two-thirds of the materials washed off into the surrounding areas were from highway deicing and sanding. The remaining one-third of material came mainly from deposition of particles from vehicles.

# SELECTED SERIES OF U.S. GEOLOGICAL SURVEY PUBLICATIONS

---

## Periodicals

**Earthquakes & Volcanoes** (issued bimonthly).

**Preliminary Determination of Epicenters** (issued monthly).

## Technical Books and Reports

**Professional Papers** are mainly comprehensive scientific reports of wide and lasting interest and importance to professional scientists and engineers. Included are reports on the results of resource studies and of topographic, hydrologic, and geologic investigations. They also include collections of related papers addressing different aspects of a single scientific topic.

**Bulletins** contain significant data and interpretations that are of lasting scientific interest but are generally more limited in scope or geographic coverage than Professional Papers. They include the results of resource studies and of geologic and topographic investigations; as well as collections of short papers related to a specific topic.

**Water-Supply Papers** are comprehensive reports that present significant interpretive results of hydrologic investigations of wide interest to professional geologists, hydrologists, and engineers. The series covers investigations in all phases of hydrology, including hydrogeology, availability of water, quality of water, and use of water.

**Circulars** present administrative information or important scientific information of wide popular interest in a format designed for distribution at no cost to the public. Information is usually of short-term interest.

**Water-Resources Investigations Reports** are papers of an interpretive nature made available to the public outside the formal USGS publications series. Copies are reproduced on request unlike formal USGS publications, and they are also available for public inspection at depositories indicated in USGS catalogs.

**Open-File Reports** include unpublished manuscript reports, maps, and other material that are made available for public consultation at depositories. They are a nonpermanent form of publication that may be cited in other publications as sources of information.

## Maps

**Geologic Quadrangle Maps** are multicolor geologic maps on topographic bases in 7 1/2- or 15-minute quadrangle formats (scales mainly 1:24,000 or 1:62,500) showing bedrock, surficial, or engineering geology. Maps generally include brief texts; some maps include structure and columnar sections only.

**Geophysical Investigations Maps** are on topographic or planimetric bases at various scales; they show results of surveys using geophysical techniques, such as gravity, magnetic, seismic, or radioactivity, which reflect subsurface structures that are of economic or geologic significance. Many maps include correlations with the geology.

**Miscellaneous Investigations Series Maps** are on planimetric or topographic bases of regular and irregular areas at various scales; they present a wide variety of format and subject matter. The series also includes 7 1/2-minute quadrangle photogeologic maps on planimetric bases which show geology as interpreted from aerial photographs. Series also includes maps of Mars and the Moon.

**Coal Investigations Maps** are geologic maps on topographic or planimetric bases at various scales showing bedrock or surficial geology, stratigraphy, and structural relations in certain coal-resource areas.

**Oil and Gas Investigations Charts** show stratigraphic information for certain oil and gas fields and other areas having petroleum potential.

**Miscellaneous Field Studies Maps** are multicolor or black-and-white maps on topographic or planimetric bases on quadrangle or irregular areas at various scales. Pre-1971 maps show bedrock geology in relation to specific mining or mineral-deposit problems; post-1971 maps are primarily black-and-white maps on various subjects such as environmental studies or wilderness mineral investigations.

**Hydrologic Investigations Atlases** are multicolored or black-and-white maps on topographic or planimetric bases presenting a wide range of geohydrologic data of both regular and irregular areas; principal scale is 1:24,000 and regional studies are at 1:250,000 scale or smaller.

## Catalogs

Permanent catalogs, as well as some others, giving comprehensive listings of U.S. Geological Survey publications are available under the conditions indicated below from the U.S. Geological Survey, Books and Open-File Reports Section, Federal Center, Box 25425, Denver, CO 80225. (See latest Price and Availability List.)

"**Publications of the Geological Survey, 1879-1961**" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

"**Publications of the Geological Survey, 1962-1970**" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

"**Publications of the U.S. Geological Survey, 1971-1981**" may be purchased by mail and over the counter in paperback book form (two volumes, publications listing and index) and as a set of microfiche.

**Supplements** for 1982, 1983, 1984, 1985, 1986, and for subsequent years since the last permanent catalog may be purchased by mail and over the counter in paperback book form.

**State catalogs**, "List of U.S. Geological Survey Geologic and Water-Supply Reports and Maps For (State)," may be purchased by mail and over the counter in paperback booklet form only.

"**Price and Availability List of U.S. Geological Survey Publications**," issued annually, is available free of charge in paperback booklet form only.

**Selected copies of a monthly catalog** "New Publications of the U.S. Geological Survey" available free of charge by mail or may be obtained over the counter in paperback booklet form only. Those wishing a free subscription to the monthly catalog "New Publications of the U.S. Geological Survey" should write to the U.S. Geological Survey, 582 National Center, Reston, VA 22092.

**Note.**--Prices of Government publications listed in older catalogs, announcements, and publications may be incorrect. Therefore, the prices charged may differ from the prices in catalogs, announcements, and publications.
